It also supports certain of Python's built-in operators through `__cmp__()` and `__repr__()` methods.

Python Library Reference

Previous: 18.24.2 Boolean Objects  Up: 18.24 xmlrpclib  Next: 18.24.4 Binary Objects

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
18.24.4 Binary Objects

This class may be initialized from string data (which may include NULs). The primary access to the content of a Binary object is provided by an attribute:

data
   The binary data encapsulated by the Binary instance. The data is provided as an 8-bit string.

Binary objects have the following methods, supported mainly for internal use by the marshalling/unmarshalling code:

dedecode( string)
   Accept a base64 string and decode it as the instance's new data.

dencode( out)
   Write the XML-RPC base 64 encoding of this binary item to the out stream object.

It also supports certain of Python's built-in operators through a ___cmp___( ) method.
18.24.5 Fault Objects

A Fault object encapsulates the content of an XML-RPC fault tag. Fault objects have the following members:

**faultCode**
A string indicating the fault type.

**faultString**
A string containing a diagnostic message associated with the fault.
18.24.6 ProtocolError Objects

A ProtocolError object describes a protocol error in the underlying transport layer (such as a 404 `not found' error if the server named by the URI does not exist). It has the following members:

**url**

The URI or URL that triggered the error.

**errcode**

The error code.

**errmsg**

The error message or diagnostic string.

**headers**

A string containing the headers of the HTTP/HTTPS request that triggered the error.
**18.24.7 MultiCall Objects**

New in version 2.4.

In [http://www.xmlrpc.com/discuss/msgReader%241208](http://www.xmlrpc.com/discuss/msgReader%241208), an approach is presented to encapsulate multiple calls to a remote server into a single request.

```python
class MultiCall(server):
    Create an object used to boxcar method calls. server is the eventual target of the call. Calls can be made to the result object, but they will immediately return None, and only store the call name and parameters in the MultiCall object. Calling the object itself causes all stored calls to be transmitted as a single system.multicall request. The result of this call is a generator; iterating over this generator yields the individual results.

A usage example of this class is

```python
multicall = MultiCall(server_proxy)
multicall.add(2, 3)
multicall.get_address("Guido")
add_result, address = multicall()
```
Example of Client
18.24.8 Convenience Functions

**boolean**( value )

Convert any Python value to one of the XML-RPC Boolean constants, True or False.

**dumps**( params[, methodname[, methodresponse[, encoding[, allow_none]]]])

Convert *params* into an XML-RPC request. or into a response if *methodresponse* is true. *params* can be either a tuple of arguments or an instance of the Fault exception class. If *methodresponse* is true, only a single value can be returned, meaning that *params* must be of length 1. *encoding*, if supplied, is the encoding to use in the generated XML; the default is UTF-8. Python's None value cannot be used in standard XML-RPC; to allow using it via an extension, provide a true value for *allow_none*.

**loads**( data[, use_datetime])

Convert an XML-RPC request or response into Python objects, a *(params, methodname)*. *params* is a tuple of argument; *methodname* is a string, or None if no method name is present in the packet. If the XML-RPC packet represents a fault condition, this function will raise a Fault exception. The *use_datetime* flag can be used to cause date/time values to be presented as datetime.datetime objects; this is false by default. Note that even if you call an XML-RPC method with datetime.date or datetime.time objects, they are converted to DateTime objects internally, so only datetime.datetime objects will be returned.

Changed in version 2.5: The *use_datetime* flag was added.
18.24.9 Example of Client Usage

```python
# simple test program (from the XML-RPC specification)
from xmlrpc import ServerProxy, Error

# server = ServerProxy("http://localhost:8000")  # local server
server = ServerProxy("http://betty.userland.com")

print server

try:
    print server.examples.getStateName(41)
except Error, v:
    print "ERROR", v
```

To access an XML-RPC server through a proxy, you need to define a custom transport. The following example, written by NoboNobo, shows how:

```python
import xmlrpclib, httplib

class ProxiedTransport(xmlrpclib.Transport):
    def set_proxy(self, proxy):
        self.proxy = proxy
    def make_connection(self, host):
        self.realhost = host
        h = httplib.HTTP(self.proxy)
        return h
    def send_request(self, connection, handler, request_body):
        connection.putrequest("POST", "http://%s%s" % (self.realhost, handler))
    def send_host(self, connection, host):
        connection.putheader('Host', self.realhost)

p = ProxiedTransport()
p.set_proxy('proxy-server:8080')
print server.currentTime.getCurrentTime()
```

Previous: 18.24.8 Convenience Functions  Up: 18.24 xmlrpclib  Next: 18.25 SimpleXMLRPCServer

Release 2.5, documentation updated on 19th September, 2006. See About this document... for information on suggesting changes.
18.25 SimpleXMLRPCServer -- Basic XML-RPC server

New in version 2.2.

The SimpleXMLRPCServer module provides a basic server framework for XML-RPC servers written in Python. Servers can either be free standing, using SimpleXMLRPCServer, or embedded in a CGI environment, using CGIXMLRPCRequestHandler.

```python
class SimpleXMLRPCServer(addr[, requestHandler[, logRequests[allow_none[, encoding]]]]):
```

Create a new server instance. This class provides methods for registration of functions that can be called by the XML-RPC protocol. The `requestHandler` parameter should be a factory for request handler instances; it defaults to SimpleXMLRPCRequestHandler. The `addr` and `requestHandler` parameters are passed to the `SocketServer.TCPServer` constructor. If `logRequests` is true (the default), requests will be logged; setting this parameter to false will turn off logging. The `allow_none` and `encoding` parameters are passed on to `xmlrpclib` and control the XML-RPC responses that will be returned from the server. Changed in version 2.5: The `allow_none` and `encoding` parameters were added.

```python
class CGIXMLRPCRequestHandler([allow_none[, encoding]])
```

Create a new instance to handle XML-RPC requests in a CGI environment. The `allow_none` and `encoding` parameters are passed on to `xmlrpclib` and control the XML-RPC responses that will be returned from the server. New in version 2.3. Changed in version 2.5: The `allow_none` and `encoding` parameters were added.

```python
class SimpleXMLRPCRequestHandler()```

Create a new request handler instance. This request handler supports POST requests and modifies logging so that the `logRequests` parameter to the
SimpleXMLRPCServer constructor parameter is honored.

Subsections

- 18.25.1 SimpleXMLRPCServer Objects
- 18.25.2 CGIXMLRPCRequestHandler

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
18.25.1 SimpleXMLRPCServer Objects

The SimpleXMLRPCServer class is based on SocketServer.TCPServer and provides a means of creating simple, stand alone XML-RPC servers.

**register_function**(*function*, *name*)

Register a function that can respond to XML-RPC requests. If *name* is given, it will be the method name associated with *function*, otherwise *function*.__name__ will be used. *name* can be either a normal or Unicode string, and may contain characters not legal in Python identifiers, including the period character.

**register_instance**(*instance*, *allow_dotted_names*)

Register an object which is used to expose method names which have not been registered using register_function(). If *instance* contains a _dispatch() method, it is called with the requested method name and the parameters from the request. Its API is def _dispatch(self, method, params) (note that params does not represent a variable argument list). If it calls an underlying function to perform its task, that function is called as func(*params), expanding the parameter list. The return value from _dispatch() is returned to the client as the result. If *instance* does not have a _dispatch() method, it is searched for an attribute matching the name of the requested method.

If the optional *allow_dotted_names* argument is true and the instance does not have a _dispatch() method, then if the requested method name contains periods, each component of the method name is searched for individually, with the effect that a simple hierarchical search is performed. The value found from this search is then called with the parameters from the request, and the return value is passed back to the client.

**Warning:** Enabling the *allow_dotted_names* option allows intruders to access your module's global variables and may allow intruders to execute arbitrary code on your
Changed in version 2.3.5, 2.4.1: `allow_dotted_names` was added to plug a security hole; prior versions are insecure.

**register_introspection_functions()**

Registers the XML-RPC introspection functions `system.listMethods`, `system.methodHelp` and `system.methodSignature`. New in version 2.3.

**register_multicall_functions()**

Registers the XML-RPC multicall function `system.multicall`.

**rpc_paths**

An attribute value that must be a tuple listing valid path portions of the URL for receiving XML-RPC requests. Requests posted to other paths will result in a 404 "no such page" HTTP error. If this tuple is empty, all paths will be considered valid. The default value is `('/', '/RPC2')`. New in version 2.5.

Example:

```python
from SimpleXMLRPCServer import SimpleXMLRPCServer

# Create server
server = SimpleXMLRPCServer(('localhost', 8000))
server.register_introspection_functions()

# Register pow() function; this will use the value of
# pow.__name__ as the name, which is just 'pow'.
server.register_function(pow)

# Register a function under a different name
def adder_function(x, y):
    return x + y
server.register_function(adder_function, 'add')

# Register an instance; all the methods of the instance are
# published as XML-RPC methods (in this case, just 'div').
class MyFuncs:
    def div(self, x, y):
        return x // y

server.register_instance(MyFuncs())
```
# Run the server's main loop
server.serve_forever()

The following client code will call the methods made available by the preceding server:

```
import xmlrpclib

s = xmlrpclib.Server('http://localhost:8000')
print s.pow(2,3)  # Returns 2**3 = 8
print s.add(2,3)  # Returns 5
print s.div(5,2)  # Returns 5//2 = 2

# Print list of available methods
print s.system.listMethods()
```
18.25.2 CGIXMLRPCRequestHandler

The CGIXMLRPCRequestHandler class can be used to handle XML-RPC requests sent to Python CGI scripts.

register_function(function[, name])

Register a function that can respond to XML-RPC requests. If name is given, it will be the method name associated with function, otherwise function.__name__ will be used. name can be either a normal or Unicode string, and may contain characters not legal in Python identifiers, including the period character.

register_instance(instance)

Register an object which is used to expose method names which have not been registered using register_function(). If instance contains a _dispatch() method, it is called with the requested method name and the parameters from the request; the return value is returned to the client as the result. If instance does not have a _dispatch() method, it is searched for an attribute matching the name of the requested method; if the requested method name contains periods, each component of the method name is searched for individually, with the effect that a simple hierarchical search is performed. The value found from this search is then called with the parameters from the request, and the return value is passed back to the client.

register_introspection_functions()

Register the XML-RPC introspection functions system.listMethods, system.methodHelp and system.methodSignature.

register_multicall_functions()

Register the XML-RPC multicall function system.multicall.

handle_request([request_text = None])

Handle a XML-RPC request. If request_text is given, it should be the POST data provided by the HTTP server, otherwise the contents of stdin will be used.
Example:

```python
class MyFuncs:
    def div(self, x, y): return x // y

handler = CGIXMLRPCRequestHandler()
handler.register_function(pow)
handler.register_function(lambda x,y: x+y, 'add')
handler.register_introspection_functions()
handler.register_instance(MyFuncs())
handler.handle_request()
```

Previous: 18.25.1 SimpleXMLRPCServer Objects  Up: 18.25 SimpleXMLRPCServer  Next: 18.26 DocXMLRPCServer

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
18.26 DocXMLRPCServer -- Self-documenting XML-RPC server

New in version 2.3.

The DocXMLRPCServer module extends the classes found in SimpleXMLRPCServer to serve HTML documentation in response to HTTP GET requests. Servers can either be free standing, using DocXMLRPCServer, or embedded in a CGI environment, using DocCGIXMLRPCRequestHandler.

```python
class DocXMLRPCServer( addr[, requestHandler[, logRequests]])
```

Create a new server instance. All parameters have the same meaning as for SimpleXMLRPCServer; requestHandler defaults to DocXMLRPCRequestHandler.

```python
class DocCGIXMLRPCRequestHandler()
```

Create a new instance to handle XML-RPC requests in a CGI environment.

```python
class DocXMLRPCRequestHandler()
```

Create a new request handler instance. This request handler supports XML-RPC POST requests, documentation GET requests, and modifies logging so that the logRequests parameter to the DocXMLRPCServer constructor parameter is honored.

Subsections

- 18.26.1 DocXMLRPCServer Objects

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
18.26.1 DocXMLRPCServer Objects

The DocXMLRPCServer class is derived from SimpleXMLRPCServer.SimpleXMLRPCServer and provides a means of creating self-documenting, stand alone XML-RPC servers. HTTP POST requests are handled as XML-RPC method calls. HTTP GET requests are handled by generating pydoc-style HTML documentation. This allows a server to provide its own web-based documentation.

```python
set_server_title(server_title)
```

Set the title used in the generated HTML documentation. This title will be used inside the HTML "title" element.

```python
set_server_name(server_name)
```

Set the name used in the generated HTML documentation. This name will appear at the top of the generated documentation inside a "h1" element.

```python
set_server_documentation(server_documentation)
```

Set the description used in the generated HTML documentation. This description will appear as a paragraph, below the server name, in the documentation.

18.26.2 DocCGIXMLRPCRequestHandler

The DocCGIXMLRPCRequestHandler class is derived from SimpleXMLRPCServer.CGIXMLRPCRequestHandler and provides a means of creating self-documenting, XML-RPC CGI scripts. HTTP POST requests are handled as XML-RPC method calls. HTTP GET requests are handled by generating pydoc-style HTML documentation. This allows a server to provide its own web-based documentation.

**set_server_title**(server_title)

Set the title used in the generated HTML documentation. This title will be used inside the HTML "title" element.

**set_server_name**(server_name)

Set the name used in the generated HTML documentation. This name will appear at the top of the generated documentation inside a "h1" element.

**set_server_documentation**(server_documentation)

Set the description used in the generated HTML documentation. This description will appear as a paragraph, below the server name, in the documentation.
19. Multimedia Services

The modules described in this chapter implement various algorithms or interfaces that are mainly useful for multimedia applications. They are available at the discretion of the installation. Here's an overview:

- **audioop**: Manipulate raw audio data.
- **imageop**: Manipulate raw image data.
- **aifc**: Read and write audio files in AIFF or AIFC format.
- **sunau**: Provide an interface to the Sun AU sound format.
- **wave**: Provide an interface to the WAV sound format.
- **chunk**: Module to read IFF chunks.
- **colors**
  - **sys**: Conversion functions between RGB and other color systems.
- **rgbimg**: Read and write image files in ``SGI RGB'' format (the module is *not* SGI specific though!).
- **imghdr**: Determine the type of image contained in a file or byte stream.
- **sndhdr**: Determine type of a sound file.
- **ossaudiodev**: Access to OSS-compatible audio devices.

---

**Python Library Reference**

Previous: 18.26.2 DocCGIXMLRPCRequestHandler  
Up: Python Library Reference  
Next: 19.1 audioop

*Release 2.5, documentation updated on 19th September, 2006.*  
See [About this document...](#) for information on suggesting changes.
19.1 audioop -- Manipulate raw audio data

The audioop module contains some useful operations on sound fragments. It operates on sound fragments consisting of signed integer samples 8, 16 or 32 bits wide, stored in Python strings. This is the same format as used by the al and sunaudiodev modules. All scalar items are integers, unless specified otherwise.

This module provides support for a-LAW, u-LAW and Intel/DVI ADPCM encodings.

A few of the more complicated operations only take 16-bit samples, otherwise the sample size (in bytes) is always a parameter of the operation.

The module defines the following variables and functions:

**exception error**
This exception is raised on all errors, such as unknown number of bytes per sample, etc.

**add(fragment1, fragment2, width)**
Return a fragment which is the addition of the two samples passed as parameters. width is the sample width in bytes, either 1, 2 or 4. Both fragments should have the same length.

**adpcm2lin(adpcmfragment, width, state)**
Decode an Intel/DVI ADPCM coded fragment to a linear fragment. See the description of lin2adpcm() for details on ADPCM coding. Return a tuple (sample, newstate) where the sample has the width specified in width.

**alaw2lin(fragment, width)**
Convert sound fragments in a-LAW encoding to linearly encoded sound fragments. a-LAW encoding always uses 8 bits samples, so width refers
only to the sample width of the output fragment here. New in version 2.5.

**avg**(*fragment*, *width*)
Return the average over all samples in the fragment.

**avgpp**(*fragment*, *width*)
Return the average peak-peak value over all samples in the fragment. No filtering is done, so the usefulness of this routine is questionable.

**bias**(*fragment*, *width*, *bias*)
Return a fragment that is the original fragment with a bias added to each sample.

**cross**(*fragment*, *width*)
Return the number of zero crossings in the fragment passed as an argument.

**findfactor**(*fragment*, *reference*)
Return a factor $F$ such that $\text{rms}(\text{add}(\text{fragment}, \text{mul}(\text{reference}, -F)))$ is minimal, i.e., return the factor with which you should multiply *reference* to make it match as well as possible to *fragment*. The fragments should both contain 2-byte samples.

The time taken by this routine is proportional to $\text{len}(\text{fragment})$.

**findfit**(*fragment*, *reference*)
Try to match *reference* as well as possible to a portion of *fragment* (which should be the longer fragment). This is (conceptually) done by taking slices out of *fragment*, using **findfactor**() to compute the best match, and minimizing the result. The fragments should both contain 2-byte samples. Return a tuple (*offset*, *factor*) where *offset* is the (integer) offset into *fragment* where the optimal match started and *factor* is the (floating-point) factor as per **findfactor**().

**findmax**(*fragment*, *length*)
Search *fragment* for a slice of length *length* samples (not bytes!) with maximum energy, i.e., return $i$ for which $\text{rms}(\text{fragment}[i*2: (i+\text{length})*2])$ is maximal. The fragments should both contain 2-byte samples.
samples.

The routine takes time proportional to \( \text{len}(\text{fragment}) \).

**getsample**\((\text{fragment}, \text{width}, \text{index})\)

Return the value of sample \( \text{index} \) from the fragment.

**lin2adpcm**\((\text{fragment}, \text{width}, \text{state})\)

Convert samples to 4 bit Intel/DVI ADPCM encoding. ADPCM coding is an adaptive coding scheme, whereby each 4 bit number is the difference between one sample and the next, divided by a (varying) step. The Intel/DVI ADPCM algorithm has been selected for use by the IMA, so it may well become a standard.

\( \text{state} \) is a tuple containing the state of the coder. The coder returns a tuple \( (\text{adpcmfrag}, \text{newstate}) \), and the \( \text{newstate} \) should be passed to the next call of \( \text{lin2adpcm}() \). In the initial call, \text{None} can be passed as the state. \( \text{adpcmfrag} \) is the ADPCM coded fragment packed 2 4-bit values per byte.

**lin2alaw**\((\text{fragment}, \text{width})\)

Convert samples in the audio fragment to a-LAW encoding and return this as a Python string. a-LAW is an audio encoding format whereby you get a dynamic range of about 13 bits using only 8 bit samples. It is used by the Sun audio hardware, among others. New in version 2.5.

**lin2lin**\((\text{fragment}, \text{width}, \text{newwidth})\)

Convert samples between 1-, 2- and 4-byte formats.

**lin2ulaw**\((\text{fragment}, \text{width})\)

Convert samples in the audio fragment to u-LAW encoding and return this as a Python string. u-LAW is an audio encoding format whereby you get a dynamic range of about 14 bits using only 8 bit samples. It is used by the Sun audio hardware, among others.

**minmax**\((\text{fragment}, \text{width})\)

Return a tuple consisting of the minimum and maximum values of all samples in the sound fragment.
\textbf{max}( \textit{fragment}, \textit{width} )

Return the maximum of the \textit{absolute value} of all samples in a fragment.

\textbf{maxpp}( \textit{fragment}, \textit{width} )

Return the maximum peak-peak value in the sound fragment.

\textbf{mul}( \textit{fragment}, \textit{width}, \textit{factor} )

Return a fragment that has all samples in the original fragment multiplied by the floating-point value \textit{factor}. Overflow is silently ignored.

Convert the frame rate of the input fragment.

\textit{state} is a tuple containing the state of the converter. The converter returns a tuple \textit{(newfragment, newstate)}, and \textit{newstate} should be passed to the next call of \textbf{ratecv}(). The initial call should pass None as the state.

The \textit{weightA} and \textit{weightB} arguments are parameters for a simple digital filter and default to 1 and 0 respectively.

\textbf{reverse}( \textit{fragment}, \textit{width} )

Reverse the samples in a fragment and returns the modified fragment.

\textbf{rms}( \textit{fragment}, \textit{width} )

Return the root-mean-square of the fragment, i.e.

$$\sqrt{\frac{\sum S_i^2}{n}}$$

This is a measure of the power in an audio signal.

\textbf{tomono}( \textit{fragment}, \textit{width}, \textit{lfactor}, \textit{rfactor} )

Convert a stereo fragment to a mono fragment. The left channel is multiplied by \textit{lfactor} and the right channel by \textit{rfactor} before adding the two channels to give a mono signal.
tostereo( fragment, width, lfactor, rfactor)
Generate a stereo fragment from a mono fragment. Each pair of samples in the stereo fragment are computed from the mono sample, whereby left channel samples are multiplied by lfactor and right channel samples by rfactor.

ulaw2lin( fragment, width)
Convert sound fragments in u-LAW encoding to linearly encoded sound fragments. u-LAW encoding always uses 8 bits samples, so width refers only to the sample width of the output fragment here.

Note that operations such as mul() or max() make no distinction between mono and stereo fragments, i.e. all samples are treated equal. If this is a problem the stereo fragment should be split into two mono fragments first and recombined later. Here is an example of how to do that:

```python
def mul_stereo(sample, width, lfactor, rfactor):
    lsample = audioop.tomono(sample, width, 1, 0)
    rsample = audioop.tomono(sample, width, 0, 1)
    lsample = audioop.mul(sample, width, lfactor)
    rsample = audioop.mul(sample, width, rfactor)
    lsample = audioop.tostereo(lsample, width, 1, 0)
    rsample = audioop.tostereo(rsample, width, 0, 1)
    return audioop.add(lsample, rsample, width)
```

If you use the ADPCM coder to build network packets and you want your protocol to be stateless (i.e. to be able to tolerate packet loss) you should not only transmit the data but also the state. Note that you should send the initial state (the one you passed to lin2adpcm()) along to the decoder, not the final state (as returned by the coder). If you want to use struct.struct() to store the state in binary you can code the first element (the predicted value) in 16 bits and the second (the delta index) in 8.

The ADPCM coders have never been tried against other ADPCM coders, only against themselves. It could well be that I misinterpreted the standards in which case they will not be interoperable with the respective standards.

The find*() routines might look a bit funny at first sight. They are primarily meant to do echo cancellation. A reasonably fast way to do this is to pick the most energetic piece of the output sample, locate that in the input sample and subtract the whole output sample from the input sample:
def echocancel(outputdata, inputdata):
    pos = audioop.findmax(outputdata, 800)  # one tenth second
    out_test = outputdata[pos*2:]
    in_test = inputdata[pos*2:]
    ipos, factor = audioop.findfit(in_test, out_test)
    # Optional (for better cancellation):
    # factor = audioop.findfactor(in_test[ipos*2:ipos*2+len(out_test)
    #     out_test])
    prefill = '\0'*(pos+ipos)*2
    postfill = '\0'*(len(inputdata)-len(prefill)-len(outputdata))
    outputdata = prefill + audioop.mul(outputdata, 2, -factor) + postf
    return audioop.add(inputdata, outputdata, 2)
19.2 *imageop* -- Manipulate raw image data

The *imageop* module contains some useful operations on images. It operates on images consisting of 8 or 32 bit pixels stored in Python strings. This is the same format as used by `gl.lrectwrite()` and the *imgfile* module.

The module defines the following variables and functions:

**exception error**
This exception is raised on all errors, such as unknown number of bits per pixel, etc.

**crop**(*image*, *psize*, *width*, *height*, *x0*, *y0*, *x1*, *y1*)
Return the selected part of *image*, which should by *width* by *height* in size and consist of pixels of *psize* bytes. *x0*, *y0*, *x1*, and *y1* are like the `gl.lrectread()` parameters, i.e. the boundary is included in the new image. The new boundaries need not be inside the picture. Pixels that fall outside the old image will have their value set to zero. If *x0* is bigger than *x1* the new image is mirrored. The same holds for the *y* coordinates.

**scale**(*image*, *psize*, *width*, *height*, *newwidth*, *newheight*)
Return *image* scaled to size *newwidth* by *newheight*. No interpolation is done, scaling is done by simple-minded pixel duplication or removal. Therefore, computer-generated images or dithered images will not look nice after scaling.

**tovideo**(*image*, *psize*, *width*, *height*)
Run a vertical low-pass filter over an image. It does so by computing each destination pixel as the average of two vertically-aligned source pixels. The main use of this routine is to forestall excessive flicker if the image is displayed on a video device that uses interlacing, hence the name.

**grey2mono**(*image*, *width*, *height*, *threshold*)
Convert a 8-bit deep greyscale image to a 1-bit deep image by thresholding
all the pixels. The resulting image is tightly packed and is probably only useful as an argument to \texttt{mono2grey()}.

**\texttt{dither2mono( image, width, height)\**

Convert an 8-bit greyscale image to a 1-bit monochrome image using a (simple-minded) dithering algorithm.

**\texttt{mono2grey( image, width, height, p0, p1)\**

Convert a 1-bit monochrome image to an 8 bit greyscale or color image. All pixels that are zero-valued on input get value \texttt{p0} on output and all one-value input pixels get value \texttt{p1} on output. To convert a monochrome black-and-white image to greyscale pass the values 0 and 255 respectively.

**\texttt{grey2grey4( image, width, height)\**

Convert an 8-bit greyscale image to a 4-bit greyscale image without dithering.

**\texttt{grey2grey2( image, width, height)\**

Convert an 8-bit greyscale image to a 2-bit greyscale image without dithering.

**\texttt{dither2grey2( image, width, height)\**

Convert an 8-bit greyscale image to a 2-bit greyscale image with dithering. As for \texttt{dither2mono()}, the dithering algorithm is currently very simple.

**\texttt{grey42grey( image, width, height)\**

Convert a 4-bit greyscale image to an 8-bit greyscale image.

**\texttt{grey22grey( image, width, height)\**

Convert a 2-bit greyscale image to an 8-bit greyscale image.

**\texttt{backward_compatible\**

If set to 0, the functions in this module use a non-backward compatible way of representing multi-byte pixels on little-endian systems. The SGI for which this module was originally written is a big-endian system, so setting this variable will have no effect. However, the code wasn't originally intended to run on anything else, so it made assumptions about byte order
which are not universal. Setting this variable to 0 will cause the byte order to be reversed on little-endian systems, so that it then is the same as on big-endian systems.
19.3 aifc -- Read and write AIFF and AIFC files

This module provides support for reading and writing AIFF and AIFF-C files. AIFF is Audio Interchange File Format, a format for storing digital audio samples in a file. AIFF-C is a newer version of the format that includes the ability to compress the audio data.

Caveat: Some operations may only work under IRIX; these will raise ImportError when attempting to import the cl module, which is only available on IRIX.

Audio files have a number of parameters that describe the audio data. The sampling rate or frame rate is the number of times per second the sound is sampled. The number of channels indicate if the audio is mono, stereo, or quadro. Each frame consists of one sample per channel. The sample size is the size in bytes of each sample. Thus a frame consists of nchannels*samplesize bytes, and a second's worth of audio consists of nchannels*samplesize*framerate bytes.

For example, CD quality audio has a sample size of two bytes (16 bits), uses two channels (stereo) and has a frame rate of 44,100 frames/second. This gives a frame size of 4 bytes (2*2), and a second's worth occupies 2*2*44100 bytes (176,400 bytes).

Module aifc defines the following function:

open( file[, mode])

Open an AIFF or AIFF-C file and return an object instance with methods that are described below. The argument file is either a string naming a file or a file object. mode must be 'r' or 'rb' when the file must be opened for reading, or 'w' or 'wb' when the file must be opened for writing. If omitted, file.mode is used if it exists, otherwise 'rb' is used. When used for writing, the file object should be seekable, unless you know ahead of time how many samples you are going to write in total and use
writeframesraw() and setnframes().

Objects returned by open() when a file is opened for reading have the following methods:

getnchannels()
    Return the number of audio channels (1 for mono, 2 for stereo).

getsampwidth()
    Return the size in bytes of individual samples.

getframerate()
    Return the sampling rate (number of audio frames per second).

getnframes()
    Return the number of audio frames in the file.

getcomptype()
    Return a four-character string describing the type of compression used in the audio file. For AIFF files, the returned value is 'NONE'.

getcompname()
    Return a human-readable description of the type of compression used in the audio file. For AIFF files, the returned value is 'not compressed'.

getparams()
    Return a tuple consisting of all of the above values in the above order.

getmarkers()
    Return a list of markers in the audio file. A marker consists of a tuple of three elements. The first is the mark ID (an integer), the second is the mark position in frames from the beginning of the data (an integer), the third is the name of the mark (a string).

getmark(id)
    Return the tuple as described in getmarkers() for the mark with the given id.
**readframes**(*nframes*)
Read and return the next *nframes* frames from the audio file. The returned data is a string containing for each frame the uncompressed samples of all channels.

**rewind()**
Rewind the read pointer. The next **readframes()** will start from the beginning.

**setpos**(*pos*)
Seek to the specified frame number.

**tell()**
Return the current frame number.

**close()**
Close the AIFF file. After calling this method, the object can no longer be used.

Objects returned by **open()** when a file is opened for writing have all the above methods, except for **readframes()** and **setpos()**. In addition the following methods exist. The **get**(* method can only be called after the corresponding **set**(* method have been called. Before the first **writeframes()** or **writeframesraw()**, all parameters except for the number of frames must be filled in.

**aiff()**
Create an AIFF file. The default is that an AIFF-C file is created, unless the name of the file ends in '.aiff' in which case the default is an AIFF file.

**aifc()**
Create an AIFF-C file. The default is that an AIFF-C file is created, unless the name of the file ends in '.aiff' in which case the default is an AIFF file.

**setnchannels**(*nchannels*)
Specify the number of channels in the audio file.
**setsampwidth**(*width*)
Specify the size in bytes of audio samples.

**setframerate**(*rate*)
Specify the sampling frequency in frames per second.

**setnframes**(*nframes*)
Specify the number of frames that are to be written to the audio file. If this parameter is not set, or not set correctly, the file needs to support seeking.

**setcomptype**(*type*, *name*)
Specify the compression type. If not specified, the audio data will not be compressed. In AIFF files, compression is not possible. The name parameter should be a human-readable description of the compression type, the type parameter should be a four-character string. Currently the following compression types are supported: NONE, ULAW, ALAW, G722.

**setparams**(*nchannels, sampwidth, framerate, comptype, compname*)
Set all the above parameters at once. The argument is a tuple consisting of the various parameters. This means that it is possible to use the result of a **getparams**() call as argument to **setparams**().

**setmark**(*id, pos, name*)
Add a mark with the given id (larger than 0), and the given name at the given position. This method can be called at any time before close().

**tell**()
Return the current write position in the output file. Useful in combination with setmark().

**writeframes**(*data*)
Write data to the output file. This method can only be called after the audio file parameters have been set.

**writeframesraw**(*data*)
Like writeframes(), except that the header of the audio file is not updated.
**close()**

Close the AIFF file. The header of the file is updated to reflect the actual size of the audio data. After calling this method, the object can no longer be used.
19.4 sunau -- Read and write Sun AU files

The sunau module provides a convenient interface to the Sun AU sound format. Note that this module is interface-compatible with the modules aifc and wave.

An audio file consists of a header followed by the data. The fields of the header are:

<table>
<thead>
<tr>
<th>Field</th>
<th>Contents</th>
</tr>
</thead>
<tbody>
<tr>
<td>magic word</td>
<td>The four bytes &quot; . snd&quot;.</td>
</tr>
<tr>
<td>header size</td>
<td>Size of the header, including info, in bytes.</td>
</tr>
<tr>
<td>data size</td>
<td>Physical size of the data, in bytes.</td>
</tr>
<tr>
<td>encoding</td>
<td>Indicates how the audio samples are encoded.</td>
</tr>
<tr>
<td>sample rate</td>
<td>The sampling rate.</td>
</tr>
<tr>
<td># of channels</td>
<td>The number of channels in the samples.</td>
</tr>
<tr>
<td>info</td>
<td>ASCII string giving a description of the audio file (padded with null bytes).</td>
</tr>
</tbody>
</table>

Apart from the info field, all header fields are 4 bytes in size. They are all 32-bit unsigned integers encoded in big-endian byte order.

The sunau module defines the following functions:

**open**(*file*, *mode*)

If *file* is a string, open the file by that name, otherwise treat it as a seekable file-like object. *mode* can be any of

- `'r'`
  - Read only mode.
- `'w'`
  - Write only mode.
Note that it does not allow read/write files.

A mode of 'r' returns a AU_read object, while a mode of 'w' or 'wb' returns a AU_write object.

**openfp(file, mode)**

A synonym for open, maintained for backwards compatibility.

The sunau module defines the following exception:

**exception Error**

An error raised when something is impossible because of Sun AU specs or implementation deficiency.

The sunau module defines the following data items:

**AUDIO_FILE_MAGIC**

An integer every valid Sun AU file begins with, stored in big-endian form. This is the string ".snd" interpreted as an integer.

**AUDIO_FILE_ENCODING_MULAW_8**
**AUDIO_FILE_ENCODING_LINEAR_8**
**AUDIO_FILE_ENCODING_LINEAR_16**
**AUDIO_FILE_ENCODING_LINEAR_24**
**AUDIO_FILE_ENCODING_LINEAR_32**
**AUDIO_FILE_ENCODING_ALAW_8**

Values of the encoding field from the AU header which are supported by this module.

**AUDIO_FILE_ENCODING_FLOAT**
**AUDIO_FILE_ENCODING_DOUBLE**
**AUDIO_FILE_ENCODING_ADPCM_G721**
**AUDIO_FILE_ENCODING_ADPCM_G722**
**AUDIO_FILE_ENCODING_ADPCM_G723_3**
**AUDIO_FILE_ENCODING_ADPCM_G723_5**

Additional known values of the encoding field from the AU header, but which are not supported by this module.

---

**Subsections**
• **19.4.1 AU_read Objects**
• **19.4.2 AU_write Objects**

Release 2.5, documentation updated on 19th September, 2006.
See *About this document...* for information on suggesting changes.
19.4.1 AU_read Objects

AU_read objects, as returned by open() above, have the following methods:

**close()**
Close the stream, and make the instance unusable. (This is called automatically on deletion.)

**getnchannels()**
Returns number of audio channels (1 for mone, 2 for stereo).

**getsampwidth()**
Returns sample width in bytes.

**getframerate()**
Returns sampling frequency.

**getnframes()**
Returns number of audio frames.

**getcomptype()**
Returns compression type. Supported compression types are 'ULAW', 'ALAW' and 'NONE'.

**getcompname()**
Human-readable version of getcomptype(). The supported types have the respective names 'CCITT G.711 u-law', 'CCITT G.711 A-law' and 'not compressed'.

**getparams()**
Returns a tuple (nchannels, sampwidth, framerate, nframes, comptype, compname), equivalent to output of the get*() methods.

**readframes(n)**
Reads and returns at most n frames of audio, as a string of bytes. The data
will be returned in linear format. If the original data is in u-LAW format, it will be converted.

```python
rewind()
```

Rewind the file pointer to the beginning of the audio stream.

The following two methods define a term `"position"` which is compatible between them, and is otherwise implementation dependent.

```python
setpos(pos)
```

Set the file pointer to the specified position. Only values returned from `tell()` should be used for `pos`.

```python
tell()
```

Return current file pointer position. Note that the returned value has nothing to do with the actual position in the file.

The following two functions are defined for compatibility with the `aifc`, and don't do anything interesting.

```python
getmarkers()
```

Returns None.

```python
getmark(id)
```

Raise an error.
19.4.2 AU_write Objects

AU_write objects, as returned by open() above, have the following methods:

**setnchannels**(n)
Set the number of channels.

**setsampwidth**(n)
Set the sample width (in bytes.)

**setframerate**(n)
Set the frame rate.

**setnframes**(n)
Set the number of frames. This can be later changed, when and if more frames are written.

**setcomptype**(type, name)
Set the compression type and description. Only 'NONE' and 'ULAW' are supported on output.

**setparams**(tuple)
The tuple should be (nchannels, sampwidth, framerate, nframes, comptype, compname), with values valid for the set*() methods. Set all parameters.

**tell()**
Return current position in the file, with the same disclaimer for the AU_read.tell() and AU_read.setpos() methods.

**writeframesraw**(data)
Write audio frames, without correcting nframes.

**writeframes**(data)
Write audio frames and make sure nframes is correct.
close()

Make sure \textit{nframes} is correct, and close the file.

This method is called upon deletion.

Note that it is invalid to set any parameters after calling \texttt{writeframes()} or \texttt{writeframesraw()}. 

\textit{Python Library Reference}

Previous: 19.4.1 \texttt{AU\_read} Objects  Up: 19.4 \texttt{sunau}  Next: 19.5 \texttt{wave}

\textit{Release 2.5, documentation updated on 19th September, 2006.  
See About this document... for information on suggesting changes.}
19.5 wave -- Read and write WAV files

The `wave` module provides a convenient interface to the WAV sound format. It does not support compression/decompression, but it does support mono/stereo.

The `wave` module defines the following function and exception:

```python
open( file[, mode])
```

If `file` is a string, open the file by that name, other treat it as a seekable file-like object. `mode` can be any of

- `'r'`, `'rb'`
  Read only mode.
- `'w'`, `'wb'`
  Write only mode.

Note that it does not allow read/write WAV files.

A `mode` of 'r' or 'rb' returns a `Wave_read` object, while a `mode` of 'w' or 'wb' returns a `Wave_write` object. If `mode` is omitted and a file-like object is passed as `file`, `file.mode` is used as the default value for `mode` (the "b" flag is still added if necessary).

```python
openfp( file, mode)
```

A synonym for `open()`, maintained for backwards compatibility.

**exception Error**

An error raised when something is impossible because it violates the WAV specification or hits an implementation deficiency.

- [19.5.2 Wave_write Objects](#)
Wave_read Objects

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
19.5.1 Wave_read Objects

Wave_read objects, as returned by open(), have the following methods:

**close()**
Close the stream, and make the instance unusable. This is called automatically on object collection.

**getnchannels()**
Returns number of audio channels (1 for mono, 2 for stereo).

**getsampwidth()**
Returns sample width in bytes.

**getframerate()**
Returns sampling frequency.

**getnframes()**
Returns number of audio frames.

**getcomptype()**
Returns compression type ('NONE' is the only supported type).

**getcompname()**
Human-readable version of getcomptype(). Usually 'not compressed' parallels 'NONE'.

**getparams()**
Returns a tuple (nchannels, sampwidth, framerate, nframes, comptype, compname), equivalent to output of the get*() methods.

**readframes( n)**
Reads and returns at most n frames of audio, as a string of bytes.

**rewind()**
Rewind the file pointer to the beginning of the audio stream.

The following two methods are defined for compatibility with the `aifc` module, and don't do anything interesting.

**getmarkers()**
- Returns None.

**getmark(id)**
- Raise an error.

The following two methods define a term ``position'' which is compatible between them, and is otherwise implementation dependent.

**setpos(pos)**
- Set the file pointer to the specified position.

**tell()**
- Return current file pointer position.
19.5.2 Wave_write Objects

Wave_write objects, as returned by `open()`, have the following methods:

**close()**
Make sure `nframes` is correct, and close the file. This method is called upon deletion.

**setnchannels( n)**
Set the number of channels.

**setsampwidth( n)**
Set the sample width to `n` bytes.

**setframerate( n)**
Set the frame rate to `n`.

**setnframes( n)**
Set the number of frames to `n`. This will be changed later if more frames are written.

**setcomptype( type, name)**
Set the compression type and description.

**setparams( tuple)**
The `tuple` should be `(nchannels, sampwidth, framerate, nframes, comptype, compname)`, with values valid for the `set*()` methods. Sets all parameters.

**tell()**
Return current position in the file, with the same disclaimer for the `Wave_read.tell()` and `Wave_read.setpos()` methods.

**writeframesraw( data)**
Write audio frames, without correcting `nframes`. 
writeframes(data)

Write audio frames and make sure nframes is correct.

Note that it is invalid to set any parameters after calling writeframes() or writeframesraw(), and any attempt to do so will raise wave.Error.
19.6 chunk -- Read IFF chunked data

This module provides an interface for reading files that use EA IFF 85 chunks. This format is used in at least the Audio Interchange File Format (AIFF/AIFF-C) and the Real Media File Format (RMFF). The WAVE audio file format is closely related and can also be read using this module.

A chunk has the following structure:

<table>
<thead>
<tr>
<th>Offset</th>
<th>Length</th>
<th>Contents</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>4</td>
<td>Chunk ID</td>
</tr>
<tr>
<td>4</td>
<td>4</td>
<td>Size of chunk in big-endian byte order, not including the header</td>
</tr>
<tr>
<td>8</td>
<td>n</td>
<td>Data bytes, where n is the size given in the preceding field</td>
</tr>
<tr>
<td>8 + n</td>
<td>0 or 1</td>
<td>Pad byte needed if n is odd and chunk alignment is used</td>
</tr>
</tbody>
</table>

The ID is a 4-byte string which identifies the type of chunk.

The size field (a 32-bit value, encoded using big-endian byte order) gives the size of the chunk data, not including the 8-byte header.

Usually an IFF-type file consists of one or more chunks. The proposed usage of the Chunk class defined here is to instantiate an instance at the start of each chunk and read from the instance until it reaches the end, after which a new instance can be instantiated. At the end of the file, creating a new instance will fail with a EOFError exception.

class Chunk(file[, align, bigendian, inclheader])

Class which represents a chunk. The file argument is expected to be a file-like object. An instance of this class is specifically allowed. The only method that is needed is read(). If the methods seek() and tell() are present and don’t raise an exception, they are also used. If these methods are present and raise an exception, they are expected to not have altered the object. If the optional argument align is true, chunks are assumed to be aligned on 2-byte boundaries. If align is false, no alignment is assumed. The default value is true. If the optional argument bigendian is false, the
chunk size is assumed to be in little-endian order. This is needed for WAVE audio files. The default value is true. If the optional argument inclheader is true, the size given in the chunk header includes the size of the header. The default value is false.

A Chunk object supports the following methods:

**getname()**
- Returns the name (ID) of the chunk. This is the first 4 bytes of the chunk.

**getsize()**
- Returns the size of the chunk.

**close()**
- Close and skip to the end of the chunk. This does not close the underlying file.

The remaining methods will raise **IOError** if called after the **close()** method has been called.

**isatty()**
- Returns False.

**seek(pos[, whence])**
- Set the chunk's current position. The **whence** argument is optional and defaults to 0 (absolute file positioning); other values are 1 (seek relative to the current position) and 2 (seek relative to the file's end). There is no return value. If the underlying file does not allow seek, only forward seeks are allowed.

**tell()**
- Return the current position into the chunk.

**read([size])**
- Read at most size bytes from the chunk (less if the read hits the end of the chunk before obtaining size bytes). If the size argument is negative or omitted, read all data until the end of the chunk. The bytes are returned as a
string object. An empty string is returned when the end of the chunk is encountered immediately.

**skip()**

Skip to the end of the chunk. All further calls to `read()` for the chunk will return '''. If you are not interested in the contents of the chunk, this method should be called so that the file points to the start of the next chunk.

---

**Footnotes**

... chunks.\(^{19.1}\)

19.7 colorsys -- Conversions between color systems

The colorsys module defines bidirectional conversions of color values between colors expressed in the RGB (Red Green Blue) color space used in computer monitors and three other coordinate systems: YIQ, HLS (Hue Lightness Saturation) and HSV (Hue Saturation Value). Coordinates in all of these color spaces are floating point values. In the YIQ space, the Y coordinate is between 0 and 1, but the I and Q coordinates can be positive or negative. In all other spaces, the coordinates are all between 0 and 1.

More information about color spaces can be found at http://www.poynton.com/ColorFAQ.html.

The colorsys module defines the following functions:

- `rgb_to_yiq(r, g, b)`: Convert the color from RGB coordinates to YIQ coordinates.
- `yiq_to_rgb(y, i, q)`: Convert the color from YIQ coordinates to RGB coordinates.
- `rgb_to_hls(r, g, b)`: Convert the color from RGB coordinates to HLS coordinates.
- `hls_to_rgb(h, l, s)`: Convert the color from HLS coordinates to RGB coordinates.
- `rgb_to_hsv(r, g, b)`: Convert the color from RGB coordinates to HSV coordinates.
- `hsv_to_rgb(h, s, v)`: Convert the color from HSV coordinates to RGB coordinates.

Example:
>>> import colorsys
>>> colorsys.rgb_to_hsv(.3, .4, .2)
(0.25, 0.5, 0.4)
>>> colorsys.hsv_to_rgb(0.25, 0.5, 0.4)
(0.3, 0.4, 0.2)
19.8 rgbimg -- Read and write ``SGI RGB'' files

**Deprecated since release 2.5.** This module is not maintained anymore and seems to be unused.

The rgbimg module allows Python programs to access SGI imglib image files (also known as .rgb files). The module is far from complete, but is provided anyway since the functionality that there is enough in some cases. Currently, colormap files are not supported.

**Note:** This module is only built by default for 32-bit platforms; it is not expected to work properly on other systems.

The module defines the following variables and functions:

**exception error**
This exception is raised on all errors, such as unsupported file type, etc.

**sizeofimage**(*file*)
This function returns a tuple \((x, y)\) where \(x\) and \(y\) are the size of the image in pixels. Only 4 byte RGBA pixels, 3 byte RGB pixels, and 1 byte greyscale pixels are currently supported.

**longimagedata**(*file*)
This function reads and decodes the image on the specified file, and returns it as a Python string. The string has 4 byte RGBA pixels. The bottom left pixel is the first in the string. This format is suitable to pass to `gl.lrectwrite()`, for instance.

**longstoimage**(*data, x, y, z, file*)
This function writes the RGBA data in `data` to image file `file`. \(x\) and \(y\) give the size of the image. \(z\) is 1 if the saved image should be 1 byte greyscale, 3 if the saved image should be 3 byte RGB data, or 4 if the saved images should be 4 byte RGBA data. The input data always contains 4 bytes per
pixel. These are the formats returned by `gl.lrectread()`.

**ttob** *(flag)*

This function sets a global flag which defines whether the scan lines of the image are read or written from bottom to top (flag is zero, compatible with SGI GL) or from top to bottom (flag is one, compatible with X). The default is zero.
19.9 imghdr -- Determine the type of an image

The `imghdr` module determines the type of image contained in a file or byte stream.

The `imghdr` module defines the following function:

```python
what(filename[, h])
```
Tests the image data contained in the file named by `filename`, and returns a string describing the image type. If optional `h` is provided, the `filename` is ignored and `h` is assumed to contain the byte stream to test.

The following image types are recognized, as listed below with the return value from `what()`:

<table>
<thead>
<tr>
<th>Value</th>
<th>Image format</th>
</tr>
</thead>
<tbody>
<tr>
<td>'rgb'</td>
<td>SGI ImgLib Files</td>
</tr>
<tr>
<td>'gif'</td>
<td>GIF 87a and 89a Files</td>
</tr>
<tr>
<td>'pbm'</td>
<td>Portable Bitmap Files</td>
</tr>
<tr>
<td>'pgm'</td>
<td>Portable Graymap Files</td>
</tr>
<tr>
<td>'ppm'</td>
<td>Portable Pixmap Files</td>
</tr>
<tr>
<td>'tiff'</td>
<td>TIFF Files</td>
</tr>
<tr>
<td>'rast'</td>
<td>Sun Raster Files</td>
</tr>
<tr>
<td>'xbm'</td>
<td>X Bitmap Files</td>
</tr>
<tr>
<td>'jpeg'</td>
<td>JPEG data in JFIF or Exif formats</td>
</tr>
<tr>
<td>'bmp'</td>
<td>BMP files</td>
</tr>
<tr>
<td>'png'</td>
<td>Portable Network Graphics</td>
</tr>
</tbody>
</table>

New in version 2.5: Exif detection.

You can extend the list of file types `imghdr` can recognize by appending to this variable:
tests

A list of functions performing the individual tests. Each function takes two arguments: the byte-stream and an open file-like object. When `what()` is called with a byte-stream, the file-like object will be `None`.

The test function should return a string describing the image type if the test succeeded, or `None` if it failed.

Example:

```python
>>> import imghdr
>>> imghdr.what('/tmp/bass.gif')
'gif'
```
19.10 sndhdr -- Determine type of sound file

The sndhdr provides utility functions which attempt to determine the type of sound data which is in a file. When these functions are able to determine what type of sound data is stored in a file, they return a tuple (type, sampling_rate, channels, frames, bits_per_sample). The value for type indicates the data type and will be one of the strings 'aifc', 'aiff', 'au', 'hcom', 'sndr', 'sndt', 'voc', 'wav', '8svx', 'sb', 'ub', or 'ul'. The sampling_rate will be either the actual value or 0 if unknown or difficult to decode. Similarly, channels will be either the number of channels or 0 if it cannot be determined or if the value is difficult to decode. The value for frames will be either the number of frames or -1. The last item in the tuple, bits_per_sample, will either be the sample size in bits or 'A' for A-LAW or 'U' for u-LAW.

what(filename)

Determines the type of sound data stored in the file filename using whathdr(). If it succeeds, returns a tuple as described above, otherwise None is returned.

whathdr(filename)

Determines the type of sound data stored in a file based on the file header. The name of the file is given by filename. This function returns a tuple as described above on success, or None.
19.11 ossaudiodev -- Access to OSS-compatible audio devices

Availability: Linux, FreeBSD.

New in version 2.3.

This module allows you to access the OSS (Open Sound System) audio interface. OSS is available for a wide range of open-source and commercial Unices, and is the standard audio interface for Linux and recent versions of FreeBSD.

See Also:

Open Sound System Programmer's Guide
the official documentation for the OSS C API

The module defines a large number of constants supplied by the OSS device driver; see <sys/soundcard.h> on either Linux or FreeBSD for a listing.

ossaudiodev defines the following variables and functions:

exception OSSAudioError
This exception is raised on certain errors. The argument is a string describing what went wrong.

(If ossaudiodev receives an error from a system call such as open(), write(), or ioctl(), it raises IOError. Errors detected directly by ossaudiodev result in OSSAudioError.)

(For backwards compatibility, the exception class is also available as ossaudiodev.error.)
`open( [device, ]mode)`

Open an audio device and return an OSS audio device object. This object supports many file-like methods, such as `read()`, `write()`, and `fileno()` (although there are subtle differences between conventional UNIX read/write semantics and those of OSS audio devices). It also supports a number of audio-specific methods; see below for the complete list of methods.

`device` is the audio device filename to use. If it is not specified, this module first looks in the environment variable AUDIODEV for a device to use. If not found, it falls back to `/dev/dsp`.

`mode` is one of `'r'` for read-only (record) access, `'w'` for write-only (playback) access and `'rw'` for both. Since many sound cards only allow one process to have the recorder or player open at a time, it is a good idea to open the device only for the activity needed. Further, some sound cards are half-duplex: they can be opened for reading or writing, but not both at once.

Note the unusual calling syntax: the `first` argument is optional, and the second is required. This is a historical artifact for compatibility with the older `linuxaudiodev` module which `ossaudiodev` supersedes.

`openmixer([device])`

Open a mixer device and return an OSS mixer device object. `device` is the mixer device filename to use. If it is not specified, this module first looks in the environment variable MIXERDEV for a device to use. If not found, it falls back to `/dev/mixer`.

Subsections

- 19.11.1 Audio Device Objects
- 19.11.2 Mixer Device Objects
Release 2.5, documentation updated on 19th September, 2006. See About this document... for information on suggesting changes.
19.11.1 Audio Device Objects

Before you can write to or read from an audio device, you must call three methods in the correct order:

1. `setfmt()` to set the output format
2. `channels()` to set the number of channels
3. `speed()` to set the sample rate

Alternately, you can use the `setparameters()` method to set all three audio parameters at once. This is more convenient, but may not be as flexible in all cases.

The audio device objects returned by `open()` define the following methods and (read-only) attributes:

**close()**
Explicitly close the audio device. When you are done writing to or reading from an audio device, you should explicitly close it. A closed device cannot be used again.

**fileno()**
Return the file descriptor associated with the device.

**read(size)**
Read `size` bytes from the audio input and return them as a Python string. Unlike most UNIX device drivers, OSS audio devices in blocking mode (the default) will block `read()` until the entire requested amount of data is available.

**write(data)**
Write the Python string `data` to the audio device and return the number of bytes written. If the audio device is in blocking mode (the default), the entire string is always written (again, this is different from usual UNIX device semantics). If the device is in non-blocking mode, some data may not be written--see `writeall()`.
**writeall**(data)

Write the entire Python string *data* to the audio device: waits until the audio device is able to accept data, writes as much data as it will accept, and repeats until *data* has been completely written. If the device is in blocking mode (the default), this has the same effect as **write(); writeall()** is only useful in non-blocking mode. Has no return value, since the amount of data written is always equal to the amount of data supplied.

The following methods each map to exactly one **ioctl()** system call. The correspondence is obvious: for example, **setfmt()** corresponds to the **SNDCTL_DSP_SETFMT** ioctl, and **sync()** to **SNDCTL_DSP_SYNC** (this can be useful when consulting the OSS documentation). If the underlying **ioctl()** fails, they all raise **IOError**.

**nonblock()**

Put the device into non-blocking mode. Once in non-blocking mode, there is no way to return it to blocking mode.

**getfmts()**

Return a bitmask of the audio output formats supported by the soundcard. Some of the formats supported by OSS are:

<table>
<thead>
<tr>
<th>Format</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>AFMT_MU_LAW</td>
<td>a logarithmic encoding (used by Sun .au files and /dev/audio)</td>
</tr>
<tr>
<td>AFMT_A_LAW</td>
<td>a logarithmic encoding</td>
</tr>
<tr>
<td>AFMTIMA_ADPCM</td>
<td>a 4:1 compressed format defined by the Interactive Multimedia Association</td>
</tr>
<tr>
<td>AFMT_U8</td>
<td>Unsigned, 8-bit audio</td>
</tr>
<tr>
<td>AFMT_S16_LE</td>
<td>Signed, 16-bit audio, little-endian byte order (as used by Intel processors)</td>
</tr>
<tr>
<td>AFMT_S16_BE</td>
<td>Signed, 16-bit audio, big-endian byte order (as used by 68k, PowerPC, Sparc)</td>
</tr>
<tr>
<td>AFMT_S8</td>
<td>Signed, 8 bit audio</td>
</tr>
<tr>
<td>AFMT_U16_LE</td>
<td>Unsigned, 16-bit little-endian audio</td>
</tr>
<tr>
<td>AFMT_U16_BE</td>
<td>Unsigned, 16-bit big-endian audio</td>
</tr>
</tbody>
</table>

Consult the OSS documentation for a full list of audio formats, and note
that most devices support only a subset of these formats. Some older
devices only support AFMT_U8; the most common format used today is
AFMT_S16_LE.

**setfmt** (*format*)

Try to set the current audio format to *format*--see **getfmts()** for a list.
Returns the audio format that the device was set to, which may not be the
requested format. May also be used to return the current audio format--do
this by passing an "`audio format" of AFMT_QUERY.

**channels** (*nchannels*)

Set the number of output channels to *nchannels*. A value of 1 indicates
monophonic sound, 2 stereophonic. Some devices may have more than 2
channels, and some high-end devices may not support mono. Returns the
number of channels the device was set to.

**speed** (*samplerate*)

Try to set the audio sampling rate to *samplerate* samples per second.
Returns the rate actually set. Most sound devices don't support arbitrary
sampling rates. Common rates are:

<table>
<thead>
<tr>
<th>Rate</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>8000</td>
<td>default rate for /dev/audio</td>
</tr>
<tr>
<td>11025</td>
<td>speech recording</td>
</tr>
<tr>
<td>22050</td>
<td></td>
</tr>
<tr>
<td>44100</td>
<td>CD quality audio (at 16 bits/sample and 2 channels)</td>
</tr>
<tr>
<td>96000</td>
<td>DVD quality audio (at 24 bits/sample)</td>
</tr>
</tbody>
</table>

**sync()**

Wait until the sound device has played every byte in its buffer. (This
happens implicitly when the device is closed.) The OSS documentation
recommends closing and re-opening the device rather than using **sync()**.

**reset()**

Immediately stop playing or recording and return the device to a state
where it can accept commands. The OSS documentation recommends
closing and re-opening the device after calling **reset()**.
**post()**
Tell the driver that there is likely to be a pause in the output, making it possible for the device to handle the pause more intelligently. You might use this after playing a spot sound effect, before waiting for user input, or before doing disk I/O.

The following convenience methods combine several ioctls, or one ioctl and some simple calculations.

**setparameters**( *format*, *nchannels*, *samplerate* [, *strict=\text{False}]*)
Set the key audio sampling parameters—sample format, number of channels, and sampling rate—in one method call. *format*, *nchannels*, and *samplerate* should be as specified in the *setfmt()*, *channels()*, and *speed()* methods. If *strict* is true, *setparameters()* checks to see if each parameter was actually set to the requested value, and raises *OSSAudioError* if not. Returns a tuple (*format*, *nchannels*, *samplerate*) indicating the parameter values that were actually set by the device driver (i.e., the same as the return values of *setfmt()*, *channels()*, and *speed()*).

For example,

```python
(fmt, channels, rate) = dsp.setparameters(fmt, channels, rate)
```

is equivalent to

```python
fmt = dsp.setfmt(fmt)
channels = dsp.channels(channels)
rate = dsp.rate(channels)
```

**bufsize()**
Returns the size of the hardware buffer, in samples.

**obufcount()**
Returns the number of samples that are in the hardware buffer yet to be played.

**obuffree()**
Returns the number of samples that could be queued into the hardware
buffer to be played without blocking.

Audio device objects also support several read-only attributes:

**closed**
Boolean indicating whether the device has been closed.

**name**
String containing the name of the device file.

**mode**
The I/O mode for the file, either "r", "rw", or "w".
19.11.2 Mixer Device Objects

The mixer object provides two file-like methods:

**close()**
This method closes the open mixer device file. Any further attempts to use the mixer after this file is closed will raise an IOError.

**fileno()**
Returns the file handle number of the open mixer device file.

The remaining methods are specific to audio mixing:

**controls()**
This method returns a bitmask specifying the available mixer controls ("Control" being a specific mixable "channel", such as SOUND_MIXER_PCM or SOUND_MIXER_SYNTH). This bitmask indicates a subset of all available mixer controls--the SOUND_MIXER_* constants defined at module level. To determine if, for example, the current mixer object supports a PCM mixer, use the following Python code:

```python
mixer=ossaudiodev.openmixer()
if mixer.controls() & (1 << ossaudiodev.SOUND_MIXER_PCM):
    # PCM is supported
    ... code ...
```

For most purposes, the SOUND_MIXER_VOLUME (master volume) and SOUND_MIXER_PCM controls should suffice--but code that uses the mixer should be flexible when it comes to choosing mixer controls. On the Gravis Ultrasound, for example, SOUND_MIXER_VOLUME does not exist.

**stereocontrols()**
Returns a bitmask indicating stereo mixer controls. If a bit is set, the corresponding control is stereo; if it is unset, the control is either monophonic or not supported by the mixer (use in combination with controls() to determine which).

See the code example for the controls() function for an example of
getting data from a bitmask.

**reccontrols()**

Returns a bitmask specifying the mixer controls that may be used to record. See the code example for `controls()` for an example of reading from a bitmask.

**get(control)**

Returns the volume of a given mixer control. The returned volume is a 2-tuple `(left_volume, right_volume)`. Volumes are specified as numbers from 0 (silent) to 100 (full volume). If the control is monophonic, a 2-tuple is still returned, but both volumes are the same.

Raises `OSSAudioError` if an invalid control was is specified, or `IOError` if an unsupported control is specified.

**set(control, (left, right))**

Sets the volume for a given mixer control to `(left, right)`. `left` and `right` must be ints and between 0 (silent) and 100 (full volume). On success, the new volume is returned as a 2-tuple. Note that this may not be exactly the same as the volume specified, because of the limited resolution of some soundcard's mixers.

Raises `OSSAudioError` if an invalid mixer control was specified, or if the specified volumes were out-of-range.

**get_recsrc()**

This method returns a bitmask indicating which control(s) are currently being used as a recording source.

**set_recsrc(bitmask)**

Call this function to specify a recording source. Returns a bitmask indicating the new recording source (or sources) if successful; raises `IOError` if an invalid source was specified. To set the current recording source to the microphone input:

```python
mixer.setrecsrc (1 << ossaudiodev.SOUND_MIXER_MIC)
```
Graphical User Interfaces

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
20. Graphical User Interfaces with Tk

Tk/Tcl has long been an integral part of Python. It provides a robust and platform independent windowing toolkit, that is available to Python programmers using the Tkinter module, and its extension, the Tix module.

The Tkinter module is a thin object-oriented layer on top of Tcl/Tk. To use Tkinter, you don't need to write Tcl code, but you will need to consult the Tk documentation, and occasionally the Tcl documentation. Tkinter is a set of wrappers that implement the Tk widgets as Python classes. In addition, the internal module _tkinter provides a threadsafe mechanism which allows Python and Tcl to interact.

Tk is not the only GUI for Python; see section 20.6, "Other User Interface Modules and Packages," for more information on other GUI toolkits for Python.

Tkinter  Interface to Tcl/Tk for graphical user interfaces
Tix  Tk Extension Widgets for Tkinter
ScrolledText  Text widget with a vertical scroll bar.
turtle  An environment for turtle graphics.
20.1 Tkinter -- Python interface to Tcl/Tk

The Tkinter module (``Tk interface'') is the standard Python interface to the Tk GUI toolkit. Both Tk and Tkinter are available on most UNIX platforms, as well as on Windows and Macintosh systems. (Tk itself is not part of Python; it is maintained at ActiveState.)

Previous: 20. Graphical User Interfaces Up: 20. Graphical User Interfaces
Next: 20.1.1 Tkinter Modules

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
20.1.1 Tkinter Modules

Most of the time, the `Tkinter` module is all you really need, but a number of additional modules are available as well. The Tk interface is located in a binary module named `_tkinter`. This module contains the low-level interface to Tk, and should never be used directly by application programmers. It is usually a shared library (or DLL), but might in some cases be statically linked with the Python interpreter.

In addition to the Tk interface module, `Tkinter` includes a number of Python modules. The two most important modules are the `Tkinter` module itself, and a module called `Tkconstants`. The former automatically imports the latter, so to use Tkinter, all you need to do is to import one module:

```
import Tkinter
```

Or, more often:

```
from Tkinter import *
```

**class Tk**( `screenName=None, baseName=None, className='Tk', useTk=1` )

The `Tk` class is instantiated without arguments. This creates a toplevel widget of Tk which usually is the main window of an application. Each instance has its own associated Tcl interpreter. Changed in version 2.4: The `useTk` parameter was added.

**Tcl**( `screenName=None, baseName=None, className='Tk', useTk=0` )

The `Tcl` function is a factory function which creates an object much like that created by the `Tk` class, except that it does not initialize the Tk subsystem. This is most often useful when driving the Tcl interpreter in an environment where one doesn't want to create extraneous toplevel windows, or where one cannot (such as UNIX/Linux systems without an X server). An object created by the `Tcl` object can have a Toplevel window created (and the Tk subsystem initialized) by calling its `loadtk` method. New in version 2.4.

Other modules that provide Tk support include:
ScrolledText
Text widget with a vertical scroll bar built in.

tkColorChooser
Dialog to let the user choose a color.

tkCommonDialog
Base class for the dialogs defined in the other modules listed here.

tkFileDialog
Common dialogs to allow the user to specify a file to open or save.

tkFont
Utilities to help work with fonts.

tkMessageBox
Access to standard Tk dialog boxes.

tkSimpleDialog
Basic dialogs and convenience functions.

TkDnd
Drag-and-drop support for Tkinter. This is experimental and should become deprecated when it is replaced with the Tk DND.

turtle
Turtle graphics in a Tk window.
20.1.2 Tkinter Life Preserver

This section is not designed to be an exhaustive tutorial on either Tk or Tkinter. Rather, it is intended as a stop gap, providing some introductory orientation on the system.

Credits:

- Tkinter was written by Steen Lumholt and Guido van Rossum.
- Tk was written by John Ousterhout while at Berkeley.
- This Life Preserver was written by Matt Conway at the University of Virginia.
- The html rendering, and some liberal editing, was produced from a FrameMaker version by Ken Manheimer.
- Fredrik Lundh elaborated and revised the class interface descriptions, to get them current with Tk 4.2.
- Mike Clarkson converted the documentation to LaTeX, and compiled the User Interface chapter of the reference manual.

- 20.1.2.1 How To Use This Section
- 20.1.2.2 A Simple Hello World Program

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
20.1.3 A (Very) Quick Look at Tcl/Tk

The class hierarchy looks complicated, but in actual practice, application programmers almost always refer to the classes at the very bottom of the hierarchy.

Notes:

- These classes are provided for the purposes of organizing certain functions under one namespace. They aren't meant to be instantiated independently.

- The Tk class is meant to be instantiated only once in an application. Application programmers need not instantiate one explicitly, the system creates one whenever any of the other classes are instantiated.

- The Widget class is not meant to be instantiated, it is meant only for subclassing to make ```real``` widgets (in C++, this is called an `abstract class`).

To make use of this reference material, there will be times when you will need to know how to read short passages of Tk and how to identify the various parts of a Tk command. (See section 20.1.4 for the Tkinter equivalents of what's below.)

Tk scripts are Tcl programs. Like all Tcl programs, Tk scripts are just lists of tokens separated by spaces. A Tk widget is just its `class`, the `options` that help configure it, and the `actions` that make it do useful things.

To make a widget in Tk, the command is always of the form:

```
classCommand newPathname options
```

`classCommand`

denotes which kind of widget to make (a button, a label, a menu...)

`newPathname`

is the new name for this widget. All names in Tk must be unique. To help enforce this, widgets in Tk are named with `pathnames`, just like files in a file system. The top level widget, the `root`, is called `. (period)` and children
are delimited by more periods. For example, .myApp.controlPanel.okButton might be the name of a widget.

**options**

configure the widget's appearance and in some cases, its behavior. The options come in the form of a list of flags and values. Flags are proceeded by a `-`, like UNIX shell command flags, and values are put in quotes if they are more than one word.

For example:

```
button .fred -fg red -text "hi there"
```

Once created, the pathname to the widget becomes a new command. This new *widget command* is the programmer's handle for getting the new widget to perform some *action*. In C, you'd express this as someAction(fred, someOptions), in C++, you would express this as fred.someAction(someOptions), and in Tk, you say:

```
.fred someAction someOptions
```

Note that the object name, `.fred`, starts with a dot.

As you'd expect, the legal values for *someAction* will depend on the widget's class: `.fred disable` works if fred is a button (fred gets greyed out), but does not work if fred is a label (disabbling of labels is not supported in Tk).

The legal values of *someOptions* is action dependent. Some actions, like disable, require no arguments, others, like a text-entry box's delete command, would need arguments to specify what range of text to delete.
See About this document for information on suggesting changes.
20.1.4 Mapping Basic Tk into Tkinter

Class commands in Tk correspond to class constructors in Tkinter.

```python
button .fred

=====> fred = Button()
```

The master of an object is implicit in the new name given to it at creation time. In Tkinter, masters are specified explicitly.

```python
button .panel.fred

=====> fred = Button(panel)
```

The configuration options in Tk are given in lists of hyphenated tags followed by values. In Tkinter, options are specified as keyword-arguments in the instance constructor, and keyword-args for configure calls or as instance indices, in dictionary style, for established instances. See section 20.1.6 on setting options.

```python
button .fred -fg red

.fred configure -fg red

OR ==> fred.config(fg = "red")
```

In Tk, to perform an action on a widget, use the widget name as a command, and follow it with an action name, possibly with arguments (options). In Tkinter, you call methods on the class instance to invoke actions on the widget. The actions (methods) that a given widget can perform are listed in the Tkinter.py module.

```python
.fred invoke

=====> fred.invoke()
```

To give a widget to the packer (geometry manager), you call pack with optional arguments. In Tkinter, the Pack class holds all this functionality, and the various forms of the pack command are implemented as methods. All widgets in Tkinter are subclassed from the Packer, and so inherit all the packing methods. See the Tix module documentation for additional information on the Form geometry manager.

```python
pack .fred -side left

=====> fred.pack(side = "left")
```
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
20.1.5 How Tk and Tkinter are Related

Note: This was derived from a graphical image; the image will be used more directly in a subsequent version of this document.

From the top down:

**Your App Here (Python)**
A Python application makes a Tkinter call.

**Tkinter (Python Module)**
This call (say, for example, creating a button widget), is implemented in the Tkinter module, which is written in Python. This Python function will parse the commands and the arguments and convert them into a form that makes them look as if they had come from a Tk script instead of a Python script.

**tkinter (C)**
These commands and their arguments will be passed to a C function in the tkinter - note the lowercase - extension module.

**Tk Widgets (C and Tcl)**
This C function is able to make calls into other C modules, including the C functions that make up the Tk library. Tk is implemented in C and some Tcl. The Tcl part of the Tk widgets is used to bind certain default behaviors to widgets, and is executed once at the point where the Python Tkinter module is imported. (The user never sees this stage).

**Tk (C)**
The Tk part of the Tk Widgets implement the final mapping to ...

**Xlib (C)**
The Xlib library to draw graphics on the screen.
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
20.2 Tix -- Extension widgets for Tk

The Tix (Tk Interface Extension) module provides an additional rich set of widgets. Although the standard Tk library has many useful widgets, they are far from complete. The Tix library provides most of the commonly needed widgets that are missing from standard Tk: HList, ComboBox, Control (a.k.a. SpinBox) and an assortment of scrollable widgets. Tix also includes many more widgets that are generally useful in a wide range of applications: Notebook, FileEntry, PanedWindow, etc; there are more than 40 of them.

With all these new widgets, you can introduce new interaction techniques into applications, creating more useful and more intuitive user interfaces. You can design your application by choosing the most appropriate widgets to match the special needs of your application and users.

  - 20.2.2.6 Image Types
  - 20.2.2.7 Miscellaneous Widgets
  - 20.2.2.8 Form Geometry Manager

20.2.3 Tix Commands

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
20.2.1 Using Tix

class Tix( screenName[, baseName[, className]])

Toplevel widget of Tix which represents mostly the main window of an application. It has an associated Tcl interpreter.

Classes in the Tix module subclasses the classes in the Tkinter module. The former imports the latter, so to use Tix with Tkinter, all you need to do is to import one module. In general, you can just import Tix, and replace the toplevel call to Tkinter.Tk with Tix.Tk:

```
import Tix
from Tkconstants import *
root = Tix.Tk()
```

To use Tix, you must have the Tix widgets installed, usually alongside your installation of the Tk widgets. To test your installation, try the following:

```
import Tix
root = Tix.Tk()
root.tk.eval('package require Tix')
```

If this fails, you have a Tk installation problem which must be resolved before proceeding. Use the environment variable TIX_LIBRARY to point to the installed Tix library directory, and make sure you have the dynamic object library (tix8183.dll or libtix8183.so) in the same directory that contains your Tk dynamic object library (tk8183.dll or libtk8183.so). The directory with the dynamic object library should also have a file called pkgIndex.tcl (case sensitive), which contains the line:

```
package ifneeded Tix 8.1 [list load "[file join $dir tix8183.dll"]"
```

---

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
20.2.2 Tix Widgets

Tix introduces over 40 widget classes to the Tkinter repertoire. There is a demo of all the Tix widgets in the Demo/tix directory of the standard distribution.

Subsections

- 20.2.2.1 Basic Widgets
- 20.2.2.2 File Selectors
- 20.2.2.3 Hierachical ListBox
- 20.2.2.4 Tabular ListBox
- 20.2.2.5 Manager Widgets
- 20.2.2.6 Image Types
- 20.2.2.7 Miscellaneous Widgets
- 20.2.2.8 Form Geometry Manager

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
20.2.3 Tix Commands

class tixCommand():
    The tix commands provide access to miscellaneous elements of Tix's internal state and the Tix application context. Most of the information manipulated by these methods pertains to the application as a whole, or to a screen or display, rather than to a particular window.

    To view the current settings, the common usage is:

        import Tix
        root = Tix.Tk()
        print root.tix_configure()

    tix_configure([cnf], **kw)
    Query or modify the configuration options of the Tix application context. If no option is specified, returns a dictionary all of the available options. If option is specified with no value, then the method returns a list describing the one named option (this list will be identical to the corresponding sublist of the value returned if no option is specified). If one or more option-value pairs are specified, then the method modifies the given option(s) to have the given value(s); in this case the method returns an empty string. Option may be any of the configuration options.

    tix_cget(option)
    Returns the current value of the configuration option given by option. Option may be any of the configuration options.

    tix_getbitmap(name)
    Locates a bitmap file of the name name.xpm or name in one of the bitmap directories (see the tix_addbitmapdir() method). By using tix_getbitmap(), you can avoid hard coding the pathnames of the bitmap files in your application. When successful, it returns the complete pathname of the bitmap file, prefixed with the character "@". The returned value can be used to configure the bitmap option of the Tk and Tix widgets.
**tix_addbitmapdir(directory)**

Tix maintains a list of directories under which the `tix_getimage()` and `tix_getbitmap()` methods will search for image files. The standard bitmap directory is `$TIX_LIBRARY/bitmaps`. The `tix_addbitmapdir()` method adds `directory` into this list. By using this method, the image files of an application can also be located using the `tix_getimage()` or `tix_getbitmap()` method.

**tix_filedialog([dlgclass])**

Returns the file selection dialog that may be shared among different calls from this application. This method will create a file selection dialog widget when it is called for the first time. This dialog will be returned by all subsequent calls to `tix_filedialog()`. An optional dlgclass parameter can be passed as a string to specify what type of file selection dialog widget is desired. Possible options are `tix`, `FileSelectDialog` or `tixExFileSelectDialog`.

**tix_getimage(self, name)**

Locates an image file of the name `name.xpm`, `name.xbm` or `name.ppm` in one of the bitmap directories (see the `tix_addbitmapdir()` method above). If more than one file with the same name (but different extensions) exist, then the image type is chosen according to the depth of the X display: `xbm` images are chosen on monochrome displays and color images are chosen on color displays. By using `tix_getimage()`, you can avoid hard coding the pathnames of the image files in your application. When successful, this method returns the name of the newly created image, which can be used to configure the `image` option of the Tk and Tix widgets.

**tix_option_get(name)**

Gets the options maintained by the Tix scheme mechanism.

**tix_resetoptions(newScheme, newFontSet[, newScmPrio])**

Resets the scheme and fontset of the Tix application to `newScheme` and `newFontSet`, respectively. This affects only those widgets created after this call. Therefore, it is best to call the resetoptions method before the creation of any widgets in a Tix application.
The optional parameter `newScmPrio` can be given to reset the priority level of the Tk options set by the Tix schemes.

Because of the way Tk handles the X option database, after Tix has been imported and initied, it is not possible to reset the color schemes and font sets using the `tix_config()` method. Instead, the `tix_resetoptions()` method must be used.
20.3 ScrolledText -- Scrolled Text Widget

Availability: Tk.

The ScrolledText module provides a class of the same name which implements a basic text widget which has a vertical scroll bar configured to do the "right thing." Using the ScrolledText class is a lot easier than setting up a text widget and scroll bar directly. The constructor is the same as that of the Tkinter.Text class.

The text widget and scrollbar are packed together in a Frame, and the methods of the Grid and Pack geometry managers are acquired from the Frame object. This allows the ScrolledText widget to be used directly to achieve most normal geometry management behavior.

Should more specific control be necessary, the following attributes are available:

**frame**

The frame which surrounds the text and scroll bar widgets.

**vbar**

The scroll bar widget.
20.4 turtle -- Turtle graphics for Tk

Availability: Tk.

The turtle module provides turtle graphics primitives, in both an object-oriented and procedure-oriented ways. Because it uses Tkinter for the underlying graphics, it needs a version of python installed with Tk support.

The procedural interface uses a pen and a canvas which are automagically created when any of the functions are called.

The turtle module defines the following functions:

**degrees()**
Set angle measurement units to degrees.

**radians()**
Set angle measurement units to radians.

**setup(**kwargs**)**
Sets the size and position of the main window. Keywords are:
- **width**: either a size in pixels or a fraction of the screen. The default is 50% of the screen.
- **height**: either a size in pixels or a fraction of the screen. The default is 50% of the screen.
- **startx**: starting position in pixels from the left edge of the screen. None is the default value and centers the window horizontally on screen.
- **starty**: starting position in pixels from the top edge of the screen. None is the default value and centers the window vertically on screen.

Examples:

```
# Uses default geometry: 50% x 50% of screen, centered.
setup()

# Sets window to 200x200 pixels, in upper left of screen
```
setup (width=200, height=200, startx=0, starty=0)

# Sets window to 75% of screen by 50% of screen, and centers it.
setup(width=.75, height=0.5, startx=None, starty=None)

title(title_str)
    Set the window's title to title.

done()
    Enters the Tk main loop. The window will continue to be displayed until
    the user closes it or the process is killed.

reset()
    Clear the screen, re-center the pen, and set variables to the default values.

clear()
    Clear the screen.

tracer(flag)
    Set tracing on/off (according to whether flag is true or not). Tracing means
    line are drawn more slowly, with an animation of an arrow along the line.

speed(speed)
    Set the speed of the turtle. Valid values for the parameter speed are
    'fastest' (no delay), 'fast', (delay 5ms), 'normal' (delay 10ms),
    'slow' (delay 15ms), and 'slowest' (delay 20ms). New in version
    2.5.

delay(delay)
    Set the speed of the turtle to delay, which is given in ms. New in version
    2.5.

forward(distance)
    Go forward distance steps.

backward(distance)
    Go backward distance steps.
left(\textit{angle})
Turn left \textit{angle} units. Units are by default degrees, but can be set via the degrees() and radians() functions.

right(\textit{angle})
Turn right \textit{angle} units. Units are by default degrees, but can be set via the degrees() and radians() functions.

up()
Move the pen up -- stop drawing.

down()
Move the pen down -- draw when moving.

width(\textit{width})
Set the line width to \textit{width}.

color(\textit{s})
color((r, g, b))
color(r, g, b)
Set the pen color. In the first form, the color is specified as a Tk color specification as a string. The second form specifies the color as a tuple of the RGB values, each in the range \([0..1]\). For the third form, the color is specified giving the RGB values as three separate parameters (each in the range \([0..1]\)).

write(\textit{text[, move]})
Write \textit{text} at the current pen position. If \textit{move} is true, the pen is moved to the bottom-right corner of the text. By default, \textit{move} is false.

fill(\textit{flag})
The complete specifications are rather complex, but the recommended usage is: call \texttt{fill(1)} before drawing a path you want to fill, and call \texttt{fill(0)} when you finish to draw the path.

begin_fill()
Switch turtle into filling mode; Must eventually be followed by a corresponding end_fill() call. Otherwise it will be ignored. New in version 2.5.

**end_fill()**
End filling mode, and fill the shape; equivalent to fill(0). New in version 2.5.

**circle(radius[, extent])**
Draw a circle with radius radius whose center-point is radius units left of the turtle. extent determines which part of a circle is drawn: if not given it defaults to a full circle.

If extent is not a full circle, one endpoint of the arc is the current pen position. The arc is drawn in a counter clockwise direction if radius is positive, otherwise in a clockwise direction. In the process, the direction of the turtle is changed by the amount of the extent.

**goto(x, y)**
**goto((x, y))**
Go to co-ordinates x, y. The co-ordinates may be specified either as two separate arguments or as a 2-tuple.

**towards(x, y)**
Return the angle of the line from the turtle's position to the point x, y. The co-ordinates may be specified either as two separate arguments, as a 2-tuple, or as another pen object. New in version 2.5.

**heading()**
Return the current orientation of the turtle. New in version 2.3.

**setheading(angle)**
Set the orientation of the turtle to angle. New in version 2.3.

**position()**
Return the current location of the turtle as an (x, y) pair. New in version 2.3.
setx(x)
Set the x coordinate of the turtle to x. New in version 2.3.

sety(y)
Set the y coordinate of the turtle to y. New in version 2.3.

window_width()
Return the width of the canvas window. New in version 2.3.

window_height()
Return the height of the canvas window. New in version 2.3.

This module also does from math import *, so see the documentation for the math module for additional constants and functions useful for turtle graphics.

demo()
Exercise the module a bit.

exception Error
Exception raised on any error caught by this module.

For examples, see the code of the demo() function.

This module defines the following classes:

class Pen()
Define a pen. All above functions can be called as a methods on the given pen. The constructor automatically creates a canvas do be drawn on.

class Turtle()
Define a pen. This is essentially a synonym for Pen(); Turtle is an empty subclass of Pen.

class RawPen(canvas)
Define a pen which draws on a canvas canvas. This is useful if you want to use the module to create graphics in a ``real" program.
20.4.1 Turtle, Pen and RawPen Objects

Most of the global functions available in the module are also available as methods of the Turtle, Pen and RawPen classes, affecting only the state of the given pen.

The only method which is more powerful as a method is `degrees()`, which takes an optional argument letting you specify the number of units corresponding to a full circle:

```
degrees([fullcircle])
```

`fullcircle` is by default 360. This can cause the pen to have any angular units whatever: give `fullcircle 2*\pi` for radians, or 400 for gradians.
20.5 Idle

Idle is the Python IDE built with the Tkinter GUI toolkit.

IDLE has the following features:

- coded in 100% pure Python, using the Tkinter GUI toolkit
- cross-platform: works on Windows and UNIX (on Mac OS, there are currently problems with Tcl/Tk)
- multi-window text editor with multiple undo, Python colorizing and many other features, e.g. smart indent and call tips
- Python shell window (a.k.a. interactive interpreter)
- debugger (not complete, but you can set breakpoints, view and step)

---

20.5.1 Menus

Subsections

- 20.5.1.1 File menu
- 20.5.1.2 Edit menu
- 20.5.1.3 Windows menu
- 20.5.1.4 Debug menu (in the Python Shell window only)

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
20.5.2 Basic editing and navigation

- Backspace deletes to the left; Del deletes to the right
- Arrow keys and Page Up/Page Down to move around
- Home/End go to begin/end of line
- C-Home/C-End go to begin/end of file
- Some Emacs bindings may also work, including C-B, C-P, C-A, C-E, C-D, C-L
Command line usage
20.5.3 Syntax colors

The coloring is applied in a background `thread`, so you may occasionally see uncolorized text. To change the color scheme, edit the [Colors] section in config.txt.

Python syntax colors:

- **Keywords**: orange
- **Strings**: green
- **Comments**: red
- **Definitions**: blue

Shell colors:

- **Console output**: brown
- **stdout**: blue
- **stderr**: dark green
- **stdin**: black

20.6 Other Graphical User Interface Packages

There are an number of extension widget sets to Tkinter.

**Python megawidgets**

is a toolkit for building high-level compound widgets in Python using the Tkinter module. It consists of a set of base classes and a library of flexible and extensible megawidgets built on this foundation. These megawidgets include notebooks, comboboxes, selection widgets, paned widgets, scrolled widgets, dialog windows, etc. Also, with the Pmw.Blt interface to BLT, the busy, graph, stripchart, tabset and vector commands are be available.

The initial ideas for Pmw were taken from the Tk itcl extensions [incr Tk] by Michael McLennan and [incr Widgets] by Mark Ulferts. Several of the megawidgets are direct translations from the itcl to Python. It offers most of the range of widgets that [incr Widgets] does, and is almost as complete as Tix, lacking however Tix’s fast HList widget for drawing trees.

**Tkinter3000 Widget Construction Kit (WCK)**

is a library that allows you to write new Tkinter widgets in pure Python. The WCK framework gives you full control over widget creation, configuration, screen appearance, and event handling. WCK widgets can be very fast and light-weight, since they can operate directly on Python data structures, without having to transfer data through the Tk/Tcl layer.

Other GUI packages are also available for Python:

**wxPython**

wxPython is a cross-platform GUI toolkit for Python that is built around the popular wxWidgets C++ toolkit. It provides a native look and feel for applications on Windows, Mac OS X, and UNIX systems by using each platform's native widgets where ever possible, (GTK+ on UNIX-like systems). In addition to an extensive set of widgets, wxPython provides
classes for online documentation and context sensitive help, printing, HTML viewing, low-level device context drawing, drag and drop, system clipboard access, an XML-based resource format and more, including an ever growing library of user-contributed modules. Both the wxWidgets and wxPython projects are under active development and continuous improvement, and have active and helpful user and developer communities.

wxPython in Action
The wxPython book, by Noel Rappin and Robin Dunn.

PyQt
PyQt is a sip-wrapped binding to the Qt toolkit. Qt is an extensive C++ GUI toolkit that is available for UNIX, Windows and Mac OS X. sip is a tool for generating bindings for C++ libraries as Python classes, and is specifically designed for Python. An online manual is available at http://www.opendocspublishing.com/pyqt/ (errata are located at http://www.valdyas.org/python/book.html).

PyKDE
PyKDE is a sip-wrapped interface to the KDE desktop libraries. KDE is a desktop environment for UNIX computers; the graphical components are based on Qt.

EXPy
is a Python extension module which provides an interface to the FOX GUI. FOX is a C++ based Toolkit for developing Graphical User Interfaces easily and effectively. It offers a wide, and growing, collection of Controls, and provides state of the art facilities such as drag and drop, selection, as well as OpenGL widgets for 3D graphical manipulation. FOX also implements icons, images, and user-convenience features such as status line help, and tooltips.

Even though FOX offers a large collection of controls already, FOX leverages C++ to allow programmers to easily build additional Controls and GUI elements, simply by taking existing controls, and creating a derived class which simply adds or redefines the desired behavior.

PyGTK
is a set of bindings for the GTK widget set. It provides an object oriented
interface that is slightly higher level than the C one. It automatically does all the type casting and reference counting that you would have to do normally with the C API. There are also bindings to GNOME, and a tutorial is available.
21. Internationalization

The modules described in this chapter help you write software that is independent of language and locale by providing mechanisms for selecting a language to be used in program messages or by tailoring output to match local conventions.

The list of modules described in this chapter is:

- **gettext** Multilingual internationalization services.
- **locale** Internationalization services.

*Release 2.5, documentation updated on 19th September, 2006.*

See [About this document...](#) for information on suggesting changes.
21.1 gettext -- Multilingual internationalization services

The gettext module provides internationalization (I18N) and localization (L10N) services for your Python modules and applications. It supports both the GNU gettext message catalog API and a higher level, class-based API that may be more appropriate for Python files. The interface described below allows you to write your module and application messages in one natural language, and provide a catalog of translated messages for running under different natural languages.

Some hints on localizing your Python modules and applications are also given.

Python Library Reference

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
21.1.1 GNU gettext API

The `gettext` module defines the following API, which is very similar to the GNU `gettext` API. If you use this API you will affect the translation of your entire application globally. Often this is what you want if your application is monolingual, with the choice of language dependent on the locale of your user. If you are localizing a Python module, or if your application needs to switch languages on the fly, you probably want to use the class-based API instead.

`bindtextdomain`\( (\textit{domain}[, \textit{localedir}])\)

Bind the `domain` to the locale directory `localedir`. More concretely, `gettext` will look for binary `.mo` files for the given domain using the path (on UNiX): `localedir/language/LC_MESSAGES/domain.mo`, where `languages` is searched for in the environment variables `LANGUAGE`, `LC_ALL`, `LC_MESSAGES`, and `LANG` respectively.

If `localedir` is omitted or `None`, then the current binding for `domain` is returned.\(^\text{21.1}\)

`bind_textdomain_codeset`\( (\textit{domain}[, \textit{codeset}])\)

Bind the `domain` to `codeset`, changing the encoding of strings returned by the `gettext()` family of functions. If `codeset` is omitted, then the current binding is returned.

New in version 2.4.

`textdomain`\( (\textit{[\textit{domain}]}))\)

Change or query the current global domain. If `domain` is `None`, then the current global domain is returned, otherwise the global domain is set to `domain`, which is returned.

`gettext`\( (\textit{message})\)

Return the localized translation of `message`, based on the current global domain, language, and locale directory. This function is usually aliased as `_` in the local namespace (see examples below).
lgettext( message)  
Equivalent to gettext(), but the translation is returned in the preferred 
system encoding, if no other encoding was explicitly set with
bind_textdomain_codeset().

New in version 2.4.

dgettext( domain, message)  
Like gettext(), but look the message up in the specified domain.

ldgettext( domain, message)  
Equivalent to dgettext(), but the translation is returned in the preferred 
system encoding, if no other encoding was explicitly set with
bind_textdomain_codeset().

New in version 2.4.

ngettext( singular, plural, n)  
Like gettext(), but consider plural forms. If a translation is found,
apply the plural formula to n, and return the resulting message (some
languages have more than two plural forms). If no translation is found,
return singular if n is 1; return plural otherwise.

The Plural formula is taken from the catalog header. It is a C or Python
expression that has a free variable n; the expression evaluates to the index
of the plural in the catalog. See the GNU gettext documentation for the
precise syntax to be used in .po files, and the formulas for a variety of
languages.

New in version 2.3.

lngettext( singular, plural, n)  
Equivalent to ngettext(), but the translation is returned in the preferred
system encoding, if no other encoding was explicitly set with
bind_textdomain_codeset().

New in version 2.4.
**dngettext** *(domain, singular, plural, n)*

Like **ngettext()**, but look the message up in the specified *domain*.

New in version 2.3.

**ldngettext** *(domain, singular, plural, n)*

Equivalent to **dngettext()**, but the translation is returned in the preferred system encoding, if no other encoding was explicitly set with **bind_textdomain_codeset()**.

New in version 2.4.

Note that GNU **gettext** also defines a **dcgettext()** method, but this was deemed not useful and so it is currently unimplemented.

Here's an example of typical usage for this API:

```python
import gettext
gettext.bindtextdomain('myapplication', '/path/to/my/language/directory')
gettext.textdomain('myapplication')
_
 = gettext.gettext
#
...
print _('This is a translatable string.')
```

---

**Footnotes**

... returned

The default locale directory is system dependent; for example, on RedHat Linux it is `/usr/share/locale`, but on Solaris it is `/usr/lib/locale`. The **gettext** module does not try to support these system dependent defaults; instead its default is `sys.prefix/share/locale`. For this reason, it is always best to call **bindtextdomain()** with an explicit absolute path at the start of your application.

---

**Python Library Reference**

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
21.1.2 Class-based API

The class-based API of the gettext module gives you more flexibility and greater convenience than the GNU gettext API. It is the recommended way of localizing your Python applications and modules. gettext defines a "translations" class which implements the parsing of GNU .mo format files, and has methods for returning either standard 8-bit strings or Unicode strings. Instances of this "translations" class can also install themselves in the built-in namespace as the function _().

find( domain[, localedir[, languages[, all]]])

This function implements the standard .mo file search algorithm. It takes a domain, identical to what textdomain() takes. Optional localedir is as in bindtextdomain() Optional languages is a list of strings, where each string is a language code.

If localedir is not given, then the default system locale directory is used. If languages is not given, then the following environment variables are searched: LANGUAGE, LC_ALL, LC_MESSAGES, and LANG. The first one returning a non-empty value is used for the languages variable. The environment variables should contain a colon separated list of languages, which will be split on the colon to produce the expected list of language code strings.

find() then expands and normalizes the languages, and then iterates through them, searching for an existing file built of these components:

localedir/language/LC_MESSAGES/domain.mo

The first such file name that exists is returned by find(). If no such file is found, then None is returned. If all is given, it returns a list of all file names, in the order in which they appear in the languages list or the environment variables.

translation( domain[, localedir[, languages[, class[, fallback[, codeset]]]]]])
Return a Translations instance based on the domain, localedir, and languages, which are first passed to find() to get a list of the associated .mo file paths. Instances with identical .mo file names are cached. The actual class instantiated is either class_ if provided, otherwise GNUTranslations. The class's constructor must take a single file object argument. If provided, codeset will change the charset used to encode translated strings.

If multiple files are found, later files are used as fallbacks for earlier ones. To allow setting the fallback, copy.copy is used to clone each translation object from the cache; the actual instance data is still shared with the cache.

If no .mo file is found, this function raises IOError if fallback is false (which is the default), and returns a NullTranslations instance if fallback is true.

Changed in version 2.4: Added the codeset parameter.

install( domain[, localedir[, unicode [, codeset[, names]]]])
This installs the function _ in Python's builtin namespace, based on domain, localedir, and codeset which are passed to the function translation(). The unicode flag is passed to the resulting translation object's install method.

For the names parameter, please see the description of the translation object's install method.

As seen below, you usually mark the strings in your application that are candidates for translation, by wrapping them in a call to the _() function, like this:

    print _('This string will be translated. ')

For convenience, you want the _() function to be installed in Python's builtin namespace, so it is easily accessible in all modules of your application.

Changed in version 2.4: Added the codeset parameter. Changed in version 2.5: Added the names parameter.
Footnotes

... used. 21.2

See the footnote for bindtextdomain() above.

Subsections

Localizing your module
21.1.3 Internationalizing your programs and modules

Internationalization (I18N) refers to the operation by which a program is made aware of multiple languages. Localization (L10N) refers to the adaptation of your program, once internationalized, to the local language and cultural habits. In order to provide multilingual messages for your Python programs, you need to take the following steps:

1. prepare your program or module by specially marking translatable strings
2. run a suite of tools over your marked files to generate raw messages catalogs
3. create language specific translations of the message catalogs
4. use the gettext module so that message strings are properly translated

In order to prepare your code for I18N, you need to look at all the strings in your files. Any string that needs to be translated should be marked by wrapping it in $\text{\_\_}('\ldots')$ -- that is, a call to the function $\text{\_\_}()$. For example:

```python
filename = 'mylog.txt'
message = $\text{\_\_}('writing a log message')$
fp = open(filename, 'w')
fp.write(message)
fp.close()
```

In this example, the string 'writing a log message' is marked as a candidate for translation, while the strings 'mylog.txt' and 'w' are not.

The Python distribution comes with two tools which help you generate the message catalogs once you've prepared your source code. These may or may not be available from a binary distribution, but they can be found in a source distribution, in the Tools/i18n directory.

The pygettext program scans all your Python source code looking for the strings you previously marked as translatable. It is similar to the GNU gettext program except that it understands all the intricacies of Python source code, but knows nothing about C or C++ source code. You don't need GNU gettext unless you're also going to be translating C code (such as C extension modules).
**pygettext** generates textual Uniforum-style human readable message catalog .pot files, essentially structured human readable files which contain every marked string in the source code, along with a placeholder for the translation strings. **pygettext** is a command line script that supports a similar command line interface as **xgettext**; for details on its use, run:

```
pygettext.py --help
```

Copies of these .pot files are then handed over to the individual human translators who write language-specific versions for every supported natural language. They send you back the filled in language-specific versions as a .po file. Using the **msgfmt.py** program (in the Tools/i18n directory), you take the .po files from your translators and generate the machine-readable .mo binary catalog files. The .mo files are what the gettext module uses for the actual translation processing during run-time.

How you use the gettext module in your code depends on whether you are internationalizing a single module or your entire application. The next two sections will discuss each case.

---

**Footnotes**

...**pygettext**

François Pinard has written a program called **xpot** which does a similar job. It is available as part of his **po-utils** package at [http://po-utils.progiciels-bpi.ca/](http://po-utils.progiciels-bpi.ca/).

...**msgfmt.py**

**msgfmt.py** is binary compatible with GNU **msgfmt** except that it provides a simpler, all-Python implementation. With this and **pygettext.py**, you generally won't need to install the GNU gettext package to internationalize your Python applications.

21.2 locale -- Internationalization services

The `locale` module opens access to the POSIX locale database and functionality. The POSIX locale mechanism allows programmers to deal with certain cultural issues in an application, without requiring the programmer to know all the specifics of each country where the software is executed.

The `locale` module is implemented on top of the `_locale` module, which in turn uses an ANSI C locale implementation if available.

The `locale` module defines the following exception and functions:

**exception Error**

Exception raised when `setlocale()` fails.

**setlocale**( `category[, locale]` )

If `locale` is specified, it may be a string, a tuple of the form `(language code, encoding)`, or `None`. If it is a tuple, it is converted to a string using the locale aliasing engine. If `locale` is given and not `None`, `setlocale()` modifies the locale setting for the `category`. The available categories are listed in the data description below. The value is the name of a locale. An empty string specifies the user's default settings. If the modification of the locale fails, the exception `Error` is raised. If successful, the new locale setting is returned.

If `locale` is omitted or `None`, the current setting for `category` is returned.

`setlocale()` is not thread safe on most systems. Applications typically start with a call of

```python
import locale
locale.setlocale(locale.LC_ALL, '')
```

This sets the locale for all categories to the user's default setting (typically specified in the LANG environment variable). If the locale is not changed
thereafter, using multithreading should not cause problems.

Changed in version 2.0: Added support for tuple values of the `locale` parameter.

`localeconv()`

Returns the database of the local conventions as a dictionary. This dictionary has the following strings as keys:

<table>
<thead>
<tr>
<th>Category</th>
<th>Key</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>LC_NUMERIC</td>
<td>'decimal_point'</td>
<td>Decimal point character.</td>

from the value space (for positive resp. negative values).

| 'mon_decimal_point' | Decimal point used for monetary values. |
| 'frac_digits' | Number of fractional digits used in local formatting monetary values. |
| 'int_frac_digits' | Number of fractional digits used in international formatting of monetary values. |
| 'mon_thousands_sep' | Group separator used for monetary values. |
| 'mon_grouping' | Equivalent to 'grouping' for monetary values. |
| 'positive_sign' | Symbol used to annotate a positive monetary value. |
| 'negative_sign' | Symbol used to annotate a negative monetary value. |
| 'p_sign_posn/n_sign_posn' | The position of the sign (for positive resp. negative values), see below. |

All numeric values can be set to CHAR_MAX to indicate that there is no value specified in this locale.

The possible values for 'p_sign_posn' and 'n_sign_posn' are given below.

<table>
<thead>
<tr>
<th>Value</th>
<th>Explanation</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>Currency and value are surrounded by parentheses.</td>
</tr>
</tbody>
</table>
1 The sign should precede the value and currency symbol.
2 The sign should follow the value and currency symbol.
3 The sign should immediately precede the value.
4 The sign should immediately follow the value.

CHAR_MAX Nothing is specified in this locale.

**nl_langinfo** *(option)*

Return some locale-specific information as a string. This function is not available on all systems, and the set of possible options might also vary across platforms. The possible argument values are numbers, for which symbolic constants are available in the locale module.

**getdefaultlocale** *[envvars]*

Tries to determine the default locale settings and returns them as a tuple of the form *(language code, encoding)*.

According to POSIX, a program which has not called `setlocale(LC_ALL, '')` runs using the portable 'C' locale. Calling `setlocale(LC_ALL, '')` lets it use the default locale as defined by the LANG variable. Since we do not want to interfere with the current locale setting we thus emulate the behavior in the way described above.

To maintain compatibility with other platforms, not only the LANG variable is tested, but a list of variables given as envvars parameter. The first found to be defined will be used. envvars defaults to the search path used in GNU gettext; it must always contain the variable name "LANG". The GNU gettext search path contains 'LANGUAGE ', 'LC_ALL ', 'LC_CTYPE ', and 'LANG ', in that order.

Except for the code 'C ', the language code corresponds to RFC 1766. *language code* and *encoding* may be None if their values cannot be determined. New in version 2.0.

**getlocale** *[category]*

Returns the current setting for the given locale category as sequence containing *language code, encoding*. *category* may be one of the LC__*
values except LC_ALL. It defaults to LC_CTYPE.

Except for the code 'C', the language code corresponds to RFC 1766. language code and encoding may be None if their values cannot be determined. New in version 2.0.

getpreferredencoding([do_setlocale])
Return the encoding used for text data, according to user preferences. User preferences are expressed differently on different systems, and might not be available programmatically on some systems, so this function only returns a guess.

On some systems, it is necessary to invoke setlocale to obtain the user preferences, so this function is not thread-safe. If invoking setlocale is not necessary or desired, do_setlocale should be set to False.

New in version 2.3.

normalize(localename)
Returns a normalized locale code for the given locale name. The returned locale code is formatted for use with setlocale(). If normalization fails, the original name is returned unchanged.

If the given encoding is not known, the function defaults to the default encoding for the locale code just like setlocale(). New in version 2.0.

resetlocale([category])
Sets the locale for category to the default setting.

The default setting is determined by calling getdefaultlocale(). category defaults to LC_ALL. New in version 2.0.

strcoll(string1, string2)
Compares two strings according to the current LC_COLLATE setting. As any other compare function, returns a negative, or a positive value, or 0, depending on whether string1 collates before or after string2 or is equal to it.
**strxfrm**(*string*)

Transforms a string to one that can be used for the built-in function `cmp()`, and still returns locale-aware results. This function can be used when the same string is compared repeatedly, e.g. when collating a sequence of strings.

**format**(*format*, *val*, *grouping*[*, monetary]*)

Formats a number *val* according to the current LC_NUMERIC setting. The format follows the conventions of the `%` operator. For floating point values, the decimal point is modified if appropriate. If *grouping* is true, also takes the grouping into account.

If *monetary* is true, the conversion uses monetary thousands separator and grouping strings.

Please note that this function will only work for exactly one `%` char specifier. For whole format strings, use `format_string()`.

Changed in version 2.5: Added the *monetary* parameter.

**format_string**(*format*, *val*, *grouping*)

Processes formatting specifiers as in `format % val`, but takes the current locale settings into account.

New in version 2.5.

**currency**(*val*, *symbol*, *grouping*[*, international]*)

Formats a number *val* according to the current LC_MONETARY settings.

The returned string includes the currency symbol if *symbol* is true, which is the default. If *grouping* is true (which is not the default), grouping is done with the value. If *international* is true (which is not the default), the international currency symbol is used.

Note that this function will not work with the `C` locale, so you have to set a locale via `setlocale()` first.

New in version 2.5.
**str** *(float)*
Formats a floating point number using the same format as the built-in function `str(float)`, but takes the decimal point into account.

**atof** *(string)*
Converts a string to a floating point number, following the **LC_NUMERIC** settings.

**atoi** *(string)*
Converts a string to an integer, following the **LC_NUMERIC** conventions.

**LC CTYPE**
Locale category for the character type functions. Depending on the settings of this category, the functions of module `string` dealing with case change their behaviour.

**LC_COLLATE**
Locale category for sorting strings. The functions `strcoll()` and `strxfrm()` of the `locale` module are affected.

**LC TIME**
Locale category for the formatting of time. The function `time.strftime()` follows these conventions.

**LC_MONETARY**
Locale category for formatting of monetary values. The available options are available from the `localeconv()` function.

**LC_MESSAGES**
Locale category for message display. Python currently does not support application specific locale-aware messages. Messages displayed by the operating system, like those returned by `os.strerror()` might be affected by this category.

**LC_NUMERIC**
Locale category for formatting numbers. The functions `format()`, `atoi()`, `atof()` and `str()` of the `locale` module are affected by that category. All other numeric formatting operations are not affected.
**LC_ALL**
Combination of all locale settings. If this flag is used when the locale is changed, setting the locale for all categories is attempted. If that fails for any category, no category is changed at all. When the locale is retrieved using this flag, a string indicating the setting for all categories is returned. This string can be later used to restore the settings.

**CHAR_MAX**
This is a symbolic constant used for different values returned by `localeconv()`.

The `nl_langinfo` function accepts one of the following keys. Most descriptions are taken from the corresponding description in the GNU C library.

**CODESET**
Return a string with the name of the character encoding used in the selected locale.

**D_T_FMT**
Return a string that can be used as a format string for `strftime(3)` to represent time and date in a locale-specific way.

**D_FMT**
Return a string that can be used as a format string for `strftime(3)` to represent a date in a locale-specific way.

**T_FMT**
Return a string that can be used as a format string for `strftime(3)` to represent a time in a locale-specific way.

**T_FMT_AMPM**
The return value can be used as a format string for `strftime` to represent time in the am/pm format.

**DAY_1 . . . DAY_7**
Return name of the n-th day of the week. **Warning:** This follows the US convention of `DAY_1` being Sunday, not the international convention (ISO 8601) that Monday is the first day of the week.

**ABDAY_1 . . . ABDAY_7**
Return abbreviated name of the n-th day of the week.

**MON_1 . . . MON_12**
Return name of the n-th month.

**ABMON_1 . . . ABMON_12**
Return abbreviated name of the n-th month.

**RADIXCHAR**
Return radix character (decimal dot, decimal comma, etc.)

**THOUSEP**
Return separator character for thousands (groups of three digits).

**YESEXPR**
Return a regular expression that can be used with the regex function to recognize a positive response to a yes/no question. **Warning:** The expression is in the syntax suitable for the `regex()` function from the C library, which might differ from the syntax used in `re`.

**NOEXPR**
Return a regular expression that can be used with the `regex(3)` function to recognize a negative response to a yes/no question.

**CRNCYSTR**
Return the currency symbol, preceded by "-" if the symbol should appear before the value, "+" if the symbol should appear after the value, or "." if the symbol should replace the radix character.

**ERA**
The return value represents the era used in the current locale.

Most locales do not define this value. An example of a locale which does define this value is the Japanese one. In Japan, the traditional representation of dates includes the name of the era corresponding to the then-emperor’s reign.

Normally it should not be necessary to use this value directly. Specifying the `E` modifier in their format strings causes the `strftime` function to use this information. The format of the returned string is not specified, and
therefore you should not assume knowledge of it on different systems.

**ERA_YEAR**
The return value gives the year in the relevant era of the locale.

**ERA_D_T_FMT**
This return value can be used as a format string for `strftime` to represent dates and times in a locale-specific era-based way.

**ERA_D_FMT**
This return value can be used as a format string for `strftime` to represent time in a locale-specific era-based way.

**ALT_DIGITS**
The return value is a representation of up to 100 values used to represent the values 0 to 99.

Example:

```python
>>> import locale
>>> loc = locale.getlocale(locale.LC_ALL) # get current locale
>>> locale.setlocale(locale.LC_ALL, 'de_DE') # use German locale; na
>>> locale.strcoll('f\xe4n', 'foo') # compare a string containing an
>>> locale.setlocale(locale.LC_ALL, '') # use user's preferred local
>>> locale.setlocale(locale.LC_ALL, 'C') # use default (C) locale
>>> locale.setlocale(locale.LC_ALL, loc) # restore saved locale
```

21.2.1 Background, details, hints, tips and caveats

The C standard defines the locale as a program-wide property that may be relatively expensive to change. On top of that, some implementation are broken in such a way that frequent locale changes may cause core dumps. This makes the locale somewhat painful to use correctly.

Initially, when a program is started, the locale is the "C" locale, no matter what the user's preferred locale is. The program must explicitly say that it wants the user's preferred locale settings by calling `setlocale(LC_ALL, '')`.

It is generally a bad idea to call `setlocale()` in some library routine, since as a side effect it affects the entire program. Saving and restoring it is almost as bad: it is expensive and affects other threads that happen to run before the settings have been restored.

If, when coding a module for general use, you need a locale independent version of an operation that is affected by the locale (such as `string.lower()`, or certain formats used with `time.strftime()`), you will have to find a way to do it without using the standard library routine. Even better is convincing yourself that using locale settings is okay. Only as a last resort should you document that your module is not compatible with non-"C" locale settings.

The case conversion functions in the `string` module are affected by the locale settings. When a call to the `setlocale()` function changes the LC_CTYPE settings, the variables `string.lowercase`, `string.uppercase` and `string.letters` are recalculated. Note that this code that uses these variable through `from ... import ...`, e.g. `from string import letters`, is not affected by subsequent `setlocale()` calls.

The only way to perform numeric operations according to the locale is to use the special functions defined by this module: `atof()`, `atoi()`, `format()`, `str()`.
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
21.2.2 For extension writers and programs that embed Python

Extension modules should never call `setlocale()`, except to find out what the current locale is. But since the return value can only be used portably to restore it, that is not very useful (except perhaps to find out whether or not the locale is "C").

When Python code uses the `locale` module to change the locale, this also affects the embedding application. If the embedding application doesn't want this to happen, it should remove the `_locale` extension module (which does all the work) from the table of built-in modules in the `config.c` file, and make sure that the `_locale` module is not accessible as a shared library.
21.2.3 Access to message catalogs

The locale module exposes the C library's gettext interface on systems that provide this interface. It consists of the functions gettext(), dgettext(), dcgettext(), textdomain(), bindtextdomain(), and bind_textdomain_codeset(). These are similar to the same functions in the gettext module, but use the C library's binary format for message catalogs, and the C library's search algorithms for locating message catalogs.

Python applications should normally find no need to invoke these functions, and should use gettext instead. A known exception to this rule are applications that link use additional C libraries which internally invoke gettext() or dcgettext(). For these applications, it may be necessary to bind the text domain, so that the libraries can properly locate their message catalogs.
22. Program Frameworks

The modules described in this chapter are frameworks that will largely dictate the structure of your program. Currently the modules described here are all oriented toward writing command-line interfaces.

The full list of modules described in this chapter is:

- **cmd**: Build line-oriented command interpreters.
- **shlex**: Simple lexical analysis for UNIX shell-like languages.

Release 2.5, documentation updated on 19th September, 2006.
See [About this document...](#) for information on suggesting changes.
22.1 cmd -- Support for line-oriented command interpreters

The Cmd class provides a simple framework for writing line-oriented command interpreters. These are often useful for test harnesses, administrative tools, and prototypes that will later be wrapped in a more sophisticated interface.

```python
class Cmd( [completekey[, stdin[, stdout]]])
```

A Cmd instance or subclass instance is a line-oriented interpreter framework. There is no good reason to instantiate Cmd itself; rather, it's useful as a superclass of an interpreter class you define yourself in order to inherit Cmd's methods and encapsulate action methods.

The optional argument `completekey` is the `readline` name of a completion key; it defaults to Tab. If `completekey` is not `None` and `readline` is available, command completion is done automatically.

The optional arguments `stdin` and `stdout` specify the input and output file objects that the Cmd instance or subclass instance will use for input and output. If not specified, they will default to `sys.stdin` and `sys.stdout`.

Changed in version 2.3: The `stdin` and `stdout` parameters were added.
22.1.1 Cmd Objects

A Cmd instance has the following methods:

**cmdloop([intro])**

Repeatedly issue a prompt, accept input, parse an initial prefix off the received input, and dispatch to action methods, passing them the remainder of the line as argument.

The optional argument is a banner or intro string to be issued before the first prompt (this overrides the intro class member).

If the `readline` module is loaded, input will automatically inherit bash-like history-list editing (e.g. Control-P scrolls back to the last command, Control-N forward to the next one, Control-F moves the cursor to the right non-destructively, Control-B moves the cursor to the left non-destructively, etc.).

An end-of-file on input is passed back as the string 'EOF'.

An interpreter instance will recognize a command name "foo" if and only if it has a method `do_foo()`. As a special case, a line beginning with the character "?" is dispatched to the method `do_help()`. As another special case, a line beginning with the character "!" is dispatched to the method `do_shell()` (if such a method is defined).

This method will return when the `postcmd()` method returns a true value. The stop argument to `postcmd()` is the return value from the command's corresponding `do_*()` method.

If completion is enabled, completing commands will be done automatically, and completing of commands args is done by calling `complete_foo()` with arguments `text`, `line`, `begidx`, and `endidx`. `text` is the string prefix we are attempting to match: all returned matches must begin with it. `line` is the current input line with leading whitespace removed, `begidx` and `endidx` are the beginning and ending indexes of the prefix text, which could be used to provide different completion depending upon which position the argument...
is in.

All subclasses of `Cmd` inherit a predefined `do_help()`. This method, called with an argument 'bar', invokes the corresponding method `help_bar()`. With no argument, `do_help()` lists all available help topics (that is, all commands with corresponding `help_*( )` methods), and also lists any undocumented commands.

**onecmd( str)**
Interpret the argument as though it had been typed in response to the prompt. This may be overridden, but should not normally need to be; see the `precmd()` and `postcmd()` methods for useful execution hooks. The return value is a flag indicating whether interpretation of commands by the interpreter should stop. If there is a `do_*( )` method for the command `str`, the return value of that method is returned, otherwise the return value from the `default( )` method is returned.

**emptyline( )**
Method called when an empty line is entered in response to the prompt. If this method is not overridden, it repeats the last nonempty command entered.

**default( line)**
Method called on an input line when the command prefix is not recognized. If this method is not overridden, it prints an error message and returns.

**completesdefault( text, line, begidx, endidx)**
Method called to complete an input line when no command-specific `complete_*( )` method is available. By default, it returns an empty list.

**precmd( line)**
Hook method executed just before the command line `line` is interpreted, but after the input prompt is generated and issued. This method is a stub in `Cmd`; it exists to be overridden by subclasses. The return value is used as the command which will be executed by the `onecmd( )` method; the `precmd( )` implementation may re-write the command or simply return `line` unchanged.
postcmd( stop, line)
Hook method executed just after a command dispatch is finished. This
method is a stub in Cmd; it exists to be overridden by subclasses. line is the
command line which was executed, and stop is a flag which indicates
whether execution will be terminated after the call to postcmd(); this
will be the return value of the onecmd() method. The return value of this
method will be used as the new value for the internal flag which
corresponds to stop; returning false will cause interpretation to continue.

preloop()
Hook method executed once when cmdloop() is called. This method is a
stub in Cmd; it exists to be overridden by subclasses.

postloop()
Hook method executed once when cmdloop() is about to return. This
method is a stub in Cmd; it exists to be overridden by subclasses.

Instances of Cmd subclasses have some public instance variables:

prompt
The prompt issued to solicit input.

identchars
The string of characters accepted for the command prefix.

lastcmd
The last nonempty command prefix seen.

intro
A string to issue as an intro or banner. May be overridden by giving the
cmdloop() method an argument.

doc_header
The header to issue if the help output has a section for documented
commands.

misc_header
The header to issue if the help output has a section for miscellaneous help
topics (that is, there are help_*() methods without corresponding do_*
() methods).

**undoc_header**
The header to issue if the help output has a section for undocumented commands (that is, there are do_*() methods without corresponding help_*() methods).

**ruler**
The character used to draw separator lines under the help-message headers. If empty, no ruler line is drawn. It defaults to ":=".

**use_rawinput**
A flag, defaulting to true. If true, cmdloop() uses raw_input() to display a prompt and read the next command; if false, sys.stdout.write() and sys.stdin.readline() are used. (This means that by importing readline, on systems that support it, the interpreter will automatically support Emacs-like line editing and command-history keystrokes.)
22.2 shlex -- Simple lexical analysis

New in version 1.5.2.

The shlex class makes it easy to write lexical analyzers for simple syntaxes resembling that of the UNIX shell. This will often be useful for writing minilanguages, (for example, in run control files for Python applications) or for parsing quoted strings.

**Note:** The shlex module currently does not support Unicode input.

The shlex module defines the following functions:

```
split([s[, comments]])
```

Split the string s using shell-like syntax. If comments is False (the default), the parsing of comments in the given string will be disabled (setting the commenters member of the shlex instance to the empty string). This function operates in POSIX mode. New in version 2.3.

The shlex module defines the following class:

```
class shlex([instream[, infile[, posix]]])
```

A shlex instance or subclass instance is a lexical analyzer object. The initialization argument, if present, specifies where to read characters from. It must be a file-/stream-like object with read() and readline() methods, or a string (strings are accepted since Python 2.3). If no argument is given, input will be taken from sys.stdin. The second optional argument is a filename string, which sets the initial value of the infile member. If the instream argument is omitted or equal to sys.stdin, this second argument defaults to `\stdin`. The posix argument was introduced in Python 2.3, and defines the operational mode. When posix is not true (default), the shlex instance will operate in compatibility mode. When operating in POSIX mode, shlex will try to be as close as possible to the POSIX shell parsing rules. See section [22.2.1](#).
See Also:

Module **ConfigParser**:
Parser for configuration files similar to the Windows .ini files.

Python Library Reference

Previous: [22.1.1 Cmd Objects](#) Up: [22. Program Frameworks](#) Next: [22.2.1 shlex Objects](#)

Release 2.5, documentation updated on 19th September, 2006.
See [About this document...](#) for information on suggesting changes.
22.2.1 shlex Objects

A shlex instance has the following methods:

**get_token()**
Return a token. If tokens have been stacked using `push_token()`, pop a token off the stack. Otherwise, read one from the input stream. If reading encounters an immediate end-of-file, `self.eof` is returned (the empty string ("")) in non-POSIX mode, and None in POSIX mode).

**push_token( str)**
Push the argument onto the token stack.

**read_token()**
Read a raw token. Ignore the pushback stack, and do not interpret source requests. (This is not ordinarily a useful entry point, and is documented here only for the sake of completeness.)

**sourcehook( filename)**
When shlex detects a source request (see source below) this method is given the following token as argument, and expected to return a tuple consisting of a filename and an open file-like object.

Normally, this method first strips any quotes off the argument. If the result is an absolute pathname, or there was no previous source request in effect, or the previous source was a stream (such as `sys.stdin`), the result is left alone. Otherwise, if the result is a relative pathname, the directory part of the name of the file immediately before it on the source inclusion stack is prepended (this behavior is like the way the C preprocessor handles `#include "file.h"`).

The result of the manipulations is treated as a filename, and returned as the first component of the tuple, with `open()` called on it to yield the second component. (Note: this is the reverse of the order of arguments in instance initialization!)
This hook is exposed so that you can use it to implement directory search paths, addition of file extensions, and other namespace hacks. There is no corresponding `close' hook, but a shlex instance will call the close() method of the sourced input stream when it returns EOF.

For more explicit control of source stacking, use the push_source() and pop_source() methods.

**push_source(stream[, filename])**

Push an input source stream onto the input stack. If the filename argument is specified it will later be available for use in error messages. This is the same method used internally by the sourcehook method. New in version 2.1.

**pop_source()**

Pop the last-pushed input source from the input stack. This is the same method used internally when the lexer reaches EOF on a stacked input stream. New in version 2.1.

**error_leader([file[, line]])**

This method generates an error message leader in the format of a UNIX C compiler error label; the format is "%s", line %d: ', where the "%s" is replaced with the name of the current source file and the "%d" with the current input line number (the optional arguments can be used to override these).

This convenience is provided to encourage shlex users to generate error messages in the standard, parseable format understood by Emacs and other UNIX tools.

Instances of shlex subclasses have some public instance variables which either control lexical analysis or can be used for debugging:

**commenters**

The string of characters that are recognized as comment beginners. All characters from the comment beginner to end of line are ignored. Includes just "#" by default.
**wordchars**
The string of characters that will accumulate into multi-character tokens. By default, includes all ASCII alphanumerics and underscore.

**whitespace**
Characters that will be considered whitespace and skipped. Whitespace bounds tokens. By default, includes space, tab, linefeed and carriage-return.

**escape**
Characters that will be considered as escape. This will be only used in POSIX mode, and includes just "\" by default. New in version 2.3.

**quotes**
Characters that will be considered string quotes. The token accumulates until the same quote is encountered again (thus, different quote types protect each other as in the shell.) By default, includes ASCII single and double quotes.

**escapedquotes**
Characters in quotes that will interpret escape characters defined in escape. This is only used in POSIX mode, and includes just "\" by default. New in version 2.3.

**whitespace_split**
If True, tokens will only be split in whitespaces. This is useful, for example, for parsing command lines with shlex, getting tokens in a similar way to shell arguments. New in version 2.3.

**infile**
The name of the current input file, as initially set at class instantiation time or stacked by later source requests. It may be useful to examine this when constructing error messages.

**instream**
The input stream from which this shlex instance is reading characters.

**source**
This member is None by default. If you assign a string to it, that string will be recognized as a lexical-level inclusion request similar to the "source"
keyword in various shells. That is, the immediately following token will opened as a filename and input taken from that stream until EOF, at which point the close() method of that stream will be called and the input source will again become the original input stream. Source requests may be stacked any number of levels deep.

**debug**

If this member is numeric and 1 or more, a shlex instance will print verbose progress output on its behavior. If you need to use this, you can read the module source code to learn the details.

**lineno**

Source line number (count of newlines seen so far plus one).

**token**

The token buffer. It may be useful to examine this when catching exceptions.

**eof**

Token used to determine end of file. This will be set to the empty string (''), in non-POSIX mode, and to None in POSIX mode. New in version 2.3.
22.2.2 Parsing Rules

When operating in non-POSIX mode, shlex will try to obey to the following rules.

- Quote characters are not recognized within words (Do"Not"Separate is parsed as the single word Do"Not"Separate);
- Escape characters are not recognized;
- Enclosing characters in quotes preserve the literal value of all characters within the quotes;
- Closing quotes separate words ("Do"Separate is parsed as "Do" and Separate);
- If whitespace_split is False, any character not declared to be a word character, whitespace, or a quote will be returned as a single-character token. If it is True, shlex will only split words in whitespaces;
- EOF is signaled with an empty string ('');
- It's not possible to parse empty strings, even if quoted.

When operating in POSIX mode, shlex will try to obey to the following parsing rules.

- Quotes are stripped out, and do not separate words ("Do"Not"Separate" is parsed as the single word DoNotSeparate);
- Non-quoted escape characters (e.g. "\") preserve the literal value of the next character that follows;
- Enclosing characters in quotes which are not part of escapedquotes (e.g. "'" ) preserve the literal value of all characters within the quotes;
- Enclosing characters in quotes which are part of escapedquotes (e.g. "\"" ) preserves the literal value of all characters within the quotes, with the exception of the characters mentioned in escape. The escape characters retain its special meaning only when followed by the quote in use, or the escape character itself. Otherwise the escape character will be considered a normal character.
- EOF is signaled with a None value;
- Quoted empty strings (' ') are allowed;
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
23. Development Tools

The modules described in this chapter help you write software. For example, the pydoc module takes a module and generates documentation based on the module's contents. The doctest and unittest modules contains frameworks for writing unit tests that automatically exercise code and verify that the expected output is produced.

The list of modules described in this chapter is:

- **pydoc**
  Documentation generator and online help system.
- **doctest**
  A framework for verifying interactive Python examples.
- **unittest**
  Unit testing framework for Python.
- **test**
  Regression tests package containing the testing suite for Python.
- **test.test_support**
  Support for Python regression tests.

Release 2.5, documentation updated on 19th September, 2006. See About this document... for information on suggesting changes.
23.1 pydoc -- Documentation generator and online help system

New in version 2.1.

The pydoc module automatically generates documentation from Python modules. The documentation can be presented as pages of text on the console, served to a Web browser, or saved to HTML files.

The built-in function help() invokes the online help system in the interactive interpreter, which uses pydoc to generate its documentation as text on the console. The same text documentation can also be viewed from outside the Python interpreter by running pydoc as a script at the operating system's command prompt. For example, running

```
    pydoc sys
```

at a shell prompt will display documentation on the sys module, in a style similar to the manual pages shown by the UNIX man command. The argument to pydoc can be the name of a function, module, or package, or a dotted reference to a class, method, or function within a module or module in a package. If the argument to pydoc looks like a path (that is, it contains the path separator for your operating system, such as a slash in UNIX), and refers to an existing Python source file, then documentation is produced for that file.

Specifying a -w flag before the argument will cause HTML documentation to be written out to a file in the current directory, instead of displaying text on the console.

Specifying a -k flag before the argument will search the synopsis lines of all available modules for the keyword given as the argument, again in a manner similar to the UNIX man command. The synopsis line of a module is the first line of its documentation string.

You can also use pydoc to start an HTTP server on the local machine that will serve documentation to visiting Web browsers. pydoc -p 1234 will start a HTTP server on port 1234, allowing you to browse the documentation at
http://localhost:1234/ in your preferred Web browser. `pydoc -g` will start the server and additionally bring up a small Tkinter-based graphical interface to help you search for documentation pages.

When `pydoc` generates documentation, it uses the current environment and path to locate modules. Thus, invoking `pydoc spam` documents precisely the version of the module you would get if you started the Python interpreter and typed "import spam".

Module docs for core modules are assumed to reside in http://www.python.org/doc/current/lib/. This can be overridden by setting the PYTHONDOCS environment variable to a different URL or to a local directory containing the Library Reference Manual pages.

---

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
23.2 doctest -- Test interactive Python examples

The `doctest` module searches for pieces of text that look like interactive Python sessions, and then executes those sessions to verify that they work exactly as shown. There are several common ways to use doctest:

- To check that a module's docstrings are up-to-date by verifying that all interactive examples still work as documented.
- To perform regression testing by verifying that interactive examples from a test file or a test object work as expected.
- To write tutorial documentation for a package, liberally illustrated with input-output examples. Depending on whether the examples or the expository text are emphasized, this has the flavor of "literate testing" or "executable documentation".

Here's a complete but small example module:

```python
"""
This is the "example" module.

The example module supplies one function, factorial(). For example,

>>> factorial(5)
120
"""

def factorial(n):
    """Return the factorial of n, an exact integer >= 0.

    If the result is small enough to fit in an int, return an int.
    Else return a long.
"

    >>> [factorial(n) for n in range(6)]
    [1, 1, 2, 6, 24, 120]
    >>> [factorial(long(n)) for n in range(6)]
    [1, 1, 2, 6, 24, 120]
    >>> factorial(30)
    2652528598121910586363084800000000L
    >>> factorial(30L)
    2652528598121910586363084800000000L
    >>> factorial(-1)
```

```
Traceback (most recent call last):
...
ValueError: n must be >= 0

Factorials of floats are OK, but the float must be an exact integer:
>>> factorial(30.1)
Traceback (most recent call last):
...
ValueError: n must be exact integer
>>> factorial(30.0)
2652528598121910586363084800000000L

It must also not be ridiculously large:
>>> factorial(1e100)
Traceback (most recent call last):
...
OverflowError: n too large
""

import math
if not n >= 0:
    raise ValueError("n must be >= 0")
if math.floor(n) != n:
    raise ValueError("n must be exact integer")
if n+1 == n:  # catch a value like 1e300
    raise OverflowError("n too large")
result = 1
factor = 2
while factor <= n:
    result *= factor
    factor += 1
return result

def _test():
    import doctest
doctest.testmod()

    if __name__ == "__main__":
        _test()

If you run example.py directly from the command line, doctest works its magic:

$ python example.py
$

There's no output! That's normal, and it means all the examples worked. Pass -v to the script, and doctest prints a detailed log of what it's trying, and prints a summary at the end:
$ python example.py -v
Trying:
    factorial(5)
Expecting:
    120
ok
Trying:
    [factorial(n) for n in range(6)]
Expecting:
    [1, 1, 2, 6, 24, 120]
ok
Trying:
    [factorial(long(n)) for n in range(6)]
Expecting:
    [1, 1, 2, 6, 24, 120]
ok

And so on, eventually ending with:

Trying:
    factorial(1e100)
Expecting:
    Traceback (most recent call last):
      ...
    OverflowError: n too large
ok
1 items had no tests:  
    __main__.test  
2 items passed all tests:  
    1 tests in __main__  
    8 tests in __main__.factorial  
9 tests in 3 items.  
9 passed and 0 failed.  
Test passed.  
$

That's all you need to know to start making productive use of doctest! Jump in. The following sections provide full details. Note that there are many examples of doctests in the standard Python test suite and libraries. Especially useful examples can be found in the standard test file Lib/test/test_doctest.py.

23.2.1 Simple Usage: Checking Examples in Docstrings

The simplest way to start using doctest (but not necessarily the way you'll continue to do it) is to end each module M with:

```python
def _test():
    import doctest
doctest.testmod()

if __name__ == "__main__":
    _test()
```

doctest then examines docstrings in module M.

Running the module as a script causes the examples in the docstrings to get executed and verified:

```bash
python M.py
```

This won't display anything unless an example fails, in which case the failing example(s) and the cause(s) of the failure(s) are printed to stdout, and the final line of output is "***Test Failed*** N failures.", where N is the number of examples that failed.

Run it with the -v switch instead:

```bash
python M.py -v
```

and a detailed report of all examples tried is printed to standard output, along with assorted summaries at the end.

You can force verbose mode by passing `verbose=True` to `testmod()`, or prohibit it by passing `verbose=False`. In either of those cases, `sys.argv` is not examined by `testmod()` (so passing `-v` or not has no effect).

For more information on `testmod()`, see section 23.2.4.
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
23.2.2 Simple Usage: Checking Examples in a Text File

Another simple application of doctest is testing interactive examples in a text file. This can be done with the `testfile()` function:

```python
import doctest
doctest.testfile("example.txt")
```

That short script executes and verifies any interactive Python examples contained in the file `example.txt`. The file content is treated as if it were a single giant docstring; the file doesn't need to contain a Python program! For example, perhaps `example.txt` contains this:

```restructuredtext
The ``example`` module

Using ``factorial``

This is an example text file in reStructuredText format. First impo
``factorial`` from the ``example`` module:

```python
>>> from example import factorial
```

Now use it:

```python
>>> factorial(6)
120
```

Running `doctest.testfile("example.txt")` then finds the error in this documentation:

```plaintext
File "./example.txt", line 14, in example.txt
Failed example:
  factorial(6)
Expected:
  120
Got:
  720
```

As with `testmod()`, `testfile()` won't display anything unless an example fails. If an example does fail, then the failing example(s) and the cause(s) of the failure(s) are printed to stdout, using the same format as `testmod()`.
By default, `testfile()` looks for files in the calling module's directory. See section 23.2.4 for a description of the optional arguments that can be used to tell it to look for files in other locations.

Like `testmod()`, `testfile()`'s verbosity can be set with the `-v` command-line switch or with the optional keyword argument `verbose`.

For more information on `testfile()`, see section 23.2.4.
23.2.3 How It Works

This section examines in detail how doctest works: which docstrings it looks at, how it finds interactive examples, what execution context it uses, how it handles exceptions, and how option flags can be used to control its behavior. This is the information that you need to know to write doctest examples; for information about actually running doctest on these examples, see the following sections.

Subsections

23.2.4 Basic API

The functions `testmod()` and `testfile()` provide a simple interface to `doctest` that should be sufficient for most basic uses. For a less formal introduction to these two functions, see sections 23.2.1 and 23.2.2.

\[
\text{testfile(filename[, module_relative][, name][, package][, globs][, verbose][, report][, optionflags][, extraglobs][, raise_on_error][, parser][, encoding])}
\]

All arguments except `filename` are optional, and should be specified in keyword form.

Test examples in the file named `filename`. Return "(failure_count, test_count)".

Optional argument `module_relative` specifies how the filename should be interpreted:

- If `module_relative` is `True` (the default), then `filename` specifies an OS-independent module-relative path. By default, this path is relative to the calling module's directory; but if the `package` argument is specified, then it is relative to that package. To ensure OS-independence, `filename` should use `/` characters to separate path segments, and may not be an absolute path (i.e., it may not begin with `/`).
- If `module_relative` is `False`, then `filename` specifies an OS-specific path. The path may be absolute or relative; relative paths are resolved with respect to the current working directory.

Optional argument `name` gives the name of the test; by default, or if `None`, `os.path.basename(filename)` is used.

Optional argument `package` is a Python package or the name of a Python package whose directory should be used as the base directory for a module-relative filename. If no package is specified, then the calling module's directory is used as the base directory for module-relative filenames. It is an
error to specify package if module_relative is False.

Optional argument globs gives a dict to be used as the globals when executing examples. A new shallow copy of this dict is created for the doctest, so its examples start with a clean slate. By default, or if None, a new empty dict is used.

Optional argument extraglobs gives a dict merged into the globals used to execute examples. This works like dict.update(): if globs and extraglobs have a common key, the associated value in extraglobs appears in the combined dict. By default, or if None, no extra globs are used. This is an advanced feature that allows parameterization of doctests. For example, a doctest can be written for a base class, using a generic name for the class, then reused to test any number of subclasses by passing an extraglobs dict mapping the generic name to the subclass to be tested.

Optional argument verbose prints lots of stuff if true, and prints only failures if false; by default, or if None, it's true if and only if '-v' is in sys.argv.

Optional argument report prints a summary at the end when true, else prints nothing at the end. In verbose mode, the summary is detailed, else the summary is very brief (in fact, empty if all tests passed).

Optional argument optionflags or's together option flags. See section 23.2.3.

Optional argument raise_on_error defaults to false. If true, an exception is raised upon the first failure or unexpected exception in an example. This allows failures to be post-mortem debugged. Default behavior is to continue running examples.

Optional argument parser specifies a DocTestParser (or subclass) that should be used to extract tests from the files. It defaults to a normal parser (i.e., DocTestParser()).

Optional argument encoding specifies an encoding that should be used to convert the file to unicode.

New in version 2.4.
Changed in version 2.5: The parameter *encoding* was added.

```

testmod([m][, name][, globs][, verbose][, report][, optionflags][, extraglobs][, raise_on_error][, exclude_empty])
```

All arguments are optional, and all except for *m* should be specified in keyword form.

Test examples in docstrings in functions and classes reachable from module *m* (or module *__main__* if *m* is not supplied or is *None*), starting with *m.__doc__*.

Also test examples reachable from dict *m.__test__*, if it exists and is not *None*. *m.__test__* maps names (strings) to functions, classes and strings; function and class docstrings are searched for examples; strings are searched directly, as if they were docstrings.

Only docstrings attached to objects belonging to module *m* are searched.

Return "(failure_count, test_count)".

Optional argument *name* gives the name of the module; by default, or if *None, m.__name__* is used.

Optional argument *exclude_empty* defaults to false. If true, objects for which no doctests are found are excluded from consideration. The default is a backward compatibility hack, so that code still using `doctest.master.summarize()` in conjunction with `testmod()` continues to get output for objects with no tests. The *exclude_empty* argument to the newer `DocTestFinder` constructor defaults to true.

Optional arguments *extraglobs, verbose, report, optionflags, raise_on_error*, and *globs* are the same as for function `testfile()` above, except that *globs* defaults to *m.__dict__*.

Changed in version 2.3: The parameter *optionflags* was added.

Changed in version 2.4: The parameters *extraglobs, raise_on_error* and *exclude_empty* were added.
Changed in version 2.5: The optional argument \textit{isprivate}, deprecated in 2.4, was removed.

There's also a function to run the doctests associated with a single object. This function is provided for backward compatibility. There are no plans to deprecate it, but it's rarely useful:

\begin{verbatim}
run_docstring_examples(f, globs[, verbose][, name][, compileflags][, optionflags])
\end{verbatim}

Test examples associated with object \textit{f}; for example, \textit{f} may be a module, function, or class object.

A shallow copy of dictionary argument \textit{globs} is used for the execution context.

Optional argument \textit{name} is used in failure messages, and defaults to "NoName".

If optional argument \textit{verbose} is true, output is generated even if there are no failures. By default, output is generated only in case of an example failure.

Optional argument \textit{compileflags} gives the set of flags that should be used by the Python compiler when running the examples. By default, or if \textit{None}, flags are deduced corresponding to the set of future features found in \textit{globs}.

Optional argument \textit{optionflags} works as for function \textit{testfile()} above.
23.2.5 Unittest API

As your collection of doctest'ed modules grows, you'll want a way to run all their doctests systematically. Prior to Python 2.4, doctest had a barely documented Tester class that supplied a rudimentary way to combine doctests from multiple modules. Tester was feeble, and in practice most serious Python testing frameworks build on the unittest module, which supplies many flexible ways to combine tests from multiple sources. So, in Python 2.4, doctest’s Tester class is deprecated, and doctest provides two functions that can be used to create unittest test suites from modules and text files containing doctests. These test suites can then be run using unittest test runners:

```python
import unittest
import doctest
import my_module_with_doctests, and_another

suite = unittest.TestSuite()
for mod in my_module_with_doctests, and_another:
    suite.addTest(doctest.DocTestSuite(mod))
runner = unittest.TextTestRunner()
runner.run(suite)
```

There are two main functions for creating unittest.TestSuite instances from text files and modules with doctests:

```
DocFileSuite([module_relative][, package][, setUp][, tearDown][, globs][, optionflags][, parser][, encoding])
```

Convert doctest tests from one or more text files to a unittest.TestSuite.

The returned unittest.TestSuite is to be run by the unittest framework and runs the interactive examples in each file. If an example in any file fails, then the synthesized unit test fails, and a failureException exception is raised showing the name of the file containing the test and a (sometimes approximate) line number.

Pass one or more paths (as strings) to text files to be examined.
Options may be provided as keyword arguments:

Optional argument `module_relative` specifies how the filenames in `paths` should be interpreted:

- If `module_relative` is `True` (the default), then each filename specifies an OS-independent module-relative path. By default, this path is relative to the calling module's directory; but if the `package` argument is specified, then it is relative to that package. To ensure OS-independence, each filename should use `/` characters to separate path segments, and may not be an absolute path (i.e., it may not begin with `/`).
- If `module_relative` is `False`, then each filename specifies an OS-specific path. The path may be absolute or relative; relative paths are resolved with respect to the current working directory.

Optional argument `package` is a Python package or the name of a Python package whose directory should be used as the base directory for module-relative filenames. If no package is specified, then the calling module's directory is used as the base directory for module-relative filenames. It is an error to specify `package` if `module_relative` is `False`.

Optional argument `setUp` specifies a set-up function for the test suite. This is called before running the tests in each file. The `setUp` function will be passed a `DocTest` object. The `setUp` function can access the test globals as the `globs` attribute of the test passed.

Optional argument `tearDown` specifies a tear-down function for the test suite. This is called after running the tests in each file. The `tearDown` function will be passed a `DocTest` object. The `tearDown` function can access the test globals as the `globs` attribute of the test passed.

Optional argument `globs` is a dictionary containing the initial global variables for the tests. A new copy of this dictionary is created for each test. By default, `globs` is a new empty dictionary.

Optional argument `optionflags` specifies the default doctest options for the tests, created by or-ing together individual option flags. See section 23.2.3. See function `set_unittest_reportflags()` below for a better way
to set reporting options.

Optional argument *parser* specifies a *DocTestParser* (or subclass) that should be used to extract tests from the files. It defaults to a normal parser (i.e., *DocTestParser*).

Optional argument *encoding* specifies an encoding that should be used to convert the file to unicode.

New in version 2.4.

Changed in version 2.5: The global **file** was added to the globals provided to doctests loaded from a text file using *DocFileSuite()*.

Changed in version 2.5: The parameter *encoding* was added.

**DocTestSuite(***module***[, **globs**][, **extraglobs**][, **test_finder**][, **setUp**][, **tearDown**][, **checker**])**

Convert doctest tests for a module to a unittest.*TestSuite.*

The returned unittest.*TestSuite* is to be run by the unittest framework and runs each doctest in the module. If any of the doctests fail, then the synthesized unit test fails, and a failureException exception is raised showing the name of the file containing the test and a (sometimes approximate) line number.

Optional argument *module* provides the module to be tested. It can be a module object or a (possibly dotted) module name. If not specified, the module calling this function is used.

Optional argument *globs* is a dictionary containing the initial global variables for the tests. A new copy of this dictionary is created for each test. By default, *globs* is a new empty dictionary.

Optional argument *extraglobs* specifies an extra set of global variables, which is merged into *globs*. By default, no extra globals are used.

Optional argument *test_finder* is the *DocTestFinder* object (or a drop-in replacement) that is used to extract doctests from the module.
Optional arguments setUp, tearDown, and optionflags are the same as for function DocFileSuite() above.

New in version 2.3.

Changed in version 2.4: The parameters globs, extraglobs, test_finder, setUp, tearDown, and optionflags were added; this function now uses the same search technique as testmod().

Under the covers, DocTestSuite() creates a unittest.TestSuite out of doctest.DocTestCase instances, and DocTestCase is a subclass of unittest.TestCase. DocTestCase isn't documented here (it's an internal detail), but studying its code can answer questions about the exact details of unittest integration.

Similarly, DocFileSuite() creates a unittest.TestSuite out of doctest.DocFileCase instances, and DocFileCase is a subclass of DocTestCase.

So both ways of creating a unittest.TestSuite run instances of DocTestCase. This is important for a subtle reason: when you run doctest functions yourself, you can control the doctest options in use directly, by passing option flags to doctest functions. However, if you're writing a unittest framework, unittest ultimately controls when and how tests get run. The framework author typically wants to control doctest reporting options (perhaps, e.g., specified by command line options), but there's no way to pass options through unittest to doctest test runners.

For this reason, doctest also supports a notion of doctest reporting flags specific to unittest support, via this function:

**set_unittest_reportflags(flags)**

Set the doctest reporting flags to use.

Argument flags or's together option flags. See section 23.2.3. Only "reporting flags" can be used.

This is a module-global setting, and affects all future doctests run by module unittest: the runTest() method of DocTestCase looks at
the option flags specified for the test case when the DocTestCase instance was constructed. If no reporting flags were specified (which is the typical and expected case), doctest's unittest reporting flags are or'ed into the option flags, and the option flags so augmented are passed to the DocTestRunner instance created to run the doctest. If any reporting flags were specified when the DocTestCase instance was constructed, doctest's unittest reporting flags are ignored.

The value of the unittest reporting flags in effect before the function was called is returned by the function.

New in version 2.4.
23.2.6 Advanced API

The basic API is a simple wrapper that's intended to make doctest easy to use. It is fairly flexible, and should meet most users' needs; however, if you require more fine-grained control over testing, or wish to extend doctest's capabilities, then you should use the advanced API.

The advanced API revolves around two container classes, which are used to store the interactive examples extracted from doctest cases:

- **Example**: A single python statement, paired with its expected output.
- **DocTest**: A collection of Examples, typically extracted from a single docstring or text file.

Additional processing classes are defined to find, parse, and run, and check doctest examples:

- **DocTestFinder**: Finds all docstrings in a given module, and uses a **DocTestParser** to create a **DocTest** from every docstring that contains interactive examples.
- **DocTestParser**: Creates a **DocTest** object from a string (such as an object's docstring).
- **DocTestRunner**: Executes the examples in a **DocTest**, and uses an **OutputChecker** to verify their output.
- **OutputChecker**: Compares the actual output from a doctest example with the expected output, and decides whether they match.

The relationships among these processing classes are summarized in the following diagram:

```
+--------+          +--------+          +--------+
| module | --> DocTestFinder --> | DocTest | --> DocTestRunner --> results
|--------+                |--------+                |--------+
        |                  ^    |                  ^    | (printed)
        |                  |    |                  |
        |                  |    |                  |
        |                  |    |                  |
          v                  v                  v
          DocTestParser    Example    OutputChecker
```

```
23.2.7 Debugging

Doctest provides several mechanisms for debugging doctest examples:

- Several functions convert doctests to executable Python programs, which can be run under the Python debugger, pdb.
- The DebugRunner class is a subclass of DocTestRunner that raises an exception for the first failing example, containing information about that example. This information can be used to perform post-mortem debugging on the example.
- The unittest cases generated by DocTestSuite() support the debug() method defined by unittest.TestCase.
- You can add a call to pdb.set_trace() in a doctest example, and you'll drop into the Python debugger when that line is executed. Then you can inspect current values of variables, and so on. For example, suppose a.py contains just this module docstring:

    """
    >>> def f(x):
    ...     g(x*2)
    >>> def g(x):
    ...     print x+3
    ...     import pdb; pdb.set_trace()
    >>> f(3)
    9
    """

Then an interactive Python session may look like this:

    >>> import a, doctest
    >>> doctest.testmod(a)
    --Return--
    > <doctest a[1]>(3)g()--None
    --> import pdb; pdb.set_trace()
     (Pdb) list
     1    def g(x):
     2     print x+3
     3   --> import pdb; pdb.set_trace()
    [EOF]
     (Pdb) print x
    6
     (Pdb) step
    --Return--
    > <doctest a[0]>(2)f()--None
Changed in version 2.4: The ability to use `pdb.set_trace()` usefully inside doctests was added.

Functions that convert doctests to Python code, and possibly run the synthesized code under the debugger:

**script_from_examples(s)**

Convert text with examples to a script.

Argument *s* is a string containing doctest examples. The string is converted to a Python script, where doctest examples in *s* are converted to regular code, and everything else is converted to Python comments. The generated script is returned as a string. For example,

```python
import doctest
print doctest.script_from_examples(r""
    Set x and y to 1 and 2.
    >>> x, y = 1, 2

    Print their sum:
    >>> print x+y
    3

"")
```

displays:

```plaintext
# Set x and y to 1 and 2.
x, y = 1, 2
#
# Print their sum:
print x+y
# Expected:
```
This function is used internally by other functions (see below), but can also be useful when you want to transform an interactive Python session into a Python script.

New in version 2.4.

**testsource**( *module, name*)

Convert the doctest for an object to a script.

Argument *module* is a module object, or dotted name of a module, containing the object whose doctests are of interest. Argument *name* is the name (within the module) of the object with the doctests of interest. The result is a string, containing the object's docstring converted to a Python script, as described for **script_from_examples()** above. For example, if module *a.py* contains a top-level function *f()* , then

```python
import a, doctest
print doctest.testsource(a, "a.f")
```

prints a script version of function *f()*'s docstring, with doctests converted to code, and the rest placed in comments.

New in version 2.3.

**debug**( *module, name*, [ *pm* ])

Debug the doctests for an object.

The *module* and *name* arguments are the same as for function **testsource()** above. The synthesized Python script for the named object's docstring is written to a temporary file, and then that file is run under the control of the Python debugger, **pdb**.

A shallow copy of *module*.

```
''
```

is used for both local and global execution context.

Optional argument *pm* controls whether post-mortem debugging is used. If *pm* has a true value, the script file is run directly, and the debugger gets involved only if the script terminates via raising an unhandled exception. If
it does, then post-mortem debugging is invoked, via `pdb.post_mortem()`, passing the traceback object from the unhandled exception. If `pm` is not specified, or is false, the script is run under the debugger from the start, via passing an appropriate `execfile()` call to `pdb.run()`.

New in version 2.3.

Changed in version 2.4: The `pm` argument was added.

```python
def debug_src(src, pm=None, globs=None)
    Debug the doctests in a string.

    This is like function `debug()` above, except that a string containing doctest examples is specified directly, via the `src` argument.

    Optional argument `pm` has the same meaning as in function `debug()` above.

    Optional argument `globs` gives a dictionary to use as both local and global execution context. If not specified, or `None`, an empty dictionary is used. If specified, a shallow copy of the dictionary is used.

    New in version 2.4.
```

The `DebugRunner` class, and the special exceptions it may raise, are of most interest to testing framework authors, and will only be sketched here. See the source code, and especially `DebugRunner`'s docstring (which is a doctest!) for more details:

```python
class DebugRunner([checker][, verbose][, optionflags])
    A subclass of `DocTestRunner` that raises an exception as soon as a failure is encountered. If an unexpected exception occurs, an `UnexpectedException` exception is raised, containing the test, the example, and the original exception. If the output doesn't match, then a `DocTestFailure` exception is raised, containing the test, the example, and the actual output.
```
For information about the constructor parameters and methods, see the
documentation for `DocTestRunner` in section 23.2.6.

There are two exceptions that may be raised by `DebugRunner` instances:

**exception DocTestFailure** *(test, example, got)*

An exception thrown by `DocTestRunner` to signal that a doctest
eexample's actual output did not match its expected output. The constructor
arguments are used to initialize the member variables of the same names.

`DocTestFailure` defines the following member variables:

**test**

The `DocTest` object that was being run when the example failed.

**example**

The `Example` that failed.

**got**

The example's actual output.

**exception UnexpectedException** *(test, example, exc_info)*

An exception thrown by `DocTestRunner` to signal that a doctest
eexample raised an unexpected exception. The constructor arguments are
used to initialize the member variables of the same names.

`UnexpectedException` defines the following member variables:

**test**

The `DocTest` object that was being run when the example failed.

**example**

The `Example` that failed.

**exc_info**

A tuple containing information about the unexpected exception, as returned
by `sys.exc_info()`.
Soapbox

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
23.2.8 Soapbox

As mentioned in the introduction, `doctest` has grown to have three primary uses:

1. Checking examples in docstrings.
2. Regression testing.
3. Executable documentation / literate testing.

These uses have different requirements, and it is important to distinguish them. In particular, filling your docstrings with obscure test cases makes for bad documentation.

When writing a docstring, choose docstring examples with care. There's an art to this that needs to be learned--it may not be natural at first. Examples should add genuine value to the documentation. A good example can often be worth many words. If done with care, the examples will be invaluable for your users, and will pay back the time it takes to collect them many times over as the years go by and things change. I'm still amazed at how often one of my `doctest` examples stops working after a "harmless" change.

Doctest also makes an excellent tool for regression testing, especially if you don't skimp on explanatory text. By interleaving prose and examples, it becomes much easier to keep track of what's actually being tested, and why. When a test fails, good prose can make it much easier to figure out what the problem is, and how it should be fixed. It's true that you could write extensive comments in code-based testing, but few programmers do. Many have found that using doctest approaches instead leads to much clearer tests. Perhaps this is simply because doctest makes writing prose a little easier than writing code, while writing comments in code is a little harder. I think it goes deeper than just that: the natural attitude when writing a doctest-based test is that you want to explain the fine points of your software, and illustrate them with examples. This in turn naturally leads to test files that start with the simplest features, and logically progress to complications and edge cases. A coherent narrative is the result, instead of a collection of isolated functions that test isolated bits of functionality seemingly at random. It's a different attitude, and produces different results, blurring the distinction between testing and explaining.
Regression testing is best confined to dedicated objects or files. There are several options for organizing tests:

- Write text files containing test cases as interactive examples, and test the files using `testfile()` or `DocFileSuite()`. This is recommended, although is easiest to do for new projects, designed from the start to use doctest.
- Define functions named `_regrtest_topic` that consist of single docstrings, containing test cases for the named topics. These functions can be included in the same file as the module, or separated out into a separate test file.
- Define a `__test__` dictionary mapping from regression test topics to docstrings containing test cases.
23.3 `unittest` -- Unit testing framework

New in version 2.1.

The Python unit testing framework, sometimes referred to as `PyUnit`, is a Python language version of JUnit, by Kent Beck and Erich Gamma. JUnit is, in turn, a Java version of Kent's Smalltalk testing framework. Each is the de facto standard unit testing framework for its respective language.

`unittest` supports test automation, sharing of setup and shutdown code for tests, aggregation of tests into collections, and independence of the tests from the reporting framework. The `unittest` module provides classes that make it easy to support these qualities for a set of tests.

To achieve this, `unittest` supports some important concepts:

**test fixture**

A test fixture represents the preparation needed to perform one or more tests, and any associate cleanup actions. This may involve, for example, creating temporary or proxy databases, directories, or starting a server process.

**test case**

A test case is the smallest unit of testing. It checks for a specific response to a particular set of inputs. `unittest` provides a base class, `TestCase`, which may be used to create new test cases.

**test suite**

A test suite is a collection of test cases, test suites, or both. It is used to aggregate tests that should be executed together.

**test runner**

A test runner is a component which orchestrates the execution of tests and provides the outcome to the user. The runner may use a graphical interface, a textual interface, or return a special value to indicate the results of
executing the tests.

The test case and test fixture concepts are supported through the `TestCase` and `FunctionTestCase` classes; the former should be used when creating new tests, and the latter can be used when integrating existing test code with a `unittest`-driven framework. When building test fixtures using `TestCase`, the `setUp()` and `tearDown()` methods can be overridden to provide initialization and cleanup for the fixture. With `FunctionTestCase`, existing functions can be passed to the constructor for these purposes. When the test is run, the fixture initialization is run first; if it succeeds, the cleanup method is run after the test has been executed, regardless of the outcome of the test. Each instance of the `TestCase` will only be used to run a single test method, so a new fixture is created for each test.

Test suites are implemented by the `TestSuite` class. This class allows individual tests and test suites to be aggregated; when the suite is executed, all tests added directly to the suite and in `"child"` test suites are run.

A test runner is an object that provides a single method, `run()`, which accepts a `TestCase` or `TestSuite` object as a parameter, and returns a result object. The class `TestResult` is provided for use as the result object. `unittest` provides the `TextTestRunner` as an example test runner which reports test results on the standard error stream by default. Alternate runners can be implemented for other environments (such as graphical environments) without any need to derive from a specific class.

23.3.1 Basic example

The unittest module provides a rich set of tools for constructing and running tests. This section demonstrates that a small subset of the tools suffice to meet the needs of most users.

Here is a short script to test three functions from the `random` module:

```python
import random
import unittest

class TestSequenceFunctions(unittest.TestCase):
    def setUp(self):
        self.seq = range(10)

    def testshuffle(self):
        # make sure the shuffled sequence does not lose any elements
        random.shuffle(self.seq)
        self.seq.sort()
        self.assertEqual(self.seq, range(10))

    def testchoice(self):
        element = random.choice(self.seq)
        self.assert_(element in self.seq)

    def testsample(self):
        self.assertRaises(ValueError, random.sample, self.seq, 20)
        for element in random.sample(self.seq, 5):
            self.assert_(element in self.seq)

if __name__ == '__main__':
    unittest.main()
```

A testcase is created by subclassing `unittest.TestCase`. The three individual tests are defined with methods whose names start with the letters "test". This naming convention informs the test runner about which methods represent tests.

The crux of each test is a call to `assertEqual()` to check for an expected result; `assert_()` to verify a condition; or `assertRaises()` to verify that an expected exception gets raised. These methods are used instead of the `assert` statement so the test runner can accumulate all test results and produce a report.
When a `setUp()` method is defined, the test runner will run that method prior to each test. Likewise, if a `tearDown()` method is defined, the test runner will invoke that method after each test. In the example, `setUp()` was used to create a fresh sequence for each test.

The final block shows a simple way to run the tests. `unittest.main()` provides a command line interface to the test script. When run from the command line, the above script produces an output that looks like this:

```
... ran testload.000s
OK
```

Instead of `unittest.main()`, there are other ways to run the tests with a finer level of control, less terse output, and no requirement to be run from the command line. For example, the last two lines may be replaced with:

```python
suite = unittest.TestLoader().loadTestsFromTestCase(TestSequenceFunctions)
unittest.TextTestRunner(verbosity=2).run(suite)
```

Running the revised script from the interpreter or another script produces the following output:

```
testchoice (__main__.TestSequenceFunctions) ... ok
testsample (__main__.TestSequenceFunctions) ... ok
testshuffle (__main__.TestSequenceFunctions) ... ok
```

```
Ran 3 tests in 0.110s
OK
```

The above examples show the most commonly used `unittest` features which are sufficient to meet many everyday testing needs. The remainder of the documentation explores the full feature set from first principles.
23.3.2 Organizing test code

The basic building blocks of unit testing are *test cases* -- single scenarios that must be set up and checked for correctness. In `unittest`, test cases are represented by instances of `unittest`'s `TestCase` class. To make your own test cases you must write subclasses of `TestCase`, or use `FunctionTestCase`.

An instance of a `TestCase`-derived class is an object that can completely run a single test method, together with optional set-up and tidy-up code.

The testing code of a `TestCase` instance should be entirely self contained, such that it can be run either in isolation or in arbitrary combination with any number of other test cases.

The simplest `TestCase` subclass will simply override the `runTest()` method in order to perform specific testing code:

```python
import unittest
class DefaultWidgetSizeTestCase(unittest.TestCase):
    def runTest(self):
        widget = Widget('The widget')
        self.assertEqual(widget.size(), (50, 50), 'incorrect default size')
```

Note that in order to test something, we use the one of the `assert*()` or `fail*()` methods provided by the `TestCase` base class. If the test fails, an exception will be raised, and `unittest` will identify the test case as a *failure*. Any other exceptions will be treated as *errors*. This helps you identify where the problem is: *failures* are caused by incorrect results - a 5 where you expected a 6. *Errors* are caused by incorrect code - e.g., a `TypeError` caused by an incorrect function call.

The way to run a test case will be described later. For now, note that to construct an instance of such a test case, we call its constructor without arguments:

```python
testCase = DefaultWidgetSizeTestCase()
```

Now, such test cases can be numerous, and their set-up can be repetitive. In the
above case, constructing a Widget in each of 100 Widget test case subclasses would mean unsightly duplication.

Luckily, we can factor out such set-up code by implementing a method called setUp(), which the testing framework will automatically call for us when we run the test:

```python
import unittest

class SimpleWidgetTestCase(unittest.TestCase):
    def setUp(self):
        self.widget = Widget('The widget')

class DefaultWidgetSizeTestCase(SimpleWidgetTestCase):
    def runTest(self):
        self.failUnless(self.widget.size() == (50,50), 'incorrect default size')

class WidgetResizeTestCase(SimpleWidgetTestCase):
    def runTest(self):
        self.widget.resize(100,150)
        self.failUnless(self.widget.size() == (100,150), 'wrong size after resize')
```

If the setUp() method raises an exception while the test is running, the framework will consider the test to have suffered an error, and the runTest() method will not be executed.

Similarly, we can provide a tearDown() method that tidies up after the runTest() method has been run:

```python
import unittest

class SimpleWidgetTestCase(unittest.TestCase):
    def setUp(self):
        self.widget = Widget('The widget')

    def tearDown(self):
        self.widget.dispose()
        self.widget = None
```

If setUp() succeeded, the tearDown() method will be run whether runTest() succeeded or not.

Such a working environment for the testing code is called a fixture.
Often, many small test cases will use the same fixture. In this case, we would end up subclassing `SimpleWidgetTestCase` into many small one-method classes such as `DefaultWidgetSizeTestCase`. This is time-consuming and discouraging, so in the same vein as JUnit, `unittest` provides a simpler mechanism:

```python
import unittest

class WidgetTestCase(unittest.TestCase):
    def setUp(self):
        self.widget = Widget('The widget')

    def tearDown(self):
        self.widget.dispose()
        self.widget = None

    def testDefaultSize(self):
        self.failUnless(self.widget.size() == (50,50),
                        'incorrect default size')

    def testResize(self):
        self.widget.resize(100,150)
        self.failUnless(self.widget.size() == (100,150),
                        'wrong size after resize')
```

Here we have not provided a `runTest()` method, but have instead provided two different test methods. Class instances will now each run one of the `test*` methods, with `self.widget` created and destroyed separately for each instance. When creating an instance we must specify the test method it is to run. We do this by passing the method name in the constructor:

```python
defaultSizeTestCase = WidgetTestCase('testDefaultSize')
resizeTestCase = WidgetTestCase('testResize')
```

Test case instances are grouped together according to the features they test. `unittest` provides a mechanism for this: the `test suite`, represented by `unittest's TestSuite` class:

```python
widgetTestSuite = unittest.TestSuite()
widgetTestSuite.addTest(WidgetTestCase('testDefaultSize'))
widgetTestSuite.addTest(WidgetTestCase('testResize'))
```

For the ease of running tests, as we will see later, it is a good idea to provide in each test module a callable object that returns a pre-built test suite:
def suite():
    suite = unittest.TestSuite()
    suite.addTest(WidgetTestCase('testDefaultSize'))
    suite.addTest(WidgetTestCase('testResize'))
    return suite

or even:

def suite():
    tests = ['testDefaultSize', 'testResize']
    return unittest.TestSuite(map(WidgetTestCase, tests))

Since it is a common pattern to create a TestCase subclass with many similarly named test functions, unittest provides a TestLoader class that can be used to automate the process of creating a test suite and populating it with individual tests. For example,

    suite = unittest.TestLoader().loadTestsFromTestCase(WidgetTestCase)

will create a test suite that will run
WidgetTestCase.testDefaultSize() and
WidgetTestCase.testResize. TestLoader uses the 'test' method name prefix to identify test methods automatically.

Note that the order in which the various test cases will be run is determined by sorting the test function names with the built-in cmp() function.

Often it is desirable to group suites of test cases together, so as to run tests for the whole system at once. This is easy, since TestSuite instances can be added to a TestSuite just as TestCase instances can be added to a TestSuite:

    suite1 = module1.TheTestSuite()
    suite2 = module2.TheTestSuite()
    alltests = unittest.TestSuite([suite1, suite2])

You can place the definitions of test cases and test suites in the same modules as the code they are to test (such as widget.py), but there are several advantages to placing the test code in a separate module, such as test_widget.py:

- The test module can be run standalone from the command line.
- The test code can more easily be separated from shipped code.
• There is less temptation to change test code to fit the code it tests without a good reason.
• Test code should be modified much less frequently than the code it tests.
• Tested code can be refactored more easily.
• Tests for modules written in C must be in separate modules anyway, so why not be consistent?
• If the testing strategy changes, there is no need to change the source code.
23.3.3 Re-using old test code

Some users will find that they have existing test code that they would like to run from unittest, without converting every old test function to a TestCase subclass.

For this reason, unittest provides a FunctionTestCase class. This subclass of TestCase can be used to wrap an existing test function. Set-up and tear-down functions can also be provided.

Given the following test function:

```python
def testSomething():
    something = makeSomething()
    assert something.name is not None
    # ...
```

one can create an equivalent test case instance as follows:

```python
testcase = unittest.FunctionTestCase(testSomething)
```

If there are additional set-up and tear-down methods that should be called as part of the test case's operation, they can also be provided like so:

```python
testcase = unittest.FunctionTestCase(testSomething,
    setUp=makeSomethingDB,
    tearDown=deleteSomethingDB)
```

To make migrating existing test suites easier, unittest supports tests raising AssertionError to indicate test failure. However, it is recommended that you use the explicit TestCase.fail*() and TestCase.assert*() methods instead, as future versions of unittest may treat AssertionError differently.

**Note:** Even though FunctionTestCase can be used to quickly convert an existing test base over to a unittest-based system, this approach is not recommended. Taking the time to set up proper TestCase subclasses will make future test refactoring infinitely easier.
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
23.3.4 Classes and functions

class **TestCase** ([`methodName`])
Instances of the `TestCase` class represent the smallest testable units in the `unittest` universe. This class is intended to be used as a base class, with specific tests being implemented by concrete subclasses. This class implements the interface needed by the test runner to allow it to drive the test, and methods that the test code can use to check for and report various kinds of failure.

Each instance of `TestCase` will run a single test method: the method named `methodName`. If you remember, we had an earlier example that went something like this:

```python
def suite():
    suite = unittest.TestSuite()
    suite.addTest(WidgetTestCase('testDefaultSize'))
    suite.addTest(WidgetTestCase('testResize'))
    return suite
```

Here, we create two instances of `WidgetTestCase`, each of which runs a single test.

`methodName` defaults to 'runTest'.

class **FunctionTestCase** ([`testFunc`, `setUp`, `tearDown`, `description`])
This class implements the portion of the `TestCase` interface which allows the test runner to drive the test, but does not provide the methods which test code can use to check and report errors. This is used to create test cases using legacy test code, allowing it to be integrated into a `unittest`-based test framework.

class **TestSuite** ([`tests`])
This class represents an aggregation of individual tests cases and test suites. The class presents the interface needed by the test runner to allow it to be run as any other test case. Running a `TestSuite` instance is the same as iterating over the suite, running each test individually.
If tests is given, it must be an iterable of individual test cases or other test suites that will be used to build the suite initially. Additional methods are provided to add test cases and suites to the collection later on.

class TestLoader()
    This class is responsible for loading tests according to various criteria and returning them wrapped in a TestSuite. It can load all tests within a given module or TestCase subclass.

class TestResult()
    This class is used to compile information about which tests have succeeded and which have failed.

defaultTestLoader
    Instance of the TestLoader class intended to be shared. If no customization of the TestLoader is needed, this instance can be used instead of repeatedly creating new instances.

class TextTestRunner([stream[, descriptions[, verbosity]]]])
    A basic test runner implementation which prints results on standard error. It has a few configurable parameters, but is essentially very simple. Graphical applications which run test suites should provide alternate implementations.

main([module[, defaultTest[, argv[, testRunner[, testRunner]]]]]])
    A command-line program that runs a set of tests; this is primarily for making test modules conveniently executable. The simplest use for this function is to include the following line at the end of a test script:

        if __name__ == '__main__':
            unittest.main()

In some cases, the existing tests may have been written using the doctest module. If so, that module provides a DocTestSuite class that can automatically build unittest.TestSuite instances from the existing doctest-based tests. New in version 2.3.
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
TestSuite Objects
23.3.5 Test Case Objects

Each `TestCase` instance represents a single test, but each concrete subclass may be used to define multiple tests -- the concrete class represents a single test fixture. The fixture is created and cleaned up for each test case.

`TestCase` instances provide three groups of methods: one group used to run the test, another used by the test implementation to check conditions and report failures, and some inquiry methods allowing information about the test itself to be gathered.

Methods in the first group (running the test) are:

`setUp()`  
Method called to prepare the test fixture. This is called immediately before calling the test method; any exception raised by this method will be considered an error rather than a test failure. The default implementation does nothing.

`tearDown()`  
Method called immediately after the test method has been called and the result recorded. This is called even if the test method raised an exception, so the implementation in subclasses may need to be particularly careful about checking internal state. Any exception raised by this method will be considered an error rather than a test failure. This method will only be called if the `setUp()` succeeds, regardless of the outcome of the test method. The default implementation does nothing.

`run([result])`  
Run the test, collecting the result into the test result object passed as `result`. If `result` is omitted or `None`, a temporary result object is created (by calling the `defaultTestCase()` method) and used; this result object is not returned to `run()`'s caller.

The same effect may be had by simply calling the `TestCase` instance.

`debug()`
Run the test without collecting the result. This allows exceptions raised by the test to be propagated to the caller, and can be used to support running tests under a debugger.

The test code can use any of the following methods to check for and report failures.

```python
assert_(expr[, msg])
failUnless(expr[, msg])

Signal a test failure if `expr` is false; the explanation for the error will be `msg` if given, otherwise it will be `None`.

assertEqual(first, second[, msg])
failUnlessEqual(first, second[, msg])

Test that `first` and `second` are equal. If the values do not compare equal, the test will fail with the explanation given by `msg`, or `None`. Note that using `failUnlessEqual()` improves upon doing the comparison as the first parameter to `failUnless()`: the default value for `msg` can be computed to include representations of both `first` and `second`.

assertNotEqual(first, second[, msg])
failIfEqual(first, second[, msg])

Test that `first` and `second` are not equal. If the values do compare equal, the test will fail with the explanation given by `msg`, or `None`. Note that using `failIfEqual()` improves upon doing the comparison as the first parameter to `failUnless()` is that the default value for `msg` can be computed to include representations of both `first` and `second`.

assertAlmostEqual(first, second[, places[, msg]])
failUnlessAlmostEqual(first, second[, places[, msg]])

Test that `first` and `second` are approximately equal by computing the difference, rounding to the given number of `places`, and comparing to zero. Note that comparing a given number of decimal places is not the same as comparing a given number of significant digits. If the values do not compare equal, the test will fail with the explanation given by `msg`, or
None.

assertNotAlmostEqual(first, second[, places[, msg]])

failIfAlmostEqual(first, second[, places[, msg]])

Test that first and second are not approximately equal by computing the difference, rounding to the given number of places, and comparing to zero. Note that comparing a given number of decimal places is not the same as comparing a given number of significant digits. If the values do not compare equal, the test will fail with the explanation given by msg, or None.

assertRaises(exception, callable,...)

failUnlessRaises(exception, callable,...)

Test that an exception is raised when callable is called with any positional or keyword arguments that are also passed to assertRaises(). The test passes if exception is raised, is an error if another exception is raised, or fails if no exception is raised. To catch any of a group of exceptions, a tuple containing the exception classes may be passed as exception.

failIf(expr[, msg])

The inverse of the failUnless() method is the failIf() method. This signals a test failure if expr is true, with msg or None for the error message.

fail([msg])

Signals a test failure unconditionally, with msg or None for the error message.

failureException

This class attribute gives the exception raised by the test() method. If a test framework needs to use a specialized exception, possibly to carry additional information, it must subclass this exception in order to "play fair" with the framework. The initial value of this attribute is AssertionError.

Testing frameworks can use the following methods to collect information on the test:
**countTestCases()**

Return the number of tests represented by this test object. For `TestCase` instances, this will always be 1.

**defaultTestResult()**

Return an instance of the test result class that should be used for this test case class (if no other result instance is provided to the `run()` method).

For `TestCase` instances, this will always be an instance of `TestResult`; subclasses of `TestCase` should override this as necessary.

**id()**

Return a string identifying the specific test case. This is usually the full name of the test method, including the module and class name.

**shortDescription()**

Returns a one-line description of the test, or `None` if no description has been provided. The default implementation of this method returns the first line of the test method's docstring, if available, or `None`. 
23.3.6 TestSuite Objects

TestSuite objects behave much like testCase objects, except they do not actually implement a test. Instead, they are used to aggregate tests into groups of tests that should be run together. Some additional methods are available to add tests to TestSuite instances:

**addTest**(test)
Add a TestCase or TestSuite to the suite.

**addTests**(tests)
Add all the tests from an iterable of TestCase and TestSuite instances to this test suite.

This is equivalent to iterating over tests, calling addTest() for each element.

TestSuite shares the following methods withTestCase:

**run**(result)
Run the tests associated with this suite, collecting the result into the test result object passed as result. Note that unlike testCase.run(), TestSuite.run() requires the result object to be passed in.

**debug**()
Run the tests associated with this suite without collecting the result. This allows exceptions raised by the test to be propagated to the caller and can be used to support running tests under a debugger.

**countTestCases**()
Return the number of tests represented by this test object, including all individual tests and sub-suites.

In the typical usage of a TestSuite object, the run() method is invoked by a TestRunner rather than by the end-user test harness.
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
23.3.7 TestResult Objects

A TestResult object stores the results of a set of tests. The TestCase and TestSuite classes ensure that results are properly recorded; test authors do not need to worry about recording the outcome of tests.

Testing frameworks built on top of unittest may want access to the TestResult object generated by running a set of tests for reporting purposes; a TestResult instance is returned by the TestRunner.run() method for this purpose.

TestResult instances have the following attributes that will be of interest when inspecting the results of running a set of tests:

**errors**
A list containing 2-tuples of TestCase instances and strings holding formatted tracebacks. Each tuple represents a test which raised an unexpected exception. Changed in version 2.2: Contains formatted tracebacks instead of sys.exc_info() results.

**failures**
A list containing 2-tuples of TestCase instances and strings holding formatted tracebacks. Each tuple represents a test where a failure was explicitly signalled using the TestCase.fail*() or TestCase.assert*() methods. Changed in version 2.2: Contains formatted tracebacks instead of sys.exc_info() results.

**testsRun**
The total number of tests run so far.

**wasSuccessful()**
Returns True if all tests run so far have passed, otherwise returns False.

**stop()**
This method can be called to signal that the set of tests being run should be aborted by setting the TestResult's shouldStop attribute to True. TestRunner objects should respect this flag and return without running
any additional tests.

For example, this feature is used by the TextTestRunner class to stop the test framework when the user signals an interrupt from the keyboard. Interactive tools which provide TestRunner implementations can use this in a similar manner.

The following methods of the TestResult class are used to maintain the internal data structures, and may be extended in subclasses to support additional reporting requirements. This is particularly useful in building tools which support interactive reporting while tests are being run.

startTest( test)
Called when the test case test is about to be run.

The default implementation simply increments the instance's testsRun counter.

stopTest( test)
Called after the test case test has been executed, regardless of the outcome.

The default implementation does nothing.

addError( test, err)
Called when the test case test raises an unexpected exception err is a tuple of the form returned by sys.exc_info(): (type, value, traceback).

The default implementation appends (test, err) to the instance's errors attribute.

addFailure( test, err)
Called when the test case test signals a failure. err is a tuple of the form returned by sys.exc_info(): (type, value, traceback).

The default implementation appends (test, err) to the instance's failures attribute.

addSuccess( test)
Called when the test case *test* succeeds.

The default implementation does nothing.
23.3.8 TestLoader Objects

The TestLoader class is used to create test suites from classes and modules. Normally, there is no need to create an instance of this class; the unittest module provides an instance that can be shared as unittest.defaultTestLoader. Using a subclass or instance, however, allows customization of some configurable properties.

TestLoader objects have the following methods:

**loadTestsFromTestCase(testCaseClass)**
Return a suite of all tests cases contained in the TestCase-derived testCaseClass.

**loadTestsFromModule(module)**
Return a suite of all tests cases contained in the given module. This method searches module for classes derived from TestCase and creates an instance of the class for each test method defined for the class.

**Warning:** While using a hierarchy of TestCase-derived classes can be convenient in sharing fixtures and helper functions, defining test methods on base classes that are not intended to be instantiated directly does not play well with this method. Doing so, however, can be useful when the fixtures are different and defined in subclasses.

**loadTestsFromName(name[, module])**
Return a suite of all tests cases given a string specifier.

The specifier name is a ``dotted name" that may resolve either to a module, a test case class, a test method within a test case class, a TestSuite instance, or a callable object which returns a TestCase or TestSuite instance. These checks are applied in the order listed here; that is, a method on a possible test case class will be picked up as ``a test method within a test case class", rather than ``a callable object".

For example, if you have a module SampleTests containing a
TestCase-derived class SampleTestCase with three test methods (test_one(), test_two(), and test_three()), the specifier 'SampleTests.SampleTestCase' would cause this method to return a suite which will run all three test methods. Using the specifier 'SampleTests.SampleTestCase.test_two' would cause it to return a test suite which will run only the test_two() test method. The specifier can refer to modules and packages which have not been imported; they will be imported as a side-effect.

The method optionally resolves name relative to the given module.

loadTestsFromNames(names[, module])
Similar to loadTestsFromName(), but takes a sequence of names rather than a single name. The return value is a test suite which supports all the tests defined for each name.

getTestCaseNames(testCaseClass)
Return a sorted sequence of method names found within testCaseClass; this should be a subclass of TestCase.

The following attributes of a TestLoader can be configured either by subclassing or assignment on an instance:

testMethodPrefix
String giving the prefix of method names which will be interpreted as test methods. The default value is 'test'.

This affects getTestCaseNames() and all the loadTestsFrom*() methods.

sortTestMethodsUsing
Function to be used to compare method names when sorting them in getTestCaseNames() and all the loadTestsFrom*() methods. The default value is the built-in cmp() function; the attribute can also be set to None to disable the sort.

suiteClass
Callable object that constructs a test suite from a list of tests. No methods
on the resulting object are needed. The default value is the TestSuite class.

This affects all the loadTestsFrom*() methods.
23.4 test -- Regression tests package for Python

The test package contains all regression tests for Python as well as the modules test.test_support and test.regrtest. test.test_support is used to enhance your tests while test.regrtest drives the testing suite.

Each module in the test package whose name starts with "test_" is a testing suite for a specific module or feature. All new tests should be written using the unittest module; using unittest is not required but makes the tests more flexible and maintenance of the tests easier. Some older tests are written to use doctest and a ``traditional'' testing style; these styles of tests will not be covered.

- 23.4.2 Running tests using test.regrtest

Python Library Reference

Previous: 23.3.8 TestLoader Objects Up: 23. Development Tools Next: 23.4.1 Writing Unit Tests
Release 2.5, documentation updated on 19th September, 2006. See About this document... for information on suggesting changes.
23.4.1 Writing Unit Tests for the test package

It is preferred that tests for the test package use the unittest module and follow a few guidelines. One is to name the test module by starting it with "test_" and end it with the name of the module being tested. The test methods in the test module should start with "test_" and end with a description of what the method is testing. This is needed so that the methods are recognized by the test driver as test methods. Also, no documentation string for the method should be included. A comment (such as "# Tests function returns only True or False") should be used to provide documentation for test methods. This is done because documentation strings get printed out if they exist and thus what test is being run is not stated.

A basic boilerplate is often used:

```python
import unittest
from test import test_support

class MyTestCase1(unittest.TestCase):
    # Only use setUp() and tearDown() if necessary
    def setUp(self):
        ... code to execute in preparation for tests ...
    def tearDown(self):
        ... code to execute to clean up after tests ...
    def test_feature_one(self):
        # Test feature one.
        ... testing code ...
    def test_feature_two(self):
        # Test feature two.
        ... testing code ...
    ... more test methods ...

class MyTestCase2(unittest.TestCase):
    ... same structure as MyTestCase1 ...
    ... more test classes ...

def test_main():
    test_support.run_unittest(MyTestCase1,
```
This boilerplate code allows the testing suite to be run by `test.regrtest` as well as on its own as a script.

The goal for regression testing is to try to break code. This leads to a few guidelines to be followed:

- The testing suite should exercise all classes, functions, and constants. This includes not just the external API that is to be presented to the outside world but also "private" code.
- Whitebox testing (examining the code being tested when the tests are being written) is preferred. Blackbox testing (testing only the published user interface) is not complete enough to make sure all boundary and edge cases are tested.
- Make sure all possible values are tested including invalid ones. This makes sure that not only all valid values are acceptable but also that improper values are handled correctly.
- Exhaust as many code paths as possible. Test where branching occurs and thus tailor input to make sure as many different paths through the code are taken.
- Add an explicit test for any bugs discovered for the tested code. This will make sure that the error does not crop up again if the code is changed in the future.
- Make sure to clean up after your tests (such as close and remove all temporary files).
- If a test is dependent on a specific condition of the operating system then verify the condition already exists before attempting the test.
- Import as few modules as possible and do it as soon as possible. This minimizes external dependencies of tests and also minimizes possible anomalous behavior from side-effects of importing a module.
- Try to maximize code reuse. On occasion, tests will vary by something as small as what type of input is used. Minimize code duplication by subclassing a basic test class with a class that specifies the input:

```python
class TestFuncAcceptsSequences(unittest.TestCase):
```
func = mySuperWhammyFunction

def test_func(self):
    self.func(self.arg)

class AcceptLists(TestFuncAcceptsSequences):
    arg = [1,2,3]

class AcceptStrings(TestFuncAcceptsSequences):
    arg = 'abc'

class AcceptTuples(TestFuncAcceptsSequences):
    arg = (1,2,3)

See Also:

*Test Driven Development*

A book by Kent Beck on writing tests before code.
23.4.2 Running tests using test.regrtest

test.regrtest can be used as a script to drive Python's regression test suite. Running the script by itself automatically starts running all regression tests in the test package. It does this by finding all modules in the package whose name starts with "test_", importing them, and executing the function test_main() if present. The names of tests to execute may also be passed to the script. Specifying a single regression test (python regrtest.py test_spam.py) will minimize output and only print whether the test passed or failed and thus minimize output.

Running test.regrtest directly allows what resources are available for tests to use to be set. You do this by using the -u command-line option. Run python regrtest.py -uall to turn on all resources; specifying all as an option for -u enables all possible resources. If all but one resource is desired (a more common case), a comma-separated list of resources that are not desired may be listed after all. The command python regrtest.py -uall,-audio,-largefile will run test.regrtest with all resources except the audio and largefile resources. For a list of all resources and more command-line options, run python regrtest.py -h.

Some other ways to execute the regression tests depend on what platform the tests are being executed on. On UNIX, you can run make test at the top-level directory where Python was built. On Windows, executing rt.bat from your PCBuild directory will run all regression tests.
23.5 test.test_support -- Utility functions for tests

The test.test_support module provides support for Python's regression tests.

This module defines the following exceptions:

**exception TestFailed**
Exception to be raised when a test fails.

**exception TestSkipped**
Subclass of TestFailed. Raised when a test is skipped. This occurs when a needed resource (such as a network connection) is not available at the time of testing.

**exception ResourceDenied**
Subclass of TestSkipped. Raised when a resource (such as a network connection) is not available. Raised by the requires() function.

The test.test_support module defines the following constants:

**verbose**
True when verbose output is enabled. Should be checked when more detailed information is desired about a running test. verbose is set by test.regrtest.

**have_unicode**
True when Unicode support is available.

**is_jython**
True if the running interpreter is Jython.

**TESTFN**
Set to the path that a temporary file may be created at. Any temporary that is created should be closed and unlinked (removed).
The `test.test_support` module defines the following functions:

**forget**( `module_name` )
Removes the module named `module_name` from `sys.modules` and deletes any byte-compiled files of the module.

**is_resource_enabled**( `resource` )
Returns `True` if `resource` is enabled and available. The list of available resources is only set when `test.regrtest` is executing the tests.

**requires**( `resource[, msg]` )
Raises `ResourceDenied` if `resource` is not available. `msg` is the argument to `ResourceDenied` if it is raised. Always returns true if called by a function whose `__name__` is '__main__'. Used when tests are executed by `test.regrtest`.

**findfile**( `filename` )
Return the path to the file named `filename`. If no match is found `filename` is returned. This does not equal a failure since it could be the path to the file.

**run_unittest**( `*classes` )
Execute `unittest.TestCase` subclasses passed to the function. The function scans the classes for methods starting with the prefix "test_" and executes the tests individually. This is the preferred way to execute tests.

**run_suite**( `suite[, testclass]` )
Execute the `unittest.TestSuite` instance `suite`. The optional argument `testclass` accepts one of the test classes in the suite so as to print out more detailed information on where the testing suite originated from.
24. The Python Debugger

The module `pdb` defines an interactive source code debugger for Python programs. It supports setting (conditional) breakpoints and single stepping at the source line level, inspection of stack frames, source code listing, and evaluation of arbitrary Python code in the context of any stack frame. It also supports post-mortem debugging and can be called under program control.

The debugger is extensible -- it is actually defined as the class `Pdb`. This is currently undocumented but easily understood by reading the source. The extension interface uses the modules `bdb` (undocumented) and `cmd`.

The debugger's prompt is "(Pdb) ". Typical usage to run a program under control of the debugger is:

```python
>>> import pdb
>>> import mymodule
>>> pdb.run('mymodule.test()')
> <string>(0)?()
(Pdb) continue
> <string>(1)?()
(Pdb) continue
NameError: 'spam'
> <string>(1)?()
(Pdb)
```

`pdb.py` can also be invoked as a script to debug other scripts. For example:

```bash
python -m pdb myscript.py
```

When invoked as a script, `pdb` will automatically enter post-mortem debugging if the program being debugged exits abnormally. After post-mortem debugging (or after normal exit of the program), `pdb` will restart the program. Automatic restarting preserves `pdb`'s state (such as breakpoints) and in most cases is more useful than quitting the debugger upon program's exit. New in version 2.4: Restarting post-mortem behavior added.

Typical usage to inspect a crashed program is:

```python
>>> import pdb
>>> import mymodule
```
>>> mymodule.test()
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
  File "./mymodule.py", line 4, in test
    test2()
  File "./mymodule.py", line 3, in test2
    print spam
NameError: spam

>>> pdb.pm()
> ./mymodule.py(3)test2()
-> print spam
(Pdb)

The module defines the following functions; each enters the debugger in a slightly different way:

run( statement[, globals[, locals]])

Execute the statement (given as a string) under debugger control. The debugger prompt appears before any code is executed; you can set breakpoints and type "continue", or you can step through the statement using "step" or "next" (all these commands are explained below). The optional globals and locals arguments specify the environment in which the code is executed; by default the dictionary of the module __main__ is used. (See the explanation of the exec statement or the eval() built-in function.)

runeval( expression[, globals[, locals]])

Evaluate the expression (given as a string) under debugger control. When runeval() returns, it returns the value of the expression. Otherwise this function is similar to run().

runcall( function[, argument, ...])

Call the function (a function or method object, not a string) with the given arguments. When runcall() returns, it returns whatever the function call returned. The debugger prompt appears as soon as the function is entered.

set_trace()

Enter the debugger at the calling stack frame. This is useful to hard-code a breakpoint at a given point in a program, even if the code is not otherwise being debugged (e.g. when an assertion fails).
**post_mortem**(*traceback*)

Enter post-mortem debugging of the given *traceback* object.

**pm()**
Enter post-mortem debugging of the traceback found in
`sys.last_traceback`.

---

- [24.1 Debugger Commands](#)
- [24.2 How It Works](#)

---

*Release 2.5, documentation updated on 19th September, 2006.*
See [About this document...](#) for information on suggesting changes.
24.1 Debugger Commands

The debugger recognizes the following commands. Most commands can be abbreviated to one or two letters; e.g. "h(elp)" means that either "h" or "help" can be used to enter the help command (but not "he" or "hel", nor "H" or "Help" or "HELP"). Arguments to commands must be separated by whitespace (spaces or tabs). Optional arguments are enclosed in square brackets ([ ]") in the command syntax; the square brackets must not be typed. Alternatives in the command syntax are separated by a vertical bar ("| ").

Entering a blank line repeats the last command entered. Exception: if the last command was a "list" command, the next 11 lines are listed.

Commands that the debugger doesn't recognize are assumed to be Python statements and are executed in the context of the program being debugged. Python statements can also be prefixed with an exclamation point ("! "). This is a powerful way to inspect the program being debugged; it is even possible to change a variable or call a function. When an exception occurs in such a statement, the exception name is printed but the debugger's state is not changed.

Multiple commands may be entered on a single line, separated by ";;". (A single ";" is not used as it is the separator for multiple commands in a line that is passed to the Python parser.) No intelligence is applied to separating the commands; the input is split at the first ";;" pair, even if it is in the middle of a quoted string.

The debugger supports aliases. Aliases can have parameters which allows one a certain level of adaptability to the context under examination.

If a file .pdbrc exists in the user's home directory or in the current directory, it is read in and executed as if it had been typed at the debugger prompt. This is particularly useful for aliases. If both files exist, the one in the home directory is read first and aliases defined there can be overridden by the local file.

h(elp) [command]

Without argument, print the list of available commands. With a command as
argument, print help about that command. "help pdb" displays the full documentation file; if the environment variable PAGER is defined, the file is piped through that command instead. Since the command argument must be an identifier, "help exec" must be entered to get help on the "!" command.

w(here)

Print a stack trace, with the most recent frame at the bottom. An arrow indicates the current frame, which determines the context of most commands.

d(own)

Move the current frame one level down in the stack trace (to a newer frame).

u(p)

Move the current frame one level up in the stack trace (to an older frame).

b(reak) [[filename:]lineno | function[, condition]]

With a lineno argument, set a break there in the current file. With a function argument, set a break at the first executable statement within that function. The line number may be prefixed with a filename and a colon, to specify a breakpoint in another file (probably one that hasn't been loaded yet). The file is searched on sys.path. Note that each breakpoint is assigned a number to which all the other breakpoint commands refer.

If a second argument is present, it is an expression which must evaluate to true before the breakpoint is honored.

Without argument, list all breaks, including for each breakpoint, the number of times that breakpoint has been hit, the current ignore count, and the associated condition if any.

tbreak [[filename:]lineno | function[, condition]]

Temporary breakpoint, which is removed automatically when it is first hit.
The arguments are the same as break.

\texttt{clear} \hspace{1em} \texttt{[bpnumber \{bpnumber \ldots\}]}

With a space separated list of breakpoint numbers, clear those breakpoints. Without argument, clear all breaks (but first ask confirmation).

\texttt{disable} \hspace{1em} \texttt{[bpnumber \{bpnumber \ldots\}]}

Disables the breakpoints given as a space separated list of breakpoint numbers. Disabling a breakpoint means it cannot cause the program to stop execution, but unlike clearing a breakpoint, it remains in the list of breakpoints and can be (re-)enabled.

\texttt{enable} \hspace{1em} \texttt{[bpnumber \{bpnumber \ldots\}]}

Enables the breakpoints specified.

\texttt{ignore} \hspace{1em} \texttt{bpnumber \{count\}}

Sets the ignore count for the given breakpoint number. If count is omitted, the ignore count is set to 0. A breakpoint becomes active when the ignore count is zero. When non-zero, the count is decremented each time the breakpoint is reached and the breakpoint is not disabled and any associated condition evaluates to true.

\texttt{condition} \hspace{1em} \texttt{bpnumber \{condition\}}

Condition is an expression which must evaluate to true before the breakpoint is honored. If condition is absent, any existing condition is removed; i.e., the breakpoint is made unconditional.

\texttt{commands} \hspace{1em} \texttt{[bpnumber]}

Specify a list of commands for breakpoint number \texttt{bpnumber}. The commands themselves appear on the following lines. Type a line containing just 'end' to terminate the commands. An example:

\begin{verbatim}
(Pdb) commands 1
(com) print some_variable
\end{verbatim}
To remove all commands from a breakpoint, type commands and follow it immediately with end; that is, give no commands.

With no bpnumber argument, commands refers to the last breakpoint set.

You can use breakpoint commands to start your program up again. Simply use the continue command, or step, or any other command that resumes execution.

Specifying any command resuming execution (currently continue, step, next, return, jump, quit and their abbreviations) terminates the command list (as if that command was immediately followed by end). This is because any time you resume execution (even with a simple next or step), you may encounter another breakpoint-which could have its own command list, leading to ambiguities about which list to execute.

If you use the 'silent' command in the command list, the usual message about stopping at a breakpoint is not printed. This may be desirable for breakpoints that are to print a specific message and then continue. If none of the other commands print anything, you see no sign that the breakpoint was reached.

New in version 2.5.

s(tep)

Execute the current line, stop at the first possible occasion (either in a function that is called or on the next line in the current function).

n(ext)

Continue execution until the next line in the current function is reached or it returns. (The difference between "next" and "step" is that "step" stops inside a called function, while "next" executes called functions at (nearly) full speed, only stopping at the next line in the current function.)

r(et)
Continue execution until the current function returns.

c(ont(inue))

Continue execution, only stop when a breakpoint is encountered.

j(ump) lineno

Set the next line that will be executed. Only available in the bottom-most frame. This lets you jump back and execute code again, or jump forward to skip code that you don't want to run.

It should be noted that not all jumps are allowed -- for instance it is not possible to jump into the middle of a for loop or out of a finally clause.

l(ist) [first[, last]]

List source code for the current file. Without arguments, list 11 lines around the current line or continue the previous listing. With one argument, list 11 lines around at that line. With two arguments, list the given range; if the second argument is less than the first, it is interpreted as a count.

a(rgs)

Print the argument list of the current function.

p expression

Evaluate the expression in the current context and print its value. Note: "print" can also be used, but is not a debugger command -- this executes the Python print statement.

pp expression

Like the "p" command, except the value of the expression is pretty-printed using the pprint module.

alias [name [command]]
Creates an alias called *name* that executes *command*. The command must *not* be enclosed in quotes. Replaceable parameters can be indicated by "%1", "%2", and so on, while "%*" is replaced by all the parameters. If no command is given, the current alias for *name* is shown. If no arguments are given, all aliases are listed.

Aliases may be nested and can contain anything that can be legally typed at the pdb prompt. Note that internal pdb commands *can* be overridden by aliases. Such a command is then hidden until the alias is removed. Aliasing is recursively applied to the first word of the command line; all other words in the line are left alone.

As an example, here are two useful aliases (especially when placed in the .pdbrc file):

```
#Print instance variables (usage "pi classInst")
alias pi for k in %1.__dict__.keys(): print "%1.",k,="",%1.__dict__[k]
#Print instance variables in self
alias ps pi self
```

**unalias name**

Deletes the specified alias.

**[!]statement**

Execute the (one-line) *statement* in the context of the current stack frame. The exclamation point can be omitted unless the first word of the statement resembles a debugger command. To set a global variable, you can prefix the assignment command with a "global" command on the same line, e.g.:

```
(Pdb) global list_options; list_options = ['-l']
(Pdb)
```

**q(uit)**

Quit from the debugger. The program being executed is aborted.
How It Works

Release 2.5, documentation updated on 19th September, 2006.  
See About this document... for information on suggesting changes.
24.2 How It Works

Some changes were made to the interpreter:

- `sys.settrace(func)` sets the global trace function
- there can also be a local trace function (see later)

Trace functions have three arguments: `frame`, `event`, and `arg`. `frame` is the current stack frame. `event` is a string: 'call', 'line', 'return', 'exception', 'c_call', 'c_return', or 'c_exception'. `arg` depends on the event type.

The global trace function is invoked (with `event` set to 'call') whenever a new local scope is entered; it should return a reference to the local trace function to be used that scope, or `None` if the scope shouldn't be traced.

The local trace function should return a reference to itself (or to another function for further tracing in that scope), or `None` to turn off tracing in that scope.

Instance methods are accepted (and very useful!) as trace functions.

The events have the following meaning:

'call'
A function is called (or some other code block entered). The global trace function is called; `arg` is `None`; the return value specifies the local trace function.

'line'
The interpreter is about to execute a new line of code (sometimes multiple line events on one line exist). The local trace function is called; `arg` is `None`; the return value specifies the new local trace function.

'return'
A function (or other code block) is about to return. The local trace function is called; `arg` is the value that will be returned. The trace function's return value is ignored.
'exception'
An exception has occurred. The local trace function is called; arg is a triple (exception, value, traceback); the return value specifies the new local trace function.

'c_call'
A C function is about to be called. This may be an extension function or a builtin. arg is the C function object.

'c_return'
A C function has returned. arg is None.

'c_exception'
A C function has thrown an exception. arg is None.

Note that as an exception is propagated down the chain of callers, an 'exception' event is generated at each level.

For more information on code and frame objects, refer to the Python Reference Manual.
25. The Python Profilers

The profiler was written after only programming in Python for 3 weeks. As a result, it is probably clumsy code, but I don't know for sure yet 'cause I'm a beginner :-). I did work hard to make the code run fast, so that profiling would be a reasonable thing to do. I tried not to repeat code fragments, but I'm sure I did some stuff in really awkward ways at times. Please send suggestions for improvements to: jar@netscape.com. I won't promise any support. ...but I'd appreciate the feedback.
Footnotes

25.1 Introduction to the profilers

A profiler is a program that describes the run time performance of a program, providing a variety of statistics. This documentation describes the profiler functionality provided in the modules `profile` and `pstats`. This profiler provides deterministic profiling of any Python programs. It also provides a series of report generation tools to allow users to rapidly examine the results of a profile operation.

The Python standard library provides three different profilers:

1. `profile`, a pure Python module, described in the sequel. Copyright © 1994, by InfoSeek Corporation. Changed in version 2.4: also reports the time spent in calls to built-in functions and methods.

2. `cProfile`, a module written in C, with a reasonable overhead that makes it suitable for profiling long-running programs. Based on `lsprof`, contributed by Brett Rosen and Ted Czotter. New in version 2.5.

3. `hotshot`, a C module focusing on minimizing the overhead while profiling, at the expense of long data post-processing times. Changed in version 2.5: the results should be more meaningful than in the past: the timing core contained a critical bug.

The `profile` and `cProfile` modules export the same interface, so they are mostly interchangeable; `cProfile` has a much lower overhead but is not so far as well-tested and might not be available on all systems. `cProfile` is really a compatibility layer on top of the internal `_lsprof` module. The `hotshot` module is reserved to specialized usages.
25.2 Instant User's Manual

This section is provided for users that "don't want to read the manual." It provides a very brief overview, and allows a user to rapidly perform profiling on an existing application.

To profile an application with a main entry point of `foo()`, you would add the following to your module:

```python
import cProfile
cProfile.run('foo()')
```

(Use `profile` instead of `cProfile` if the latter is not available on your system.)

The above action would cause `foo()` to be run, and a series of informative lines (the profile) to be printed. The above approach is most useful when working with the interpreter. If you would like to save the results of a profile into a file for later examination, you can supply a file name as the second argument to the `run()` function:

```python
import cProfile
cProfile.run('foo()', 'fooprof')
```

The file `cProfile.py` can also be invoked as a script to profile another script. For example:

```bash
python -m cProfile myscript.py
```

cProfile.py accepts two optional arguments on the command line:

```
cProfile.py [-o output_file] [-s sort_order]
```

-s only applies to standard output (-o is not supplied). Look in the Stats documentation for valid sort values.

When you wish to review the profile, you should use the methods in the `pstats` module. Typically you would load the statistics data as follows:

```python
import pstats
```
\[ p = \text{pstats.Stats('fooprof')} \]

The class `Stats` (the above code just created an instance of this class) has a variety of methods for manipulating and printing the data that was just read into `p`. When you ran `cProfile.run()` above, what was printed was the result of three method calls:

\[ p\.\text{strip_dirs()}.\text{sort_stats(-1)}.\text{print_stats()} \]

The first method removed the extraneous path from all the module names. The second method sorted all the entries according to the standard module/line/name string that is printed. The third method printed out all the statistics. You might try the following sort calls:

\[ p\.\text{sort_stats('name')} \]
\[ p\.\text{print_stats()} \]

The first call will actually sort the list by function name, and the second call will print out the statistics. The following are some interesting calls to experiment with:

\[ p\.\text{sort_stats('cumulative')}\.\text{print_stats(10)} \]

This sorts the profile by cumulative time in a function, and then only prints the ten most significant lines. If you want to understand what algorithms are taking time, the above line is what you would use.

If you were looking to see what functions were looping a lot, and taking a lot of time, you would do:

\[ p\.\text{sort_stats('time')}\.\text{print_stats(10)} \]

to sort according to time spent within each function, and then print the statistics for the top ten functions.

You might also try:

\[ p\.\text{sort_stats('file')}\.\text{print_stats('__init__')} \]

This will sort all the statistics by file name, and then print out statistics for only the class init methods (since they are spelled with `__init__` in them). As one final example, you could try:
p.sort_stats('time', 'cum').print_stats(.5, 'init')

This line sorts statistics with a primary key of time, and a secondary key of cumulative time, and then prints out some of the statistics. To be specific, the list is first culled down to 50% (re: ".5") of its original size, then only lines containing init are maintained, and that sub-sub-list is printed.

If you wondered what functions called the above functions, you could now (p is still sorted according to the last criteria) do:

    p.print_callers(.5, 'init')

and you would get a list of callers for each of the listed functions.

If you want more functionality, you're going to have to read the manual, or guess what the following functions do:

    p.print_callees()
    p.add('fooprof')

Invoked as a script, the pstats module is a statistics browser for reading and examining profile dumps. It has a simple line-oriented interface (implemented using cmd) and interactive help.
25.3 What Is Deterministic Profiling?

Deterministic profiling is meant to reflect the fact that all function call, function return, and exception events are monitored, and precise timings are made for the intervals between these events (during which time the user's code is executing). In contrast, statistical profiling (which is not done by this module) randomly samples the effective instruction pointer, and deduces where time is being spent. The latter technique traditionally involves less overhead (as the code does not need to be instrumented), but provides only relative indications of where time is being spent.

In Python, since there is an interpreter active during execution, the presence of instrumented code is not required to do deterministic profiling. Python automatically provides a hook (optional callback) for each event. In addition, the interpreted nature of Python tends to add so much overhead to execution, that deterministic profiling tends to only add small processing overhead in typical applications. The result is that deterministic profiling is not that expensive, yet provides extensive run time statistics about the execution of a Python program.

Call count statistics can be used to identify bugs in code (surprising counts), and to identify possible inline-expansion points (high call counts). Internal time statistics can be used to identify "hot loops" that should be carefully optimized. Cumulative time statistics should be used to identify high level errors in the selection of algorithms. Note that the unusual handling of cumulative times in this profiler allows statistics for recursive implementations of algorithms to be directly compared to iterative implementations.
25.4 Reference Manual - profile and cProfile

The primary entry point for the profiler is the global function `profile.run()` (resp. `cProfile.run()`). It is typically used to create any profile information. The reports are formatted and printed using methods of the class `pstats.Stats`. The following is a description of all of these standard entry points and functions. For a more in-depth view of some of the code, consider reading the later section on Profiler Extensions, which includes discussion of how to derive ``better'' profilers from the classes presented, or reading the source code for these modules.

```
run(command[, filename])
```

This function takes a single argument that has can be passed to the `exec` statement, and an optional file name. In all cases this routine attempts to `exec` its first argument, and gather profiling statistics from the execution. If no file name is present, then this function automatically prints a simple profiling report, sorted by the standard name string (file/line/function-name) that is presented in each line. The following is a typical output from such a call:

```
2706 function calls (2004 primitive calls) in 4.504 CPU sec
Ordered by: standard name

ncalls  tottime  percall  cumtime  percall  filename:lineno(function)
2       0.006    0.003   0.953    0.477  pobject.py:75(save_objects)
43/3    0.533    0.012   0.749    0.250  pobject.py:99(evaluate)
...
```

The first line indicates that 2706 calls were monitored. Of those calls, 2004 were primitive. We define primitive to mean that the call was not induced via recursion. The next line: `Ordered by: standard name`, indicates that the text string in the far right column was used to sort the output. The column headings include:
ncalls
   for the number of calls,

tottime
   for the total time spent in the given function (and excluding time made
   in calls to sub-functions),

percall
   is the quotient of tottime divided by ncalls

cumtime
   is the total time spent in this and all subfunctions (from invocation till
   exit). This figure is accurate even for recursive functions.

percall
   is the quotient of cumtime divided by primitive calls

filename:lineno(function)
   provides the respective data of each function

   When there are two numbers in the first column (for example, "43/3"),
   then the latter is the number of primitive calls, and the former is the actual
   number of calls. Note that when the function does not recurse, these two
   values are the same, and only the single figure is printed.

runctx( command, globals, locals[, filename])
   This function is similar to run(), with added arguments to supply the
   globals and locals dictionaries for the command string.

Analysis of the profiler data is done using the Stats class.

Note: The Stats class is defined in the pstats module.

class Stats( filename[, stream=sys.stdout[, ...]])
   This class constructor creates an instance of a "statistics object" from a
   filename (or set of filenames). Stats objects are manipulated by methods,
   in order to print useful reports. You may specify an alternate output stream
   by giving the keyword argument, stream.
The file selected by the above constructor must have been created by the corresponding version of profile or cProfile. To be specific, there is no file compatibility guaranteed with future versions of this profiler, and there is no compatibility with files produced by other profilers.

If several files are provided, all the statistics for identical functions will be coalesced, so that an overall view of several processes can be considered in a single report. If additional files need to be combined with data in an existing Stats object, the add() method can be used.

Changed in version 2.5: The stream parameter was added.
25.4.1 The Stats Class

Stats objects have the following methods:

**strip_dirs()**
This method for the Stats class removes all leading path information from file names. It is very useful in reducing the size of the printout to fit within (close to) 80 columns. This method modifies the object, and the stripped information is lost. After performing a strip operation, the object is considered to have its entries in a ``random'' order, as it was just after object initialization and loading. If `strip_dirs()` causes two function names to be indistinguishable (they are on the same line of the same filename, and have the same function name), then the statistics for these two entries are accumulated into a single entry.

**add(filename[, ...])**
This method of the Stats class accumulates additional profiling information into the current profiling object. Its arguments should refer to filenames created by the corresponding version of `profile.run()` or `cProfile.run()`. Statistics for identically named (re: file, line, name) functions are automatically accumulated into single function statistics.

**dump_stats(filename)**
Save the data loaded into the Stats object to a file named `filename`. The file is created if it does not exist, and is overwritten if it already exists. This is equivalent to the method of the same name on the `profile.Profile` and `cProfile.Profile` classes. New in version 2.3.

**sort_stats(key[, ...])**
This method modifies the Stats object by sorting it according to the supplied criteria. The argument is typically a string identifying the basis of a sort (example: 'time' or 'name').

When more than one key is provided, then additional keys are used as secondary criteria when there is equality in all keys selected before them. For example, `sort_stats('name', 'file')` will sort all the entries
according to their function name, and resolve all ties (identical function names) by sorting by file name.

Abbreviations can be used for any key names, as long as the abbreviation is unambiguous. The following are the keys currently defined:

<table>
<thead>
<tr>
<th>Valid Arg</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>'calls'</td>
<td>call count</td>
</tr>
<tr>
<td>'cumulative'</td>
<td>cumulative time</td>
</tr>
<tr>
<td>'file'</td>
<td>file name</td>
</tr>
<tr>
<td>'module'</td>
<td>file name</td>
</tr>
<tr>
<td>'pcalls'</td>
<td>primitive call count</td>
</tr>
<tr>
<td>'line'</td>
<td>line number</td>
</tr>
<tr>
<td>'name'</td>
<td>function name</td>
</tr>
<tr>
<td>'nfl'</td>
<td>name/file/line</td>
</tr>
<tr>
<td>'stdname'</td>
<td>standard name</td>
</tr>
<tr>
<td>'time'</td>
<td>internal time</td>
</tr>
</tbody>
</table>

Note that all sorts on statistics are in descending order (placing most time consuming items first), where as name, file, and line number searches are in ascending order (alphabetical). The subtle distinction between 'nfl' and 'stdname' is that the standard name is a sort of the name as printed, which means that the embedded line numbers get compared in an odd way. For example, lines 3, 20, and 40 would (if the file names were the same) appear in the string order 20, 3 and 40. In contrast, 'nfl' does a numeric compare of the line numbers. In fact, sort_stats('nfl') is the same as sort_stats('name', 'file', 'line').

For backward-compatibility reasons, the numeric arguments -1, 0, 1, and 2 are permitted. They are interpreted as 'stdname', 'calls', 'time', and 'cumulative' respectively. If this old style format (numeric) is used, only one sort key (the numeric key) will be used, and additional arguments will be silently ignored.

reverse_order()

This method for the Stats class reverses the ordering of the basic list within the object. Note that by default ascending vs descending order is
properly selected based on the sort key of choice.

**print_stats([restriction, ...])**

This method for the Stats class prints out a report as described in the `profile.run()` definition.

The order of the printing is based on the last `sort_stats()` operation done on the object (subject to caveats in `add()` and `strip_dirs()`).

The arguments provided (if any) can be used to limit the list down to the significant entries. Initially, the list is taken to be the complete set of profiled functions. Each restriction is either an integer (to select a count of lines), or a decimal fraction between 0.0 and 1.0 inclusive (to select a percentage of lines), or a regular expression (to pattern match the standard name that is printed; as of Python 1.5b1, this uses the Perl-style regular expression syntax defined by the `re` module). If several restrictions are provided, then they are applied sequentially. For example:

```
  print_stats(.1, 'foo:')
```

would first limit the printing to first 10% of list, and then only print functions that were part of filename .*foo:. In contrast, the command:

```
  print_stats('foo:', .1)
```

would limit the list to all functions having file names .*foo:, and then proceed to only print the first 10% of them.

**print_callers([restriction, ...])**

This method for the Stats class prints a list of all functions that called each function in the profiled database. The ordering is identical to that provided by `print_stats()`, and the definition of the restricting argument is also identical. Each caller is reported on its own line. The format differs slightly depending on the profiler that produced the stats:

- With `profile`, a number is shown in parentheses after each caller to show how many times this specific call was made. For convenience, a second non-parenthesized number repeats the cumulative time spent in the function at the right.
• With cProfile, each caller is preceded by three numbers: the number of times this specific call was made, and the total and cumulative times spent in the current function while it was invoked by this specific caller.

**print_callees([restriction, ...])**

This method for the Stats class prints a list of all function that were called by the indicated function. Aside from this reversal of direction of calls (re: called vs was called by), the arguments and ordering are identical to the print_callers() method.
25.5 Limitations

One limitation has to do with accuracy of timing information. There is a fundamental problem with deterministic profilers involving accuracy. The most obvious restriction is that the underlying ``clock'' is only ticking at a rate (typically) of about .001 seconds. Hence no measurements will be more accurate than the underlying clock. If enough measurements are taken, then the ```error'' will tend to average out. Unfortunately, removing this first error induces a second source of error.

The second problem is that it ```takes a while'' from when an event is dispatched until the profiler's call to get the time actually gets the state of the clock. Similarly, there is a certain lag when exiting the profiler event handler from the time that the clock's value was obtained (and then squirreled away), until the user's code is once again executing. As a result, functions that are called many times, or call many functions, will typically accumulate this error. The error that accumulates in this fashion is typically less than the accuracy of the clock (less than one clock tick), but it can accumulate and become very significant.

The problem is more important with profile than with the lower-overhead cProfile. For this reason, profile provides a means of calibrating itself for a given platform so that this error can be probabilistically (on the average) removed. After the profiler is calibrated, it will be more accurate (in a least square sense), but it will sometimes produce negative numbers (when call counts are exceptionally low, and the gods of probability work against you :-). ) Do not be alarmed by negative numbers in the profile. They should only appear if you have calibrated your profiler, and the results are actually better than without calibration.
25.6 Calibration

The profiler of the profile module subtracts a constant from each event handling time to compensate for the overhead of calling the time function, and socking away the results. By default, the constant is 0. The following procedure can be used to obtain a better constant for a given platform (see discussion in section Limitations above).

```python
import profile
pr = profile.Profile()
for i in range(5):
    print pr.calibrate(10000)
```

The method executes the number of Python calls given by the argument, directly and again under the profiler, measuring the time for both. It then computes the hidden overhead per profiler event, and returns that as a float. For example, on an 800 MHz Pentium running Windows 2000, and using Python's time.clock() as the timer, the magical number is about 12.5e-6.

The object of this exercise is to get a fairly consistent result. If your computer is very fast, or your timer function has poor resolution, you might have to pass 100000, or even 1000000, to get consistent results.

When you have a consistent answer, there are three ways you can use it:

```python
import profile

# 1. Apply computed bias to all Profile instances created hereafter.
profile.Profile.bias = your_computed_bias

# 2. Apply computed bias to a specific Profile instance.
pr = profile.Profile()
pr.bias = your_computed_bias

# 3. Specify computed bias in instance constructor.
pr = profile.Profile(bias=your_computed_bias)
```

If you have a choice, you are better off choosing a smaller constant, and then your results will "less often" show up as negative in profile statistics.
Prior to Python 2.2, it was necessary to edit the profiler source code to embed the bias as a literal number. You still can, but that method is no longer described, because no longer needed.
25.7 Extensions -- Deriving Better Profilers

The Profile class of both modules, profile and cProfile, were written so that derived classes could be developed to extend the profiler. The details are not described here, as doing this successfully requires an expert understanding of how the Profile class works internally. Study the source code of the module carefully if you want to pursue this.

If all you want to do is change how current time is determined (for example, to force use of wall-clock time or elapsed process time), pass the timing function you want to the Profile class constructor:

```python
pr = profile.Profile(your_time_func)
```

The resulting profiler will then call `your_time_func()`.

**profile.Profile**

`your_time_func()` should return a single number, or a list of numbers whose sum is the current time (like what `os.times()` returns). If the function returns a single time number, or the list of returned numbers has length 2, then you will get an especially fast version of the dispatch routine.

Be warned that you should calibrate the profiler class for the timer function that you choose. For most machines, a timer that returns a lone integer value will provide the best results in terms of low overhead during profiling. (`os.times()` is pretty bad, as it returns a tuple of floating point values). If you want to substitute a better timer in the cleanest fashion, derive a class and hardwire a replacement dispatch method that best handles your timer call, along with the appropriate calibration constant.

**cProfile.Profile**

`your_time_func()` should return a single number. If it returns plain integers, you can also invoke the class constructor with a second argument specifying the real duration of one unit of time. For example, if `your_integer_time_func()` returns times measured in thousands of
seconds, you would construct the `Profile` instance as follows:

```python
pr = profile.Profile(your_integer_time_func, 0.001)
```

As the `cProfile.Profile` class cannot be calibrated, custom timer functions should be used with care and should be as fast as possible. For the best results with a custom timer, it might be necessary to hard-code it in the C source of the internal `_lsprof` module.
25.8.1 Profile Objects
25.8 hotshot -- High performance logging profiler

New in version 2.2.

This module provides a nicer interface to the _hotshot C module. Hotshot is a replacement for the existing profile module. As it's written mostly in C, it should result in a much smaller performance impact than the existing profile module.

**Note:** The hotshot module focuses on minimizing the overhead while profiling, at the expense of long data post-processing times. For common usages it is recommended to use cProfile instead. hotshot is not maintained and might be removed from the standard library in the future.

Changed in version 2.5: the results should be more meaningful than in the past: the timing core contained a critical bug.

**Warning:** The hotshot profiler does not yet work well with threads. It is useful to use an unthreaded script to run the profiler over the code you're interested in measuring if at all possible.

```python
class Profile( logfile[, lineevents[, linetimings]])
```

The profiler object. The argument `logfile` is the name of a log file to use for logged profile data. The argument `lineevents` specifies whether to generate events for every source line, or just on function call/return. It defaults to 0 (only log function call/return). The argument `linetimings` specifies whether to record timing information. It defaults to 1 (store timing information).

**Subsections**
• 25.8.1 Profile Objects
• 25.8.2 Using hotshot data
• 25.8.3 Example Usage

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
25.8.1 Profile Objects

Profile objects have the following methods:

\textbf{addinfo}(key, value)

Add an arbitrary labelled value to the profile output.

\textbf{close}()

Close the logfile and terminate the profiler.

\textbf{fileno}()

Return the file descriptor of the profiler's log file.

\textbf{run}(cmd)

Profile an \texttt{exec}-compatible string in the script environment. The globals from the \texttt{\_main\_} module are used as both the globals and locals for the script.

\textbf{runcall}(func, *args, **keywords)

Profile a single call of a callable. Additional positional and keyword arguments may be passed along; the result of the call is returned, and exceptions are allowed to propagate cleanly, while ensuring that profiling is disabled on the way out.

\textbf{runctx}(cmd, globals, locals)

Evaluate an \texttt{exec}-compatible string in a specific environment. The string is compiled before profiling begins.

\textbf{start}()

Start the profiler.

\textbf{stop}()

Stop the profiler.
25.8.2 Using hotshot data

New in version 2.2.

This module loads hotshot profiling data into the standard \texttt{pstats} Stats objects.

\texttt{load( filename)}

Load hotshot data from \texttt{filename}. Returns an instance of the \texttt{pstats.Stats} class.

\textbf{See Also:}

Module \texttt{profile}:
The profile module's \texttt{Stats} class.
25.8.3 Example Usage

Note that this example runs the python `"benchmark"` pystones. It can take some time to run, and will produce large output files.

>>> import hotshot, hotshot.stats, test.pystone
>>> prof = hotshot.Profile("stones.prof")
>>> benchtime, stones = prof.runcall(test.pystone.pystones)
>>> prof.close()
>>> stats = hotshot.stats.load("stones.prof")
>>> stats.strip_dirs()
>>> stats.sort_stats('time', 'calls')
>>> stats.print_stats(20)

850004 function calls in 10.090 CPU seconds

Ordered by: internal time, call count

```
ncalls  tottime  percall  cumtime  percall filename:lineno(function)
1      3.295    3.295    10.090   10.090 pystone.py:79(Proc0)
150000  1.315    0.000    1.315    0.000 pystone.py:203(Proc7)
50000   1.313    0.000    1.463    0.000 pystone.py:229(Func2)
```

...
25.9 timeit -- Measure execution time of small code snippets

New in version 2.3.

This module provides a simple way to time small bits of Python code. It has both command line as well as callable interfaces. It avoids a number of common traps for measuring execution times. See also Tim Peters' introduction to the "Algorithms" chapter in the Python Cookbook, published by O'Reilly.

The module defines the following public class:

class Timer([stmt='pass' [, setup='pass' [, timer=<timer function>]]])

Class for timing execution speed of small code snippets.

The constructor takes a statement to be timed, an additional statement used for setup, and a timer function. Both statements default to 'pass'; the timer function is platform-dependent (see the module doc string). The statements may contain newlines, as long as they don't contain multi-line string literals.

To measure the execution time of the first statement, use the timeit() method. The repeat() method is a convenience to call timeit() multiple times and return a list of results.

print_exc([file=None])

Helper to print a traceback from the timed code.

Typical use:

t = Timer(...)  # outside the try/except
try:
    t.timeit(...)  # or t.repeat(...)
except:
    t.print_exc()
The advantage over the standard traceback is that source lines in the compiled template will be displayed. The optional file argument directs where the traceback is sent; it defaults to `sys.stderr`.

```
repeat([repeat=3 [ number=1000000]])
```

Call `timeit()` a few times.

This is a convenience function that calls the `timeit()` repeatedly, returning a list of results. The first argument specifies how many times to call `timeit()`. The second argument specifies the `number` argument for `timeit()`.

---

**Note:** It's tempting to calculate mean and standard deviation from the result vector and report these. However, this is not very useful. In a typical case, the lowest value gives a lower bound for how fast your machine can run the given code snippet; higher values in the result vector are typically not caused by variability in Python's speed, but by other processes interfering with your timing accuracy. So the `min()` of the result is probably the only number you should be interested in. After that, you should look at the entire vector and apply common sense rather than statistics.

```
timeit([number=1000000])
```

Time `number` executions of the main statement. This executes the setup statement once, and then returns the time it takes to execute the main statement a number of times, measured in seconds as a float. The argument is the number of times through the loop, defaulting to one million. The main statement, the setup statement and the timer function to be used are passed to the constructor.

---

**Note:** By default, `timeit()` temporarily turns off garbage collection during the timing. The advantage of this approach is that it makes independent timings more comparable. This disadvantage is that GC may be an
important component of the performance of the function being measured. If so, GC can be re-enabled as the first statement in the setup string. For example:

```python
timeit.Timer('for i in xrange(10): oct(i)', 'gc.enable()').timeit()
```
25.9.1 Command Line Interface

When called as a program from the command line, the following form is used:

```
python timeit.py [-n N] [-r N] [-s S] [-t] [-c] [-h] [statement ...]
```

where the following options are understood:

- **-n N**/ **--number=N**
  how many times to execute 'statement'

- **-r N**/ **--repeat=N**
  how many times to repeat the timer (default 3)

- **-s S**/ **--setup=S**
  statement to be executed once initially (default 'pass')

- **-t**/ **--time**
  use `time.time()` (default on all platforms but Windows)

- **-c**/ **--clock**
  use `time.clock()` (default on Windows)

- **-v**/ **--verbose**
  print raw timing results; repeat for more digits precision

- **-h**/ **--help**
  print a short usage message and exit

A multi-line statement may be given by specifying each line as a separate statement argument; indented lines are possible by enclosing an argument in quotes and using leading spaces. Multiple -s options are treated similarly.

If -n is not given, a suitable number of loops is calculated by trying successive powers of 10 until the total time is at least 0.2 seconds.

The default timer function is platform dependent. On Windows, `time.clock()` has microsecond granularity but `time.time()`'s granularity is 1/60th of a second; on UNIX, `time.clock()` has 1/100th of a second granularity and `time.time()` is much more precise. On either platform, the default timer functions measure wall clock time, not the CPU time. This means that other processes running on the same computer may interfere with the timing. The best thing to do when accurate timing is necessary is to repeat the timing a few times and use the best time. The -r option is good for this; the
default of 3 repetitions is probably enough in most cases. On UNIX, you can use \texttt{time.clock()} to measure CPU time.

\begin{quote}
\textbf{Note:} There is a certain baseline overhead associated with executing a pass statement. The code here doesn't try to hide it, but you should be aware of it. The baseline overhead can be measured by invoking the program without arguments.
\end{quote}

The baseline overhead differs between Python versions! Also, to fairly compare older Python versions to Python 2.3, you may want to use Python's \texttt{-O} option for the older versions to avoid timing \texttt{SET\_LINENO} instructions.
25.9.2 Examples

Here are two example sessions (one using the command line, one using the module interface) that compare the cost of using `hasattr()` vs. `try/except` to test for missing and present object attributes.

```python
>>> import timeit
>>> s = """
... try:
...     str.__nonzero__
... except AttributeError:
...     pass
... """
>>> t = timeit.Timer(stmt=s)
>>> print "%.2f usec/pass" % (1000000 * t.timeit(number=100000)/1000)
17.09 usec/pass
>>> s = """
... if hasattr(str, '__nonzero__'):
...     pass
... """
>>> t = timeit.Timer(stmt=s)
>>> print "%.2f usec/pass" % (1000000 * t.timeit(number=100000)/1000)
4.85 usec/pass
>>> s = """
... try:
...     int.__nonzero__
... except AttributeError:
...     pass
... """
>>> t = timeit.Timer(stmt=s)
>>> print "%.2f usec/pass" % (1000000 * t.timeit(number=100000)/1000)
1.97 usec/pass
>>> s = """
... if hasattr(int, '__nonzero__'):
...     pass
... """
>>> t = timeit.Timer(stmt=s)
>>> print "%.2f usec/pass" % (1000000 * t.timeit(number=100000)/1000)
3.15 usec/pass
```

To give the `timeit` module access to functions you define, you can pass a
setup parameter which contains an import statement:

```python
def test():
    "Stupid test function"
    L = []
    for i in range(100):
        L.append(i)

if __name__=='__main__':
    from timeit import Timer
    t = Timer("test()", "from __main__ import test")
    print t.timeit()
```

Python Library Reference

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
25.10 trace -- Trace or track Python statement execution

The trace module allows you to trace program execution, generate annotated statement coverage listings, print caller/callee relationships and list functions executed during a program run. It can be used in another program or from the command line.

Subsections

- 25.10.1 Command Line Usage
- 25.10.2 Programming Interface

Previous: 25.9.2 Examples  Up: 25. The Python Profilers  Next: 25.10.1 Command Line Usage

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
25.10.1 Command Line Usage

The `trace` module can be invoked from the command line. It can be as simple as

```
python -m trace --count somefile.py ...
```

The above will generate annotated listings of all Python modules imported during the execution of `somefile.py`.

The following command-line arguments are supported:

---trace, -t
Display lines as they are executed.

--count, -c
Produce a set of annotated listing files upon program completion that shows how many times each statement was executed.

--report, -r
Produce an annotated list from an earlier program run that used the --count and --file arguments.

--no-report, -R
Do not generate annotated listings. This is useful if you intend to make several runs with --count then produce a single set of annotated listings at the end.

--listfuncs, -l
List the functions executed by running the program.

--trackcalls, -T
Generate calling relationships exposed by running the program.

--file, -f
Name a file containing (or to contain) counts.

--coverdir, -C
Name a directory in which to save annotated listing files.
--missing, -m
When generating annotated listings, mark lines which were not executed with `>>>>>>>'.

--summary, -s
When using --count or --report, write a brief summary to stdout for each file processed.

--ignore-module
Ignore the named module and its submodules (if it is a package). May be given multiple times.

--ignore-dir
Ignore all modules and packages in the named directory and subdirectories. May be given multiple times.
25.10.2 Programming Interface

```
[count=1, trace=1, countfuncs=0, countcallers=0,

class Trace( ignoremods=(), ignoredirs=(), infile=None,
            outfile=None))]
```

Create an object to trace execution of a single statement or expression. All parameters are optional. `count` enables counting of line numbers. `trace` enables line execution tracing. `countfuncs` enables listing of the functions called during the run. `countcallers` enables call relationship tracking. `ignoremods` is a list of modules or packages to ignore. `ignoredirs` is a list of directories whose modules or packages should be ignored. `infile` is the file from which to read stored count information. `outfile` is a file in which to write updated count information.

```
run( cmd)
```

Run `cmd` under control of the Trace object with the current tracing parameters.

```
runcxtx( cmd[, globals=None[, locals=None]])
```

Run `cmd` under control of the Trace object with the current tracing parameters in the defined global and local environments. If not defined, `globals` and `locals` default to empty dictionaries.

```
runcfunc( func, *args, **kwds)
```

Call `func` with the given arguments under control of the `Trace` object with the current tracing parameters.

This is a simple example showing the use of this module:

```
import sys
import trace

# create a Trace object, telling it what to ignore, and whether to
# do tracing or line-counting or both.
tracer = trace.Trace(    ignoredirs=[sys.prefix, sys.exec_prefix],
        trace=0,    count=1)
```
# run the new command using the given tracer
tracer.run('main()')

# make a report, placing output in /tmp
r = tracer.results()
r.write_results(show_missing=True, coverdir="/tmp")
26. Python Runtime Services

The modules described in this chapter provide a wide range of services related to the Python interpreter and its interaction with its environment. Here's an overview:

- `sys` Access system-specific parameters and functions.
- `__builtin__` The module that provides the built-in namespace.
- `__main__` The environment where the top-level script is run.
- `warnings` Issue warning messages and control their disposition.
- `contextlib` Utilities for `with`-statement contexts.
- `atexit` Register and execute cleanup functions.
- `traceback` Print or retrieve a stack traceback.
- `__future__` Future statement definitions
- `gc` Interface to the cycle-detecting garbage collector.
- `inspect` Extract information and source code from live objects.
- `site` A standard way to reference site-specific modules.
- `user` A standard way to reference user-specific modules.
- `fpectl` Provide control for floating point exception handling.
26.1 sys -- System-specific parameters and functions

This module provides access to some variables used or maintained by the interpreter and to functions that interact strongly with the interpreter. It is always available.

argv
The list of command line arguments passed to a Python script. `argv[0]` is the script name (it is operating system dependent whether this is a full pathname or not). If the command was executed using the `-c` command line option to the interpreter, `argv[0]` is set to the string '-c'. If no script name was passed to the Python interpreter, `argv` has zero length.

byteorder
An indicator of the native byte order. This will have the value 'big' on big-endian (most-significant byte first) platforms, and 'little' on little-endian (least-significant byte first) platforms. New in version 2.0.

subversion
A triple (repo, branch, version) representing the Subversion information of the Python interpreter. `repo` is the name of the repository, 'CPython'. `branch` is a string of one of the forms 'trunk', 'branches/name' or 'tags/name'. `version` is the output of `svnversion`, if the interpreter was built from a Subversion checkout; it contains the revision number (range) and possibly a trailing 'M' if there were local modifications. If the tree was exported (or `svnversion` was not available), it is the revision of `Include/patchlevel.h` if the branch is a tag. Otherwise, it is `None`. New in version 2.5.

builtin_module_names
A tuple of strings giving the names of all modules that are compiled into this Python interpreter. (This information is not available in any other way -- `modules.keys()` only lists the imported modules.)

copyright
A string containing the copyright pertaining to the Python interpreter.

$current_frames()$
Return a dictionary mapping each thread's identifier to the topmost stack frame currently active in that thread at the time the function is called. Note that functions in the `traceback` module can build the call stack given such a frame.

This is most useful for debugging deadlock: this function does not require the deadlocked threads' cooperation, and such threads' call stacks are frozen for as long as they remain deadlocked. The frame returned for a non-deadlocked thread may bear no relationship to that thread's current activity by the time calling code examines the frame.

This function should be used for internal and specialized purposes only. New in version 2.5.

$dllhandle$
Integer specifying the handle of the Python DLL. Availability: Windows.

displayhook($value$)
If $value$ is not `None`, this function prints it to `sys.stdout`, and saves it in `__builtin__._displayhook`.

`sys.displayhook` is called on the result of evaluating an expression entered in an interactive Python session. The display of these values can be customized by assigning another one-argument function to `sys.displayhook`.

excepthook($type$, $value$, $traceback$)
This function prints out a given traceback and exception to `sys.stderr`.

When an exception is raised and uncaught, the interpreter calls `sys.excepthook` with three arguments, the exception class, exception instance, and a traceback object. In an interactive session this happens just before control is returned to the prompt; in a Python program this happens just before the program exits. The handling of such top-level exceptions can be customized by assigning another three-argument function to
sys.excepthook.

__displayhook__
__excepthook__

These objects contain the original values of displayhook and excepthook at the start of the program. They are saved so that displayhook and excepthook can be restored in case they happen to get replaced with broken objects.

exc_info()

This function returns a tuple of three values that give information about the exception that is currently being handled. The information returned is specific both to the current thread and to the current stack frame. If the current stack frame is not handling an exception, the information is taken from the calling stack frame, or its caller, and so on until a stack frame is found that is handling an exception. Here, "handling an exception" is defined as "executing or having executed an except clause." For any stack frame, only information about the most recently handled exception is accessible.

If no exception is being handled anywhere on the stack, a tuple containing three None values is returned. Otherwise, the values returned are (type, value, traceback). Their meaning is: type gets the exception type of the exception being handled (a class object); value gets the exception parameter (its associated value or the second argument to raise, which is always a class instance if the exception type is a class object); traceback gets a traceback object (see the Reference Manual) which encapsulates the call stack at the point where the exception originally occurred.

If exc_clear() is called, this function will return three None values until either another exception is raised in the current thread or the execution stack returns to a frame where another exception is being handled.

Warning: Assigning the traceback return value to a local variable in a function that is handling an exception will cause a circular reference. This will prevent anything referenced by a local variable in the same function or by the traceback from being garbage collected. Since most functions don't need access to the traceback, the best solution is to use something like exc_type, value = sys.exc_info()[2] to extract only the
exception type and value. If you do need the traceback, make sure to delete it after use (best done with a try ... finally statement) or to call exc_info() in a function that does not itself handle an exception. Note: Beginning with Python 2.2, such cycles are automatically reclaimed when garbage collection is enabled and they become unreachable, but it remains more efficient to avoid creating cycles.

exc_clear()
This function clears all information relating to the current or last exception that occurred in the current thread. After calling this function, exc_info() will return three None values until another exception is raised in the current thread or the execution stack returns to a frame where another exception is being handled.

This function is only needed in only a few obscure situations. These include logging and error handling systems that report information on the last or current exception. This function can also be used to try to free resources and trigger object finalization, though no guarantee is made as to what objects will be freed, if any. New in version 2.3.

exc_type
exc_value
exc_traceback
Deprecated since release 1.5. Use exc_info() instead.

Since they are global variables, they are not specific to the current thread, so their use is not safe in a multi-threaded program. When no exception is being handled, exc_type is set to None and the other two are undefined.

exec_prefix
A string giving the site-specific directory prefix where the platform-dependent Python files are installed; by default, this is also '/usr/local'. This can be set at build time with the --exec-prefix argument to the configure script. Specifically, all configuration files (e.g. the pyconfig.h header file) are installed in the directory exec_prefix + '/lib/pythonversion/config', and shared library modules are installed in exec_prefix + '/lib/pythonversion/lib-dynload', where version is equal to version[:3].
executable
A string giving the name of the executable binary for the Python interpreter, on systems where this makes sense.

exit([arg])
Exit from Python. This is implemented by raising the SystemExit exception, so cleanup actions specified by finally clauses of try statements are honored, and it is possible to intercept the exit attempt at an outer level. The optional argument arg can be an integer giving the exit status (defaulting to zero), or another type of object. If it is an integer, zero is considered "successful termination" and any nonzero value is considered "abnormal termination" by shells and the like. Most systems require it to be in the range 0-127, and produce undefined results otherwise. Some systems have a convention for assigning specific meanings to specific exit codes, but these are generally underdeveloped; Unix programs generally use 2 for command line syntax errors and 1 for all other kind of errors. If another type of object is passed, None is equivalent to passing zero, and any other object is printed to sys.stderr and results in an exit code of 1. In particular, sys.exit("some error message") is a quick way to exit a program when an error occurs.

exitfunc
This value is not actually defined by the module, but can be set by the user (or by a program) to specify a clean-up action at program exit. When set, it should be a parameterless function. This function will be called when the interpreter exits. Only one function may be installed in this way; to allow multiple functions which will be called at termination, use the atexit module. Note: The exit function is not called when the program is killed by a signal, when a Python fatal internal error is detected, or when os._exit() is called.
Deprecated since release 2.4. Use atexit instead.

getcheckinterval()
Return the interpreter's "check interval"; see setcheckinterval(). New in version 2.3.

defaultencoding()
Return the name of the current default string encoding used by the Unicode
implementation. New in version 2.0.

getdlopenflags()

Return the current value of the flags that are used for dlopen() calls. The flag constants are defined in the dl and DLFCN modules. Availability: UNIX. New in version 2.2.

getfilesystemencoding()

Return the name of the encoding used to convert Unicode filenames into system file names, or None if the system default encoding is used. The result value depends on the operating system:

- On Windows 9x, the encoding is `mbcs`.
- On Mac OS X, the encoding is `utf-8`.
- On UNIX, the encoding is the user's preference according to the result of nl_langinfo(CODESET), or None if the nl_langinfo(CODESET) failed.
- On Windows NT+, file names are Unicode natively, so no conversion is performed. getfilesystemencoding() still returns 'mbcs', as this is the encoding that applications should use when they explicitly want to convert Unicode strings to byte strings that are equivalent when used as file names.

New in version 2.3.

getrefcount(object)

Return the reference count of the object. The count returned is generally one higher than you might expect, because it includes the (temporary) reference as an argument to getrefcount().

getrecursionlimit()

Return the current value of the recursion limit, the maximum depth of the Python interpreter stack. This limit prevents infinite recursion from causing an overflow of the C stack and crashing Python. It can be set by setrecursionlimit().

_getframe([depth])

Return a frame object from the call stack. If optional integer depth is given, return the frame object that many calls below the top of the stack. If that is
deeper than the call stack, \texttt{ValueError} is raised. The default for \textit{depth} is zero, returning the frame at the top of the call stack.

This function should be used for internal and specialized purposes only.

\textbf{getwindowsversion()}  
Return a tuple containing five components, describing the Windows version currently running. The elements are \textit{major}, \textit{minor}, \textit{build}, \textit{platform}, and \textit{text}. \textit{text} contains a string while all other values are integers.

\textit{platform} may be one of the following values:

<table>
<thead>
<tr>
<th>Constant</th>
<th>Platform</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>Win32s on Windows 3.1</td>
</tr>
<tr>
<td>1</td>
<td>Windows 95/98/ME</td>
</tr>
<tr>
<td>2</td>
<td>Windows NT/2000/XP</td>
</tr>
<tr>
<td>3</td>
<td>Windows CE</td>
</tr>
</tbody>
</table>

This function wraps the Win32 \texttt{GetVersionEx()} function; see the Microsoft documentation for more information about these fields.

Availability: Windows. New in version 2.3.

\textbf{hexversion}  
The version number encoded as a single integer. This is guaranteed to increase with each version, including proper support for non-production releases. For example, to test that the Python interpreter is at least version 1.5.2, use:

```
if sys.hexversion >= 0x010502f0:
    # use some advanced feature
    ...
else:
    # use an alternative implementation or warn the user
    ...
```

This is called "\texttt{hexversion}" since it only really looks meaningful when viewed as the result of passing it to the built-in \texttt{hex()} function. The \texttt{version_info} value may be used for a more human-friendly encoding of the same information. New in version 1.5.2.
last_type
last_value
last_traceback
These three variables are not always defined; they are set when an exception is not handled and the interpreter prints an error message and a stack traceback. Their intended use is to allow an interactive user to import a debugger module and engage in post-mortem debugging without having to re-execute the command that caused the error. (Typical use is "import pdb; pdb.pm()" to enter the post-mortem debugger; see chapter 24, "The Python Debugger," for more information.)

The meaning of the variables is the same as that of the return values from exc_info() above. (Since there is only one interactive thread, threadsafety is not a concern for these variables, unlike for exc_type etc.)

maxint
The largest positive integer supported by Python's regular integer type. This is at least 2**31-1. The largest negative integer is -maxint-1 -- the asymmetry results from the use of 2's complement binary arithmetic.

maxunicode
An integer giving the largest supported code point for a Unicode character. The value of this depends on the configuration option that specifies whether Unicode characters are stored as UCS-2 or UCS-4.

modules
This is a dictionary that maps module names to modules which have already been loaded. This can be manipulated to force reloading of modules and other tricks. Note that removing a module from this dictionary is not the same as calling reload() on the corresponding module object.

path
A list of strings that specifies the search path for modules. Initialized from the environment variable PYTHONPATH, plus an installation-dependent default.

As initialized upon program startup, the first item of this list, path[0], is the directory containing the script that was used to invoke the Python interpreter. If the script directory is not available (e.g. if the interpreter is
invoked interactively or if the script is read from standard input), path[0] is the empty string, which directs Python to search modules in the current directory first. Notice that the script directory is inserted before the entries inserted as a result of PYTHONPATH.

A program is free to modify this list for its own purposes.

Changed in version 2.3: Unicode strings are no longer ignored.

**platform**
This string contains a platform identifier, e.g. 'sunos5' or 'linux1'. This can be used to append platform-specific components to path, for instance.

**prefix**
A string giving the site-specific directory prefix where the platform independent Python files are installed; by default, this is the string '/usr/local'. This can be set at build time with the --prefix argument to the configure script. The main collection of Python library modules is installed in the directory prefix + '/lib/pythonversion' while the platform independent header files (all except pyconfig.h) are stored in prefix + '/include/pythonversion', where version is equal to version[:3].

**ps1**
**ps2**
Strings specifying the primary and secondary prompt of the interpreter. These are only defined if the interpreter is in interactive mode. Their initial values in this case are '>>> ' and '... '. If a non-string object is assigned to either variable, its str() is re-evaluated each time the interpreter prepares to read a new interactive command; this can be used to implement a dynamic prompt.

**setcheckinterval**( interval)
Set the interpreter's `check interval". This integer value determines how often the interpreter checks for periodic things such as thread switches and signal handlers. The default is 100, meaning the check is performed every 100 Python virtual instructions. Setting it to a larger value may increase performance for programs using threads. Setting it to a value <= 0 checks
every virtual instruction, maximizing responsiveness as well as overhead.

**setdefaultencoding**( *name*)
Set the current default string encoding used by the Unicode implementation. If *name* does not match any available encoding, LookupError is raised. This function is only intended to be used by the [site](https://docs.python.org/3/library/site.html) module implementation and, where needed, by [sitecustomize](https://docs.python.org/3/library/site.html#site.sitecustomize). Once used by the [site](https://docs.python.org/3/library/site.html) module, it is removed from the [sys](https://docs.python.org/3/library/sys.html) module's namespace. New in version 2.0.

**setdlopenflags**( *n*)
Set the flags used by the interpreter for dlopen() calls, such as when the interpreter loads extension modules. Among other things, this will enable a lazy resolving of symbols when importing a module, if called as [sys.setdlopenflags](https://docs.python.org/3/library/sys.html#sys.setdlopenflags)(0). To share symbols across extension modules, call as [sys.setdlopenflags](https://docs.python.org/3/library/sys.html#sys.setdlopenflags)(dl.RTLD_NOW | dl.RTLD_GLOBAL). Symbolic names for the flag modules can be either found in the d1 module, or in the DLFCN module. If DLFCN is not available, it can be generated from /usr/include/dlfcn.h using the [h2py](https://h2py.readthedocs.io/en/latest/) script. Availability: UNIX. New in version 2.2.

**setprofile**( *profilefunc*)
Set the system's profile function, which allows you to implement a Python source code profiler in Python. See chapter 25 for more information on the Python profiler. The system's profile function is called similarly to the system's trace function (see [settrace()](https://docs.python.org/3/library/sys.html#sys.settrace)), but it isn't called for each executed line of code (only on call and return, but the return event is reported even when an exception has been set). The function is thread-specific, but there is no way for the profiler to know about context switches between threads, so it does not make sense to use this in the presence of multiple threads. Also, its return value is not used, so it can simply return None.

**setrecursionlimit**( *limit*)
Set the maximum depth of the Python interpreter stack to *limit*. This limit prevents infinite recursion from causing an overflow of the C stack and crashing Python.
The highest possible limit is platform-dependent. A user may need to set the limit higher when she has a program that requires deep recursion and a platform that supports a higher limit. This should be done with care, because a too-high limit can lead to a crash.

`settrace(tracefunc)`
Set the system's trace function, which allows you to implement a Python source code debugger in Python. See section 24.2, "How It Works," in the chapter on the Python debugger. The function is thread-specific; for a debugger to support multiple threads, it must be registered using `settrace()` for each thread being debugged. **Note:** The `settrace()` function is intended only for implementing debuggers, profilers, coverage tools and the like. Its behavior is part of the implementation platform, rather than part of the language definition, and thus may not be available in all Python implementations.

`settscdump(on_flag)`
Activate dumping of VM measurements using the Pentium timestamp counter, if `on_flag` is true. Deactivate these dumps if `on_flag` is off. The function is available only if Python was compiled with `--with-tsc`. To understand the output of this dump, read `Python/ceval.c` in the Python sources. New in version 2.4.

`stdin`  
`stdout`  
`stderr`  

File objects corresponding to the interpreter's standard input, output and error streams. `stdin` is used for all interpreter input except for scripts but including calls to `input()` and `raw_input()`. `stdout` is used for the output of `print` and expression statements and for the prompts of `input()` and `raw_input()`. The interpreter's own prompts and (almost all of) its error messages go to `stderr`. `stdout` and `stderr` needn't be built-in file objects: any object is acceptable as long as it has a `write()` method that takes a string argument. (Changing these objects doesn't affect the standard I/O streams of processes executed by `os.popen()`, `os.system()` or the `exec*()` family of functions in the `os` module.)

`stdin`
These objects contain the original values of \texttt{stdin}, \texttt{stderr} and \texttt{stdout} at the start of the program. They are used during finalization, and could be useful to restore the actual files to known working file objects in case they have been overwritten with a broken object.

**tracebacklimit**

When this variable is set to an integer value, it determines the maximum number of levels of traceback information printed when an unhandled exception occurs. The default is \texttt{1000}. When set to \texttt{0} or less, all traceback information is suppressed and only the exception type and value are printed.

**version**

A string containing the version number of the Python interpreter plus additional information on the build number and compiler used. It has a value of the form \texttt{'version (#build_number, build_date, build_time) [compiler]'}. The first three characters are used to identify the version in the installation directories (where appropriate on each platform). An example:

```python
>>> import sys
>>> sys.version
'1.5.2 (#0 Apr 13 1999, 10:51:12) [MSC 32 bit (Intel)]'
```

**api_version**

The C API version for this interpreter. Programmers may find this useful when debugging version conflicts between Python and extension modules. New in version 2.3.

**version_info**

A tuple containing the five components of the version number: \texttt{major}, \texttt{minor}, \texttt{micro}, \texttt{releaselevel}, and \texttt{serial}. All values except \texttt{releaselevel} are integers; the release level is \texttt{'alpha'}, \texttt{'beta'}, \texttt{'candidate'}, or \texttt{'final'}. The \texttt{version_info} value corresponding to the Python version 2.0 is \texttt{(2, 0, 0, 'final', 0)}. New in version 2.0.

**warnoptions**

This is an implementation detail of the warnings framework; do not modify this value. Refer to the \texttt{warnings} module for more information on the
warnings framework.

**winver**

The version number used to form registry keys on Windows platforms. This is stored as string resource 1000 in the Python DLL. The value is normally the first three characters of *version*. It is provided in the *sys* module for informational purposes; modifying this value has no effect on the registry keys used by Python. Availability: Windows.

### See Also:

Module **site**:

This describes how to use `.pth` files to extend `sys.path`. 
26.2 __builtin__ -- Built-in objects

This module provides direct access to all `built-in' identifiers of Python; for example, __builtin__.open is the full name for the built-in function open(). See chapter 2, ``Built-in Objects.''

This module is not normally accessed explicitly by most applications, but can be useful in modules that provide objects with the same name as a built-in value, but in which the built-in of that name is also needed. For example, in a module that wants to implement an open() function that wraps the built-in open(), this module can be used directly:

```python
import __builtin__

def open(path):
    f = __builtin__.open(path, 'r')
    return UpperCaser(f)

class UpperCaser:
    '''Wrapper around a file that converts output to upper-case.''

    def __init__(self, f):
        self._f = f

    def read(self, count=-1):
        return self._f.read(count).upper()

    # ...
```

As an implementation detail, most modules have the name __builtins__ (note the "s") made available as part of their globals. The value of __builtins__ is normally either this module or the value of this module's __dict__ attribute. Since this is an implementation detail, it may not be used by alternate implementations of Python.
26.3 __main__ -- Top-level script environment

This module represents the (otherwise anonymous) scope in which the interpreter's main program executes -- commands read either from standard input, from a script file, or from an interactive prompt. It is this environment in which the idiomatic ``conditional script'' stanza causes a script to run:

```python
if __name__ == "__main__":
    main()
```

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
Warning Categories
26.4 warnings -- Warning control

New in version 2.1.

Warning messages are typically issued in situations where it is useful to alert the user of some condition in a program, where that condition (normally) doesn't warrant raising an exception and terminating the program. For example, one might want to issue a warning when a program uses an obsolete module.

Python programmers issue warnings by calling the `warn()` function defined in this module. (C programmers use `PyErr_Warn()`; see the Python/C API Reference Manual for details).

Warning messages are normally written to `sys.stderr`, but their disposition can be changed flexibly, from ignoring all warnings to turning them into exceptions. The disposition of warnings can vary based on the warning category (see below), the text of the warning message, and the source location where it is issued. Repetitions of a particular warning for the same source location are typically suppressed.

There are two stages in warning control: first, each time a warning is issued, a determination is made whether a message should be issued or not; next, if a message is to be issued, it is formatted and printed using a user-settable hook.

The determination whether to issue a warning message is controlled by the warning filter, which is a sequence of matching rules and actions. Rules can be added to the filter by calling `filterwarnings()` and reset to its default state by calling `resetwarnings()`.

The printing of warning messages is done by calling `showwarning()`, which may be overridden; the default implementation of this function formats the message by calling `formatwarning()`, which is also available for use by custom implementations.

- [26.4.1 Warning Categories](#)
26.4.2 The Warnings Filter
26.4.3 Available Functions

Warning Categories

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
26.4.1 Warning Categories

There are a number of built-in exceptions that represent warning categories. This categorization is useful to be able to filter out groups of warnings. The following warnings category classes are currently defined:

<table>
<thead>
<tr>
<th>Class</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Warning</td>
<td>This is the base class of all warning category classes. It is a subclass of Exception.</td>
</tr>
<tr>
<td>UserWarning</td>
<td>The default category for warn().</td>
</tr>
<tr>
<td>DeprecationWarning</td>
<td>Base category for warnings about deprecated features.</td>
</tr>
<tr>
<td>SyntaxWarning</td>
<td>Base category for warnings about dubious syntactic features.</td>
</tr>
<tr>
<td>RuntimeWarning</td>
<td>Base category for warnings about dubious runtime features.</td>
</tr>
<tr>
<td>FutureWarning</td>
<td>Base category for warnings about constructs that will change semantically in the future.</td>
</tr>
<tr>
<td>PendingDeprecationWarning</td>
<td>Base category for warnings about features that will be deprecated in the future (ignored by default).</td>
</tr>
<tr>
<td>ImportWarning</td>
<td>Base category for warnings triggered during the process of importing a module (ignored by default).</td>
</tr>
<tr>
<td>UnicodeWarning</td>
<td>Base category for warnings related to Unicode.</td>
</tr>
</tbody>
</table>

While these are technically built-in exceptions, they are documented here, because conceptually they belong to the warnings mechanism.

User code can define additional warning categories by subclassing one of the standard warning categories. A warning category must always be a subclass of the Warning class.
26.4.2 The Warnings Filter

The warnings filter controls whether warnings are ignored, displayed, or turned into errors (raising an exception).

Conceptually, the warnings filter maintains an ordered list of filter specifications; any specific warning is matched against each filter specification in the list in turn until a match is found; the match determines the disposition of the match. Each entry is a tuple of the form \((action, message, category, module, lineno)\), where:

- \textit{action} is one of the following strings:

<table>
<thead>
<tr>
<th>Value</th>
<th>Disposition</th>
</tr>
</thead>
<tbody>
<tr>
<td>&quot;error&quot;</td>
<td>turn matching warnings into exceptions</td>
</tr>
<tr>
<td>&quot;ignore&quot;</td>
<td>never print matching warnings</td>
</tr>
<tr>
<td>&quot;always&quot;</td>
<td>always print matching warnings</td>
</tr>
<tr>
<td>&quot;default&quot;</td>
<td>print the first occurrence of matching warnings for each location where the warning is issued</td>
</tr>
<tr>
<td>&quot;module&quot;</td>
<td>print the first occurrence of matching warnings for each module where the warning is issued</td>
</tr>
<tr>
<td>&quot;once&quot;</td>
<td>print only the first occurrence of matching warnings, regardless of location</td>
</tr>
</tbody>
</table>

- \textit{message} is a string containing a regular expression that the warning message must match (the match is compiled to always be case-insensitive)

- \textit{category} is a class (a subclass of \texttt{Warning}) of which the warning category must be a subclass in order to match

- \textit{module} is a string containing a regular expression that the module name must match (the match is compiled to be case-sensitive)

- \textit{lineno} is an integer that the line number where the warning occurred must match, or \(0\) to match all line numbers

Since the \texttt{Warning} class is derived from the built-in \texttt{Exception} class, to turn a warning into an error we simply raise \texttt{category(message)}. 
The warnings filter is initialized by `-W` options passed to the Python interpreter command line. The interpreter saves the arguments for all `-W` options without interpretation in `sys.warnoptions`; the `warnings` module parses these when it is first imported (invalid options are ignored, after printing a message to `sys.stderr`).

The warnings that are ignored by default may be enabled by passing `-Wd` to the interpreter. This enables default handling for all warnings, including those that are normally ignored by default. This is particular useful for enabling `ImportWarning` when debugging problems importing a developed package. `ImportWarning` can also be enabled explicitly in Python code using:

```
warnings.simplefilter('default', ImportWarning)
```

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
26.4.3 Available Functions

**warn** (*message[, category[, stacklevel]]*)

Issue a warning, or maybe ignore it or raise an exception. The *category* argument, if given, must be a warning category class (see above); it defaults to `UserWarning`. Alternatively *message* can be a `Warning` instance, in which case *category* will be ignored and `message.__class__` will be used. In this case the message text will be `str(message)`. This function raises an exception if the particular warning issued is changed into an error by the warnings filter see above. The *stacklevel* argument can be used by wrapper functions written in Python, like this:

```python
    def deprecation(message):
        warnings.warn(message, DeprecationWarning, stacklevel=2)
```

This makes the warning refer to `deprecation()`'s caller, rather than to the source of `deprecation()` itself (since the latter would defeat the purpose of the warning message).

**warn_explicit** (*message, category, filename, lineno[, module[, registry[, module_globals]]]*)

This is a low-level interface to the functionality of `warn()`, passing in explicitly the message, category, filename and line number, and optionally the module name and the registry (which should be the __warningregistry__ dictionary of the module). The module name defaults to the filename with `.py` stripped; if no registry is passed, the warning is never suppressed. *message* must be a string and *category* a subclass of `Warning` or *message* may be a `Warning` instance, in which case *category* will be ignored.

*module_globals*, if supplied, should be the global namespace in use by the code for which the warning is issued. (This argument is used to support displaying source for modules found in zipfiles or other non-filesystem import sources, and was added in Python 2.5.)

**showwarning** (*message, category, filename, lineno[, file]*)
Write a warning to a file. The default implementation calls `formatwarning(message, category, filename, lineno)` and writes the resulting string to `file`, which defaults to `sys.stderr`. You may replace this function with an alternative implementation by assigning to `warnings.showwarning`.

`formatwarning(message, category, filename, lineno)` Format a warning the standard way. This returns a string which may contain embedded newlines and ends in a newline.

`filterwarnings(action[, message[, category[, module[, lineno[, append]]]]])` Insert an entry into the list of warnings filters. The entry is inserted at the front by default; if `append` is true, it is inserted at the end. This checks the types of the arguments, compiles the message and module regular expressions, and inserts them as a tuple in the list of warnings filters. Entries closer to the front of the list override entries later in the list, if both match a particular warning. Omitted arguments default to a value that matches everything.

`simplefilter(action[, category[, lineno[, append]]])` Insert a simple entry into the list of warnings filters. The meaning of the function parameters is as for `filterwarnings()`, but regular expressions are not needed as the filter inserted always matches any message in any module as long as the category and line number match.

`resetwarnings()` Reset the warnings filter. This discards the effect of all previous calls to `filterwarnings()`, including that of the `-W` command line options and calls to `simplefilter()`.
26.5 contextlib -- Utilities for with-statement contexts.

New in version 2.5.

This module provides utilities for common tasks involving the with statement.

Functions provided:

contextmanager(func)

This function is a decorator that can be used to define a factory function for with statement context managers, without needing to create a class or separate __enter__() and __exit__() methods.

A simple example (this is not recommended as a real way of generating HTML!):

```python
from __future__ import with_statement
from contextlib import contextmanager

@contextmanager
def tag(name):
    print "<%s>" % name
    yield
    print "</%s>" % name

>>> with tag("h1"):
...     print "foo"
...
<h1>
foo
</h1>
```

The function being decorated must return a generator-iterator when called. This iterator must yield exactly one value, which will be bound to the targets in the with statement’s as clause, if any.

At the point where the generator yields, the block nested in the with statement is executed. The generator is then resumed after the block is exited. If an unhandled exception occurs in the block, it is reraised inside
the generator at the point where the yield occurred. Thus, you can use a `try...except...finally` statement to trap the error (if any), or ensure that some cleanup takes place. If an exception is trapped merely in order to log it or to perform some action (rather than to suppress it entirely), the generator must reraise that exception. Otherwise the generator context manager will indicate to the `with` statement that the exception has been handled, and execution will resume with the statement immediately following the `with` statement.

**nested**(`mgr1[, mgr2[, ...]]`)  
Combine multiple context managers into a single nested context manager.

Code like this:

```python
from contextlib import nested

with nested(A, B, C) as (X, Y, Z):
    do_something()
```

is equivalent to this:

```python
with A as X:
    with B as Y:
        with C as Z:
            do_something()
```

Note that if the `__exit__()` method of one of the nested context managers indicates an exception should be suppressed, no exception information will be passed to any remaining outer context managers. Similarly, if the `__exit__()` method of one of the nested managers raises an exception, any previous exception state will be lost; the new exception will be passed to the `__exit__()` methods of any remaining outer context managers. In general, `__exit__()` methods should avoid raising exceptions, and in particular they should not re-raise a passed-in exception.

**closing**(`thing`)  
Return a context manager that closes `thing` upon completion of the block. This is basically equivalent to:

```python
from contextlib import contextmanager

@contextmanager
```
```python
def closing(thing):
    try:
        yield thing
    finally:
        thing.close()
```

And lets you write code like this:

```python
from __future__ import with_statement
from contextlib import closing
import codecs

with closing(urllib.urlopen('http://www.python.org')) as page:
    for line in page:
        print line
```

without needing to explicitly close `page`. Even if an error occurs, `page.close()` will be called when the `with` block is exited.

The specification, background, and examples for the Python `with` statement.
26.6 atexit -- Exit handlers

New in version 2.0.

The `atexit` module defines a single function to register cleanup functions. Functions thus registered are automatically executed upon normal interpreter termination.

Note: the functions registered via this module are not called when the program is killed by a signal, when a Python fatal internal error is detected, or when `os._exit()` is called.

This is an alternate interface to the functionality provided by the `sys.exitfunc` variable.

Note: This module is unlikely to work correctly when used with other code that sets `sys.exitfunc`. In particular, other core Python modules are free to use `atexit` without the programmer's knowledge. Authors who use `sys.exitfunc` should convert their code to use `atexit` instead. The simplest way to convert code that sets `sys.exitfunc` is to import `atexit` and register the function that had been bound to `sys.exitfunc`.

```python
register(func[, *args[, **kargs]])
```

Register `func` as a function to be executed at termination. Any optional arguments that are to be passed to `func` must be passed as arguments to `register()`.

At normal program termination (for instance, if `sys.exit()` is called or the main module's execution completes), all functions registered are called in last in, first out order. The assumption is that lower level modules will normally be imported before higher level modules and thus must be cleaned up later.

If an exception is raised during execution of the exit handlers, a traceback is printed (unless `SystemExit` is raised) and the exception information is saved. After all exit handlers have had a chance to run the last exception to
be raised is re-raised.

*Release 2.5, documentation updated on 19th September, 2006.*
See *About this document...* for information on suggesting changes.
26.6.1 atexit Example

The following simple example demonstrates how a module can initialize a counter from a file when it is imported and save the counter's updated value automatically when the program terminates without relying on the application making an explicit call into this module at termination.

```python
try:
    _count = int(open("/tmp/counter").read())
except IOError:
    _count = 0

def incrcounter(n):
    global _count
    _count = _count + n

def savecounter():
    open("/tmp/counter", "w").write("%d" % _count)

import atexit
atexit.register(savecounter)
```

Positional and keyword arguments may also be passed to `register()` to be passed along to the registered function when it is called:

```python
def goodbye(name, adjective):
    print 'Goodbye, %s, it was %s to meet you.' % (name, adjective)

import atexit
atexit.register(goodbye, 'Donny', 'nice')

# or:
atexit.register(goodbye, adjective='nice', name='Donny')
```
26.7 traceback -- Print or retrieve a stack traceback

This module provides a standard interface to extract, format and print stack traces of Python programs. It exactly mimics the behavior of the Python interpreter when it prints a stack trace. This is useful when you want to print stack traces under program control, such as in a ``wrapper'' around the interpreter.

The module uses traceback objects -- this is the object type that is stored in the variables `sys.exc_traceback` (deprecated) and `sys.last_traceback` and returned as the third item from `sys.exc_info()`.

The module defines the following functions:

**print_tb**(traceback[, limit[, file]])

Print up to limit stack trace entries from traceback. If limit is omitted or None, all entries are printed. If file is omitted or None, the output goes to `sys.stderr`; otherwise it should be an open file or file-like object to receive the output.

**print_exception**(type, value, traceback[, limit[, file]])

Print exception information and up to limit stack trace entries from traceback to file. This differs from `print_tb()` in the following ways: (1) if traceback is not None, it prints a header "Traceback (most recent call last):"; (2) it prints the exception type and value after the stack trace; (3) if type is SyntaxError and value has the appropriate format, it prints the line where the syntax error occurred with a caret indicating the approximate position of the error.

**print_exc**([limit[, file]])

This is a shorthand for `print_exception(sys.exc_type, sys.exc_value, sys.exc_traceback, limit, file)`. (In fact, it uses `sys.exc_info()` to retrieve the same information in a thread-safe
way instead of using the deprecated variables.)

**format_exc**([*limit]*)

This is like `print_exc(limit)` but returns a string instead of printing to a file. New in version 2.4.

**print_last**([*limit[, file]*])

This is a shorthand for `print_exception(sys.last_type, sys.last_value, sys.last_traceback, limit, file)`.

**print_stack**([*f[, limit[, file]*]])

This function prints a stack trace from its invocation point. The optional *f* argument can be used to specify an alternate stack frame to start. The optional *limit* and *file* arguments have the same meaning as for `print_exception()`.

**extract_tb**(*traceback[, limit]*)

Return a list of up to *limit* ``pre-processed'' stack trace entries extracted from the traceback object `traceback`. It is useful for alternate formatting of stack traces. If *limit* is omitted or `None`, all entries are extracted. A ``pre-processed'' stack trace entry is a quadruple (`filename`, *line number*, *function name*, *text`) representing the information that is usually printed for a stack trace. The *text* is a string with leading and trailing whitespace stripped; if the source is not available it is `None`.

**extract_stack**([*f[, limit]*])

Extract the raw traceback from the current stack frame. The return value has the same format as for `extract_tb()`. The optional *f* and *limit* arguments have the same meaning as for `print_stack()`.

**format_list**(*list*)

Given a list of tuples as returned by `extract_tb()` or `extract_stack()`, return a list of strings ready for printing. Each string in the resulting list corresponds to the item with the same index in the argument list. Each string ends in a newline; the strings may contain internal newlines as well, for those items whose source text line is not
None.

**format_exception_only**(type, value)
Format the exception part of a traceback. The arguments are the exception type and value such as given by `sys.last_type` and `sys.last_value`. The return value is a list of strings, each ending in a newline. Normally, the list contains a single string; however, for `SyntaxError` exceptions, it contains several lines that (when printed) display detailed information about where the syntax error occurred. The message indicating which exception occurred is the always last string in the list.

**format_exception**(type, value, tb[, limit])
Format a stack trace and the exception information. The arguments have the same meaning as the corresponding arguments to `print_exception()`.

The return value is a list of strings, each ending in a newline and some containing internal newlines. When these lines are concatenated and printed, exactly the same text is printed as does `print_exception()`.

**format_tb**(tb[, limit])
A shorthand for `format_list(extract_tb(tb, limit))`.

**format_stack**([f[, limit]])
A shorthand for `format_list(extract_stack(f, limit))`.

**tb_lineno**(tb)
This function returns the current line number set in the traceback object. This function was necessary because in versions of Python prior to 2.3 when the `-O` flag was passed to Python the `tb.tb_lineno` was not updated correctly. This function has no use in versions past 2.3.

- [26.7.1 Traceback Example](#)
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
26.7.1 Traceback Example

This simple example implements a basic read-eval-print loop, similar to (but less useful than) the standard Python interactive interpreter loop. For a more complete implementation of the interpreter loop, refer to the code module.

```python
import sys, traceback

def run_user_code(envdir):
    source = raw_input(">>> ")
    try:
        exec source in envdir
    except:
        print "Exception in user code:"
        print '-'*60
        traceback.print_exc(file=sys.stdout)
        print '-'*60

    envdir = {}
    while 1:
        run_user_code(envdir)
```

Release 2.5, documentation updated on 19th September, 2006. See About this document... for information on suggesting changes.
26.8 __future__ -- Future statement definitions

__future__ is a real module, and serves three purposes:

- To avoid confusing existing tools that analyze import statements and expect to find the modules they're importing.

- To ensure that future_statements run under releases prior to 2.1 at least yield runtime exceptions (the import of __future__ will fail, because there was no module of that name prior to 2.1).

- To document when incompatible changes were introduced, and when they will be -- or were -- made mandatory. This is a form of executable documentation, and can be inspected programatically via importing __future__ and examining its contents.

Each statement in __future__.py is of the form:

```python
FeatureName = "_Feature(" OptionalRelease "," MandatoryRelease ","
CompilerFlag ")"
```

where, normally, OptionalRelease is less than MandatoryRelease, and both are 5-tuples of the same form as sys.version_info:

```python
(PY_MAJOR_VERSION, # the 2 in 2.1.0a3; an int
PY_MINOR_VERSION, # the 1; an int
PY_MICRO_VERSION, # the 0; an int
PY_RELEASE_LEVEL, # "alpha", "beta", "candidate" or "final"; st
PY_RELEASE_SERIAL # the 3; an int
)
```

OptionalRelease records the first release in which the feature was accepted.

In the case of a MandatoryRelease that has not yet occurred, MandatoryRelease predicts the release in which the feature will become part of the language.
Else *MandatoryRelease* records when the feature became part of the language; in releases at or after that, modules no longer need a future statement to use the feature in question, but may continue to use such imports.

*MandatoryRelease* may also be *None*, meaning that a planned feature got dropped.

Instances of class *_Feature* have two corresponding methods, *getOptionalRelease()* and *getMandatoryRelease()*.

*CompilerFlag* is the (bitfield) flag that should be passed in the fourth argument to the builtin function *compile()* to enable the feature in dynamically compiled code. This flag is stored in the *compiler_flag* attribute on *_Feature* instances.

No feature description will ever be deleted from `__future__`.

---

*Python Library Reference*

*Release 2.5, documentation updated on 19th September, 2006.*

*See About this document... for information on suggesting changes.*
26.9 gc -- Garbage Collector interface

This module provides an interface to the optional garbage collector. It provides the ability to disable the collector, tune the collection frequency, and set debugging options. It also provides access to unreachable objects that the collector found but cannot free. Since the collector supplements the reference counting already used in Python, you can disable the collector if you are sure your program does not create reference cycles. Automatic collection can be disabled by calling `gc.disable()`. To debug a leaking program call `gc.set_debug(gc.DEBUG_LEAK)`. Notice that this includes `gc.DEBUG_SAVEALL`, causing garbage-collected objects to be saved in `gc.garbage` for inspection.

The `gc` module provides the following functions:

- **enable()**
  
  Enable automatic garbage collection.

- **disable()**
  
  Disable automatic garbage collection.

- **isenabled()**
  
  Returns true if automatic collection is enabled.

- **collect([generation])**
  
  With no arguments, run a full collection. The optional argument `generation` may be an integer specifying which generation to collect (from 0 to 2). A `ValueError` is raised if the generation number is invalid. The number of unreachable objects found is returned.

  Changed in version 2.5: The optional `generation` argument was added.

- **set_debug(flags)**
  
  Set the garbage collection debugging flags. Debugging information will be
written to \texttt{sys.stderr}. See below for a list of debugging flags which can be combined using bit operations to control debugging.

\textbf{get\_debug}()
\begin{flushleft}
Return the debugging flags currently set.
\end{flushleft}

\textbf{get\_objects}()
\begin{flushleft}
Returns a list of all objects tracked by the collector, excluding the list returned. New in version 2.2.
\end{flushleft}

\textbf{set\_threshold} \texttt{(threshold0[, threshold1[, threshold2]])}
\begin{flushleft}
Set the garbage collection thresholds (the collection frequency). Setting \texttt{threshold0} to zero disables collection.
\end{flushleft}

The GC classifies objects into three generations depending on how many collection sweeps they have survived. New objects are placed in the youngest generation (generation 0). If an object survives a collection it is moved into the next older generation. Since generation 2 is the oldest generation, objects in that generation remain there after a collection. In order to decide when to run, the collector keeps track of the number object allocations and deallocations since the last collection. When the number of allocations minus the number of deallocations exceeds \texttt{threshold0}, collection starts. Initially only generation 0 is examined. If generation 0 has been examined more than \texttt{threshold1} times since generation 1 has been examined, then generation 1 is examined as well. Similarly, \texttt{threshold2} controls the number of collections of generation 1 before collecting generation 2.

\textbf{get\_count}()
\begin{flushleft}
Return the current collection counts as a tuple of \texttt{(count0, count1, count2)}. New in version 2.5.
\end{flushleft}

\textbf{get\_threshold}()
\begin{flushleft}
Return the current collection thresholds as a tuple of \texttt{(threshold0, threshold1, threshold2)}.
\end{flushleft}

\textbf{get\_referrers} \texttt{(\*objs)}
Return the list of objects that directly refer to any of objs. This function will only locate those containers which support garbage collection; extension types which do refer to other objects but do not support garbage collection will not be found.

Note that objects which have already been dereferenced, but which live in cycles and have not yet been collected by the garbage collector can be listed among the resulting referrers. To get only currently live objects, call `collect()` before calling `get_referrers()`.

Care must be taken when using objects returned by `get_referrers()` because some of them could still be under construction and hence in a temporarily invalid state. Avoid using `get_referrers()` for any purpose other than debugging.

New in version 2.2.

```python
get_referents(*objs)
```

Return a list of objects directly referred to by any of the arguments. The referents returned are those objects visited by the arguments’ C-level `tp_traverse` methods (if any), and may not be all objects actually directly reachable. `tp_traverse` methods are supported only by objects that support garbage collection, and are only required to visit objects that may be involved in a cycle. So, for example, if an integer is directly reachable from an argument, that integer object may or may not appear in the result list.

New in version 2.3.

The following variable is provided for read-only access (you can mutate its value but should not rebind it):

```python
garbage
```

A list of objects which the collector found to be unreachable but could not be freed (uncollectable objects). By default, this list contains only objects with `__del__()` methods. Objects that have `__del__()` methods and are part of a reference cycle cause the entire reference cycle to be uncollectable, including objects not necessarily in the cycle but reachable only from it. Python doesn't collect such cycles automatically because, in
general, it isn't possible for Python to guess a safe order in which to run the __del__() methods. If you know a safe order, you can force the issue by examining the garbage list, and explicitly breaking cycles due to your objects within the list. Note that these objects are kept alive even so by virtue of being in the garbage list, so they should be removed from garbage too. For example, after breaking cycles, do del gc.garbage[:] to empty the list. It's generally better to avoid the issue by not creating cycles containing objects with __del__() methods, and garbage can be examined in that case to verify that no such cycles are being created.

If DEBUG_SAVEALL is set, then all unreachable objects will be added to this list rather than freed.

The following constants are provided for use with set_debug():

**DEBUG_STATS**
Print statistics during collection. This information can be useful when tuning the collection frequency.

**DEBUG_COLLECTABLE**
Print information on collectable objects found.

**DEBUG_UNCOLLECTABLE**
Print information of uncollectable objects found (objects which are not reachable but cannot be freed by the collector). These objects will be added to the garbage list.

**DEBUG_INSTANCES**
When DEBUG_COLLECTABLE or DEBUG_UNCOLLECTABLE is set, print information about instance objects found.

**DEBUG_OBJECTS**
When DEBUG_COLLECTABLE or DEBUG_UNCOLLECTABLE is set, print information about objects other than instance objects found.

**DEBUG_SAVEALL**
When set, all unreachable objects found will be appended to garbage rather than being freed. This can be useful for debugging a leaking program.
DEBUG_LEAK

The debugging flags necessary for the collector to print information about a leaking program (equal to DEBUG_COLLECTABLE | DEBUG_UNCOLLECTABLE | DEBUG_INSTANCES | DEBUG_OBJECTS | DEBUG_SAVEALL).

Footnotes

... methods. 26.1

Prior to Python 2.2, the list contained all instance objects in unreachable cycles, not only those with __del__() methods.
26.10 inspect -- Inspect live objects

New in version 2.1.

The inspect module provides several useful functions to help get information about live objects such as modules, classes, methods, functions, tracebacks, frame objects, and code objects. For example, it can help you examine the contents of a class, retrieve the source code of a method, extract and format the argument list for a function, or get all the information you need to display a detailed traceback.

There are four main kinds of services provided by this module: type checking, getting source code, inspecting classes and functions, and examining the interpreter stack.

Subsections

- 26.10.1 Types and members
- 26.10.2 Retrieving source code
- 26.10.3 Classes and functions
- 26.10.4 The interpreter stack

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
## 26.10.1 Types and members

The `getmembers()` function retrieves the members of an object such as a class or module. The eleven functions whose names begin with "is" are mainly provided as convenient choices for the second argument to `getmembers()`. They also help you determine when you can expect to find the following special attributes:

<table>
<thead>
<tr>
<th>Type</th>
<th>Attribute</th>
<th>Description</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>module</td>
<td><code>__doc__</code></td>
<td>documentation string</td>
<td></td>
</tr>
<tr>
<td></td>
<td><code>__file__</code></td>
<td>filename (missing for built-in modules)</td>
<td></td>
</tr>
<tr>
<td>class</td>
<td><code>__doc__</code></td>
<td>documentation string</td>
<td></td>
</tr>
<tr>
<td></td>
<td><code>__module__</code></td>
<td>name of module in which this class was defined</td>
<td></td>
</tr>
<tr>
<td>method</td>
<td><code>__doc__</code></td>
<td>documentation string</td>
<td></td>
</tr>
<tr>
<td></td>
<td><code>__name__</code></td>
<td>name with which this method was defined</td>
<td></td>
</tr>
<tr>
<td></td>
<td><code>im_class</code></td>
<td>class object that asked for this method</td>
<td>(1)</td>
</tr>
<tr>
<td></td>
<td><code>im_func</code></td>
<td>function object containing implementation of method</td>
<td></td>
</tr>
<tr>
<td></td>
<td><code>im_self</code></td>
<td>instance to which this method is bound, or None</td>
<td></td>
</tr>
<tr>
<td>function</td>
<td><code>__doc__</code></td>
<td>documentation string</td>
<td></td>
</tr>
<tr>
<td></td>
<td><code>__name__</code></td>
<td>name with which this function was defined</td>
<td></td>
</tr>
<tr>
<td></td>
<td><code>func_code</code></td>
<td>code object containing compiled function bytecode</td>
<td></td>
</tr>
<tr>
<td></td>
<td><code>func_defaults</code></td>
<td>tuple of any default values for arguments</td>
<td></td>
</tr>
<tr>
<td></td>
<td><code>func_doc</code></td>
<td>(same as <code>__doc__</code>)</td>
<td></td>
</tr>
<tr>
<td></td>
<td><code>func_globals</code></td>
<td>global namespace in which this function was defined</td>
<td></td>
</tr>
<tr>
<td></td>
<td><code>func_name</code></td>
<td>(same as <code>__name__</code>)</td>
<td></td>
</tr>
<tr>
<td>traceback</td>
<td><code>tb_frame</code></td>
<td>frame object at this level</td>

<td><strong>self</strong></td>
<td>instance to which a method is bound, or None</td>
<td></td>
</tr>
</tbody>
</table>

Note:

(1) Changed in version 2.2: im_class used to refer to the class that defined the method.

getmembers( object[, predicate])

Return all the members of an object in a list of (name, value) pairs sorted by name. If the optional predicate argument is supplied, only members for which the predicate returns a true value are included.

getmoduleinfo( path)

Return a tuple of values that describe how Python will interpret the file identified by path if it is a module, or None if it would not be identified as a module. The return tuple is (name, suffix, mode, mtype), where name is the name of the module without the name of any enclosing package, suffix is the trailing part of the file name (which may not be a dot-delimited extension), mode is the open() mode that would be used ('r' or 'rb'), and mtype is an integer giving the type of the module. mtype will have a value which can be compared to the constants defined in the imp
module; see the documentation for that module for more information on
module types.

getmodulename( path)
    Return the name of the module named by the file path, without including
the names of enclosing packages. This uses the same algorithm as the
interpreter uses when searching for modules. If the name cannot be matched
according to the interpreter's rules, None is returned.

ismodule( object)
    Return true if the object is a module.

iscool (object)
    Return true if the object is a class.

ismethod( object)
    Return true if the object is a method.

isfunction( object)
    Return true if the object is a Python function or unnamed (lambda)
function.

istraceback( object)
    Return true if the object is a traceback.

isframe( object)
    Return true if the object is a frame.

isceode( object)
    Return true if the object is a code.

isbuiltin( object)
    Return true if the object is a built-in function.

isroutine( object)
    Return true if the object is a user-defined or built-in function or method.
ismethoddescriptor(object)
Return true if the object is a method descriptor, but not if ismethod() or isclass() or isfunction() are true.

This is new as of Python 2.2, and, for example, is true of int.__add__. An object passing this test has a __get__ attribute but not a __set__ attribute, but beyond that the set of attributes varies. __name__ is usually sensible, and __doc__ often is.

Methods implemented via descriptors that also pass one of the other tests return false from the ismethoddescriptor() test, simply because the other tests promise more - you can, e.g., count on having the im_func attribute (etc) when an object passes ismethod().

isdatadescriptor(object)
Return true if the object is a data descriptor.

Data descriptors have both a __get__ and a __set__ attribute. Examples are properties (defined in Python), getsets, and members. The latter two are defined in C and there are more specific tests available for those types, which is robust across Python implementations. Typically, data descriptors will also have __name__ and __doc__ attributes (properties, getsets, and members have both of these attributes), but this is not guaranteed. New in version 2.3.

isgetsetdescriptor(object)
Return true if the object is a getset descriptor.

getsets are attributes defined in extension modules via PyGetSetDef structures. For Python implementations without such types, this method will always return False. New in version 2.5.

ismemberdescriptor(object)
Return true if the object is a member descriptor.

Member descriptors are attributes defined in extension modules via PyMemberDef structures. For Python implementations without such types, this method will always return False. New in version 2.5.
Release 2.5, documentation updated on 19th September, 2006.  
See About this document... for information on suggesting changes.
26.10.2 Retrieving source code

`getdoc(object)`
Get the documentation string for an object. All tabs are expanded to spaces. To clean up docstrings that are indented to line up with blocks of code, any whitespace than can be uniformly removed from the second line onwards is removed.

`getcomments(object)`
Return in a single string any lines of comments immediately preceding the object's source code (for a class, function, or method), or at the top of the Python source file (if the object is a module).

`getfile(object)`
Return the name of the (text or binary) file in which an object was defined. This will fail with a `TypeError` if the object is a built-in module, class, or function.

`getmodule(object)`
Try to guess which module an object was defined in.

`getsourcefile(object)`
Return the name of the Python source file in which an object was defined. This will fail with a `TypeError` if the object is a built-in module, class, or function.

`getsourcelines(object)`
Return a list of source lines and starting line number for an object. The argument may be a module, class, method, function, traceback, frame, or code object. The source code is returned as a list of the lines corresponding to the object and the line number indicates where in the original source file the first line of code was found. An `IOError` is raised if the source code cannot be retrieved.

`getsource(object)`
Return the text of the source code for an object. The argument may be a
module, class, method, function, traceback, frame, or code object. The source code is returned as a single string. An IOError is raised if the source code cannot be retrieved.
26.10.3 Classes and functions

getclasstree(classes[, unique])

Arrange the given list of classes into a hierarchy of nested lists. Where a nested list appears, it contains classes derived from the class whose entry immediately precedes the list. Each entry is a 2-tuple containing a class and a tuple of its base classes. If the unique argument is true, exactly one entry appears in the returned structure for each class in the given list. Otherwise, classes using multiple inheritance and their descendants will appear multiple times.

getargspec(func)

Get the names and default values of a function's arguments. A tuple of four things is returned: (args, varargs, varkw, defaults). args is a list of the argument names (it may contain nested lists). varargs and varkw are the names of the * and ** arguments or None. defaults is a tuple of default argument values or None if there are no default arguments; if this tuple has n elements, they correspond to the last n elements listed in args.

getargvalues(frame)

Get information about arguments passed into a particular frame. A tuple of four things is returned: (args, varargs, varkw, locals). args is a list of the argument names (it may contain nested lists). varargs and varkw are the names of the * and ** arguments or None. locals is the locals dictionary of the given frame.

formatargspec(args[, varargs, varkw, defaults, formatarg, formatvarargs, formatvarkw, formatvalue, join])

Format a pretty argument spec from the four values returned by getargspec(). The format* arguments are the corresponding optional formatting functions that are called to turn names and values into strings.

formatargvalues(args[, varargs, varkw, locals, formatarg, formatvarargs, formatvarkw, formatvalue, join])
Format a pretty argument spec from the four values returned by `getargvalues()`. The `format*` arguments are the corresponding optional formatting functions that are called to turn names and values into strings.

`getmro(cls)`

Return a tuple of class `cls`'s base classes, including `cls`, in method resolution order. No class appears more than once in this tuple. Note that the method resolution order depends on `cls`'s type. Unless a very peculiar user-defined metatype is in use, `cls` will be the first element of the tuple.
26.10.4 The interpreter stack

When the following functions return ``frame records,'' each record is a tuple of six items: the frame object, the filename, the line number of the current line, the function name, a list of lines of context from the source code, and the index of the current line within that list.

**Warning:** Keeping references to frame objects, as found in the first element of the frame records these functions return, can cause your program to create reference cycles. Once a reference cycle has been created, the lifespan of all objects which can be accessed from the objects which form the cycle can become much longer even if Python's optional cycle detector is enabled. If such cycles must be created, it is important to ensure they are explicitly broken to avoid the delayed destruction of objects and increased memory consumption which occurs.

Though the cycle detector will catch these, destruction of the frames (and local variables) can be made deterministic by removing the cycle in a `finally` clause. This is also important if the cycle detector was disabled when Python was compiled or using `gc.disable()`. For example:

```python
def handle_stackframe_without_leak():
    frame = inspect.currentframe()
    try:
        # do something with the frame
    finally:
        del frame
```

The optional `context` argument supported by most of these functions specifies the number of lines of context to return, which are centered around the current line.

**getframeinfo**( `frame[, context]` )

Get information about a frame or traceback object. A 5-tuple is returned, the last five elements of the frame's frame record.
getouterframes( frame[, context])

Get a list of frame records for a frame and all outer frames. These frames represent the calls that lead to the creation of frame. The first entry in the returned list represents frame; the last entry represents the outermost call on frame's stack.

getinnerframes( traceback[, context])

Get a list of frame records for a traceback's frame and all inner frames. These frames represent calls made as a consequence of frame. The first entry in the list represents traceback; the last entry represents where the exception was raised.

currentframe()

Return the frame object for the caller's stack frame.

stack([context])

Return a list of frame records for the caller's stack. The first entry in the returned list represents the caller; the last entry represents the outermost call on the stack.

trace([context])

Return a list of frame records for the stack between the current frame and the frame in which an exception currently being handled was raised in. The first entry in the list represents the caller; the last entry represents where the exception was raised.
26.11 site -- Site-specific configuration hook

This module is automatically imported during initialization. The automatic import can be suppressed using the interpreter's -S option.

Importing this module will append site-specific paths to the module search path.

It starts by constructing up to four directories from a head and a tail part. For the head part, it uses sys.prefix and sys.exec_prefix; empty heads are skipped. For the tail part, it uses the empty string and then lib/site-packages (on Windows) or lib/python2.5/site-packages and then lib/site-python (on UNIX and Macintosh). For each of the distinct head-tail combinations, it sees if it refers to an existing directory, and if so, adds it to sys.path and also inspects the newly added path for configuration files.

A path configuration file is a file whose name has the form package.pth and exists in one of the four directories mentioned above; its contents are additional items (one per line) to be added to sys.path. Non-existing items are never added to sys.path, but no check is made that the item refers to a directory (rather than a file). No item is added to sys.path more than once. Blank lines and lines beginning with # are skipped. Lines starting with import are executed.

For example, suppose sys.prefix and sys.exec_prefix are set to /usr/local. The Python 2.5 library is then installed in /usr/local/lib/python2.5 (where only the first three characters of sys.version are used to form the installation path name). Suppose this has a subdirectory /usr/local/lib/python2.5/site-packages with three subsubdirectories, foo, bar and spam, and two path configuration files, foo.pth and bar.pth. Assume foo.pth contains the following:

```plaintext
# foo package configuration
foo
bar
bletch
```
and `bar.pth` contains:

```
# bar package configuration
bar
```

Then the following directories are added to `sys.path`, in this order:

```
/usr/local/lib/python2.3/site-packages/bar
/usr/local/lib/python2.3/site-packages/foo
```

Note that `bletch` is omitted because it doesn't exist; the `bar` directory precedes the `foo` directory because `bar.pth` comes alphabetically before `foo.pth`; and `spam` is omitted because it is not mentioned in either path configuration file.

After these path manipulations, an attempt is made to import a module named `sitecustomize`, which can perform arbitrary site-specific customizations. If this import fails with an `ImportError` exception, it is silently ignored.

Note that for some non-UNIX systems, `sys.prefix` and `sys.exec_prefix` are empty, and the path manipulations are skipped; however the import of `sitecustomize` is still attempted.
26.12 user -- User-specific configuration hook

As a policy, Python doesn't run user-specified code on startup of Python programs. (Only interactive sessions execute the script specified in the PYTHONSTARTUP environment variable if it exists).

However, some programs or sites may find it convenient to allow users to have a standard customization file, which gets run when a program requests it. This module implements such a mechanism. A program that wishes to use the mechanism must execute the statement

```python
import user
```

The `user` module looks for a file `.pythonrc.py` in the user's home directory and if it can be opened, executes it (using `execfile()`) in its own (the module `user`'s) global namespace. Errors during this phase are not caught; that's up to the program that imports the `user` module, if it wishes. The home directory is assumed to be named by the HOME environment variable; if this is not set, the current directory is used.

The user's `.pythonrc.py` could conceivably test for `sys.version` if it wishes to do different things depending on the Python version.

A warning to users: be very conservative in what you place in your `.pythonrc.py` file. Since you don't know which programs will use it, changing the behavior of standard modules or functions is generally not a good idea.

A suggestion for programmers who wish to use this mechanism: a simple way to let users specify options for your package is to have them define variables in their `.pythonrc.py` file that you test in your module. For example, a module `spam` that has a verbosity level can look for a variable `user.spam_verbose`, as follows:

```python
import user

verbose = bool(getattr(user, "spam_verbose", 0))
```
(The three-argument form of `getattr()` is used in case the user has not defined `spam_verbose` in their `.pythonrc.py` file.)

Programs with extensive customization needs are better off reading a program-specific customization file.

Programs with security or privacy concerns should not import this module; a user can easily break into a program by placing arbitrary code in the `.pythonrc.py` file.

Modules for general use should not import this module; it may interfere with the operation of the importing program.

**See Also:**

Module `site`:

Site-wide customization mechanism.
26.13 fpectl -- Floating point exception control

Availability: **Unix.**

Most computers carry out floating point operations in conformance with the so-called IEEE-754 standard. On any real computer, some floating point operations produce results that cannot be expressed as a normal floating point value. For example, try

```python
>>> import math
>>> math.exp(1000)
inf
>>> math.exp(1000) / math.exp(1000)
nan
```

(The example above will work on many platforms. DEC Alpha may be one exception.) "Inf" is a special, non-numeric value in IEEE-754 that stands for "infinity", and "nan" means "not a number." Note that, other than the non-numeric results, nothing special happened when you asked Python to carry out those calculations. That is in fact the default behaviour prescribed in the IEEE-754 standard, and if it works for you, stop reading now.

In some circumstances, it would be better to raise an exception and stop processing at the point where the faulty operation was attempted. The `fpectl` module is for use in that situation. It provides control over floating point units from several hardware manufacturers, allowing the user to turn on the generation of **SIGFPE** whenever any of the IEEE-754 exceptions Division by Zero, Overflow, or Invalid Operation occurs. In tandem with a pair of wrapper macros that are inserted into the C code comprising your python system, **SIGFPE** is trapped and converted into the Python **FloatingPointError** exception.

The `fpectl` module defines the following functions and may raise the given exception:

```python
turnon_sigfpe()
```

    Turn on the generation of **SIGFPE**, and set up an appropriate signal
handler.

**turnoff_sigfpe()**
Reset default handling of floating point exceptions.

**exception FloatingPointError**
After `turnon_sigfpe()` has been executed, a floating point operation that raises one of the IEEE-754 exceptions Division by Zero, Overflow, or Invalid operation will in turn raise this standard Python exception.

**Python Library Reference**

Release 2.5, documentation updated on 19th September, 2006.
See [About this document...](#) for information on suggesting changes.
26.13.1 Example

The following example demonstrates how to start up and test operation of the fpectl module.

```python
>>> import fpectl
>>> import fpetest
>>> fpectl.turnon_sigfpe()
>>> fpetest.test()
overflow    PASS
FloatingPointError: Overflow

div by 0    PASS
FloatingPointError: Division by zero
[  more output from test elided ]
>>> import math
>>> math.exp(1000)
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
FloatingPointError: in math_1
```

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
26.13.2 Limitations and other considerations

Setting up a given processor to trap IEEE-754 floating point errors currently requires custom code on a per-architecture basis. You may have to modify `fpectl` to control your particular hardware.

Conversion of an IEEE-754 exception to a Python exception requires that the wrapper macros `PyFPE_START_PROTECT` and `PyFPE_END_PROTECT` be inserted into your code in an appropriate fashion. Python itself has been modified to support the `fpectl` module, but many other codes of interest to numerical analysts have not.

The `fpectl` module is not thread-safe.

See Also:

Some files in the source distribution may be interesting in learning more about how this module operates. The include file `include/pyfpe.h` discusses the implementation of this module at some length. `Modules/fpetestmodule.c` gives several examples of use. Many additional examples can be found in `Objects/floatobject.c`.

27. Custom Python Interpreters

The modules described in this chapter allow writing interfaces similar to Python's interactive interpreter. If you want a Python interpreter that supports some special feature in addition to the Python language, you should look at the code module. (The codeop module is lower-level, used to support compiling a possibly-incomplete chunk of Python code.)

The full list of modules described in this chapter is:

- **code** Base classes for interactive Python interpreters.
- **codeop** Compile (possibly incomplete) Python code.
27.1 code -- Interpreter base classes

The code module provides facilities to implement read-eval-print loops in Python. Two classes and convenience functions are included which can be used to build applications which provide an interactive interpreter prompt.

class InteractiveInterpreter([locals])

This class deals with parsing and interpreter state (the user's namespace); it does not deal with input buffering or prompting or input file naming (the filename is always passed in explicitly). The optional locals argument specifies the dictionary in which code will be executed; it defaults to a newly created dictionary with key '__name__' set to '__console__' and key '__doc__' set to None.

class InteractiveConsole([locals[, filename]])

Closely emulate the behavior of the interactive Python interpreter. This class builds on InteractiveInterpreter and adds prompting using the familiar sys.ps1 and sys.ps2, and input buffering.

interact([banner[, readfunc[, local]]])

Convenience function to run a read-eval-print loop. This creates a new instance of InteractiveConsole and sets readfunc to be used as the raw_input() method, if provided. If local is provided, it is passed to the InteractiveConsole constructor for use as the default namespace for the interpreter loop. The interact() method of the instance is then run with banner passed as the banner to use, if provided. The console object is discarded after use.

compile_command(source[, filename[, symbol]])

This function is useful for programs that want to emulate Python's interpreter main loop (a.k.a. the read-eval-print loop). The tricky part is to determine when the user has entered an incomplete command that can be completed by entering more text (as opposed to a complete command or a syntax error). This function almost always makes the same decision as the real interpreter main loop.
source is the source string; filename is the optional filename from which source was read, defaulting to '<input>'; and symbol is the optional grammar start symbol, which should be either 'single' (the default) or 'eval'.

Returns a code object (the same as compile(source, filename, symbol)) if the command is complete and valid; None if the command is incomplete; raises SyntaxError if the command is complete and contains a syntax error, or raises OverflowError or ValueError if the command contains an invalid literal.
27.1.1 Interactive Interpreter Objects

**runsource**(*source[, filename[, symbol]])

Compile and run some source in the interpreter. Arguments are the same as for compile_command(); the default for filename is '&lt;input&gt;', and for symbol is 'single'. One several things can happen:

- The input is incorrect; compile_command() raised an exception (SyntaxError or OverflowError). A syntax traceback will be printed by calling the showsyntaxerror() method. runsource() returns False.

- The input is incomplete, and more input is required; compile_command() returned None. runsource() returns True.

- The input is complete; compile_command() returned a code object. The code is executed by calling the runcode() (which also handles run-time exceptions, except for SystemExit). runsource() returns False.

The return value can be used to decide whether to use sys.ps1 or sys.ps2 to prompt the next line.

**runcode**(*code*)

Execute a code object. When an exception occurs, showtraceback() is called to display a traceback. All exceptions are caught except SystemExit, which is allowed to propagate.

A note about KeyboardInterrupt: this exception may occur elsewhere in this code, and may not always be caught. The caller should be prepared to deal with it.

**showsyntaxerror**([filename])

Display the syntax error that just occurred. This does not display a stack trace because there isn't one for syntax errors. If filename is given, it is
stuffed into the exception instead of the default filename provided by
Python's parser, because it always uses '<string>' when reading from a
string. The output is written by the write() method.

**showtraceback()**
Display the exception that just occurred. We remove the first stack item
because it is within the interpreter object implementation. The output is
written by the write() method.

**write(data)**
Write a string to the standard error stream (sys.stderr). Derived classes
should override this to provide the appropriate output handling as needed.
27.1.2 Interactive Console Objects

The `InteractiveConsole` class is a subclass of `InteractiveInterpreter`, and so offers all the methods of the interpreter objects as well as the following additions.

**interact([banner])**
Closely emulate the interactive Python console. The optional banner argument specify the banner to print before the first interaction; by default it prints a banner similar to the one printed by the standard Python interpreter, followed by the class name of the console object in parentheses (so as not to confuse this with the real interpreter - since it's so close!).

**push(line)**
Push a line of source text to the interpreter. The line should not have a trailing newline; it may have internal newlines. The line is appended to a buffer and the interpreter's `runsource()` method is called with the concatenated contents of the buffer as source. If this indicates that the command was executed or invalid, the buffer is reset; otherwise, the command is incomplete, and the buffer is left as it was after the line was appended. The return value is `True` if more input is required, `False` if the line was dealt with in some way (this is the same as `runsource()`).

**resetbuffer()**
Remove any unhandled source text from the input buffer.

**raw_input([prompt])**
Write a prompt and read a line. The returned line does not include the trailing newline. When the user enters the EOF key sequence, `EOFError` is raised. The base implementation uses the built-in function `raw_input()`; a subclass may replace this with a different implementation.
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
27.2 codeop -- Compile Python code

The codeop module provides utilities upon which the Python read-eval-print loop can be emulated, as is done in the code module. As a result, you probably don't want to use the module directly; if you want to include such a loop in your program you probably want to use the code module instead.

There are two parts to this job:

1. Being able to tell if a line of input completes a Python statement: in short, telling whether to print `>>>` or `...` next.
2. Remembering which future statements the user has entered, so subsequent input can be compiled with these in effect.

The codeop module provides a way of doing each of these things, and a way of doing them both.

To do just the former:

\[\text{compile_command}(\text{source}[\text{, filename}[\text{, symbol}]])\]

Tries to compile source, which should be a string of Python code and return a code object if source is valid Python code. In that case, the filename attribute of the code object will be filename, which defaults to '<<input>>'. Returns None if source is not valid Python code, but is a prefix of valid Python code.

If there is a problem with source, an exception will be raised. SyntaxError is raised if there is invalid Python syntax, and OverflowError or ValueError if there is an invalid literal.

The symbol argument determines whether source is compiled as a statement ('single', the default) or as an expression ('eval'). Any other value will cause ValueError to be raised.

Caveat: It is possible (but not likely) that the parser stops parsing with a successful outcome before reaching the end of the source; in this case, trailing symbols may be ignored instead of causing an error. For example, a
backslash followed by two newlines may be followed by arbitrary garbage. This will be fixed once the API for the parser is better.

class Compile()
Instances of this class have __call__() methods identical in signature to the built-in function compile(), but with the difference that if the instance compiles program text containing a __future__ statement, the instance 'remembers' and compiles all subsequent program texts with the statement in force.

class CommandCompiler()
Instances of this class have __call__() methods identical in signature to compile_command(); the difference is that if the instance compiles program text containing a __future__ statement, the instance 'remembers' and compiles all subsequent program texts with the statement in force.

A note on version compatibility: the Compile and CommandCompiler are new in Python 2.2. If you want to enable the future-tracking features of 2.2 but also retain compatibility with 2.1 and earlier versions of Python you can either write

```python
try:
    from codeop import CommandCompiler
    compile_command = CommandCompiler()
    del CommandCompiler
except ImportError:
    from codeop import compile_command
```

which is a low-impact change, but introduces possibly unwanted global state into your program, or you can write:

```python
try:
    from codeop import CommandCompiler
except ImportError:
    def CommandCompiler():
        from codeop import compile_command
        return compile_command
```

and then call CommandCompiler every time you need a fresh compiler object.
28. Restricted Execution

**Warning:** In Python 2.3 these modules have been disabled due to various known and not readily fixable security holes. The modules are still documented here to help in reading old code that uses the `re` and `Bastion` modules.

Restricted execution is the basic framework in Python that allows for the segregation of trusted and untrusted code. The framework is based on the notion that trusted Python code (a supervisor) can create a `padded cell` (or environment) with limited permissions, and run the untrusted code within this cell. The untrusted code cannot break out of its cell, and can only interact with sensitive system resources through interfaces defined and managed by the trusted code. The term "restricted execution" is favored over "safe-Python" since true safety is hard to define, and is determined by the way the restricted environment is created. Note that the restricted environments can be nested, with inner cells creating subcells of lesser, but never greater, privilege.

An interesting aspect of Python's restricted execution model is that the interfaces presented to untrusted code usually have the same names as those presented to trusted code. Therefore no special interfaces need to be learned to write code designed to run in a restricted environment. And because the exact nature of the padded cell is determined by the supervisor, different restrictions can be imposed, depending on the application. For example, it might be deemed "safe" for untrusted code to read any file within a specified directory, but never to write a file. In this case, the supervisor may redefine the built-in `open()` function so that it raises an exception whenever the `mode` parameter is `'w'`. It might also perform a `chroot()`-like operation on the `filename` parameter, such that root is always relative to some safe "sandbox" area of the filesystem. In this case, the untrusted code would still see an built-in `open()` function in its environment, with the same calling interface. The semantics would be identical too, with `IOError`s being raised when the supervisor determined that an unallowable parameter is being used.

The Python run-time determines whether a particular code block is executing in
restricted execution mode based on the identity of the __builtins__ object in its global variables: if this is (the dictionary of) the standard __builtin__ module, the code is deemed to be unrestricted, else it is deemed to be restricted.

Python code executing in restricted mode faces a number of limitations that are designed to prevent it from escaping from the padded cell. For instance, the function object attribute func_globals and the class and instance object attribute __dict__ are unavailable.

Two modules provide the framework for setting up restricted execution environments:

rexec Basic restricted execution framework.
Bastion Providing restricted access to objects.

See Also:

Grail Home Page Grail, an Internet browser written in Python, uses these modules to support Python applets. More information on the use of Python’s restricted execution mode in Grail is available on the Web site.
28.1 rexec -- Restricted execution framework

Changed in version 2.3: Disabled module.

Warning: The documentation has been left in place to help in reading old code that uses the module.

This module contains the RExec class, which supports r_eval(), r_execfile(), r_exec(), and r_import() methods, which are restricted versions of the standard Python functions eval(), execfile() and the exec and import statements. Code executed in this restricted environment will only have access to modules and functions that are deemed safe; you can subclass RExec to add or remove capabilities as desired.

Warning: While the rexec module is designed to perform as described below, it does have a few known vulnerabilities which could be exploited by carefully written code. Thus it should not be relied upon in situations requiring ``production ready'' security. In such situations, execution via sub-processes or very careful ``cleansing'' of both code and data to be processed may be necessary. Alternatively, help in patching known rexec vulnerabilities would be welcomed.

Note: The RExec class can prevent code from performing unsafe operations like reading or writing disk files, or using TCP/IP sockets. However, it does not protect against code using extremely large amounts of memory or processor time.

class RExec([hooks[, verbose]])
Returns an instance of the RExec class.

*hooks* is an instance of the RHooks class or a subclass of it. If it is omitted or None, the default RHooks class is instantiated. Whenever the rexec module searches for a module (even a built-in one) or reads a module's code, it doesn't actually go out to the file system itself. Rather, it calls methods of an RHooks instance that was passed to or created by its constructor. (Actually, the RExec object doesn't make these calls -- they are made by a module loader object that's part of the RExec object. This allows another level of flexibility, which can be useful when changing the mechanics of import within the restricted environment.)

By providing an alternate RHooks object, we can control the file system accesses made to import a module, without changing the actual algorithm that controls the order in which those accesses are made. For instance, we could substitute an RHooks object that passes all filesystem requests to a file server elsewhere, via some RPC mechanism such as ILU. Grail's applet loader uses this to support importing applets from a URL for a directory.

If *verbose* is true, additional debugging output may be sent to standard output.

It is important to be aware that code running in a restricted environment can still call the `sys.exit()` function. To disallow restricted code from exiting the interpreter, always protect calls that cause restricted code to run with a `try/except` statement that catches the SystemExit exception. Removing the `sys.exit()` function from the restricted environment is not sufficient -- the restricted code could still use `raise SystemExit`. Removing SystemExit is not a reasonable option; some library code makes use of this and would break were it not available.

**See Also:**

*Grail Home Page*

Grail is a Web browser written entirely in Python. It uses the rexec module as a foundation for supporting Python applets, and can be used as an example usage of this module.
28.1.1 RExec Objects

RExec instances support the following methods:

r_eval(code)
   code must either be a string containing a Python expression, or a compiled
code object, which will be evaluated in the restricted environment's
__main__ module. The value of the expression or code object will be
returned.

r_exec(code)
   code must either be a string containing one or more lines of Python code, or
a compiled code object, which will be executed in the restricted
environment's __main__ module.

r_execfile(filename)
   Execute the Python code contained in the file filename in the restricted
environment's __main__ module.

Methods whose names begin with "s_" are similar to the functions beginning
with "r_", but the code will be granted access to restricted versions of the
standard I/O streams sys.stdin, sys.stderr, and sys.stdout.

s_eval(code)
   code must be a string containing a Python expression, which will be
evaluated in the restricted environment.

s_exec(code)
   code must be a string containing one or more lines of Python code, which
will be executed in the restricted environment.

s_execfile(code)
   Execute the Python code contained in the file filename in the restricted
environment.

RExec objects must also support various methods which will be implicitly
called by code executing in the restricted environment. Overriding these methods in a subclass is used to change the policies enforced by a restricted environment.

**r_import(module, globals[, locals[, fromlist]]))**
Import the module `module`, raising an `ImportError` exception if the module is considered unsafe.

**r_open(filename[, mode[, bufsize]])**
Method called when `open()` is called in the restricted environment. The arguments are identical to those of `open()`, and a file object (or a class instance compatible with file objects) should be returned. `RExec`'s default behaviour is allow opening any file for reading, but forbidding any attempt to write a file. See the example below for an implementation of a less restrictive `r_open()`.

**r_reload(module)**
Reload the module object `module`, re-parsing and re-initializing it.

**r_unload(module)**
Unload the module object `module` (remove it from the restricted environment's `sys.modules` dictionary).

And their equivalents with access to restricted standard I/O streams:

**s_import(module, globals[, locals[, fromlist]]))**
Import the module `module`, raising an `ImportError` exception if the module is considered unsafe.

**s_reload(module)**
Reload the module object `module`, re-parsing and re-initializing it.

**s_unload(module)**
Unload the module object `module`. 
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
28.1.2 Defining restricted environments

The `RExec` class has the following class attributes, which are used by the `__init__()` method. Changing them on an existing instance won't have any effect; instead, create a subclass of `RExec` and assign them new values in the class definition. Instances of the new class will then use those new values. All these attributes are tuples of strings.

**nok_builtin_names**
Contains the names of built-in functions which will *not* be available to programs running in the restricted environment. The value for `RExec` is (`'open', 'reload', '__import__'`). (This gives the exceptions, because by far the majority of built-in functions are harmless. A subclass that wants to override this variable should probably start with the value from the base class and concatenate additional forbidden functions -- when new dangerous built-in functions are added to Python, they will also be added to this module.)

**ok_builtin_modules**
Contains the names of built-in modules which can be safely imported. The value for `RExec` is (`'audioop', 'array', 'binascii', 'cmath', 'errno', 'imageop', 'marshal', 'math', 'md5', 'operator', 'parser', 'regex', 'select', 'sha', '_sre', 'strop', 'struct', 'time'`). A similar remark about overriding this variable applies -- use the value from the base class as a starting point.

**ok_path**
Contains the directories which will be searched when an `import` is performed in the restricted environment. The value for `RExec` is the same as `sys.path` (at the time the module is loaded) for unrestricted code.

**ok_posix_names**
Contains the names of the functions in the `os` module which will be available to programs running in the restricted environment. The value for `RExec` is (`'error', 'fstat', 'listdir', 'lstat', 'readlink', 'stat', 'times', 'uname', 'getpid',`
'getppid', 'getcwd', 'getuid', 'getgid',
'geteuid', 'getegid').

**ok_sys_names**
Contains the names of the functions and variables in the `sys` module which will be available to programs running in the restricted environment. The value for RExec is ('ps1', 'ps2', 'copyright', 'version', 'platform', 'exit', 'maxint').

**ok_file_types**
Contains the file types from which modules are allowed to be loaded. Each file type is an integer constant defined in the `imp` module. The meaningful values are PY_SOURCE, PYCompiled, and C_EXTENSION. The value for RExec is (C_EXTENSION, PY_SOURCE). Adding PYCompiled in subclasses is not recommended; an attacker could exit the restricted execution mode by putting a forged byte-compiled file (.pyc) anywhere in your file system, for example by writing it to /tmp or uploading it to the /incoming directory of your public FTP server.
28.1.3 An example

Let us say that we want a slightly more relaxed policy than the standard RExec class. For example, if we're willing to allow files in /tmp to be written, we can subclass the RExec class:

```python
class TmpWriterRExec(rexec.RExec):
    def r_open(self, file, mode='r', buf=-1):
        if mode in ('r', 'rb'):
            pass
        elif mode in ('w', 'wb', 'a', 'ab'):
            # check filename : must begin with /tmp/
            if file[:5]!='/tmp/':
                raise IOError, "can't write outside /tmp"
            elif (string.find(file, '/../') >= 0 or
                  file[:3] == '../' or file[-3:] == '/../'):
                raise IOError, "'..' in filename forbidden"
        else:
            raise IOError, "Illegal open() mode"
        return open(file, mode, buf)
```

Notice that the above code will occasionally forbid a perfectly valid filename; for example, code in the restricted environment won't be able to open a file called /tmp/foo/../bar. To fix this, the r_open() method would have to simplify the filename to /tmp/bar, which would require splitting apart the filename and performing various operations on it. In cases where security is at stake, it may be preferable to write simple code which is sometimes overly restrictive, instead of more general code that is also more complex and may harbor a subtle security hole.
28.2 Bastion -- Restricting access to objects

Changed in version 2.3: Disabled module.

**Warning:** The documentation has been left in place to help in reading old code that uses the module.

According to the dictionary, a bastion is ``a fortified area or position'', or ``something that is considered a stronghold.'' It's a suitable name for this module, which provides a way to forbid access to certain attributes of an object. It must always be used with the `reexec` module, in order to allow restricted-mode programs access to certain safe attributes of an object, while denying access to other, unsafe attributes.

**Bastion**(*object*, *filter*, *name*, *class*)

Protect the object `object`, returning a bastion for the object. Any attempt to access one of the object's attributes will have to be approved by the `filter` function; if the access is denied an `AttributeError` exception will be raised.

If present, `filter` must be a function that accepts a string containing an attribute name, and returns true if access to that attribute will be permitted; if `filter` returns false, the access is denied. The default filter denies access to any function beginning with an underscore ("_"). The bastion's string representation will be "<Bastion for name>" if a value for `name` is provided; otherwise, "repr(object)" will be used.

`class`, if present, should be a subclass of `BastionClass`; see the code in `bastion.py` for the details. Overriding the default `BastionClass` will rarely be required.

**class BastionClass**(*getfunc*, *name*)
Class which actually implements bastion objects. This is the default class used by `Bastion()`. The `getfunc` parameter is a function which returns the value of an attribute which should be exposed to the restricted execution environment when called with the name of the attribute as the only parameter. `name` is used to construct the `repr()` of the `BastionClass` instance.
29. Importing Modules

The modules described in this chapter provide new ways to import other Python modules and hooks for customizing the import process.

The full list of modules described in this chapter is:

- **imp**: Access the implementation of the `import` statement.
- **zipimport**: Support for importing Python modules from ZIP archives.
- **pkgutil**: Utilities to support extension of packages.
- **modulefinder**: Find modules used by a script.
- **runpy**: Locate and execute Python modules as scripts.

Release 2.5, documentation updated on 19th September, 2006.
See [About this document...](#) for information on suggesting changes.
29.1 imp -- Access the import internals

This module provides an interface to the mechanisms used to implement the import statement. It defines the following constants and functions:

get_magic()

Return the magic string value used to recognize byte-compiled code files (.pyc files). (This value may be different for each Python version.)

get_suffixes()

Return a list of triples, each describing a particular type of module. Each triple has the form (suffix, mode, type), where suffix is a string to be appended to the module name to form the filename to search for, mode is the mode string to pass to the built-in open() function to open the file (this can be 'r' for text files or 'rb' for binary files), and type is the file type, which has one of the values PY_SOURCE, PY_COMPILED, or C_EXTENSION, described below.

find_module(name[, path])

Try to find the module name on the search path path. If path is a list of directory names, each directory is searched for files with any of the suffixes returned by get_suffixes() above. Invalid names in the list are silently ignored (but all list items must be strings). If path is omitted or None, the list of directory names given by sys.path is searched, but first it searches a few special places: it tries to find a built-in module with the given name (C_BUILTIN), then a frozen module (PY_FROZEN), and on some systems some other places are looked in as well (on the Mac, it looks for a resource (PY_RESOURCE); on Windows, it looks in the registry which may point to a specific file).

If search is successful, the return value is a triple (file, pathname, description) where file is an open file object positioned at the beginning, pathname is the pathname of the file found, and description is a triple as
contained in the list returned by `get_suffixes()` describing the kind of module found. If the module does not live in a file, the returned `file` is `None`, `filename` is the empty string, and the `description` tuple contains empty strings for its suffix and mode; the module type is as indicated in parentheses above. If the search is unsuccessful, `ImportError` is raised. Other exceptions indicate problems with the arguments or environment.

This function does not handle hierarchical module names (names containing dots). In order to find `P.M`, that is, submodule `M` of package `P`, use `find_module()` and `load_module()` to find and load package `P`, and then use `find_module()` with the `path` argument set to `P.__path__`. When `P` itself has a dotted name, apply this recipe recursively.

`load_module(name, file, filename, description)`

Load a module that was previously found by `find_module()` (or by an otherwise conducted search yielding compatible results). This function does more than importing the module: if the module was already imported, it is equivalent to a `reload()`! The `name` argument indicates the full module name (including the package name, if this is a submodule of a package). The `file` argument is an open file, and `filename` is the corresponding file name; these can be `None` and `'`, respectively, when the module is not being loaded from a file. The `description` argument is a tuple, as would be returned by `get_suffixes()`, describing what kind of module must be loaded.

If the load is successful, the return value is the module object; otherwise, an exception (usually `ImportError`) is raised.

**Important:** the caller is responsible for closing the `file` argument, if it was not `None`, even when an exception is raised. This is best done using a `try` ... `finally` statement.

`new_module(name)`

Return a new empty module object called `name`. This object is not inserted in `sys.modules`.

`lock_held()`
Return True if the import lock is currently held, else False. On platforms without threads, always return False.

On platforms with threads, a thread executing an import holds an internal lock until the import is complete. This lock blocks other threads from doing an import until the original import completes, which in turn prevents other threads from seeing incomplete module objects constructed by the original thread while in the process of completing its import (and the imports, if any, triggered by that).

**acquire_lock()**
Acquires the interpreter's import lock for the current thread. This lock should be used by import hooks to ensure thread-safety when importing modules. On platforms without threads, this function does nothing. New in version 2.3.

**release_lock()**
Release the interpreter's import lock. On platforms without threads, this function does nothing. New in version 2.3.

The following constants with integer values, defined in this module, are used to indicate the search result of find_module().

**PY_SOURCE**
The module was found as a source file.

**PY_COMPILED**
The module was found as a compiled code object file.

**C_EXTENSION**
The module was found as dynamically loadable shared library.

**PYRESOURCE**
The module was found as a Mac OS 9 resource. This value can only be returned on a Mac OS 9 or earlier Macintosh.

**PKG_DIRECTORY**
The module was found as a package directory.
**C_BUILTIN**
The module was found as a built-in module.

**PY_FROZEN**
The module was found as a frozen module (see init_frozen()).

The following constant and functions are obsolete; their functionality is available through find_module() or load_module(). They are kept around for backward compatibility:

**SEARCH_ERROR**
Unused.

**init_builtin**(name)
Initialize the built-in module called name and return its module object. If the module was already initialized, it will be initialized again. A few modules cannot be initialized twice -- attempting to initialize these again will raise an ImportError exception. If there is no built-in module called name, None is returned.

**init_frozen**(name)
Initialize the frozen module called name and return its module object. If the module was already initialized, it will be initialized again. If there is no frozen module called name, None is returned. (Frozen modules are modules written in Python whose compiled byte-code object is incorporated into a custom-built Python interpreter by Python's freeze utility. See Tools/freezefile for now.)

**is_builtin**(name)
Return 1 if there is a built-in module called name which can be initialized again. Return -1 if there is a built-in module called name which cannot be initialized again (see init builtin()). Return 0 if there is no built-in module called name.

**is_frozen**(name)
Return True if there is a frozen module (see init_frozen()) called name, or False if there is no such module.
**load_compiled**(*name, pathname, [file]*)

Load and initialize a module implemented as a byte-compiled code file and return its module object. If the module was already initialized, it will be initialized *again*. The *name* argument is used to create or access a module object. The *pathname* argument points to the byte-compiled code file. The *file* argument is the byte-compiled code file, open for reading in binary mode, from the beginning. It must currently be a real file object, not a user-defined class emulating a file.

**load_dynamic**(*name, pathname[, file]*)

Load and initialize a module implemented as a dynamically loadable shared library and return its module object. If the module was already initialized, it will be initialized *again*. Some modules don't like that and may raise an exception. The *pathname* argument must point to the shared library. The *name* argument is used to construct the name of the initialization function: an external C function called "initname()" in the shared library is called. The optional *file* argument is ignored. (Note: using shared libraries is highly system dependent, and not all systems support it.)

**load_source**(*name, pathname[, file]*)

Load and initialize a module implemented as a Python source file and return its module object. If the module was already initialized, it will be initialized *again*. The *name* argument is used to create or access a module object. The *pathname* argument points to the source file. The *file* argument is the source file, open for reading as text, from the beginning. It must currently be a real file object, not a user-defined class emulating a file. Note that if a properly matching byte-compiled file (with suffix .pyc or .pyo) exists, it will be used instead of parsing the given source file.

**class NullImporter**(*path_string*)

The NullImporter type is a [PEP 302](https://www.python.org/dev/peps/pep-0302) import hook that handles non-directory path strings by failing to find any modules. Calling this type with an existing directory or empty string raises `ImportError`. Otherwise, a NullImporter instance is returned.

Python adds instances of this type to `sys.path_importer_cache` for any path entries that are not directories and are not handled by any other
path hooks on `sys.path_hooks`. Instances have only one method:

```python
find_module(fullname [, path])
```
This method always returns `None`, indicating that the requested module could not be found.

New in version 2.5.

**Python Library Reference**

Previous: [29. Importing Modules](#) Up: [29. Importing Modules](#) Next: [29.1.1 Examples](#)

Release 2.5, documentation updated on 19th September, 2006.
See [About this document...](#) for information on suggesting changes.
29.1.1 Examples

The following function emulates what was the standard import statement up to Python 1.4 (no hierarchical module names). (This *implementation* wouldn't work in that version, since `find_module()` has been extended and `load_module()` has been added in 1.4.)

```python
import imp
import sys

def __import__(name, globals=None, locals=None, fromlist=None):
    # Fast path: see if the module has already been imported.
    try:
        return sys.modules[name]
    except KeyError:
        pass

    # If any of the following calls raises an exception,
    # there's a problem we can't handle -- let the caller handle it.

    fp, pathname, description = imp.find_module(name)

    try:
        return imp.load_module(name, fp, pathname, description)
    finally:
        # Since we may exit via an exception, close fp explicitly.
        if fp:
            fp.close()
```

A more complete example that implements hierarchical module names and includes a `reload()` function can be found in the module `knee`. The `knee` module can be found in `Demo/imputil/` in the Python source distribution.
29.2 zipimport -- Import modules from Zip archives

New in version 2.3.

This module adds the ability to import Python modules (*.py, *.py[co]) and packages from ZIP-format archives. It is usually not needed to use the `zipimport` module explicitly; it is automatically used by the builtin `import` mechanism for `sys.path` items that are paths to ZIP archives.

Typically, `sys.path` is a list of directory names as strings. This module also allows an item of `sys.path` to be a string naming a ZIP file archive. The ZIP archive can contain a subdirectory structure to support package imports, and a path within the archive can be specified to only import from a subdirectory. For example, the path `/tmp/example.zip/lib/` would only import from the `lib/` subdirectory within the archive.

Any files may be present in the ZIP archive, but only files `.py` and `.py[co]` are available for import. ZIP import of dynamic modules (.pyd, .so) is disallowed. Note that if an archive only contains `.py` files, Python will not attempt to modify the archive by adding the corresponding `.pyc` or `.pyo` file, meaning that if a ZIP archive doesn't contain `.pyc` files, importing may be rather slow.

Using the built-in `reload()` function will fail if called on a module loaded from a ZIP archive; it is unlikely that `reload()` would be needed, since this would imply that the ZIP has been altered during runtime.

The available attributes of this module are:

**exception Zip ImportError**
Exception raised by zipimporter objects. It's a subclass of `ImportError`, so it can be caught as `ImportError`, too.

**class zipimporter**
The class for importing ZIP files. See `}`zipimporter Objects" (section 29.2.1) for constructor details.

Python Library Reference

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
29.2.1 zipimporter Objects

class zipimporter(archivepath)
    Create a new zipimporter instance. archivepath must be a path to a zipfile. ZipImportError is raised if archivepath doesn't point to a valid ZIP archive.

find_module(fullname[, path])
    Search for a module specified by fullname. fullname must be the fully qualified (dotted) module name. It returns the zipimporter instance itself if the module was found, or None if it wasn't. The optional path argument is ignored--it's there for compatibility with the importer protocol.

get_code(fullname)
    Return the code object for the specified module. Raise ZipImportError if the module couldn't be found.

get_data(pathname)
    Return the data associated with pathname. Raise IOError if the file wasn't found.

get_source(fullname)
    Return the source code for the specified module. Raise ZipImportError if the module couldn't be found, return None if the archive does contain the module, but has no source for it.

is_package(fullname)
    Return True if the module specified by fullname is a package. Raise ZipImportError if the module couldn't be found.

load_module(fullname)
    Load the module specified by fullname. fullname must be the fully qualified (dotted) module name. It returns the imported module, or raises ZipImportError if it wasn't found.
29.2.2 Examples

Here is an example that imports a module from a ZIP archive - note that the `zipimport` module is not explicitly used.

```
$ unzip -l /tmp/example.zip
Archive: /tmp/example.zip
   Length   Date   Time    Name
        ----  ----   ----    ----
   8467  11-26-02 22:30    jwzthreading.py

8467        1 file

$ ./python
Python 2.3 (#1, Aug 1 2003, 19:54:32)
>>> import sys
>>> sys.path.insert(0, '/tmp/example.zip')  # Add .zip file to front
>>> import jwzthreading
>>> jwzthreading.__file__
'/tmp/example.zip/jwzthreading.py'
```
29.3 **pkgutil -- Package extension utility**

New in version 2.3.

This module provides a single function:

**extend_path(path, name)**

Extend the search path for the modules which comprise a package. Intended use is to place the following code in a package's __init__.py:

```python
from pkgutil import extend_path
__path__ = extend_path(__path__, __name__)
```

This will add to the package's __path__ all subdirectories of directories on sys.path named after the package. This is useful if one wants to distribute different parts of a single logical package as multiple directories.

It also looks for *.pkg files beginning where * matches the name argument. This feature is similar to *.pth files (see the site module for more information), except that it doesn't special-case lines starting with import. A *.pkg file is trusted at face value: apart from checking for duplicates, all entries found in a *.pkg file are added to the path, regardless of whether they exist on the filesystem. (This is a feature.)

If the input path is not a list (as is the case for frozen packages) it is returned unchanged. The input path is not modified; an extended copy is returned. Items are only appended to the copy at the end.

It is assumed that sys.path is a sequence. Items of sys.path that are not (Unicode or 8-bit) strings referring to existing directories are ignored. Unicode items on sys.path that cause errors when used as filenames may cause this function to raise an exception (in line with os.path.isdir() behavior).
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
29.4 modulefinder -- Find modules used by a script

New in version 2.3.

This module provides a ModuleFinder class that can be used to determine the set of modules imported by a script. modulefinder.py can also be run as a script, giving the filename of a Python script as its argument, after which a report of the imported modules will be printed.

AddPackagePath( pkg_name, path)

Record that the package named pkg_name can be found in the specified path.

ReplacePackage( oldname, newname)

Allows specifying that the module named oldname is in fact the package named newname. The most common usage would be to handle how the _xmlplus package replaces the xml package.

class ModuleFinder( [path=None, debug=0, excludes=[], replace_paths= []])

This class provides run_script() and report() methods to determine the set of modules imported by a script. path can be a list of directories to search for modules; if not specified, sys.path is used. debug sets the debugging level; higher values make the class print debugging messages about what it's doing. excludes is a list of module names to exclude from the analysis. replace_paths is a list of (oldpath, newpath) tuples that will be replaced in module paths.

report()

Print a report to standard output that lists the modules imported by the script and their paths, as well as modules that are missing or seem to be missing.
run_script(pathname)

Analyze the contents of the pathname file, which must contain Python code.
29.5 runpy -- Locating and executing Python modules.

New in version 2.5.

The runpy module is used to locate and run Python modules without importing them first. Its main use is to implement the -m command line switch that allows scripts to be located using the Python module namespace rather than the filesystem.

When executed as a script, the module effectively operates as follows:

```python
del sys.argv[0]  # Remove the runpy module from the arguments
run_module(sys.argv[0], run_name="__main__", alter_sys=True)
```

The runpy module provides a single function:

```python
run_module(mod_name[, init_globals][, run_name][, alter_sys])
```

Execute the code of the specified module and return the resulting module globals dictionary. The module's code is first located using the standard import mechanism (refer to PEP 302 for details) and then executed in a fresh module namespace.

The optional dictionary argument init_globals may be used to pre-populate the globals dictionary before the code is executed. The supplied dictionary will not be modified. If any of the special global variables below are defined in the supplied dictionary, those definitions are overridden by the run_module function.

The special global variables __name__, __file__, __loader__ and __builtins__ are set in the globals dictionary before the module code is executed.

__name__ is set to run_name if this optional argument is supplied, and the mod_name argument otherwise.
__loader__ is set to the PEP 302 module loader used to retrieve the code for the module (This loader may be a wrapper around the standard import mechanism).

__file__ is set to the name provided by the module loader. If the loader does not make filename information available, this variable is set to None.

__builtins__ is automatically initialised with a reference to the top level namespace of the __builtin__ module.

If the argument alter_sys is supplied and evaluates to True, then sys.argv[0] is updated with the value of __file__ and sys.modules[__name__] is updated with a temporary module object for the module being executed. Both sys.argv[0] and sys.modules[__name__] are restored to their original values before the function returns.

Note that this manipulation of sys is not thread-safe. Other threads may see the partially initialised module, as well as the altered list of arguments. It is recommended that the sys module be left alone when invoking this function from threaded code.

PEP 338, Executing modules as scripts
PEP written and implemented by Nick Coghlan.
30. Python Language Services

Python provides a number of modules to assist in working with the Python language. These modules support tokenizing, parsing, syntax analysis, bytecode disassembly, and various other facilities.

These modules include:

- **parser**: Access parse trees for Python source code.
- **symbol**: Constants representing internal nodes of the parse tree.
- **token**: Constants representing terminal nodes of the parse tree.
- **keyword**: Test whether a string is a keyword in Python.
- **tokenizer**: Lexical scanner for Python source code.
- **tabnanny**: Tool for detecting white space related problems in Python source files in a directory tree.
- **pyclbr**: Supports information extraction for a Python class browser.
- **py_compile**: Compile Python source files to byte-code files.
- **compileall**: Tools for byte-compiling all Python source files in a directory tree.
- **dis**: Disassembler for Python byte code.
- **pickletools**: Contains extensive comments about the pickle protocols and pickle-machine opcodes, as well as some useful functions.
- **distutils**: Support for building and installing Python modules into an existing Python installation.
30.1 parser -- Access Python parse trees

The parser module provides an interface to Python's internal parser and byte-code compiler. The primary purpose for this interface is to allow Python code to edit the parse tree of a Python expression and create executable code from this. This is better than trying to parse and modify an arbitrary Python code fragment as a string because parsing is performed in a manner identical to the code forming the application. It is also faster.

There are a few things to note about this module which are important to making use of the data structures created. This is not a tutorial on editing the parse trees for Python code, but some examples of using the parser module are presented.

Most importantly, a good understanding of the Python grammar processed by the internal parser is required. For full information on the language syntax, refer to the Python Language Reference. The parser itself is created from a grammar specification defined in the file Grammar/Grammar in the standard Python distribution. The parse trees stored in the AST objects created by this module are the actual output from the internal parser when created by the expr() or suite() functions, described below. The AST objects created by sequence2ast() faithfully simulate those structures. Be aware that the values of the sequences which are considered "correct" will vary from one version of Python to another as the formal grammar for the language is revised. However, transporting code from one Python version to another as source text will always allow correct parse trees to be created in the target version, with the only restriction being that migrating to an older version of the interpreter will not support more recent language constructs. The parse trees are not typically compatible from one version to another, whereas source code has always been forward-compatible.

Each element of the sequences returned by ast2list() or ast2tuple() has a simple form. Sequences representing non-terminal elements in the grammar always have a length greater than one. The first element is an integer which identifies a production in the grammar. These integers are given symbolic names in the C header file Include/graminit.h and the Python module symbol1.
Each additional element of the sequence represents a component of the production as recognized in the input string: these are always sequences which have the same form as the parent. An important aspect of this structure which should be noted is that keywords used to identify the parent node type, such as the keyword `if` in an `if_stmt`, are included in the node tree without any special treatment. For example, the `if` keyword is represented by the tuple `(1, 'if')`, where 1 is the numeric value associated with all `NAME` tokens, including variable and function names defined by the user. In an alternate form returned when line number information is requested, the same token might be represented as `(1, 'if', 12)`, where the 12 represents the line number at which the terminal symbol was found.

Terminal elements are represented in much the same way, but without any child elements and the addition of the source text which was identified. The example of the `if` keyword above is representative. The various types of terminal symbols are defined in the C header file `Include/token.h` and the Python module `token`.

The AST objects are not required to support the functionality of this module, but are provided for three purposes: to allow an application to amortize the cost of processing complex parse trees, to provide a parse tree representation which conserves memory space when compared to the Python list or tuple representation, and to ease the creation of additional modules in C which manipulate parse trees. A simple ``wrapper`` class may be created in Python to hide the use of AST objects.

The parser module defines functions for a few distinct purposes. The most important purposes are to create AST objects and to convert AST objects to other representations such as parse trees and compiled code objects, but there are also functions which serve to query the type of parse tree represented by an AST object.

**See Also:**

Module `symbol`:
Useful constants representing internal nodes of the parse tree.

Module `token`:
Useful constants representing leaf nodes of the parse tree and functions for testing node values.

  - 30.1.6.2 Information Discovery

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
30.1.1 Creating AST Objects

AST objects may be created from source code or from a parse tree. When creating an AST object from source, different functions are used to create the 'eval' and 'exec' forms.

expr(source)

The expr() function parses the parameter source as if it were an input to "compile(source, 'file.py', 'eval')". If the parse succeeds, an AST object is created to hold the internal parse tree representation, otherwise an appropriate exception is thrown.

suite(source)

The suite() function parses the parameter source as if it were an input to "compile(source, 'file.py', 'exec')". If the parse succeeds, an AST object is created to hold the internal parse tree representation, otherwise an appropriate exception is thrown.

sequence2ast(sequence)

This function accepts a parse tree represented as a sequence and builds an internal representation if possible. If it can validate that the tree conforms to the Python grammar and all nodes are valid node types in the host version of Python, an AST object is created from the internal representation and returned to the called. If there is a problem creating the internal representation, or if the tree cannot be validated, a ParserError exception is thrown. An AST object created this way should not be assumed to compile correctly; normal exceptions thrown by compilation may still be initiated when the AST object is passed to compileast(). This may indicate problems not related to syntax (such as a MemoryError exception), but may also be due to constructs such as the result of parsing del f(0), which escapes the Python parser but is checked by the bytecode compiler.

Sequences representing terminal tokens may be represented as either two-element lists of the form (1, 'name') or as three-element lists of the form (1, 'name', 56). If the third element is present, it is assumed to
be a valid line number. The line number may be specified for any subset of the terminal symbols in the input tree.

**tuple2ast**(*sequence*)

This is the same function as `sequence2ast()`. This entry point is maintained for backward compatibility.
30.1.2 Converting AST Objects

AST objects, regardless of the input used to create them, may be converted to parse trees represented as list- or tuple- trees, or may be compiled into executable code objects. Parse trees may be extracted with or without line numbering information.

\texttt{ast2list( ast[, line\_info])}

This function accepts an AST object from the caller in \texttt{ast} and returns a Python list representing the equivalent parse tree. The resulting list representation can be used for inspection or the creation of a new parse tree in list form. This function does not fail so long as memory is available to build the list representation. If the parse tree will only be used for inspection, \texttt{ast2tuple()} should be used instead to reduce memory consumption and fragmentation. When the list representation is required, this function is significantly faster than retrieving a tuple representation and converting that to nested lists.

If \texttt{line\_info} is true, line number information will be included for all terminal tokens as a third element of the list representing the token. Note that the line number provided specifies the line on which the token \textit{ends}. This information is omitted if the flag is false or omitted.

\texttt{ast2tuple( ast[, line\_info])}

This function accepts an AST object from the caller in \texttt{ast} and returns a Python tuple representing the equivalent parse tree. Other than returning a tuple instead of a list, this function is identical to \texttt{ast2list()}. If \texttt{line\_info} is true, line number information will be included for all terminal tokens as a third element of the list representing the token. This information is omitted if the flag is false or omitted.

\texttt{compileast( ast[, filename  =  '<ast>'])}

The Python byte compiler can be invoked on an AST object to produce code objects which can be used as part of an \texttt{exec} statement or a call to the built-in \texttt{eval()} function. This function provides the interface to the
compiler, passing the internal parse tree from \textit{ast} to the parser, using the source file name specified by the \textit{filename} parameter. The default value supplied for \textit{filename} indicates that the source was an AST object.

Compiling an AST object may result in exceptions related to compilation; an example would be a \texttt{SyntaxError} caused by the parse tree for \texttt{del f(\theta)}: this statement is considered legal within the formal grammar for Python but is not a legal language construct. The \texttt{SyntaxError} raised for this condition is actually generated by the Python byte-compiler normally, which is why it can be raised at this point by the \texttt{parser} module. Most causes of compilation failure can be diagnosed programmatically by inspection of the parse tree.
30.1.3 Queries on AST Objects

Two functions are provided which allow an application to determine if an AST was created as an expression or a suite. Neither of these functions can be used to determine if an AST was created from source code via `expr()` or `suite()` or from a parse tree via `sequence2ast()`.

**isexpr (ast)**

When `ast` represents an 'eval' form, this function returns true, otherwise it returns false. This is useful, since code objects normally cannot be queried for this information using existing built-in functions. Note that the code objects created by `compileast()` cannot be queried like this either, and are identical to those created by the built-in `compile()` function.

**issuite (ast)**

This function mirrors `isexpr()` in that it reports whether an AST object represents an 'exec' form, commonly known as a ``suite.'' It is not safe to assume that this function is equivalent to "not isexpr(ast)", as additional syntactic fragments may be supported in the future.
30.1.4 Exceptions and Error Handling

The parser module defines a single exception, but may also pass other built-in exceptions from other portions of the Python runtime environment. See each function for information about the exceptions it can raise.

**exception ParserError**

Exception raised when a failure occurs within the parser module. This is generally produced for validation failures rather than the built in SyntaxError thrown during normal parsing. The exception argument is either a string describing the reason of the failure or a tuple containing a sequence causing the failure from a parse tree passed to sequence2ast() and an explanatory string. Calls to sequence2ast() need to be able to handle either type of exception, while calls to other functions in the module will only need to be aware of the simple string values.

Note that the functions compileast(), expr(), and suite() may throw exceptions which are normally thrown by the parsing and compilation process. These include the built in exceptions MemoryError, OverflowError, SyntaxError, and SystemError. In these cases, these exceptions carry all the meaning normally associated with them. Refer to the descriptions of each function for detailed information.
30.1.5 AST Objects

Ordered and equality comparisons are supported between AST objects. Pickling of AST objects (using the pickle module) is also supported.

ASTType
The type of the objects returned by expr(), suite() and sequence2ast().

AST objects have the following methods:

compile([filename])
Same as compileast(ast, filename).

isexpr()
Same as isexpr(ast).

issuite()
Same as issuite(ast).

tolist([line_info])
Same as ast2list(ast, line_info).

totuple([line_info])
Same as ast2tuple(ast, line_info).
30.1.6 Examples

The parser modules allows operations to be performed on the parse tree of Python source code before the bytecode is generated, and provides for inspection of the parse tree for information gathering purposes. Two examples are presented. The simple example demonstrates emulation of the `compile()` built-in function and the complex example shows the use of a parse tree for information discovery.

Subsections

- 30.1.6.1 Emulation of `compile()`
- 30.1.6.2 Information Discovery
30.2 symbol -- Constants used with Python parse trees

This module provides constants which represent the numeric values of internal nodes of the parse tree. Unlike most Python constants, these use lower-case names. Refer to the file Grammar/Grammar in the Python distribution for the definitions of the names in the context of the language grammar. The specific numeric values which the names map to may change between Python versions.

This module also provides one additional data object:

**sym_name**

Dictionary mapping the numeric values of the constants defined in this module back to name strings, allowing more human-readable representation of parse trees to be generated.

See Also:

Module **parser**: The second example for the **parser** module shows how to use the **symbol** module.

---

Release 2.5, documentation updated on 19th September, 2006. 
See **About this document...** for information on suggesting changes.
30.3 token -- Constants used with Python parse trees

This module provides constants which represent the numeric values of leaf nodes of the parse tree (terminal tokens). Refer to the file Grammar/Grammar in the Python distribution for the definitions of the names in the context of the language grammar. The specific numeric values which the names map to may change between Python versions.

This module also provides one data object and some functions. The functions mirror definitions in the Python C header files.

**tok_name**
Dictionary mapping the numeric values of the constants defined in this module back to name strings, allowing more human-readable representation of parse trees to be generated.

**ISTERMINAL**(x)
Return true for terminal token values.

**ISNONTERMINAL**(x)
Return true for non-terminal token values.

**ISEOF**(x)
Return true if x is the marker indicating the end of input.

### See Also:
Module [parser](#)
The second example for the [parser](#) module shows how to use the [symbol](#) module.
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
30.4 keyword -- Testing for Python keywords

This module allows a Python program to determine if a string is a keyword.

**iskeyword**(*s*)

Return true if *s* is a Python keyword.

**kwlist**

Sequence containing all the keywords defined for the interpreter. If any keywords are defined to only be active when particular __future__ statements are in effect, these will be included as well.
30.5 tokenize -- Tokenizer for Python source

The `tokenize` module provides a lexical scanner for Python source code, implemented in Python. The scanner in this module returns comments as tokens as well, making it useful for implementing ``pretty-printers," including colorizers for on-screen displays.

The primary entry point is a generator:

```
generate_tokens( readline)
```

The `generate_tokens()` generator requires one argument, `readline`, which must be a callable object which provides the same interface as the `readline()` method of built-in file objects (see section 3.9). Each call to the function should return one line of input as a string.

The generator produces 5-tuples with these members: the token type; the token string; a 2-tuple (`srow`, `scol`) of ints specifying the row and column where the token begins in the source; a 2-tuple (`erow`, `ecol`) of ints specifying the row and column where the token ends in the source; and the line on which the token was found. The line passed is the `logical` line; continuation lines are included. New in version 2.2.

An older entry point is retained for backward compatibility:

```
tokenize( readline[, tokeneater])
```

The `tokenize()` function accepts two parameters: one representing the input stream, and one providing an output mechanism for `tokenize()`.

The first parameter, `readline`, must be a callable object which provides the same interface as the `readline()` method of built-in file objects (see section 3.9). Each call to the function should return one line of input as a string. Alternately, `readline` may be a callable object that signals completion by raising `StopIteration`. Changed in version 2.5: Added `StopIteration` support.
The second parameter, *tokeneater*, must also be a callable object. It is called once for each token, with five arguments, corresponding to the tuples generated by `generate_tokens()`.

All constants from the `token` module are also exported from `tokenize`, as are two additional token type values that might be passed to the `tokeneater` function by `tokenize()`:

**COMMENT**
Token value used to indicate a comment.

**NL**
Token value used to indicate a non-terminating newline. The NEWLINE token indicates the end of a logical line of Python code; NL tokens are generated when a logical line of code is continued over multiple physical lines.

Another function is provided to reverse the tokenization process. This is useful for creating tools that tokenize a script, modify the token stream, and write back the modified script.

**untokenize( iterable)**
Converts tokens back into Python source code. The *iterable* must return sequences with at least two elements, the token type and the token string. Any additional sequence elements are ignored.

The reconstructed script is returned as a single string. The result is guaranteed to tokenize back to match the input so that the conversion is lossless and round-trips are assured. The guarantee applies only to the token type and token string as the spacing between tokens (column positions) may change. New in version 2.5.

Example of a script re-writer that transforms float literals into Decimal objects:

```python
def decistmt(s):
    """Substitute Decimals for floats in a string of statements."

    >>> from decimal import Decimal
    >>> s = 'print +21.3e-5*- .1234/81.7'
    >>> decistmt(s)
    "print +Decimal ('21.3e-5')*-Decimal ('.1234')/Decimal ('81.7')"```
>>> exec(s)
-3.21716034272e-007
>>> exec(decistmt(s))
-3.217160342717258261933904529E-7

""
result = []
g = generate_tokens(StringIO(s).readline)  # tokenize the string
for toknum, tokval, _, _, _ in g:
    if toknum == NUMBER and '.' in tokval:  # replace NUMBER tok
        result.extend([
            (NAME, 'Decimal'),
            (OP, '('),
            (STRING, repr(tokval)),
            (OP, ')')
        ])  
else:
    result.append((toknum, tokval))
return untokenize(result)

---

Python Library Reference

Previous: 30.4 keyword Up: 30. Python Language Services Next: 30.6 tabnanny

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
30.6 tabnanny -- Detection of ambiguous indentation

For the time being this module is intended to be called as a script. However it is possible to import it into an IDE and use the function check() described below.

**Warning:** The API provided by this module is likely to change in future releases; such changes may not be backward compatible.

```python
def check(file_or_dir):
    if file_or_dir is a directory and not a symbolic link, then recursively descend the directory tree named by file_or_dir, checking all .py files along the way. If file_or_dir is an ordinary Python source file, it is checked for whitespace related problems. The diagnostic messages are written to standard output using the print statement.
```

**verbose**
Flag indicating whether to print verbose messages. This is incremented by the -v option if called as a script.

**filename_only**
Flag indicating whether to print only the filenames of files containing whitespace related problems. This is set to true by the -q option if called as a script.

**exception NannyNag**
Raised by token eater() if detecting an ambiguous indent. Captured and handled in check().

```python
def token eater(type, token, start, end, line):
    This function is used by check() as a callback parameter to the function tokenize.tokenize().
```
See Also:

Module **tokenize**:  
Lexical scanner for Python source code.
30.7 pyc1br -- Python class browser support

The pyc1br can be used to determine some limited information about the classes, methods and top-level functions defined in a module. The information provided is sufficient to implement a traditional three-pane class browser. The information is extracted from the source code rather than by importing the module, so this module is safe to use with untrusted source code. This restriction makes it impossible to use this module with modules not implemented in Python, including many standard and optional extension modules.

readmodule( module[, path])

Read a module and return a dictionary mapping class names to class descriptor objects. The parameter module should be the name of a module as a string; it may be the name of a module within a package. The path parameter should be a sequence, and is used to augment the value of sys.path, which is used to locate module source code.

readmodule_ex( module[, path])

Like readmodule(), but the returned dictionary, in addition to mapping class names to class descriptor objects, also maps top-level function names to function descriptor objects. Moreover, if the module being read is a package, the key '__path__' in the returned dictionary has as its value a list which contains the package search path.
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
30.7.1 Class Descriptor Objects

The class descriptor objects used as values in the dictionary returned by readmodule() and readmodule_ex() provide the following data members:

**module**
The name of the module defining the class described by the class descriptor.

**name**
The name of the class.

**super**
A list of class descriptors which describe the immediate base classes of the class being described. Classes which are named as superclasses but which are not discoverable by readmodule() are listed as a string with the class name instead of class descriptors.

**methods**
A dictionary mapping method names to line numbers.

**file**
Name of the file containing the class statement defining the class.

**lineno**
The line number of the class statement within the file named by file.
30.7.2 Function Descriptor Objects

The function descriptor objects used as values in the dictionary returned by `readmodule_ex()` provide the following data members:

- **module**
  The name of the module defining the function described by the function descriptor.

- **name**
  The name of the function.

- **file**
  Name of the file containing the `def` statement defining the function.

- **lineno**
  The line number of the `def` statement within the file named by `file`.

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
30.8 py_compile -- Compile Python source files

The py_compile module provides a function to generate a byte-code file from a source file, and another function used when the module source file is invoked as a script.

Though not often needed, this function can be useful when installing modules for shared use, especially if some of the users may not have permission to write the byte-code cache files in the directory containing the source code.

**exception PyCompileError**

Exception raised when an error occurs while attempting to compile the file.

**compile**(*file*, *cfile*, *dfile*, *doraise*)

Compile a source file to byte-code and write out the byte-code cache file. The source code is loaded from the file name `file`. The byte-code is written to `cfile`, which defaults to `file + 'c'` ("o" if optimization is enabled in the current interpreter). If `dfile` is specified, it is used as the name of the source file in error messages instead of `file`. If `doraise` is true, a PyCompileError is raised when an error is encountered while compiling `file`. If `doraise` is false (the default), an error string is written to `sys.stderr`, but no exception is raised.

**main**(*args*)

Compile several source files. The files named in `args` (or on the command line, if `args` is not specified) are compiled and the resulting bytecode is cached in the normal manner. This function does not search a directory structure to locate source files; it only compiles files named explicitly.

When this module is run as a script, the `main()` is used to compile all the files named on the command line.

**See Also:**
Module **compileall**: Utilities to compile all Python source files in a directory tree.
30.9 compileall -- Byte-compile Python libraries

This module provides some utility functions to support installing Python libraries. These functions compile Python source files in a directory tree, allowing users without permission to write to the libraries to take advantage of cached byte-code files.

The source file for this module may also be used as a script to compile Python sources in directories named on the command line or in sys.path.

**compile_dir** *(dir[, maxlevels[, ddir[, force[, rx[, quiet]]]]])*  
Recursively descend the directory tree named by *dir*, compiling all .py files along the way. The *maxlevels* parameter is used to limit the depth of the recursion; it defaults to 10. If *ddir* is given, it is used as the base path from which the filenames used in error messages will be generated. If *force* is true, modules are re-compiled even if the timestamps are up to date.

If *rx* is given, it specifies a regular expression of file names to exclude from the search; that expression is searched for in the full path.

If *quiet* is true, nothing is printed to the standard output in normal operation.

**compile_path** *( [skip_curdir[, maxlevels[, force]]] )*  
Byte-compile all the .py files found along sys.path. If *skip_curdir* is true (the default), the current directory is not included in the search. The *maxlevels* and *force* parameters default to 0 and are passed to the **compile_dir()** function.

To force a recompile of all the .py files in the Lib/ subdirectory and all its subdirectories:

```python
import compileall
compileall.compile_dir('Lib/', force=True)
```
# Perform same compilation, excluding files in .svn directories.
import re
compileall.compile_dir('Lib/', rx=re.compile('/\.[.]svn'), force=True)

See Also:

Module **py_compile**:

Byte-compile a single source file.
30.10 dis -- Disassembler for Python byte code

The dis module supports the analysis of Python byte code by disassembling it. Since there is no Python assembler, this module defines the Python assembly language. The Python byte code which this module takes as an input is defined in the file Include/opcode.h and used by the compiler and the interpreter.

Example: Given the function myfunc:

```python
def myfunc(alist):
    return len(alist)
```

the following command can be used to get the disassembly of `myfunc()`:

```python
>>> dis.dis(myfunc)
  2          0 LOAD_GLOBAL              0 (len)
  3          0 LOAD_FAST               0 (alist)
  6 CALL_FUNCTION                      1
  9 RETURN_VALUE
```

(The ``2'' is a line number).

The dis module defines the following functions and constants:

```python
dis([bytesource])
```

Disassemble the bytesource object. bytesource can denote either a module, a class, a method, a function, or a code object. For a module, it disassembles all functions. For a class, it disassembles all methods. For a single code sequence, it prints one line per byte code instruction. If no object is provided, it disassembles the last traceback.

```python
distb([tb])
```

Disassembles the top-of-stack function of a traceback, using the last traceback if none was passed. The instruction causing the exception is indicated.
disassemble(code[, lasti])
Disassembles a code object, indicating the last instruction if lasti was provided. The output is divided in the following columns:

1. the line number, for the first instruction of each line
2. the current instruction, indicated as "\-\-\>",
3. a labelled instruction, indicated with "\>>",
4. the address of the instruction,
5. the operation code name,
6. operation parameters, and
7. interpretation of the parameters in parentheses.

The parameter interpretation recognizes local and global variable names, constant values, branch targets, and compare operators.

disco(code[, lasti])
A synonym for disassemble. It is more convenient to type, and kept for compatibility with earlier Python releases.

opname
Sequence of operation names, indexable using the byte code.

opmap
Dictionary mapping byte codes to operation names.

cmp_op
Sequence of all compare operation names.

hasconst
Sequence of byte codes that have a constant parameter.

hasfree
Sequence of byte codes that access a free variable.

hasname
Sequence of byte codes that access an attribute by name.

hasjrel
Sequence of byte codes that have a relative jump target.
hasjabs
Sequence of byte codes that have an absolute jump target.

haslocal
Sequence of byte codes that access a local variable.

hascompare
Sequence of byte codes of Boolean operations.

Subsections

- 30.10.1 Python Byte Code Instructions
30.10.1 Python Byte Code Instructions

The Python compiler currently generates the following byte code instructions.

**STOP_CODE**
Indicates end-of-code to the compiler, not used by the interpreter.

**NOP**
Do nothing code. Used as a placeholder by the bytecode optimizer.

**POP_TOP**
Removes the top-of-stack (TOS) item.

**ROT_TWO**
Swaps the two top-most stack items.

**ROT_THREE**
Lifts second and third stack item one position up, moves top down to position three.

**ROT_FOUR**
Lifts second, third and forth stack item one position up, moves top down to position four.

**DUP_TOP**
Duplicates the reference on top of the stack.

Unary Operations take the top of the stack, apply the operation, and push the result back on the stack.

**UNARY_POSITIVE**
Implements TOS = +TOS.

**UNARY_NEGATIVE**
Implements TOS = -TOS.

**UNARY_NOT**
Implements TOS = not TOS.
UNARY_CONVERT
   Implements TOS = `TOS`.

UNARY_INVERT
   Implements TOS = ~TOS.

GET_ITER
   Implements TOS = iter(TOS).

Binary operations remove the top of the stack (TOS) and the second top-most stack item (TOS1) from the stack. They perform the operation, and put the result back on the stack.

BINARY_POWER
   Implements TOS = TOS1 ** TOS.

BINARY_MULTIPLY
   Implements TOS = TOS1 * TOS.

BINARY_DIVIDE
   Implements TOS = TOS1 / TOS when from __future__ import division is not in effect.

BINARY_FLOOR_DIVIDE
   Implements TOS = TOS1 // TOS.

BINARY_TRUE_DIVIDE
   Implements TOS = TOS1 / TOS when from __future__ import division is in effect.

BINARY_MODULO
   Implements TOS = TOS1 % TOS.

BINARY_ADD
   Implements TOS = TOS1 + TOS.

BINARY_SUBTRACT
   Implements TOS = TOS1 - TOS.

BINARY_SUBSCR
Implements \( \text{TOS} = \text{TOS1}[\text{TOS}] \).

**BINARY_LSHIFT**
Implements \( \text{TOS} = \text{TOS1} \ll \text{TOS} \).

**BINARY_RSHIFT**
Implements \( \text{TOS} = \text{TOS1} \gg \text{TOS} \).

**BINARY_AND**
Implements \( \text{TOS} = \text{TOS1} & \text{TOS} \).

**BINARY_XOR**
Implements \( \text{TOS} = \text{TOS1} ^ \text{TOS} \).

**BINARY_OR**
Implements \( \text{TOS} = \text{TOS1} | \text{TOS} \).

In-place operations are like binary operations, in that they remove TOS and TOS1, and push the result back on the stack, but the operation is done in-place when TOS1 supports it, and the resulting TOS may be (but does not have to be) the original TOS1.

**INPLACE_POWER**
Implements in-place \( \text{TOS} = \text{TOS1} ** \text{TOS} \).

**INPLACE_MULTIPLY**
Implements in-place \( \text{TOS} = \text{TOS1} * \text{TOS} \).

**INPLACE_DIVIDE**
Implements in-place \( \text{TOS} = \text{TOS1} / \text{TOS} \) when \text{from \_\_future\_} \text{import \ division} \) is not in effect.

**INPLACE_FLOOR_DIVIDE**
Implements in-place \( \text{TOS} = \text{TOS1} // \text{TOS} \).

**INPLACE_TRUE_DIVIDE**
Implements in-place \( \text{TOS} = \text{TOS1} / \text{TOS} \) when \text{from \_\_future\_} \text{import \ division} \) is in effect.

**INPLACE_MODULO**
Implements in-place \( \text{TOS} = \text{TOS1} \mod \text{TOS} \).

**INPLACE_ADD**
Implements in-place \( \text{TOS} = \text{TOS1} + \text{TOS} \).

**INPLACE_SUBTRACT**
Implements in-place \( \text{TOS} = \text{TOS1} - \text{TOS} \).

**INPLACE_LSHIFT**
Implements in-place \( \text{TOS} = \text{TOS1} \ll \text{TOS} \).

**INPLACE_RSHIFT**
Implements in-place \( \text{TOS} = \text{TOS1} \gg \text{TOS} \).

**INPLACE_AND**
Implements in-place \( \text{TOS} = \text{TOS1} \& \text{TOS} \).

**INPLACE_XOR**
Implements in-place \( \text{TOS} = \text{TOS1} \^ \text{TOS} \).

**INPLACE_OR**
Implements in-place \( \text{TOS} = \text{TOS1} \mid \text{TOS} \).

The slice opcodes take up to three parameters.

**SLICE+0**
Implements \( \text{TOS} = \text{TOS}[\cdot:] \).

**SLICE+1**
Implements \( \text{TOS} = \text{TOS1}[\text{TOS}:] \).

**SLICE+2**
Implements \( \text{TOS} = \text{TOS1}[\cdot:\text{TOS}] \).

**SLICE+3**
Implements \( \text{TOS} = \text{TOS2}[\text{TOS1}:	ext{TOS}] \).

Slice assignment needs even an additional parameter. As any statement, they put nothing on the stack.
STORE_SLICE+0
  Implements TOS[:] = TOS1.

STORE_SLICE+1
  Implements TOS1[TOS:] = TOS2.

STORE_SLICE+2
  Implements TOS1[:TOS] = TOS2.

STORE_SLICE+3
  Implements TOS2[TOS1:TOS] = TOS3.

DELETE_SLICE+0
  Implements del TOS[:].

DELETE_SLICE+1
  Implements del TOS1[TOS:].

DELETE_SLICE+2
  Implements del TOS1[:TOS].

DELETE_SLICE+3
  Implements del TOS2[TOS1:TOS].

STORE_SUBSCR
  Implements TOS1[TOS] = TOS2.

DELETE_SUBSCR
  Implements del TOS1[TOS].

Miscellaneous opcodes.

PRINT_EXPR
  Implements the expression statement for the interactive mode. TOS is removed from the stack and printed. In non-interactive mode, an expression statement is terminated with POP_STACK.

PRINT_ITEM
  Prints TOS to the file-like object bound to sys.stdout. There is one such instruction for each item in the print statement.
PRINT_ITEM_TO
Like PRINT_ITEM, but prints the item second from TOS to the file-like object at TOS. This is used by the extended print statement.

PRINT_NEWLINE
Prints a new line on sys.stdout. This is generated as the last operation of a print statement, unless the statement ends with a comma.

PRINT_NEWLINE_TO
Like PRINT_NEWLINE, but prints the new line on the file-like object on the TOS. This is used by the extended print statement.

BREAK_LOOP
Terminates a loop due to a break statement.

CONTINUE_LOOP  target
Continues a loop due to a continue statement. target is the address to jump to (which should be a FOR_ITER instruction).

LIST_APPEND
Calls list.append(TOS1, TOS). Used to implement list comprehensions.

LOAD_LOCALS
Pushes a reference to the locals of the current scope on the stack. This is used in the code for a class definition: After the class body is evaluated, the locals are passed to the class definition.

RETURN_VALUE
Returns with TOS to the caller of the function.

YIELD_VALUE
Pops TOS and yields it from a generator.

IMPORT_STAR
Loads all symbols not starting with "_" directly from the module TOS to the local namespace. The module is popped after loading all names. This opcode implements from module import *.
**EXEC_STMT**
Implements `exec TOS2, TOS1, TOS`. The compiler fills missing optional parameters with `None`.

**POP_BLOCK**
Removes one block from the block stack. Per frame, there is a stack of blocks, denoting nested loops, try statements, and such.

**END_FINALLY**
Terminates a `finally` clause. The interpreter recalls whether the exception has to be re-raised, or whether the function returns, and continues with the outer-next block.

**BUILD_CLASS**
Creates a new class object. TOS is the methods dictionary, TOS1 the tuple of the names of the base classes, and TOS2 the class name.

All of the following opcodes expect arguments. An argument is two bytes, with the more significant byte last.

**STORE_NAME**  `namei`
Implements `name = TOS`. `namei` is the index of `name` in the attribute `co_names` of the code object. The compiler tries to use `STORE_LOCAL` or `STORE_GLOBAL` if possible.

**DELETE_NAME**  `namei`
Implements `del name`, where `namei` is the index into `co_names` attribute of the code object.

**UNPACK_SEQUENCE**  `count`
Unpacks TOS into `count` individual values, which are put onto the stack right-to-left.

**DUP_TOPX**  `count`
Duplicate `count` items, keeping them in the same order. Due to implementation limits, `count` should be between 1 and 5 inclusive.

**STORE_ATTR**  `namei`
Implements `TOS.name = TOS1`, where `namei` is the index of name in
co_names.

**DELETE_ATTR**  *namei*
Implements `del TOS.name`, using `namei` as index into `co_names`.

**STORE_GLOBAL**  *namei*
Works as **STORE_NAME**, but stores the name as a global.

**DELETE_GLOBAL**  *namei*
Works as **DELETE_NAME**, but deletes a global name.

**LOAD_CONST**  *consti*
Pushes "co_consts[*consti]" onto the stack.

**LOAD_NAME**  *namei*
Pushes the value associated with "co_names[*namei]" onto the stack.

**BUILD_TUPLE**  *count*
Creates a tuple consuming *count* items from the stack, and pushes the resulting tuple onto the stack.

**BUILD_LIST**  *count*
Works as **BUILD_TUPLE**, but creates a list.

**BUILD_MAP**  *zero*
Pushes a new empty dictionary object onto the stack. The argument is ignored and set to zero by the compiler.

**LOAD_ATTR**  *namei*
Replaces TOS with `getattr(TOS, co_names[*namei])`.

**COMPARE_OP**  *opname*
Performs a Boolean operation. The operation name can be found in `cmp_op[*opname]`.

**IMPORT_NAME**  *namei*
Imports the module `co_names[*namei]`. The module object is pushed onto the stack. The current namespace is not affected: for a proper import statement, a subsequent **STORE_FAST** instruction modifies the namespace.
**IMPORT_FROM**  *namei*
Loads the attribute `co_names[*namei*]` from the module found in TOS. The resulting object is pushed onto the stack, to be subsequently stored by a `STORE_FAST` instruction.

**JUMP_FORWARD**  *delta*
Increments byte code counter by `delta`.

**JUMP_IF_TRUE**  *delta*
If TOS is true, increment the byte code counter by `delta`. TOS is left on the stack.

**JUMP_IF_FALSE**  *delta*
If TOS is false, increment the byte code counter by `delta`. TOS is not changed.

**JUMP_ABSOLUTE**  *target*
Set byte code counter to `target`.

**FOR_ITER**  *delta*
TOS is an iterator. Call its `next()` method. If this yields a new value, push it on the stack (leaving the iterator below it). If the iterator indicates it is exhausted TOS is popped, and the byte code counter is incremented by `delta`.

**LOAD_GLOBAL**  *namei*
 Loads the global named `co_names[*namei*]` onto the stack.

**SETUP_LOOP**  *delta*
Pushes a block for a loop onto the block stack. The block spans from the current instruction with a size of `delta` bytes.

**SETUP_EXCEPT**  *delta*
Pushes a try block from a try-except clause onto the block stack. `delta` points to the first except block.

**SETUP_FINALLY**  *delta*
Pushes a try block from a try-except clause onto the block stack. `delta` points to the finally block.
LOAD_FAST  var_num
    Pushes a reference to the local co_varnames[var_num] onto the stack.

STORE_FAST  var_num
    Stores TOS into the local co_varnames[var_num].

DELETE_FAST  var_num
    Deletes local co_varnames[var_num].

LOAD_CLOSURE  i
    Pushes a reference to the cell contained in slot i of the cell and free variable storage. The name of the variable is co_cellvars[i] if i is less than the length of co_cellvars. Otherwise it is co_freevars[i - len(co_cellvars)].

LOAD_DEREF  i
    Loads the cell contained in slot i of the cell and free variable storage. Pushes a reference to the object the cell contains on the stack.

STORE_DEREF  i
    Stores TOS into the cell contained in slot i of the cell and free variable storage.

SET_LINENO  lineno
    This opcode is obsolete.

RAISE_VARARGS  argc
    Raises an exception. argc indicates the number of parameters to the raise statement, ranging from 0 to 3. The handler will find the traceback as TOS2, the parameter as TOS1, and the exception as TOS.

CALL_FUNCTION  argc
    Calls a function. The low byte of argc indicates the number of positional parameters, the high byte the number of keyword parameters. On the stack, the opcode finds the keyword parameters first. For each keyword argument, the value is on top of the key. Below the keyword parameters, the positional parameters are on the stack, with the right-most parameter on top. Below the parameters, the function object to call is on the stack.
MAKE_FUNCTION  argc
Pushes a new function object on the stack. TOS is the code associated with the function. The function object is defined to have argc default parameters, which are found below TOS.

MAKE_CLOSURE  argc
Creates a new function object, sets its func_closure slot, and pushes it on the stack. TOS is the code associated with the function. If the code object has N free variables, the next N items on the stack are the cells for these variables. The function also has argc default parameters, where are found before the cells.

BUILD_SLICE  argc
Pushes a slice object on the stack. argc must be 2 or 3. If it is 2, slice(TOS1, TOS) is pushed; if it is 3, slice(TOS2, TOS1, TOS) is pushed. See the slice() built-in function for more information.

EXTENDED_ARG  ext
Prefixes any opcode which has an argument too big to fit into the default two bytes. ext holds two additional bytes which, taken together with the subsequent opcode's argument, comprise a four-byte argument, ext being the two most-significant bytes.

CALL_FUNCTION_VAR  argc
Calls a function. argc is interpreted as in CALL_FUNCTION. The top element on the stack contains the variable argument list, followed by keyword and positional arguments.

CALL_FUNCTION_KW  argc
Calls a function. argc is interpreted as in CALL_FUNCTION. The top element on the stack contains the keyword arguments dictionary, followed by explicit keyword and positional arguments.

CALL_FUNCTION_VAR_KW  argc
Calls a function. argc is interpreted as in CALL_FUNCTION. The top element on the stack contains the keyword arguments dictionary, followed by the variable-arguments tuple, followed by explicit keyword and positional arguments.
**HAVE_ARGUMENT**

This is not really an opcode. It identifies the dividing line between opcodes which don't take arguments `< HAVE_ARGUMENT` and those which do `>= HAVE_ARGUMENT`. 

---

**Python Library Reference**

Previous: 30.10 dis Up: 30.10 dis Next: 30.11 pickletools

Release 2.5, documentation updated on 19th September, 2006. See About this document... for information on suggesting changes.
30.11 pickletools -- Tools for pickle developers.

New in version 2.3.

This module contains various constants relating to the intimate details of the pickle module, some lengthy comments about the implementation, and a few useful functions for analyzing pickled data. The contents of this module are useful for Python core developers who are working on the pickle and cPickle implementations; ordinary users of the pickle module probably won't find the pickletools module relevant.

dis(pickle[, out=None, memo=None, indentlevel=4])

Outputs a symbolic disassembly of the pickle to the file-like object out, defaulting to sys.stdout. pickle can be a string or a file-like object. memo can be a Python dictionary that will be used as the pickle's memo; it can be used to perform disassemblies across multiple pickles created by the same pickler. Successive levels, indicated by MARK opcodes in the stream, are indented by indentlevel spaces.

genops(pickle)

Provides an iterator over all of the opcodes in a pickle, returning a sequence of (opcode, arg, pos) triples. opcode is an instance of an OpcodeInfo class; arg is the decoded value, as a Python object, of the opcode's argument; pos is the position at which this opcode is located. pickle can be a string or a file-like object.
30.12 distutils -- Building and installing Python modules

The distutils package provides support for building and installing additional modules into a Python installation. The new modules may be either 100%-pure Python, or may be extension modules written in C, or may be collections of Python packages which include modules coded in both Python and C.

This package is discussed in two separate documents which are included in the Python documentation package. To learn about distributing new modules using the distutils facilities, read Distributing Python Modules; this includes documentation needed to extend distutils. To learn about installing Python modules, whether or not the author made use of the distutils package, read Installing Python Modules.

See Also:

Distributing Python Modules
   The manual for developers and packagers of Python modules. This describes how to prepare distutils-based packages so that they may be easily installed into an existing Python installation.

Installing Python Modules
   An `administrators` manual which includes information on installing modules into an existing Python installation. You do not need to be a Python programmer to read this manual.
See About this document... for information on suggesting changes.
31. Python compiler package

The Python compiler package is a tool for analyzing Python source code and generating Python bytecode. The compiler contains libraries to generate an abstract syntax tree from Python source code and to generate Python bytecode from the tree.

The \texttt{compiler} package is a Python source to bytecode translator written in Python. It uses the built-in parser and standard \texttt{parser} module to generated a concrete syntax tree. This tree is used to generate an abstract syntax tree (AST) and then Python bytecode.

The full functionality of the package duplicates the builtin compiler provided with the Python interpreter. It is intended to match its behavior almost exactly. Why implement another compiler that does the same thing? The package is useful for a variety of purposes. It can be modified more easily than the builtin compiler. The AST it generates is useful for analyzing Python source code.

This chapter explains how the various components of the \texttt{compiler} package work. It blends reference material with a tutorial.

The following modules are part of the \texttt{compiler} package:

- \texttt{compiler}
- \texttt{compiler.ast}
- \texttt{compiler.visitor}
31.1 The basic interface

The top-level of the package defines four functions. If you import `compiler`, you will get these functions and a collection of modules contained in the package.

`parse` \((buf)\)

Returns an abstract syntax tree for the Python source code in \(buf\). The function raises `SyntaxError` if there is an error in the source code. The return value is a `compiler.ast.Module` instance that contains the tree.

`parseFile` \((path)\)

Return an abstract syntax tree for the Python source code in the file specified by \(path\). It is equivalent to `parse(open(path).read())`.

`walk` \((ast, visitor[, verbose])\)

Do a pre-order walk over the abstract syntax tree \(ast\). Call the appropriate method on the \(visitor\) instance for each node encountered.

`compile` \((source, filename, mode, flags=\text{None}, dont_inherit=\text{None})\)

Compile the string \(source\), a Python module, statement or expression, into a code object that can be executed by the `exec` statement or `eval()` function. This function is a replacement for the built-in `compile()` function.

The \texttt{filename} will be used for run-time error messages.

The \texttt{mode} must be 'exec' to compile a module, 'single' to compile a single (interactive) statement, or 'eval' to compile an expression.

The \texttt{flags} and \texttt{dont_inherit} arguments affect future-related statements, but are not supported yet.

`compileFile` \((source)\)

Compiles the file \(source\) and generates a .pyc file.

The `compiler` package contains the following modules: \texttt{ast}, \texttt{consts},
future, misc, pyassem, pycodegen, symbols, transformer, and visitor.
31.2 Limitations

There are some problems with the error checking of the compiler package. The interpreter detects syntax errors in two distinct phases. One set of errors is detected by the interpreter's parser, the other set by the compiler. The compiler package relies on the interpreter's parser, so it gets the first phases of error checking for free. It implements the second phase itself, and that implementation is incomplete. For example, the compiler package does not raise an error if a name appears more than once in an argument list: `def f(x, x): ...`

A future version of the compiler should fix these problems.
31.3 Python Abstract Syntax

The compiler.ast module defines an abstract syntax for Python. In the abstract syntax tree, each node represents a syntactic construct. The root of the tree is Module object.

The abstract syntax offers a higher level interface to parsed Python source code. The parser module and the compiler written in C for the Python interpreter use a concrete syntax tree. The concrete syntax is tied closely to the grammar description used for the Python parser. Instead of a single node for a construct, there are often several levels of nested nodes that are introduced by Python's precedence rules.

The abstract syntax tree is created by the compiler.transformer module. The transformer relies on the builtin Python parser to generate a concrete syntax tree. It generates an abstract syntax tree from the concrete tree.

The transformer module was created by Greg Stein and Bill Tutt for an experimental Python-to-C compiler. The current version contains a number of modifications and improvements, but the basic form of the abstract syntax and of the transformer are due to Stein and Tutt.

Subsections

- 31.3.1 AST Nodes
- 31.3.2 Assignment nodes
- 31.3.3 Examples
31.3.1 AST Nodes

The `compiler.ast` module is generated from a text file that describes each node type and its elements. Each node type is represented as a class that inherits from the abstract base class `compiler.ast.Node` and defines a set of named attributes for child nodes.

```python
class Node()
```

The `Node` instances are created automatically by the parser generator. The recommended interface for specific `Node` instances is to use the public attributes to access child nodes. A public attribute may be bound to a single node or to a sequence of nodes, depending on the `Node` type. For example, the `bases` attribute of the `Class` node, is bound to a list of base class nodes, and the `doc` attribute is bound to a single node.

Each `Node` instance has a `lineno` attribute which may be `None`. XXX Not sure what the rules are for which nodes will have a useful lineno.

All `Node` objects offer the following methods:

```python
getChildren()
```

Returns a flattened list of the child nodes and objects in the order they occur. Specifically, the order of the nodes is the order in which they appear in the Python grammar. Not all of the children are `Node` instances. The names of functions and classes, for example, are plain strings.

```python
getChildNodes()
```

Returns a flattened list of the child nodes in the order they occur. This method is like `getChildren()`, except that it only returns those children that are `Node` instances.

Two examples illustrate the general structure of `Node` classes. The `while` statement is defined by the following grammar production:

```
while_stmt:   "while" expression ":" suite
["else" ":" suite]
```
The While node has three attributes: `test`, `body`, and `else_`. (If the natural name for an attribute is also a Python reserved word, it can't be used as an attribute name. An underscore is appended to the word to make it a legal identifier, hence `else_` instead of `else`.)

The if statement is more complicated because it can include several tests.

```python
def if_stmt: 'if' test ' ':' suite ('elif' test ':' suite)* ['else' ':' suite]
```

The If node only defines two attributes: `tests` and `else_`. The `tests` attribute is a sequence of test expression, consequent body pairs. There is one pair for each `if/elif` clause. The first element of the pair is the test expression. The second elements is a Stmt node that contains the code to execute if the test is true.

The `getChildren()` method of If returns a flat list of child nodes. If there are three `if/elif` clauses and no `else` clause, then `getChildren()` will return a list of six elements: the first test expression, the first Stmt, the second text expression, etc.

The following table lists each of the Node subclasses defined in `compiler.ast` and each of the public attributes available on their instances. The values of most of the attributes are themselves Node instances or sequences of instances. When the value is something other than an instance, the type is noted in the comment. The attributes are listed in the order in which they are returned by `getChildren()` and `getChildNodes()`.

31.3.2 Assignment nodes

There is a collection of nodes used to represent assignments. Each assignment statement in the source code becomes a single Assign node in the AST. The nodes attribute is a list that contains a node for each assignment target. This is necessary because assignment can be chained, e.g. \( a = b = 2 \). Each Node in the list will be one of the following classes: AssAttr, AssList, AssName, or AssTuple.

Each target assignment node will describe the kind of object being assigned to: AssName for a simple name, e.g. \( a = 1 \). AssAttr for an attribute assigned, e.g. \( a.x = 1 \). AssList and AssTuple for list and tuple expansion respectively, e.g. \( a, b, c = a\_tuple \).

The target assignment nodes also have a flags attribute that indicates whether the node is being used for assignment or in a delete statement. The AssName is also used to represent a delete statement, e.g. \( \text{del } x \).

When an expression contains several attribute references, an assignment or delete statement will contain only one AssAttr node - for the final attribute reference. The other attribute references will be represented as Getattr nodes in the expr attribute of the AssAttr instance.
31.3.3 Examples

This section shows several simple examples of ASTs for Python source code. The examples demonstrate how to use the `parse()` function, what the repr of an AST looks like, and how to access attributes of an AST node.

The first module defines a single function. Assume it is stored in `/tmp/doublelib.py`.

"""This is an example module.

This is the docstring.
"""

def double(x):
    "Return twice the argument"
    return x * 2

In the interactive interpreter session below, I have reformatted the long AST reprs for readability. The AST reprs use unqualified class names. If you want to create an instance from a repr, you must import the class names from the `compiler.ast` module.

```python
>>> import compiler
>>> mod = compiler.parseFile("/tmp/doublelib.py")
>>> mod
Module('This is an example module.

This is the docstring.
',
    Stmt([Function(None, 'double', ['x'], [], 0,
    'Return twice the argument',
    Stmt([Return(Mul((Name('x'), Const(2))))]))]))
>>> from compiler.ast import *
>>> Module('This is an example module.

This is the docstring.
',
    Stmt([Function(None, 'double', ['x'], [], 0,
    'Return twice the argument',
    Stmt([Return(Mul((Name('x'), Const(2))))]))]))
>>> mod.doc
'This is an example module.

This is the docstring.'
>>> for node in mod.node.nodes:
...     print node
...     print
...     Function(None, 'double', ['x'], [], 0, 'Return twice the argument',
        Stmt([Return(Mul((Name('x'), Const(2))))]))
```
>>> func = mod.node.nodes[0]
>>> func.code
Stmt([Return(Mul((Name('x'), Const(2))))])
31.4 Using Visitors to Walk ASTs

The visitor pattern is ... The compiler package uses a variant on the visitor pattern that takes advantage of Python's introspection features to eliminate the need for much of the visitor's infrastructure.

The classes being visited do not need to be programmed to accept visitors. The visitor need only define visit methods for classes it is specifically interested in; a default visit method can handle the rest.

XXX The magic visit() method for visitors.

\[
\text{walk}(\text{tree}, \text{visitor}[\text{, verbose}])
\]

class ASTVisitor()

The ASTVisitor is responsible for walking over the tree in the correct order. A walk begins with a call to preorder(). For each node, it checks the visitor argument to preorder() for a method named `visitNodeType,' where NodeType is the name of the node's class, e.g. for a While node a visitWhile() would be called. If the method exists, it is called with the node as its first argument.

The visitor method for a particular node type can control how child nodes are visited during the walk. The ASTVisitor modifies the visitor argument by adding a visit method to the visitor; this method can be used to visit a particular child node. If no visitor is found for a particular node type, the default() method is called.

ASTVisitor objects have the following methods:

XXX describe extra arguments

\[
\text{default}(\text{node}[\text{, ...}])
\]

\[
\text{dispatch}(\text{node}[\text{, ...}])
\]
preorder(\ tree, \ visitor)
31.5 Bytecode Generation

The code generator is a visitor that emits bytecodes. Each visit method can call the `emit()` method to emit a new bytecode. The basic code generator is specialized for modules, classes, and functions. An assembler converts that emitted instructions to the low-level bytecode format. It handles things like generator of constant lists of code objects and calculation of jump offsets.
32. Abstract Syntax Trees

New in version 2.5.

The _ast module helps Python applications to process trees of the Python abstract syntax grammar. The Python compiler currently provides read-only access to such trees, meaning that applications can only create a tree for a given piece of Python source code; generating byte code from a (potentially modified) tree is not supported. The abstract syntax itself might change with each Python release; this module helps to find out programmatically what the current grammar looks like.

An abstract syntax tree can be generated by passing _ast.PyCF_ONLY_AST as a flag to the compile builtin function. The result will be a tree of objects whose classes all inherit from _ast.AST.

The actual classes are derived from the Parser/Python.asdl file, which is reproduced below. There is one class defined for each left-hand side symbol in the abstract grammar (for example, _ast.stmt or _ast.expr). In addition, there is one class defined for each constructor on the right-hand side; these classes inherit from the classes for the left-hand side trees. For example, _ast.BinOp inherits from _ast.expr. For production rules with alternatives (aka "sums"), the left-hand side class is abstract: only instances of specific constructor nodes are ever created.

Each concrete class has an attribute _fields which gives the names of all child nodes.

Each instance of a concrete class has one attribute for each child node, of the type as defined in the grammar. For example, _ast.BinOp instances have an attribute left of type _ast.expr. Instances of _ast.expr and _ast.stmt subclasses also have lineno and col_offset attributes. The lineno is the line number of source text (1 indexed so the first line is line 1) and the col_offset is the utf8 byte offset of the first token that generated the node. The utf8 offset is recorded because the parser uses utf8 internally.

If these attributes are marked as optional in the grammar (using a question
mark), the value might be None. If the attributes can have zero-or-more values (marked with an asterisk), the values are represented as Python lists.

Subsections

- **32.1 Abstract Grammar**

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
32.1 Abstract Grammar

The module defines a string constant __version__ which is the decimal subversion revision number of the file shown below.

The abstract grammar is currently defined as follows:

```python
-- ASDL's five builtin types are identifier, int, string, object, bool
module Python version "$Revision: 43614 "$ {
    mod = Module(stmt* body)
    | Interactive(stmt* body)
    | Expression(expr body)
    -- not really an actual node but useful in Jython's type
    | Suite(stmt* body)

    stmt = FunctionDef(identifier name, arguments args,
                        stmt* body, expr* decorators)
    | ClassDef(identifier name, expr* bases, stmt* body)
    | Return(expr? value)
    | Delete(expr* targets)
    | Assign(expr* targets, expr value)
    | AugAssign(expr target, operator op, expr value)
    -- not sure if bool is allowed, can always use int
    | Print(expr? dest, expr* values, bool nl)
    -- use 'orelse' because else is a keyword in target language
    | For(expr target, expr iter, stmt* body, stmt* orelse)
    | While(expr test, stmt* body, stmt* orelse)
    | If(expr test, stmt* body, stmt* orelse)
    | With(expr context_expr, expr? optional_vars, stmt* body)
    -- 'type' is a bad name
    | Raise(expr? type, expr? inst, expr? tback)
    | TryExcept(stmt* body, excepthandler* handlers, stmt*)
    | TryFinally(stmt* body, stmt* finalbody)
    | Assert(expr test, expr? msg)
    | Import(alias* names)
    | ImportFrom(identifier module, alias* names, int? level)
    -- Doesn't capture requirement that locals must be

--         lineno and col_offset fields, particularly
--        ast is exposed to Python.
excepthandler = (expr? type, expr? name, stmt* body, int lin
        int col_offset)

arguments = (expr* args, identifier? vararg,
        identifier? kwarg, expr* defaults)

-- keyword arguments supplied to call
keyword = (identifier arg, expr value)

-- import name with optional 'as' alias.
alias = (identifier name, identifier? asname)

}
33. Miscellaneous Services

The modules described in this chapter provide miscellaneous services that are available in all Python versions. Here's an overview:

**formatter**

Generic output formatter and device interface.

---

Release 2.5, documentation updated on 19th September, 2006.
See [About this document...](#) for information on suggesting changes.
33.1.1 The Formatter Interface
33.1 formatter -- Generic output formatting

This module supports two interface definitions, each with multiple implementations. The *formatter* interface is used by the *HTMLParser* class of the *htmllib* module, and the *writer* interface is required by the formatter interface.

Formatter objects transform an abstract flow of formatting events into specific output events on writer objects. Formatters manage several stack structures to allow various properties of a writer object to be changed and restored; writers need not be able to handle relative changes nor any sort of ``change back'' operation. Specific writer properties which may be controlled via formatter objects are horizontal alignment, font, and left margin indentations. A mechanism is provided which supports providing arbitrary, non-exclusive style settings to a writer as well. Additional interfaces facilitate formatting events which are not reversible, such as paragraph separation.

Writer objects encapsulate device interfaces. Abstract devices, such as file formats, are supported as well as physical devices. The provided implementations all work with abstract devices. The interface makes available mechanisms for setting the properties which formatter objects manage and inserting data into the output.

Subsections

- 33.1.1 The Formatter Interface
- 33.1.2 Formatter Implementations
- 33.1.3 The Writer Interface
- 33.1.4 Writer Implementations

Previous: 33. Miscellaneous Services  Up: 33. Miscellaneous Services  Next: 33.1.1 The Formatter Interface
Release 2.5, documentation updated on 19th September, 2006. See About this document... for information on suggesting changes.
Implementations
33.1.1 The Formatter Interface

Interfaces to create formatters are dependent on the specific formatter class being instantiated. The interfaces described below are the required interfaces which all formatters must support once initialized.

One data element is defined at the module level:

**AS_IS**
Value which can be used in the font specification passed to the `push_font()` method described below, or as the new value to any other `push_property()` method. Pushing the AS_IS value allows the corresponding `pop_property()` method to be called without having to track whether the property was changed.

The following attributes are defined for formatter instance objects:

**writer**
The writer instance with which the formatter interacts.

**end_paragraph**( `blanklines` )
Close any open paragraphs and insert at least `blanklines` before the next paragraph.

**add_line_break**( )
Add a hard line break if one does not already exist. This does not break the logical paragraph.

**add_hor_rule**( `*args`, `**kw` )
Insert a horizontal rule in the output. A hard break is inserted if there is data in the current paragraph, but the logical paragraph is not broken. The arguments and keywords are passed on to the writer's `send_line_break()` method.

**add_flow_data**( `data` )
Provide data which should be formatted with collapsed whitespace. White space from preceding and successive calls to
add_flowing_data() is considered as well when the whitespace collapse is performed. The data which is passed to this method is expected to be word-wrapped by the output device. Note that any word-wrapping still must be performed by the writer object due to the need to rely on device and font information.

add_literal_data(data)

Provide data which should be passed to the writer unchanged. Whitespace, including newline and tab characters, are considered legal in the value of data.

add_label_data(format, counter)

Insert a label which should be placed to the left of the current left margin. This should be used for constructing bulleted or numbered lists. If the format value is a string, it is interpreted as a format specification for counter, which should be an integer. The result of this formatting becomes the value of the label; if format is not a string it is used as the label value directly. The label value is passed as the only argument to the writer's send_label_data() method. Interpretation of non-string label values is dependent on the associated writer.

Format specifications are strings which, in combination with a counter value, are used to compute label values. Each character in the format string is copied to the label value, with some characters recognized to indicate a transform on the counter value. Specifically, the character "1" represents the counter value formatter as an Arabic number, the characters "A" and "a" represent alphabetic representations of the counter value in upper and lower case, respectively, and "I" and "i" represent the counter value in Roman numerals, in upper and lower case. Note that the alphabetic and roman transforms require that the counter value be greater than zero.

flush_softspace()

Send any pending whitespace buffered from a previous call to add_flowing_data() to the associated writer object. This should be called before any direct manipulation of the writer object.

push_alignment(align)

Push a new alignment setting onto the alignment stack. This may be AS_IS
if no change is desired. If the alignment value is changed from the previous setting, the writer's `new_alignment()` method is called with the `align` value.

**pop_alignment()**
Restore the previous alignment.

**push_font((size, italic, bold, teletype))**
Change some or all font properties of the writer object. Properties which are not set to `AS_IS` are set to the values passed in while others are maintained at their current settings. The writer's `new_font()` method is called with the fully resolved font specification.

**pop_font()**
Restore the previous font.

**push_margin(margin)**
Increase the number of left margin indentations by one, associating the logical tag `margin` with the new indentation. The initial margin level is 0. Changed values of the logical tag must be true values; false values other than `AS_IS` are not sufficient to change the margin.

**pop_margin()**
Restore the previous margin.

**push_style(*styles)**
Push any number of arbitrary style specifications. All styles are pushed onto the styles stack in order. A tuple representing the entire stack, including `AS_IS` values, is passed to the writer's `new_styles()` method.

**pop_style([n = 1])**
Pop the last n style specifications passed to `push_style()`. A tuple representing the revised stack, including `AS_IS` values, is passed to the writer's `new_styles()` method.

**set_spacing(spacing)**
Set the spacing style for the writer.
assert_line_data([flag = 1])

Inform the formatter that data has been added to the current paragraph out-of-band. This should be used when the writer has been manipulated directly. The optional flag argument can be set to false if the writer manipulations produced a hard line break at the end of the output.
33.1.2 Formatter Implementations

Two implementations of formatter objects are provided by this module. Most applications may use one of these classes without modification or subclassing.

```python
class NullFormatter([writer])
    A formatter which does nothing. If writer is omitted, a NullWriter instance is created. No methods of the writer are called by NullFormatter instances. Implementations should inherit from this class if implementing a writer interface but don't need to inherit any implementation.
```

class AbstractFormatter(writer)
    The standard formatter. This implementation has demonstrated wide applicability to many writers, and may be used directly in most circumstances. It has been used to implement a full-featured World Wide Web browser.
```
33.1.3 The Writer Interface

Interfaces to create writers are dependent on the specific writer class being instantiated. The interfaces described below are the required interfaces which all writers must support once initialized. Note that while most applications can use the AbstractFormatter class as a formatter, the writer must typically be provided by the application.

`flush()`
Flush any buffered output or device control events.

`new_alignment(align)`
Set the alignment style. The `align` value can be any object, but by convention is a string or `None`, where `None` indicates that the writer's `"preferred"` alignment should be used. Conventional `align` values are 'left', 'center', 'right', and 'justify'.

`new_font(font)`
Set the font style. The value of `font` will be `None`, indicating that the device's default font should be used, or a tuple of the form `(size, italic, bold, teletype)`. Size will be a string indicating the size of font that should be used; specific strings and their interpretation must be defined by the application. The `italic`, `bold`, and `teletype` values are Boolean values specifying which of those font attributes should be used.

`new_margin(margin, level)`
Set the margin level to the integer `level` and the logical tag to `margin`. Interpretation of the logical tag is at the writer's discretion; the only restriction on the value of the logical tag is that it not be a false value for non-zero values of `level`.

`new_spacing(spacing)`
Set the spacing style to `spacing`.

`new_styles(styles)`
Set additional styles. The `styles` value is a tuple of arbitrary values; the
value AS_IS should be ignored. The styles tuple may be interpreted either as a set or as a stack depending on the requirements of the application and writer implementation.

**send_line_break()**
Break the current line.

**send_paragraph( blankline)**
Produce a paragraph separation of at least blankline blank lines, or the equivalent. The blankline value will be an integer. Note that the implementation will receive a call to send_line_break() before this call if a line break is needed; this method should not include ending the last line of the paragraph. It is only responsible for vertical spacing between paragraphs.

**send_hor_rule( *args, **kw)**
Display a horizontal rule on the output device. The arguments to this method are entirely application- and writer-specific, and should be interpreted with care. The method implementation may assume that a line break has already been issued via send_line_break().

**send_flowing_data( data)**
Output character data which may be word-wrapped and re-flowed as needed. Within any sequence of calls to this method, the writer may assume that spans of multiple whitespace characters have been collapsed to single space characters.

**send_literal_data( data)**
Output character data which has already been formatted for display. Generally, this should be interpreted to mean that line breaks indicated by newline characters should be preserved and no new line breaks should be introduced. The data may contain embedded newline and tab characters, unlike data provided to the send_formatted_data() interface.

**send_label_data( data)**
Set data to the left of the current left margin, if possible. The value of data is not restricted; treatment of non-string values is entirely application- and
writer-dependent. This method will only be called at the beginning of a line.
33.1.4 Writer Implementations

Three implementations of the writer object interface are provided as examples by this module. Most applications will need to derive new writer classes from the NullWriter class.

**class NullWriter()**

A writer which only provides the interface definition; no actions are taken on any methods. This should be the base class for all writers which do not need to inherit any implementation methods.

**class AbstractWriter()**

A writer which can be used in debugging formatters, but not much else. Each method simply announces itself by printing its name and arguments on standard output.

**class DumbWriter([file, maxcol = 72])**

Simple writer class which writes output on the file object passed in as *file* or, if *file* is omitted, on standard output. The output is simply word-wrapped to the number of columns specified by *maxcol*. This class is suitable for reflowing a sequence of paragraphs.
34. SGI IRIX Specific Services

The modules described in this chapter provide interfaces to features that are unique to SGI's IRIX operating system (versions 4 and 5).

**al**  Audio functions on the SGI.

**AL**  Constants used with the `al` module.

**cd**  Interface to the CD-ROM on Silicon Graphics systems.

**f1**  FORMS library for applications with graphical user interfaces.

**FL**  Constants used with the `f1` module.

**flp**  Functions for loading stored FORMS designs.

**fm**  *Font Manager* interface for SGI workstations.

**gl**  Functions from the Silicon Graphics *Graphics Library*.

**DEVICE**  Constants used with the `gl` module.

**GL**  Constants used with the `gl` module.

**imgfile**  Support for SGI imglib files.

**jpeg**  Read and write image files in compressed JPEG format.
34.1 al -- Audio functions on the SGI

Availability: IRIX.

This module provides access to the audio facilities of the SGI Indy and Indigo workstations. See section 3A of the IRIX man pages for details. You'll need to read those man pages to understand what these functions do! Some of the functions are not available in IRIX releases before 4.0.5. Again, see the manual to check whether a specific function is available on your platform.

All functions and methods defined in this module are equivalent to the C functions with "AL" prefixed to their name.

Symbolic constants from the C header file <audio.h> are defined in the standard module AL, see below.

**Warning:** The current version of the audio library may dump core when bad argument values are passed rather than returning an error status. Unfortunately, since the precise circumstances under which this may happen are undocumented and hard to check, the Python interface can provide no protection against this kind of problems. (One example is specifying an excessive queue size -- there is no documented upper limit.)

The module defines the following functions:

**openport**( name, direction[, config])

The name and direction arguments are strings. The optional config argument is a configuration object as returned by newconfig(). The return value is an audio port object; methods of audio port objects are described below.

**newconfig()**

The return value is a new audio configuration object; methods of audio configuration objects are described below.

**queryparams**( device)
The device argument is an integer. The return value is a list of integers containing the data returned by \texttt{ALqueryparams()}.

\textbf{getparams}( \textit{device, list} )

The \textit{device} argument is an integer. The list argument is a list such as returned by \texttt{queryparams()}; it is modified in place (!).

\textbf{setparams}( \textit{device, list} )

The \textit{device} argument is an integer. The \textit{list} argument is a list such as returned by \texttt{queryparams()}.
34.1.1 Configuration Objects

Configuration objects returned by `newconfig()` have the following methods:

`getqueue(size)`
Return the queue size.

`setqueue(size)`
Set the queue size.

`getwidth()`
Get the sample width.

`setwidth(width)`
Set the sample width.

`getchannels()`
Get the channel count.

`setchannels(nchannels)`
Set the channel count.

`getsampfmt()`
Get the sample format.

`setsampfmt(sampfmt)`
Set the sample format.

`getfloatmax()`
Get the maximum value for floating sample formats.

`setfloatmax(floatmax)`
Set the maximum value for floating sample formats.
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
34.1.2 Port Objects

Port objects, as returned by openport(), have the following methods:

**closeport()**
Close the port.

**getfd()**
Return the file descriptor as an int.

**getfilled()**
Return the number of filled samples.

**getfillable()**
Return the number of fillable samples.

**readsamps( nsamples)**
Read a number of samples from the queue, blocking if necessary. Return the data as a string containing the raw data, (e.g., 2 bytes per sample in big-endian byte order (high byte, low byte) if you have set the sample width to 2 bytes).

**writesamps( samples)**
Write samples into the queue, blocking if necessary. The samples are encoded as described for the readsamps() return value.

**getfillpoint()**
Return the `fill point'.

**setfillpoint( fillpoint)**
Set the `fill point'.

**getconfig()**
Return a configuration object containing the current configuration of the port.
setconfig( *config*)
   Set the configuration from the argument, a configuration object.

getstatus( *list*)
   Get status information on last error.
34.2 AL -- Constants used with the al module

Availability: IRIX.

This module defines symbolic constants needed to use the built-in module al (see above); they are equivalent to those defined in the C header file <audio.h> except that the name prefix "AL_" is omitted. Read the module source for a complete list of the defined names. Suggested use:

```python
import al
from AL import *
```

---

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
34.3 cd -- CD-ROM access on SGI systems

Availability: **IRIX**.

This module provides an interface to the Silicon Graphics CD library. It is available only on Silicon Graphics systems.

The way the library works is as follows. A program opens the CD-ROM device with `open()` and creates a parser to parse the data from the CD with `createparser()`. The object returned by `open()` can be used to read data from the CD, but also to get status information for the CD-ROM device, and to get information about the CD, such as the table of contents. Data from the CD is passed to the parser, which parses the frames, and calls any callback functions that have previously been added.

An audio CD is divided into *tracks* or *programs* (the terms are used interchangeably). Tracks can be subdivided into *indices*. An audio CD contains a *table of contents* which gives the starts of the tracks on the CD. Index 0 is usually the pause before the start of a track. The start of the track as given by the table of contents is normally the start of index 1.

Positions on a CD can be represented in two ways. Either a frame number or a tuple of three values, minutes, seconds and frames. Most functions use the latter representation. Positions can be both relative to the beginning of the CD, and to the beginning of the track.

Module cd defines the following functions and constants:

**createparser()**
Create and return an opaque parser object. The methods of the parser object are described below.

**msftoframe(minutes, seconds, frames)**
Converts a *minutes, seconds, frames* tuple representing time in absolute time code into the corresponding CD frame number.
open([device[, mode]])
Open the CD-ROM device. The return value is an opaque player object; methods of the player object are described below. The device is the name of the SCSI device file, e.g. '/dev/scsi/sc0d4l0', or None. If omitted or None, the hardware inventory is consulted to locate a CD-ROM drive. The mode, if not omitted, should be the string 'r'.

The module defines the following variables:

**exception error**
Exception raised on various errors.

**DATASIZE**
The size of one frame's worth of audio data. This is the size of the audio data as passed to the callback of type audio.

**BLOCKSIZE**
The size of one uninterpreted frame of audio data.

The following variables are states as returned by getstatus():

**READY**
The drive is ready for operation loaded with an audio CD.

**NODISC**
The drive does not have a CD loaded.

**CDROM**
The drive is loaded with a CD-ROM. Subsequent play or read operations will return I/O errors.

**ERROR**
An error occurred while trying to read the disc or its table of contents.

**PLAYING**
The drive is in CD player mode playing an audio CD through its audio jacks.

**PAUSED**
The drive is in CD layer mode with play paused.

STILL

The equivalent of PAUSED on older (non 3301) model Toshiba CD-ROM drives. Such drives have never been shipped by SGI.

audio
pnum
index
ptime
atime
catalog
ident
control

Integer constants describing the various types of parser callbacks that can be set by the addcallback() method of CD parser objects (see below).

Subsections

- 34.3.1 Player Objects
- 34.3.2 Parser Objects
34.3.1 Player Objects

Player objects (returned by `open()`) have the following methods:

**allowremoval()**
Unlocks the eject button on the CD-ROM drive permitting the user to eject the caddy if desired.

**bestreadsize()**
Returns the best value to use for the `num_frames` parameter of the `reada()` method. Best is defined as the value that permits a continuous flow of data from the CD-ROM drive.

**close()**
Frees the resources associated with the player object. After calling `close()`, the methods of the object should no longer be used.

**eject()**
Ejects the caddy from the CD-ROM drive.

**getstatus()**
Returns information pertaining to the current state of the CD-ROM drive. The returned information is a tuple with the following values: `state`, `track`, `rtime`, `atime`, `ttme`, `first`, `last`, `scsi_audio`, `cur_block`. `rtime` is the time relative to the start of the current track; `atime` is the time relative to the beginning of the disc; `ttme` is the total time on the disc. For more information on the meaning of the values, see the man page `CDgetstatus(3dm)`. The value of `state` is one of the following: `ERROR`, `NODISC`, `READY`, `PLAYING`, `PAUSED`, `STILL`, or `CDROM`.

**gettrackinfo( track)**
Returns information about the specified track. The returned information is a tuple consisting of two elements, the start time of the track and the duration of the track.

**msftoblock( min, sec, frame)**
Converts a minutes, seconds, frames triple representing a time in absolute time code into the corresponding logical block number for the given CD-ROM drive. You should use msftostream() rather than msftoblock() for comparing times. The logical block number differs from the frame number by an offset required by certain CD-ROM drives.

**play**(start, play)
Starts playback of an audio CD in the CD-ROM drive at the specified track. The audio output appears on the CD-ROM drive's headphone and audio jacks (if fitted). Play stops at the end of the disc. start is the number of the track at which to start playing the CD; if play is 0, the CD will be set to an initial paused state. The method togglepause() can then be used to commence play.

**playabs**(minutes, seconds, frames, play)
Like play(), except that the start is given in minutes, seconds, and frames instead of a track number.

**playtrack**(start, play)
Like play(), except that playing stops at the end of the track.

**playtrackabs**(track, minutes, seconds, frames, play)
Like play(), except that playing begins at the specified absolute time and ends at the end of the specified track.

**preventremoval()**
Locks the eject button on the CD-ROM drive thus preventing the user from arbitrarily ejecting the caddy.

**readda**(num_frames)
Reads the specified number of frames from an audio CD mounted in the CD-ROM drive. The return value is a string representing the audio frames. This string can be passed unaltered to the parseframe() method of the parser object.

**seek**(minutes, seconds, frames)
Sets the pointer that indicates the starting point of the next read of digital
audio data from a CD-ROM. The pointer is set to an absolute time code location specified in minutes, seconds, and frames. The return value is the logical block number to which the pointer has been set.

**seekblock**(*block*)

Sets the pointer that indicates the starting point of the next read of digital audio data from a CD-ROM. The pointer is set to the specified logical block number. The return value is the logical block number to which the pointer has been set.

**seektrack**(*track*)

Sets the pointer that indicates the starting point of the next read of digital audio data from a CD-ROM. The pointer is set to the specified track. The return value is the logical block number to which the pointer has been set.

**stop**()

Stops the current playing operation.

**togglepause**()

Pauses the CD if it is playing, and makes it play if it is paused.
34.3.2 Parser Objects

Parser objects (returned by `createparser()`) have the following methods:

**addcallback** *(type, func, arg)*

Adds a callback for the parser. The parser has callbacks for eight different types of data in the digital audio data stream. Constants for these types are defined at the cd module level (see above). The callback is called as follows: `func(arg, type, data)`, where *arg* is the user supplied argument, *type* is the particular type of callback, and *data* is the data returned for this *type* of callback. The type of the data depends on the *type* of callback as follows:

<table>
<thead>
<tr>
<th>Type</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>audio</td>
<td>String which can be passed unmodified to <code>al.writesamps()</code></td>
</tr>
<tr>
<td>pnum</td>
<td>Integer giving the program (track) number.</td>
</tr>
<tr>
<td>index</td>
<td>Integer giving the index number.</td>
</tr>
<tr>
<td>ptime</td>
<td>Tuple consisting of the program time in minutes, seconds, and frames.</td>
</tr>
<tr>
<td>atime</td>
<td>Tuple consisting of the absolute time in minutes, seconds, and frames.</td>
</tr>
<tr>
<td>catalog</td>
<td>String of 13 characters, giving the catalog number of the CD.</td>
</tr>
<tr>
<td>ident</td>
<td>String of 12 characters, giving the ISRC identification number of the recording. The string consists of two characters country code, three characters owner code, two characters giving the year, and five characters giving a serial number.</td>
</tr>
<tr>
<td>control</td>
<td>Integer giving the control bits from the CD subcode data</td>
</tr>
</tbody>
</table>

**deletparser()**

Deletes the parser and frees the memory it was using. The object should not be used after this call. This call is done automatically when the last reference to the object is removed.
**parseframe**(*frame*)

Parses one or more frames of digital audio data from a CD such as returned by `readda()` . It determines which subcodes are present in the data. If these subcodes have changed since the last frame, then `parseframe()` executes a callback of the appropriate type passing to it the subcode data found in the frame. Unlike the C function, more than one frame of digital audio data can be passed to this method.

**removecallback**(*type*)

Removes the callback for the given *type*.

**resetparser**()

Resets the fields of the parser used for tracking subcodes to an initial state. `resetparser()` should be called after the disc has been changed.
34.4 f1 -- FORMS library for graphical user interfaces

Availability: IRIX.

This module provides an interface to the FORMS Library by Mark Overmars. The source for the library can be retrieved by anonymous ftp from host "ftp.cs.ruu.nl", directory SGI/FORMS. It was last tested with version 2.0b.

Most functions are literal translations of their C equivalents, dropping the initial "f1_" from their name. Constants used by the library are defined in module f1_described below.

The creation of objects is a little different in Python than in C: instead of the `current form' maintained by the library to which new FORMS objects are added, all functions that add a FORMS object to a form are methods of the Python object representing the form. Consequently, there are no Python equivalents for the C functions f1_addto_form() and f1_end_form(), and the equivalent of f1_bgn_form() is called f1_make_form().

Watch out for the somewhat confusing terminology: FORMS uses the word object for the buttons, sliders etc. that you can place in a form. In Python, `object' means any value. The Python interface to FORMS introduces two new Python object types: form objects (representing an entire form) and FORMS objects (representing one button, slider etc.). Hopefully this isn't too confusing.

There are no `free objects' in the Python interface to FORMS, nor is there an easy way to add object classes written in Python. The FORMS interface to GL event handling is available, though, so you can mix FORMS with pure GL windows.

Please note: importing f1 implies a call to the GL function foreground() and to the FORMS routine f1_init().

*Release 2.5, documentation updated on 19th September, 2006.*
*See About this document... for information on suggesting changes.*
34.4.1 Functions Defined in Module fl

Module fl defines the following functions. For more information about what they do, see the description of the equivalent C function in the FORMS documentation:

**make_form**(type, width, height)
Create a form with given type, width and height. This returns a form object, whose methods are described below.

**do_forms()**
The standard FORMS main loop. Returns a Python object representing the FORMS object needing interaction, or the special value FL.EVENT.

**check_forms()**
Check for FORMS events. Returns what do_forms() above returns, or None if there is no event that immediately needs interaction.

**set_event_call_back**(function)
Set the event callback function.

**set_graphics_mode**(rgbmode, doublebuffering)
Set the graphics modes.

**get_rgbmode()**
Return the current rgb mode. This is the value of the C global variable fl_rgbmode.

**show_message**(str1, str2, str3)
Show a dialog box with a three-line message and an OK button.

**show_question**(str1, str2, str3)
Show a dialog box with a three-line message and YES and NO buttons. It returns 1 if the user pressed YES, 0 if NO.
**show_choice**(*str1, str2, str3, but1[, but2[, but3]])

Show a dialog box with a three-line message and up to three buttons. It returns the number of the button clicked by the user (1, 2 or 3).

**show_input**(*prompt, default*)

Show a dialog box with a one-line prompt message and text field in which the user can enter a string. The second argument is the default input string. It returns the string value as edited by the user.

**show_file_selector**(*message, directory, pattern, default*)

Show a dialog box in which the user can select a file. It returns the absolute filename selected by the user, or None if the user presses Cancel.

**get_directory**()

**get_pattern**()

**get_filename**()

These functions return the directory, pattern and filename (the tail part only) selected by the user in the last **show_file_selector**() call.

**qdevice**(*dev*)

**unqdevice**(*dev*)

**isqueued**(*dev*)

**qtest**(*dev*)

**qread**()

**qreset**()

**qenter**(*dev, val*)

**get_mouse**()

**tie**(*button, valuator1, valuator2*)

These functions are the FORMS interfaces to the corresponding GL functions. Use these if you want to handle some GL events yourself when using **fl.do_events()**. When a GL event is detected that FORMS cannot handle, **fl.do_forms()** returns the special value **FL.EVENT** and you should call **fl.qread()** to read the event from the queue. Don't use the equivalent GL functions!
color()
mapcolor()
getmcolor()

See the description in the FORMS documentation of `fl_color()`, `fl_mapcolor()` and `fl_getmcolor()`.
34.4.2 Form Objects

Form objects (returned by `make_form()` above) have the following methods. Each method corresponds to a C function whose name is prefixed with "fl_"; and whose first argument is a form pointer; please refer to the official FORMS documentation for descriptions.

All the `add_*()` methods return a Python object representing the FORMS object. Methods of FORMS objects are described below. Most kinds of FORMS object also have some methods specific to that kind; these methods are listed here.

```python
show_form(placement, bordertype, name)
    Show the form.

hide_form()
    Hide the form.

redraw_form()
    Redraw the form.

set_form_position(x, y)
    Set the form's position.

freeze_form()
    Freeze the form.

unfreeze_form()
    Unfreeze the form.

activate_form()
    Activate the form.

deactivate_form()
    Deactivate the form.
```
bgn_group()
Begin a new group of objects; return a group object.

del_group()
End the current group of objects.

find_first()
Find the first object in the form.

find_last()
Find the last object in the form.

add_box( type, x, y, w, h, name)
Add a box object to the form. No extra methods.

add_text( type, x, y, w, h, name)
Add a text object to the form. No extra methods.

add_clock( type, x, y, w, h, name)
Add a clock object to the form.
Method: get_clock().

add_button( type, x, y, w, h, name)
Add a button object to the form.
Methods: get_button(), set_button().

add_lightbutton( type, x, y, w, h, name)
Add a lightbutton object to the form.
Methods: get_button(), set_button().

add_roundbutton( type, x, y, w, h, name)
Add a roundbutton object to the form.
Methods: get_button(), set_button().

add_slider( type, x, y, w, h, name)
Add a slider object to the form.
Methods: set_slider_value(), get_slider_value(),
set_slider_bounds(), get_slider_bounds(),
set_slider_return(), set_slider_size(),
set_slider_precision(), set_slider_step().

add_valslider( type, x, y, w, h, name)
Add a valslider object to the form.
Methods: set_slider_value(), get_slider_value(),
set_slider_bounds(), get_slider_bounds(),
set_slider_return(), set_slider_size(),
set_slider_precision(), set_slider_step().

add_dial( type, x, y, w, h, name)
Add a dial object to the form.
Methods: set_dial_value(), get_dial_value(),
set_dial_bounds(), get_dial_bounds().

add_positioner( type, x, y, w, h, name)
Add a positioner object to the form.
Methods: set_positioner_xvalue(),
set_positioner_yvalue(), set_positioner_xbounds(),
set_positioner_ybounds(), get_positioner_xvalue(),
get_positioner_yvalue(), get_positioner_xbounds(),
get_positioner_ybounds().

add_counter( type, x, y, w, h, name)
Add a counter object to the form.
Methods: set_counter_value(), get_counter_value(),
set_counter_bounds(), set_counter_step(),
set_counter_precision(), set_counter_return().

add_input( type, x, y, w, h, name)
Add a input object to the form.
Methods: set_input(), get_input(), set_input_color(),
set_input_return().

add_menu( type, x, y, w, h, name)
Add a menu object to the form.
Methods: set_menu(), get_menu(), addto_menu().

add_choice( type, x, y, w, h, name)
Add a choice object to the form.
Methods: set_choice(), get_choice(), clear_choice(),
addto_choice(), replace_choice(), delete_choice(),
get_choice_text(), set_choice_fontsize(),
set_choice_fontstyle().

add_browser( type, x, y, w, h, name)
Add a browser object to the form.
Methods: set_browser_topline(), clear_browser(),
add_browser_line(), addto_browser(),
insert_browser_line(), delete_browser_line(),
replace_browser_line(), get_browser_line(),
load_browser(), get_browser_maxline(),
select_browser_line(), deselect_browser_line(),
deselect_browser(), isselected_browser_line(),
get_browser(), set_browser_fontsize(),
set_browser_fontstyle(), set_browser_specialkey().

add_timer( type, x, y, w, h, name)
Add a timer object to the form.
Methods: set_timer(), get_timer().

Form objects have the following data attributes; see the FORMS documentation:

<table>
<thead>
<tr>
<th>Name</th>
<th>C Type</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>window</td>
<td>int (read-only)</td>
<td>GL window id</td>
</tr>
<tr>
<td>w</td>
<td>float</td>
<td>form width</td>
</tr>
<tr>
<td>h</td>
<td>float</td>
<td>form height</td>
</tr>
<tr>
<td>x</td>
<td>float</td>
<td>form x origin</td>
</tr>
<tr>
<td>y</td>
<td>float</td>
<td>form y origin</td>
</tr>
<tr>
<td>deactivated</td>
<td>int</td>
<td>nonzero if form is deactivated</td>
</tr>
<tr>
<td>visible</td>
<td>int</td>
<td>nonzero if form is visible</td>
</tr>
<tr>
<td>frozen</td>

Previous: 34.4.1 Functions Defined in  Up: 34.4.2  Next: 34.4.3 FORMS Objects

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
34.4.3 FORMS Objects

Besides methods specific to particular kinds of FORMS objects, all FORMS objects also have the following methods:

```python
set_call_back(function, argument)
```
Set the object's callback function and argument. When the object needs interaction, the callback function will be called with two arguments: the object, and the callback argument. (FORMS objects without a callback function are returned by `fl.do_forms()` or `fl.check_forms()` when they need interaction.) Call this method without arguments to remove the callback function.

```python
delete_object()
```
Delete the object.

```python
show_object()
```
Show the object.

```python
hide_object()
```
Hide the object.

```python
redraw_object()
```
Redraw the object.

```python
freeze_object()
```
Freeze the object.

```python
unfreeze_object()
```
Unfreeze the object.

FORMS objects have these data attributes; see the FORMS documentation:

34.5 FL -- Constants used with the fl module

Availability: IRIX.

This module defines symbolic constants needed to use the built-in module fl (see above); they are equivalent to those defined in the C header file <forms.h> except that the name prefix "FL_" is omitted. Read the module source for a complete list of the defined names. Suggested use:

```python
import fl
from FL import *
```
34.6 f1p -- Functions for loading stored FORMS designs

Availability: IRIX.

This module defines functions that can read form definitions created by the `form designer' (fdesign) program that comes with the FORMS library (see module f1 above).

For now, see the file f1p.doc in the Python library source directory for a description.

XXX A complete description should be inserted here!
34.7 fm -- Font Manager interface

Availability: IRIX.

This module provides access to the IRIS Font Manager library. It is available only on Silicon Graphics machines. See also: 4Sight User's Guide, section 1, chapter 5: ``Using the IRIS Font Manager."

This is not yet a full interface to the IRIS Font Manager. Among the unsupported features are: matrix operations; cache operations; character operations (use string operations instead); some details of font info; individual glyph metrics; and printer matching.

It supports the following operations:

**init()**
Initialization function. Calls fmInit(). It is normally not necessary to call this function, since it is called automatically the first time the fm module is imported.

**findfont(fontname)**
Return a font handle object. Calls fmFindFont(fontname).

**enumerate()**
Returns a list of available font names. This is an interface to fmenumerate().

**prstr(string)**
Render a string using the current font (see the setfont() font handle method below). Calls fmPrstr(string).

**setpath(string)**
Sets the font search path. Calls fmSetpath(string). (XXX Does not work!?!)

**fontpath()**
Returns the current font search path.

Font handle objects support the following operations:

**scalefont** *(factor)*

Returns a handle for a scaled version of this font. Calls `fmscalefont(fh, factor)`.

**setfont()**

Makes this font the current font. Note: the effect is undone silently when the font handle object is deleted. Calls `fmsetfont(fh)`.

**getfontname()**

Returns this font's name. Calls `fmgetfontname(fh)`.

**getcomment()**

Returns the comment string associated with this font. Raises an exception if there is none. Calls `fmgetcomment(fh)`.

**getfontinfo()**

Returns a tuple giving some pertinent data about this font. This is an interface to `fmgetfontinfo()`. The returned tuple contains the following numbers: *(printermatched, fixed_width, xorig, yorig, xsize, ysize, height, nglyphs)*.

**getstrwidth** *(string)*

Returns the width, in pixels, of *string* when drawn in this font. Calls `fmgetstrwidth(fh, string)`.
34.8 g1 -- Graphics Library interface

Availability: IRIX.

This module provides access to the Silicon Graphics Graphics Library. It is available only on Silicon Graphics machines.

**Warning:** Some illegal calls to the GL library cause the Python interpreter to dump core. In particular, the use of most GL calls is unsafe before the first window is opened.

The module is too large to document here in its entirety, but the following should help you to get started. The parameter conventions for the C functions are translated to Python as follows:

- All (short, long, unsigned) int values are represented by Python integers.
- All float and double values are represented by Python floating point numbers. In most cases, Python integers are also allowed.
- All arrays are represented by one-dimensional Python lists. In most cases, tuples are also allowed.
- All string and character arguments are represented by Python strings, for instance, `winopen('Hi There!')` and `rotate(900, 'z')`.
- All (short, long, unsigned) integer arguments or return values that are only used to specify the length of an array argument are omitted. For example, the C call
  
  `lmdef(deftype, index, np, props)`

  is translated to Python as
  
  `lmdef(deftype, index, props)`

- Output arguments are omitted from the argument list; they are transmitted as function return values instead. If more than one value must be returned, the return value is a tuple. If the C function has both a regular return value (that is not omitted because of the previous rule) and an output argument, the return value comes first in the tuple. Examples: the C call
  
  `lmdef(deftype, index, props)`
getmcolor(i, &red, &green, &blue)

is translated to Python as

red, green, blue = getmcolor(i)

The following functions are non-standard or have special argument conventions:

**varray( argument)**
Equivalent to but faster than a number of v3d() calls. The argument is a list (or tuple) of points. Each point must be a tuple of coordinates \((x, y, z)\) or \((x, y)\). The points may be 2- or 3-dimensional but must all have the same dimension. Float and int values may be mixed however. The points are always converted to 3D double precision points by assuming \(z = 0.0\) if necessary (as indicated in the man page), and for each point v3d() is called.

**narray()**
Equivalent to but faster than a number of n3f and v3f calls. The argument is an array (list or tuple) of pairs of normals and points. Each pair is a tuple of a point and a normal for that point. Each point or normal must be a tuple of coordinates \((x, y, z)\). Three coordinates must be given. Float and int values may be mixed. For each pair, n3f() is called for the normal, and then v3f() is called for the point.

**vnarray()**
Similar to narray() but the pairs have the point first and the normal second.

**nurbssurface( s_k, t_k, ctl, s_ord, t_ord, type)**
Defines a nurbs surface. The dimensions of \(ctl[]\) are computed as follows: \([\text{len}(s_k) - s_{ord}], [\text{len}(t_k) - t_{ord}]\).

**nurbscurve( knots, ctlpoints, order, type)**
Defines a nurbs curve. The length of ctlpoints is \(\text{len}(knots) - order\).

**pwlcurve( points, type)**
Defines a piecewise-linear curve. points is a list of points. type must be
pick\((n)\)
select\((n)\)

The only argument to these functions specifies the desired size of the pick or select buffer.

endpick()
endselect()

These functions have no arguments. They return a list of integers representing the used part of the pick/select buffer. No method is provided to detect buffer overrun.

Here is a tiny but complete example GL program in Python:

```python
import gl, GL, time

def main():
    gl.foreground()
    gl.prefposition(500, 900, 500, 900)
    w = gl.winopen('CrissCross')
    gl.ortho2(0.0, 400.0, 0.0, 400.0)
    gl.color(GL.WHITE)
    gl.clear()
    gl.color(GL.RED)
    gl.bgnline()
    gl.v2f(0.0, 0.0)
    gl.v2f(400.0, 400.0)
    gl.endline()
    gl.bgnline()
    gl.v2f(400.0, 0.0)
    gl.v2f(0.0, 400.0)
    gl.endline()
    time.sleep(5)

main()
```

See Also:

*PyOpenGL: The Python OpenGL Binding*

An interface to OpenGL is also available; see information about the PyOpenGL project online at [http://pyopengl.sourceforge.net/](http://pyopengl.sourceforge.net/). This
may be a better option if support for SGI hardware from before about 1996 is not required.
Previous: 34.8 gl  Up: 34. SGI IRIX Specific  Next: 34.10 GL
34.9 DEVICE -- Constants used with the gl module

Availability: IRIX.

This module defines the constants used by the Silicon Graphics Graphics Library that C programmers find in the header file <gl/device.h>. Read the module source file for details.
34.10 GL -- Constants used with the gl module

Availability: IRIX.

This module contains constants used by the Silicon Graphics Graphics Library from the C header file <g1/g1.h>. Read the module source file for details.
34.11 imgfile -- Support for SGI imglib files

Availability: IRIX.

The `imgfile` module allows Python programs to access SGI imglib image files (also known as .rgb files). The module is far from complete, but is provided anyway since the functionality that there is enough in some cases. Currently, colormap files are not supported.

The module defines the following variables and functions:

**exception error**
This exception is raised on all errors, such as unsupported file type, etc.

**getsizes(file)**
This function returns a tuple \((x, y, z)\) where \(x\) and \(y\) are the size of the image in pixels and \(z\) is the number of bytes per pixel. Only 3 byte RGB pixels and 1 byte greyscale pixels are currently supported.

**read(file)**
This function reads and decodes the image on the specified file, and returns it as a Python string. The string has either 1 byte greyscale pixels or 4 byte RGBA pixels. The bottom left pixel is the first in the string. This format is suitable to pass to `gl.lrectwrite()`, for instance.

**readscaled(file, x, y, filter[, blur])**
This function is identical to read but it returns an image that is scaled to the given \(x\) and \(y\) sizes. If the `filter` and `blur` parameters are omitted scaling is done by simply dropping or duplicating pixels, so the result will be less than perfect, especially for computer-generated images.

Alternatively, you can specify a filter to use to smooth the image after scaling. The filter forms supported are 'impulse', 'box', 'triangle', 'quadratic' and 'gaussian'. If a filter is specified
blur is an optional parameter specifying the blurriness of the filter. It defaults to 1.0.

readscaled() makes no attempt to keep the aspect ratio correct, so that is the users' responsibility.

ttob(flag)
This function sets a global flag which defines whether the scan lines of the image are read or written from bottom to top (flag is zero, compatible with SGI GL) or from top to bottom (flag is one, compatible with X). The default is zero.

write(file, data, x, y, z)
This function writes the RGB or greyscale data in data to image file file. x and y give the size of the image, z is 1 for 1 byte greyscale images or 3 for RGB images (which are stored as 4 byte values of which only the lower three bytes are used). These are the formats returned by gl.lrectread().
34.12 jpeg -- Read and write JPEG files

Availability: IRIX.

The module jpeg provides access to the jpeg compressor and decompressor written by the Independent JPEG Group (IJG). JPEG is a standard for compressing pictures; it is defined in ISO 10918. For details on JPEG or the Independent JPEG Group software refer to the JPEG standard or the documentation provided with the software.

A portable interface to JPEG image files is available with the Python Imaging Library (PIL) by Fredrik Lundh. Information on PIL is available at http://www.pythonware.com/products/pil/.

The jpeg module defines an exception and some functions.

**exception error**
Exception raised by `compress()` and `decompress()` in case of errors.

**compress(data, w, h, b)**
Treat data as a pixmap of width w and height h, with b bytes per pixel. The data is in SGI GL order, so the first pixel is in the lower-left corner. This means that `gl.lrectread()` return data can immediately be passed to `compress()`. Currently only 1 byte and 4 byte pixels are allowed, the former being treated as greyscale and the latter as RGB color. `compress()` returns a string that contains the compressed picture, in JFIF format.

**decompress(data)**
Data is a string containing a picture in JFIF format. It returns a tuple `(data, width, height, bytesperpixel)`. Again, the data is suitable to pass to `gl.lrectwrite()`.

**setoption(name, value)**
Set various options. Subsequent `compress()` and `decompress()` calls will use these options. The following options are available:

<table>
<thead>
<tr>
<th>Option</th>
<th>Effect</th>
</tr>
</thead>
<tbody>
<tr>
<td>'forcegray'</td>
<td>Force output to be grayscale, even if input is RGB.</td>
</tr>
<tr>
<td>'quality'</td>
<td>Set the quality of the compressed image to a value between 0 and 100 (default is 75). This only affects compression.</td>
</tr>
<tr>
<td>'optimize'</td>
<td>Perform Huffman table optimization. Takes longer, but results in smaller compressed image. This only affects compression.</td>
</tr>
<tr>
<td>'smooth'</td>
<td>Perform inter-block smoothing on uncompressed image. Only useful for low-quality images. This only affects decompression.</td>
</tr>
</tbody>
</table>

The ISO standard for JPEG is also published as ITU T.81. This is available online in PDF form.
35. SunOS Specific Services

The modules described in this chapter provide interfaces to features that are unique to SunOS 5 (also known as Solaris version 2).

Subsections

- 35.1 sunaudiodev -- Access to Sun audio hardware
  - 35.1.1 Audio Device Objects
- 35.2 SUNAUDIODEV -- Constants used with sunaudiodev

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
35.1 sunaudiodev -- Access to Sun audio hardware

Availability: SunOS.

This module allows you to access the Sun audio interface. The Sun audio hardware is capable of recording and playing back audio data in u-LAW format with a sample rate of 8K per second. A full description can be found in the audio(7I) manual page.

The module SUNAUDIODEV defines constants which may be used with this module.

This module defines the following variables and functions:

**exception error**
This exception is raised on all errors. The argument is a string describing what went wrong.

**open( mode)**
This function opens the audio device and returns a Sun audio device object. This object can then be used to do I/O on. The *mode* parameter is one of 'r' for record-only access, 'w' for play-only access, 'rw' for both and 'control' for access to the control device. Since only one process is allowed to have the recorder or player open at the same time it is a good idea to open the device only for the activity needed. See audio(7I) for details.

As per the manpage, this module first looks in the environment variable AUDIODEV for the base audio device filename. If not found, it falls back to /dev/audio. The control device is calculated by appending ``ctl'' to the base audio device.

---

35.1.1 Audio Device Objects

Previous: 35. SunOS Specific Services  Up: 35. SunOS Specific Services
Next: 35.1.1 Audio Device Objects

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
35.1.1 Audio Device Objects

The audio device objects are returned by `open()` define the following methods (except control objects which only provide `getinfo()`, `setinfo()`, `fileno()`, and `drain()`):

**close()**
This method explicitly closes the device. It is useful in situations where deleting the object does not immediately close it since there are other references to it. A closed device should not be used again.

**fileno()**
Returns the file descriptor associated with the device. This can be used to set up SIGPOLL notification, as described below.

**drain()**
This method waits until all pending output is processed and then returns. Calling this method is often not necessary: destroying the object will automatically close the audio device and this will do an implicit drain.

**flush()**
This method discards all pending output. It can be used avoid the slow response to a user's stop request (due to buffering of up to one second of sound).

**getinfo()**
This method retrieves status information like input and output volume, etc. and returns it in the form of an audio status object. This object has no methods but it contains a number of attributes describing the current device status. The names and meanings of the attributes are described in `<sun/audioio.h>` and in the `audio(7I)` manual page. Member names are slightly different from their C counterparts: a status object is only a single structure. Members of the `play` substructure have "o_" prepended to their name and members of the `record` structure have "i_". So, the C member `play.sample_rate` is accessed as `o_sample_rate`, `record.gain` as `i_gain` and `monitor_gain` plainly as
monitor_gain.

**ibufcount()**
This method returns the number of samples that are buffered on the recording side, i.e. the program will not block on a **read()** call of so many samples.

**obufcount()**
This method returns the number of samples buffered on the playback side. Unfortunately, this number cannot be used to determine a number of samples that can be written without blocking since the kernel output queue length seems to be variable.

**read(size)**
This method reads size samples from the audio input and returns them as a Python string. The function blocks until enough data is available.

**setinfo(status)**
This method sets the audio device status parameters. The status parameter is an device status object as returned by **getinfo()** and possibly modified by the program.

**write(samples)**
Write is passed a Python string containing audio samples to be played. If there is enough buffer space free it will immediately return, otherwise it will block.

The audio device supports asynchronous notification of various events, through the SIGPOLL signal. Here's an example of how you might enable this in Python:

```python
def handle_sigpoll(signum, frame):
    print 'I got a SIGPOLL update'

import fcntl, signal, STROPTS

signal.signal(signal.SIGPOLL, handle_sigpoll)
fcntl.ioctl(audio_obj.fileno(), STROPTS.I_SETSIG, STROPTS.S_MSG)
```
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
35.2 SUNAUDIODEV -- Constants used with sunaudiodev

Availability: SunOS.

This is a companion module to sunaudiodev which defines useful symbolic constants like MIN_GAIN, MAX_GAIN, SPEAKER, etc. The names of the constants are the same names as used in the C include file <sun/audioio.h>, with the leading string "AUDIO_" stripped.
36. MS Windows Specific Services

This chapter describes modules that are only available on MS Windows platforms.

- **msilib**: Creation of Microsoft Installer files, and CAB files.
- **msvcrt**: Miscellaneous useful routines from the MS VC++ runtime.
- **_winreg**: Routines and objects for manipulating the Windows registry.
- **winsound**: Access to the sound-playing machinery for Windows.
36.1.1 Database Objects
36.1 msilib -- Read and write Microsoft Installer files

Availability: Windows.

New in version 2.5.

The msilib supports the creation of Microsoft Installer (.msi) files. Because these files often contain an embedded ``cabinet'' file (.cab), it also exposes an API to create CAB files. Support for reading .cab files is currently not implemented; read support for the .msi database is possible.

This package aims to provide complete access to all tables in an .msi file, therefore, it is a fairly low-level API. Two primary applications of this package are the distutils command bdist_msi, and the creation of Python installer package itself (although that currently uses a different version of msilib).

The package contents can be roughly split into four parts: low-level CAB routines, low-level MSI routines, higher-level MSI routines, and standard table structures.

**FCICreate**(cabname, files)
Create a new CAB file named cabname. files must be a list of tuples, each containing the name of the file on disk, and the name of the file inside the CAB file.

The files are added to the CAB file in the order they appear in the list. All files are added into a single CAB file, using the MSZIP compression algorithm.

Callbacks to Python for the various steps of MSI creation are currently not exposed.

**UUIDCreate()**
Return the string representation of a new unique identifier. This wraps the
Windows API functions UuidCreate and UuidToString.

**OpenDatabase**(path, persist)

Return a new database object by calling MsiOpenDatabase. path is the file name of the MSI file; persist can be one of the constants MSIDBOPEN_CREATEDIRECT, MSIDBOPEN_CREATE, MSIDBOPEN_DIRECT, MSIDBOPEN_READONLY, or MSIDBOPEN_TRANSACT, and may include the flag MSIDBOPEN_PATCHFILE. See the Microsoft documentation for the meaning of these flags; depending on the flags, an existing database is opened, or a new one created.

**CreateRecord**(count)

Return a new record object by calling MSICreateRecord. count is the number of fields of the record.

**init_database**(name, schema, ProductName, ProductCode, ProductVersion, Manufacturer)

Create and return a new database name, initialize it with schema, and set the properties ProductName, ProductCode, ProductVersion, and Manufacturer.

schema must be a module object containing tables and _Validation_records attributes; typically, msilib.schema should be used.

The database will contain just the schema and the validation records when this function returns.

**add_data**(database, records)

Add all records to database. records should be a list of tuples, each one containing all fields of a record according to the schema of the table. For optional fields, None can be passed.

Field values can be int or long numbers, strings, or instances of the Binary class.

**class Binary**(filename)
Represents entries in the Binary table; inserting such an object using `add_data` reads the file named `filename` into the table.

**add_tables(database, module)**
Add all table content from `module` to `database`. `module` must contain an attribute `tables` listing all tables for which content should be added, and one attribute per table that has the actual content.

This is typically used to install the sequence tables.

**add_stream(database, name, path)**
Add the file `path` into the `_Stream` table of `database`, with the stream name `name`.

**gen_uuid()**
Return a new UUID, in the format that MSI typically requires (i.e. in curly braces, and with all hexdigits in upper-case).

---

• 36.1.9 GUI classes
• 36.1.10 Precomputed tables
36.1.1 Database Objects

OpenView( sql)

Return a view object, by calling MSIDatabaseOpenView. sql is the SQL statement to execute.

Commit()

Commit the changes pending in the current transaction, by calling MSIDatabaseCommit.

GetSummaryInformation( count)

Return a new summary information object, by calling MsiGetSummaryInformation. count is the maximum number of updated values.

See Also:

MSIOpenView
MSIDatabaseCommit
MSIGetSummaryInformation
### 36.1.2 View Objects

**Execute**([params=None])

Execute the SQL query of the view, through **MSIViewExecute**. *params* is an optional record describing actual values of the parameter tokens in the query.

**GetColumnInfo**(kind)

Return a record describing the columns of the view, through calling **MsiViewGetColumnInfo**. *kind* can be either **MSICOLINFO_NAMES** or **MSICOLINFO_TYPES**.

**Fetch**()

Return a result record of the query, through calling **MsiViewFetch**.

**Modify**(kind, data)

Modify the view, by calling **MsiViewModify**. *kind* can be one of **MSIMODIFY_SEEK**, **MSIMODIFY_REFRESH**, **MSIMODIFY_INSERT**, **MSIMODIFY_UPDATE**, **MSIMODIFY_ASSIGN**, **MSIMODIFY_REPLACE**, **MSIMODIFY_MERGE**, **MSIMODIFY_DELETE**, **MSIMODIFY_INSERT_TEMPORARY**, **MSIMODIFY_VALIDATE**, **MSIMODIFY_VALIDATE_NEW**, **MSIMODIFY_VALIDATE_FIELD**, or **MSIMODIFY_VALIDATE_DELETE**.

*data* must be a record describing the new data.

**Close**()

Close the view, through **MsiViewClose**.

---

**See Also:**

*MsiViewExecute*

**MSIViewGetColumnInfo**
36.1.3 Summary Information Objects

GetProperty( field)
Return a property of the summary, through MsiSummaryInfoGetProperty. field is the name of the property, and can be one of the constants PID_CODEPAGE, PID_TITLE, PID_SUBJECT, PID_AUTHOR, PID_KEYWORDS, PID_COMMENTS, PID_TEMPLATE, PID_LASTAUTHOR, PID_REVNUMBER, PID_LASTPRINTED, PID_CREATE_DTM, PID_LASTSAVE_DTM, PID_PAGECOUNT, PID_WORDCOUNT, PID_CHARCOUNT, PID_APPNAME, or PID_SECURITY.

GetPropertyCount()
Return the number of summary properties, through MsiSummaryInfoGetPropertyCount.

SetProperty( field, value)
Set a property through MsiSummaryInfoSetProperty. field can have the same values as inGetProperty, value is the new value of the property. Possible value types are integer and string.

Persist()
Write the modified properties to the summary information stream, using MsiSummaryInfoPersist.

See Also:

MsiSummaryInfoGetProperty
MsiSummaryInfoGetPropertyCount
MsiSummaryInfoSetProperty
MsiSummaryInfoPersist
Release 2.5, documentation updated on 19th September, 2006.
See [About this document...](#) for information on suggesting changes.
36.1.4 Record Objects

GetFieldCount()

Return the number of fields of the record, through MsiRecordGetFieldCount.

SetString(field, value)

Set field to value through MsiRecordSetString. field must be an integer; value a string.

SetStream(field, value)

Set field to the contents of the file named value, through MsiRecordSetStream. field must be an integer; value a string.

SetInteger(field, value)

Set field to value through MsiRecordSetInteger. Both field and value must be an integer.

ClearData()

Set all fields of the record to 0, through MsiRecordClearData.

See Also:

MsiRecordGetFieldCount

MsiRecordSetString

MsiRecordSetStream

MsiRecordSetInteger

MsiRecordClear
Errors

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
36.1.5 Errors

All wrappers around MSI functions raise `MsiError`; the string inside the exception will contain more detail.
36.1.6 CAB Objects

class CAB( name)

The class CAB represents a CAB file. During MSI construction, files will be added simultaneously to the Files table, and to a CAB file. Then, when all files have been added, the CAB file can be written, then added to the MSI file.

name is the name of the CAB file in the MSI file.

append( full, logical)

Add the file with the pathname full to the CAB file, under the name logical. If there is already a file named logical, a new file name is created.

Return the index of the file in the CAB file, and the new name of the file inside the CAB file.

append( database)

Generate a CAB file, add it as a stream to the MSI file, put it into the Media table, and remove the generated file from the disk.
36.1.7 Directory Objects

class Directory(database, cab, basedir, physical, logical, default, component, [componentflags])

Create a new directory in the Directory table. There is a current component at each point in time for the directory, which is either explicitly created through start_component, or implicitly when files are added for the first time. Files are added into the current component, and into the cab file. To create a directory, a base directory object needs to be specified (can be None), the path to the physical directory, and a logical directory name. default specifies the DefaultDir slot in the directory table. componentflags specifies the default flags that new components get.

start_component([component[, feature[, flags[, keyfile[, uuid]]]]])

Add an entry to the Component table, and make this component the current component for this directory. If no component name is given, the directory name is used. If no feature is given, the current feature is used. If no flags are given, the directory's default flags are used. If no keyfile is given, the KeyPath is left null in the Component table.

add_file(file[, src[, version[, language]]])

Add a file to the current component of the directory, starting a new one if there is no current component. By default, the file name in the source and the file table will be identical. If the src file is specified, it is interpreted relative to the current directory. Optionally, a version and a language can be specified for the entry in the File table.

glob(pattern[, exclude])

Add a list of files to the current component as specified in the glob pattern. Individual files can be excluded in the exclude list.

remove_pyc()

Remove .pyc/.pyo files on uninstall.
36.1.8 Features

```
class Feature(database, id, title, desc, display[, level=1[, parent[{}],
directory[, attributes=0]]]])
```

Add a new record to the Feature table, using the values id, parent.id, title, desc, display, level, directory, and attributes. The resulting feature object can be passed to the start_component method of Directory.

```
set_current()
```

Make this feature the current feature of msilib. New components are automatically added to the default feature, unless a feature is explicitly specified.

See Also:

Feature Table
36.1.9 GUI classes

msilib provides several classes that wrap the GUI tables in an MSI database. However, no standard user interface is provided; use bdist_msi to create MSI files with a user-interface for installing Python packages.

class Control( dlg, name)
   Base class of the dialog controls. dlg is the dialog object the control belongs to, and name is the control's name.

event( event, argument[ , condition = `1` [, ordering]])
   Make an entry into the ControlEvent table for this control.

mapping( event, attribute)
   Make an entry into the EventMapping table for this control.

condition( action, condition)
   Make an entry into the ControlCondition table for this control.

class RadioButtonGroup( dlg, name, property)
   Create a radio button control named name. property is the installer property that gets set when a radio button is selected.

add( name, x, y, width, height, text [, value])
   Add a radio button named name to the group, at the coordinates x, y, width, height, and with the label text. If value is omitted, it defaults to name.

class Dialog( db, name, x, y, w, h, attr, title, first, default, cancel)
   Return a new Dialog object. An entry in the Dialog table is made, with the specified coordinates, dialog attributes, title, name of the first, default, and cancel controls.

control( name, type, x, y, width, height, attributes, property, text, control_next, help)
Return a new Control object. An entry in the Control table is made with the specified parameters.

This is a generic method; for specific types, specialized methods are provided.

**text**(*name, x, y, width, height, attributes, text*)
Add and return a Text control.

**bitmap**(*name, x, y, width, height, text*)
Add and return a Bitmap control.

**line**(*name, x, y, width, height*)
Add and return a Line control.

**pushbutton**(*name, x, y, width, height, attributes, text, next_control*)
Add and return a PushButton control.

**radiogroup**(*name, x, y, width, height, attributes, property, text, next_control*)
Add and return a RadioButtonGroup control.

**checkbox**(*name, x, y, width, height, attributes, property, text, next_control*)
Add and return a CheckBox control.

Previous: [36.1.8 Features](#) Up: [36.1 msilib](#) Next: [36.1.10 Precomputed tables](#)

Release 2.5, documentation updated on 19th September, 2006.
See [About this document...](#) for information on suggesting changes.
36.1.10 Precomputed tables

msilib provides a few subpackages that contain only schema and table definitions. Currently, these definitions are based on MSI version 2.0.

**schema**
This is the standard MSI schema for MSI 2.0, with the `tables` variable providing a list of table definitions, and `_Validation_records` providing the data for MSI validation.

**sequence**
This module contains table contents for the standard sequence tables: `AdminExecuteSequence`, `AdminUISequence`, `AdvtExecuteSequence`, `InstallExecuteSequence`, and `InstallUISequence`.

**text**
This module contains definitions for the UIText and ActionText tables, for the standard installer actions.
36.2 msvcrtn - Useful routines from the MS VC++ runtime

Availability: Windows.

These functions provide access to some useful capabilities on Windows platforms. Some higher-level modules use these functions to build the Windows implementations of their services. For example, the `getpass` module uses this in the implementation of the `getpass()` function.

Further documentation on these functions can be found in the Platform API documentation.

- 36.2.3 Other Functions

---

Python Library Reference

Previous: 36.1.10 Precomputed tables Up: 36. MS Windows Specific Next: 36.2.1 File Operations

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
36.2.1 File Operations

**locking( fd, mode, nbytes)**
Lock part of a file based on file descriptor *fd* from the C runtime. Raises IOError on failure. The locked region of the file extends from the current file position for *nbytes* bytes, and may continue beyond the end of the file. *mode* must be one of the LK_* constants listed below. Multiple regions in a file may be locked at the same time, but may not overlap. Adjacent regions are not merged; they must be unlocked individually.

**LK_LOCK**
**LK_RLCK**
Locks the specified bytes. If the bytes cannot be locked, the program immediately tries again after 1 second. If, after 10 attempts, the bytes cannot be locked, IOError is raised.

**LK_NBLCK**
**LK_NBRLCK**
Locks the specified bytes. If the bytes cannot be locked, IOError is raised.

**LK_UNLCK**
Unlocks the specified bytes, which must have been previously locked.

**setmode( fd, flags)**
Set the line-end translation mode for the file descriptor *fd*. To set it to text mode, *flags* should be os.O_TEXT; for binary, it should be os.O_BINARY.

**open_osfhandle( handle, flags)**
Create a C runtime file descriptor from the file handle *handle*. The *flags* parameter should be a bit-wise OR of os.O_APPEND, os.O_RDONLY, and os.O_TEXT. The returned file descriptor may be used as a parameter to os.fdopen() to create a file object.

**get_osfhandle( fd)**
Return the file handle for the file descriptor `fd`. Raises `IOError` if `fd` is not recognized.
36.2.2 Console I/O

**kbhit()**
Return true if a keypress is waiting to be read.

**getch()**
Read a keypress and return the resulting character. Nothing is echoed to the console. This call will block if a keypress is not already available, but will not wait for Enter to be pressed. If the pressed key was a special function key, this will return '\000' or '\xe0'; the next call will return the keycode. The control-c keypress cannot be read with this function.

**getche()**
Similar to **getch()**, but the keypress will be echoed if it represents a printable character.

**putch**( char)
Print the character char to the console without buffering.

**ungetch**( char)
Cause the character char to be "pushed back" into the console buffer; it will be the next character read by **getch()** or **getche()**.

*Release 2.5, documentation updated on 19th September, 2006.*
See [About this document...](#) for information on suggesting changes.
36.2.3 Other Functions

heapmin()

Force the malloc() heap to clean itself up and return unused blocks to the operating system. This only works on Windows NT. On failure, this raises IOError.
36.3 _winreg - Windows registry access

Availability: Windows.

New in version 2.0.

These functions expose the Windows registry API to Python. Instead of using an integer as the registry handle, a handle object is used to ensure that the handles are closed correctly, even if the programmer neglects to explicitly close them.

This module exposes a very low-level interface to the Windows registry; it is expected that in the future a new winreg module will be created offering a higher-level interface to the registry API.

This module offers the following functions:

**CloseKey**( *hkey*)

Closes a previously opened registry key. The *hkey* argument specifies a previously opened key.

Note that if *hkey* is not closed using this method (or via *handle.Close()*), it is closed when the *hkey* object is destroyed by Python.

**ConnectRegistry**( *computer_name*, *key*)

Establishes a connection to a predefined registry handle on another computer, and returns a *handle object*

*computer_name* is the name of the remote computer, of the form r"\\computername". If None, the local computer is used.

*key* is the predefined handle to connect to.

The return value is the handle of the opened key. If the function fails, an *EnvironmentError* exception is raised.
CreateKey( key, sub_key)

Creates or opens the specified key, returning a handle object

key is an already open key, or one of the predefined HKEY_* constants.

sub_key is a string that names the key this method opens or creates.

If key is one of the predefined keys, sub_key may be None. In that case, the handle returned is the same key handle passed in to the function.

If the key already exists, this function opens the existing key.

The return value is the handle of the opened key. If the function fails, an EnvironmentError exception is raised.

DeleteKey( key, sub_key)

Deletes the specified key.

key is an already open key, or any one of the predefined HKEY_* constants.

sub_key is a string that must be a subkey of the key identified by the key parameter. This value must not be None, and the key may not have subkeys.

This method can not delete keys with subkeys.

If the method succeeds, the entire key, including all of its values, is removed. If the method fails, an EnvironmentError exception is raised.

DeleteValue( key, value)

Removes a named value from a registry key.

key is an already open key, or one of the predefined HKEY_* constants.

value is a string that identifies the value to remove.

EnumKey( key, index)

Enumerates subkeys of an open registry key, returning a string.
key is an already open key, or any one of the predefined HKEY_* constants.

index is an integer that identifies the index of the key to retrieve.

The function retrieves the name of one subkey each time it is called. It is typically called repeatedly until an EnvironmentError exception is raised, indicating, no more values are available.

EnumValue( key, index)
Enumerates values of an open registry key, returning a tuple.

key is an already open key, or any one of the predefined HKEY_* constants.

index is an integer that identifies the index of the value to retrieve.

The function retrieves the name of one subkey each time it is called. It is typically called repeatedly, until an EnvironmentError exception is raised, indicating no more values.

The result is a tuple of 3 items:

<table>
<thead>
<tr>
<th>Index</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>A string that identifies the value name</td>
</tr>
<tr>
<td>1</td>
<td>An object that holds the value data, and whose type depends on the underlying registry type</td>
</tr>
<tr>
<td>2</td>
<td>An integer that identifies the type of the value data</td>
</tr>
</tbody>
</table>

FlushKey( key)
Writes all the attributes of a key to the registry.

key is an already open key, or one of the predefined HKEY_* constants.

It is not necessary to call RegFlushKey to change a key. Registry changes are flushed to disk by the registry using its lazy flusher. Registry changes are also flushed to disk at system shutdown. Unlike CloseKey(), the FlushKey() method returns only when all the data has been written to the registry. An application should only call FlushKey() if it requires absolute certainty that registry changes are on disk.
If you don't know whether a `FlushKey()` call is required, it probably isn't.

**RegLoadKey(key, sub_key, file_name)**

Creates a subkey under the specified key and stores registration information from a specified file into that subkey.

*key* is an already open key, or any of the predefined HKEY_* constants.

*sub_key* is a string that identifies the sub_key to load.

*file_name* is the name of the file to load registry data from. This file must have been created with the `SaveKey()` function. Under the file allocation table (FAT) file system, the filename may not have an extension.

A call to LoadKey() fails if the calling process does not have the `SE_RESTORE_PRIVILEGE` privilege. Note that privileges are different than permissions - see the Win32 documentation for more details.

If *key* is a handle returned by `ConnectRegistry()`, then the path specified in *file_name* is relative to the remote computer.

The Win32 documentation implies *key* must be in the HKEY_USER or HKEY_LOCAL_MACHINE tree. This may or may not be true.

**OpenKey(key, sub_key[, res = 0][, sam = KEY_READ])**

Opens the specified key, returning a handle object

*key* is an already open key, or any one of the predefined HKEY_* constants.

*sub_key* is a string that identifies the sub_key to open.

*res* is a reserved integer, and must be zero. The default is zero.

*sam* is an integer that specifies an access mask that describes the desired security access for the key. Default is KEY_READ

The result is a new handle to the specified key.
If the function fails, `EnvironmentError` is raised.

**OpenKeyEx()**

The functionality of `OpenKeyEx()` is provided via `OpenKey()`, by the use of default arguments.

**QueryInfoKey** *(key)*

Returns information about a key, as a tuple.

`key` is an already open key, or one of the predefined `HKEY_*` constants.

The result is a tuple of 3 items:

<table>
<thead>
<tr>
<th>Index</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>An integer giving the number of sub keys this key has.</td>
</tr>
<tr>
<td>1</td>
<td>An integer giving the number of values this key has.</td>
</tr>
<tr>
<td>2</td>
<td>A long integer giving when the key was last modified (if available) as 100's of nanoseconds since Jan 1, 1600.</td>
</tr>
</tbody>
</table>

**QueryValue** *(key, sub_key)*

Retrieves the unnamed value for a key, as a string

`key` is an already open key, or one of the predefined `HKEY_*` constants.

`sub_key` is a string that holds the name of the subkey with which the value is associated. If this parameter is `None` or empty, the function retrieves the value set by the `SetValue()` method for the key identified by `key`.

Values in the registry have name, type, and data components. This method retrieves the data for a key's first value that has a NULL name. But the underlying API call doesn't return the type, Lame Lame Lame, DO NOT USE THIS!!

**QueryValueEx** *(key, value_name)*

Retrieves the type and data for a specified value name associated with an open registry key.

`key` is an already open key, or one of the predefined `HKEY_*` constants.
value_name is a string indicating the value to query.

The result is a tuple of 2 items:

<table>
<thead>
<tr>
<th>Index</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>The value of the registry item.</td>
</tr>
<tr>
<td>1</td>
<td>An integer giving the registry type for this value.</td>
</tr>
</tbody>
</table>

**SaveKey( key, file_name)**
Saves the specified key, and all its subkeys to the specified file.

*key* is an already open key, or one of the predefined HKEY_* constants.

*file_name* is the name of the file to save registry data to. This file cannot already exist. If this filename includes an extension, it cannot be used on file allocation table (FAT) file systems by the LoadKey(), ReplaceKey() or RestoreKey() methods.

If *key* represents a key on a remote computer, the path described by *file_name* is relative to the remote computer. The caller of this method must possess the SeBackupPrivilege security privilege. Note that privileges are different than permissions - see the Win32 documentation for more details.

This function passes NULL for security_attributes to the API.

**SetValue( key, sub_key, type, value)**
Associates a value with a specified key.

*key* is an already open key, or one of the predefined HKEY_* constants.

*sub_key* is a string that names the subkey with which the value is associated.

*type* is an integer that specifies the type of the data. Currently this must be REG_SZ, meaning only strings are supported. Use the SetValueEx() function for support for other data types.

*value* is a string that specifies the new value.
If the key specified by the *sub_key* parameter does not exist, the *SetValue* function creates it.

Value lengths are limited by available memory. Long values (more than 2048 bytes) should be stored as files with the filenames stored in the configuration registry. This helps the registry perform efficiently.

The key identified by the *key* parameter must have been opened with *KEY_SET_VALUE* access.

**SetValueEx**(*key, value_name, reserved, type, value*)
Stores data in the value field of an open registry key.

*key* is an already open key, or one of the predefined HKEY_* constants.

*sub_key* is a string that names the subkey with which the value is associated.

*type* is an integer that specifies the type of the data. This should be one of the following constants defined in this module:

<table>
<thead>
<tr>
<th>Constant</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>REG_BINARY</td>
<td>Binary data in any form.</td>
</tr>
<tr>
<td>REG_DWORD</td>
<td>A 32-bit number.</td>
</tr>
<tr>
<td>REG_DWORD_LITTLE_ENDIAN</td>
<td>A 32-bit number in little-endian format.</td>
</tr>
<tr>
<td>REG_DWORD_BIG_ENDIAN</td>
<td>A 32-bit number in big-endian format.</td>
</tr>
<tr>
<td>REG_EXPAND_SZ</td>
<td>Null-terminated string containing references to environment variables (&quot;%PATH%&quot;)</td>
</tr>
<tr>
<td>REG_LINK</td>
<td>A Unicode symbolic link.</td>
</tr>
<tr>
<td>REG_MULTI_SZ</td>
<td>A sequence of null-terminated strings, terminated by two null characters. (Python handles this termination automatically.)</td>
</tr>
<tr>
<td>REG_NONE</td>
<td>No defined value type.</td>
</tr>
<tr>
<td>REG_RESOURCE_LIST</td>
<td>A device-driver resource list.</td>
</tr>
</tbody>
</table>
REG_SZ | A null-terminated string.

reserved can be anything - zero is always passed to the API.

value is a string that specifies the new value.

This method can also set additional value and type information for the specified key. The key identified by the key parameter must have been opened with KEY_SET_VALUE access.

To open the key, use the CreateKeyEx() or OpenKey() methods.

Value lengths are limited by available memory. Long values (more than 2048 bytes) should be stored as files with the filenames stored in the configuration registry. This helps the registry perform efficiently.

Subsections

- 36.3.1 Registry Handle Objects
36.3.1 Registry Handle Objects

This object wraps a Windows HKEY object, automatically closing it when the object is destroyed. To guarantee cleanup, you can call either the \texttt{Close()} method on the object, or the \texttt{CloseKey()} function.

All registry functions in this module return one of these objects.

All registry functions in this module which accept a handle object also accept an integer, however, use of the handle object is encouraged.

Handle objects provide semantics for \texttt{\_\_nonzero\_()} - thus

\begin{verbatim}
    if handle:
        print "Yes"
\end{verbatim}

will print \texttt{Yes} if the handle is currently valid (has not been closed or detached).

The object also support comparison semantics, so handle objects will compare true if they both reference the same underlying Windows handle value.

Handle objects can be converted to an integer (e.g., using the built-in \texttt{int()} function), in which case the underlying Windows handle value is returned. You can also use the \texttt{Detach()} method to return the integer handle, and also disconnect the Windows handle from the handle object.

\textbf{Close()}

Closes the underlying Windows handle.

If the handle is already closed, no error is raised.

\textbf{Detach()}

Detaches the Windows handle from the handle object.

The result is an integer (or long on 64 bit Windows) that holds the value of the handle before it is detached. If the handle is already detached or closed, this will return zero.

After calling this function, the handle is effectively invalidated, but the
handle is not closed. You would call this function when you need the underlying Win32 handle to exist beyond the lifetime of the handle object.
36.4 winsound -- Sound-playing interface for Windows

Availability: Windows.

New in version 1.5.2.

The winsound module provides access to the basic sound-playing machinery provided by Windows platforms. It includes functions and several constants.

**Beep** (*frequency, duration*)

Beep the PC's speaker. The *frequency* parameter specifies frequency, in hertz, of the sound, and must be in the range 37 through 32,767. The *duration* parameter specifies the number of milliseconds the sound should last. If the system is not able to beep the speaker, `RuntimeError` is raised. **Note:** Under Windows 95 and 98, the Windows `Beep()` function exists but is useless (it ignores its arguments). In that case Python simulates it via direct port manipulation (added in version 2.1). It's unknown whether that will work on all systems. New in version 1.6.

**PlaySound** (*sound, flags*)

Call the underlying `PlaySound()` function from the Platform API. The *sound* parameter may be a filename, audio data as a string, or None. Its interpretation depends on the value of *flags*, which can be a bit-wise ORed combination of the constants described below. If the system indicates an error, `RuntimeError` is raised.

**MessageBeep** ([*type=MB_OK]*)

Call the underlying `MessageBeep()` function from the Platform API. This plays a sound as specified in the registry. The *type* argument specifies which sound to play; possible values are -1, MB_ICONASTERISK, MB_ICONEXCLAMATION, MB_ICONHAND, MB_ICONQUESTION, and MB_OK, all described below. The value -1 produces a ``simple beep``; this is the final fallback if a sound cannot be played otherwise. New in version 2.3.
SND_FILENAME
The `sound` parameter is the name of a WAV file. Do not use with SND_ALIAS.

SND_ALIAS
The `sound` parameter is a sound association name from the registry. If the registry contains no such name, play the system default sound unless SND_NODEFAULT is also specified. If no default sound is registered, raise RuntimeError. Do not use with SND_FILENAME.

All Win32 systems support at least the following; most systems support many more:

<table>
<thead>
<tr>
<th>PlaySound() name</th>
<th>Corresponding Control Panel Sound name</th>
</tr>
</thead>
<tbody>
<tr>
<td>'SystemAsterisk'</td>
<td>Asterisk</td>
</tr>
<tr>
<td>'SystemExclamation'</td>
<td>Exclamation</td>
</tr>
<tr>
<td>'SystemExit'</td>
<td>Exit Windows</td>
</tr>
<tr>
<td>'SystemHand'</td>
<td>Critical Stop</td>
</tr>
<tr>
<td>'SystemQuestion'</td>
<td>Question</td>
</tr>
</tbody>
</table>

For example:

```python
import winsound
# Play Windows exit sound.
winsound.PlaySound("SystemExit", winsound.SND_ALIAS)

# Probably play Windows default sound, if any is registered (but"
# "*" probably isn't the registered name of any sound).
winsound.PlaySound("*", winsound.SND_ALIAS)
```

SND_LOOP
Play the sound repeatedly. The SND_ASYNC flag must also be used to avoid blocking. Cannot be used with SND_MEMORY.

SND_MEMORY
The `sound` parameter to PlaySound() is a memory image of a WAV file, as a string.

Note: This module does not support playing from a memory image
asynchronously, so a combination of this flag and SND_ASYNC will raise RuntimeError.

**SND_PURGE**
Stop playing all instances of the specified sound.

**SND_ASYNC**
Return immediately, allowing sounds to play asynchronously.

**SND_NODEFAULT**
If the specified sound cannot be found, do not play the system default sound.

**SND_NOSTOP**
Do not interrupt sounds currently playing.

**SND_NOWAIT**
Return immediately if the sound driver is busy.

**MB_ICONASTERISK**
Play the SystemDefault sound.

**MB_ICONEXCLAMATION**
Play the SystemExclamation sound.

**MB_ICONHAND**
Play the SystemHand sound.

**MB_ICONQUESTION**
Play the SystemQuestion sound.

**MB_OK**
Play the SystemDefault sound.
See *About this document*... for information on suggesting changes.
A. Undocumented Modules

Here's a quick listing of modules that are currently undocumented, but that should be documented. Feel free to contribute documentation for them! (Send via email to docs@python.org.)

The idea and original contents for this chapter were taken from a posting by Fredrik Lundh; the specific contents of this chapter have been substantially revised.

Subsections

- A.1 Frameworks
- A.2 Miscellaneous useful utilities
- A.3 Platform specific modules
- A.4 Multimedia
- A.5 Obsolete
- A.6 SGI-specific Extension modules

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
A.1 Frameworks

Frameworks tend to be harder to document, but are well worth the effort spent.

None at this time.
A.2 Miscellaneous useful utilities

Some of these are very old and/or not very robust; marked with ``hmm."

bdb

-- A generic Python debugger base class (used by pdb).

ihooks

-- Import hook support (for rexec; may become obsolete).
A.3 Platform specific modules

These modules are used to implement the `os.path` module, and are not documented beyond this mention. There's little need to document these.

**ntpath**
-- Implementation of `os.path` on Win32, Win64, WinCE, and OS/2 platforms.

**posixpath**
-- Implementation of `os.path` on POSIX.

**bsddb185**
-- Backwards compatibility module for systems which still use the Berkeley DB 1.85 module. It is normally only available on certain BSD UNIX-based systems. It should never be used directly.
A.4 Multimedia

audiodев
-- Platform-independent API for playing audio data.

linuxaudiodев
-- Play audio data on the Linux audio device. Replaced in Python 2.3 by the ossaudiodев module.

sunaudio
-- Interpret Sun audio headers (may become obsolete or a tool/demo).

toaiff
-- Convert "arbitrary" sound files to AIFF files; should probably become a tool or demo. Requires the external program sox.
A.5 Obsolete

These modules are not normally available for import; additional work must be done to make them available.

These extension modules written in C are not built by default. Under Unix, these must be enabled by uncommenting the appropriate lines in Modules/Setup in the build tree and either rebuilding Python if the modules are statically linked, or building and installing the shared object if using dynamically-loaded extensions.

**timing**

-- Measure time intervals to high resolution (use `time.clock()` instead).
A.6 SGI-specific Extension modules

The following are SGI specific, and may be out of touch with the current version of reality.

cl

-- Interface to the SGI compression library.

sv

-- Interface to the "simple video" board on SGI Indigo (obsolete hardware).
B. Reporting Bugs

Python is a mature programming language which has established a reputation for stability. In order to maintain this reputation, the developers would like to know of any deficiencies you find in Python or its documentation.

Before submitting a report, you will be required to log into SourceForge; this will make it possible for the developers to contact you for additional information if needed. It is not possible to submit a bug report anonymously.

All bug reports should be submitted via the Python Bug Tracker on SourceForge ([http://sourceforge.net/bugs/?group_id=5470](http://sourceforge.net/bugs/?group_id=5470)). The bug tracker offers a Web form which allows pertinent information to be entered and submitted to the developers.

The first step in filing a report is to determine whether the problem has already been reported. The advantage in doing so, aside from saving the developers time, is that you learn what has been done to fix it; it may be that the problem has already been fixed for the next release, or additional information is needed (in which case you are welcome to provide it if you can!). To do this, search the bug database using the search box on the left side of the page.

If the problem you're reporting is not already in the bug tracker, go back to the Python Bug Tracker ([http://sourceforge.net/bugs/?group_id=5470](http://sourceforge.net/bugs/?group_id=5470)). Select the "Submit a Bug" link at the top of the page to open the bug reporting form.

The submission form has a number of fields. The only fields that are required are the "Summary" and "Details" fields. For the summary, enter a very short description of the problem; less than ten words is good. In the Details field, describe the problem in detail, including what you expected to happen and what did happen. Be sure to include the version of Python you used, whether any extension modules were involved, and what hardware and software platform you were using (including version information as appropriate).

The only other field that you may want to set is the "Category" field, which allows you to place the bug report into a broad category (such as "Documentation" or "Library").
Each bug report will be assigned to a developer who will determine what needs to be done to correct the problem. You will receive an update each time action is taken on the bug.

See Also:

*How to Report Bugs Effectively*

Article which goes into some detail about how to create a useful bug report. This describes what kind of information is useful and why it is useful.

*Bug Writing Guidelines*

Information about writing a good bug report. Some of this is specific to the Mozilla project, but describes general good practices.
C. History and License

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
C.1 History of the software

Python was created in the early 1990s by Guido van Rossum at Stichting Mathematisch Centrum (CWI, see http://www.cwi.nl/) in the Netherlands as a successor of a language called ABC. Guido remains Python's principal author, although it includes many contributions from others.

In 1995, Guido continued his work on Python at the Corporation for National Research Initiatives (CNRI, see http://www.cnri.reston.va.us/) in Reston, Virginia where he released several versions of the software.

In May 2000, Guido and the Python core development team moved to BeOpen.com to form the BeOpen PythonLabs team. In October of the same year, the PythonLabs team moved to Digital Creations (now Zope Corporation; see http://www.zope.com/). In 2001, the Python Software Foundation (PSF, see http://www.python.org/psf/) was formed, a non-profit organization created specifically to own Python-related Intellectual Property. Zope Corporation is a sponsoring member of the PSF.

All Python releases are Open Source (see http://www.opensource.org/ for the Open Source Definition). Historically, most, but not all, Python releases have also been GPL-compatible; the table below summarizes the various releases.

</table>
Note: GPL-compatible doesn't mean that we're distributing Python under the GPL. All Python licenses, unlike the GPL, let you distribute a modified version without making your changes open source. The GPL-compatible licenses make it possible to combine Python with other software that is released under the GPL; the others don't.

Thanks to the many outside volunteers who have worked under Guido's direction to make these releases possible.
C.2 Terms and conditions for accessing or otherwise using Python

PSF LICENSE AGREEMENT FOR PYTHON 2.5

1. This LICENSE AGREEMENT is between the Python Software Foundation (``PSF''), and the Individual or Organization (``Licensee'') accessing and otherwise using Python 2.5 software in source or binary form and its associated documentation.

2. Subject to the terms and conditions of this License Agreement, PSF hereby grants Licensee a nonexclusive, royalty-free, world-wide license to reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use Python 2.5 alone or in any derivative version, provided, however, that PSF's License Agreement and PSF's notice of copyright, i.e., ``Copyright © 2001-2006 Python Software Foundation; All Rights Reserved'' are retained in Python 2.5 alone or in any derivative version prepared by Licensee.

3. In the event Licensee prepares a derivative work that is based on or incorporates Python 2.5 or any part thereof, and wants to make the derivative work available to others as provided herein, then Licensee hereby agrees to include in any such work a brief summary of the changes made to Python 2.5.

4. PSF is making Python 2.5 available to Licensee on an ``AS IS'' basis. PSF MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT LIMITATION, PSF MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF PYTHON 2.5 WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.

5. PSF SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS
OF PYTHON 2.5 FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF MODIFYING, DISTRIBUTING, OR OTHERWISE USING PYTHON 2.5, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.

6. This License Agreement will automatically terminate upon a material breach of its terms and conditions.

7. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between PSF and Licensee. This License Agreement does not grant permission to use PSF trademarks or trade name in a trademark sense to endorse or promote products or services of Licensee, or any third party.

8. By copying, installing or otherwise using Python 2.5, Licensee agrees to be bound by the terms and conditions of this License Agreement.

BEOPEN.COM LICENSE AGREEMENT FOR PYTHON 2.0

BEOPEN PYTHON OPEN SOURCE LICENSE AGREEMENT VERSION 1

1. This LICENSE AGREEMENT is between BeOpen.com (``BeOpen''), having an office at 160 Saratoga Avenue, Santa Clara, CA 95051, and the Individual or Organization (``Licensee'') accessing and otherwise using this software in source or binary form and its associated documentation (``the Software '').

2. Subject to the terms and conditions of this BeOpen Python License Agreement, BeOpen hereby grants Licensee a non-exclusive, royalty-free, world-wide license to reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use the Software alone or in any derivative version, provided, however, that the BeOpen Python License is retained in the Software, alone or in any derivative version prepared by Licensee.

3. BeOpen is making the Software available to Licensee on an ``AS IS'' basis. BEOPEN MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT
LIMITATION, BEOPEN MAKES NO AND DISCLAIMS ANY
REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR
FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF
THE SOFTWARE WILL NOT INFRINGE ANY THIRD PARTY
RIGHTS.

4. BEOPEN SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER
USERS OF THE SOFTWARE FOR ANY INCIDENTAL, SPECIAL, OR
CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF USING,
MODIFYING OR DISTRIBUTING THE SOFTWARE, OR ANY
DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY
THEREOF.

5. This License Agreement will automatically terminate upon a material
breach of its terms and conditions.

6. This License Agreement shall be governed by and interpreted in all respects
by the law of the State of California, excluding conflict of law provisions.
Nothing in this License Agreement shall be deemed to create any
relationship of agency, partnership, or joint venture between BeOpen and
Licensee. This License Agreement does not grant permission to use
BeOpen trademarks or trade names in a trademark sense to endorse or
promote products or services of Licensee, or any third party. As an
exception, the ``BeOpen Python'' logos available at
http://www.pythonlabs.com/logos.html may be used according to the
permissions granted on that web page.

7. By copying, installing or otherwise using the software, Licensee agrees to
be bound by the terms and conditions of this License Agreement.

CNRI LICENSE AGREEMENT FOR PYTHON 1.6.1

1. This LICENSE AGREEMENT is between the Corporation for National
Research Initiatives, having an office at 1895 Preston White Drive, Reston,
VA 20191 (`CNRI"), and the Individual or Organization (`Licensee"
accessing and otherwise using Python 1.6.1 software in source or binary
form and its associated documentation.

2. Subject to the terms and conditions of this License Agreement, CNRI
hereby grants Licensee a nonexclusive, royalty-free, world-wide license to
reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use Python 1.6.1 alone or in any derivative version, provided, however, that CNRI's License Agreement and CNRI's notice of copyright, i.e., ``Copyright © 1995-2001 Corporation for National Research Initiatives; All Rights Reserved" are retained in Python 1.6.1 alone or in any derivative version prepared by Licensee. Alternately, in lieu of CNRI's License Agreement, Licensee may substitute the following text (omitting the quotes): ``Python 1.6.1 is made available subject to the terms and conditions in CNRI's License Agreement. This Agreement together with Python 1.6.1 may be located on the Internet using the following unique, persistent identifier (known as a handle): 1895.22/1013. This Agreement may also be obtained from a proxy server on the Internet using the following URL: http://hdl.handle.net/1895.22/1013."

3. In the event Licensee prepares a derivative work that is based on or incorporates Python 1.6.1 or any part thereof, and wants to make the derivative work available to others as provided herein, then Licensee hereby agrees to include in any such work a brief summary of the changes made to Python 1.6.1.

4. CNRI is making Python 1.6.1 available to Licensee on an `AS IS" basis. CNRI MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT LIMITATION, CNRI MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF PYTHON 1.6.1 WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.

5. CNRI SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS OF PYTHON 1.6.1 FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF MODIFYING, DISTRIBUTING, OR OTHERWISE USING PYTHON 1.6.1, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.

6. This License Agreement will automatically terminate upon a material breach of its terms and conditions.

7. This License Agreement shall be governed by the federal intellectual
property law of the United States, including without limitation the federal copyright law, and, to the extent such U.S. federal law does not apply, by the law of the Commonwealth of Virginia, excluding Virginia's conflict of law provisions. Notwithstanding the foregoing, with regard to derivative works based on Python 1.6.1 that incorporate non-separable material that was previously distributed under the GNU General Public License (GPL), the law of the Commonwealth of Virginia shall govern this License Agreement only as to issues arising under or with respect to Paragraphs 4, 5, and 7 of this License Agreement. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between CNRI and Licensee. This License Agreement does not grant permission to use CNRI trademarks or trade name in a trademark sense to endorse or promote products or services of Licensee, or any third party.

8. By clicking on the ``ACCEPT" button where indicated, or by copying, installing or otherwise using Python 1.6.1, Licensee agrees to be bound by the terms and conditions of this License Agreement.

ACCEPT

CWI LICENSE AGREEMENT FOR PYTHON 0.9.0 THROUGH 1.2

Copyright © 1991 - 1995, Stichting Mathematisch Centrum Amsterdam, The Netherlands. All rights reserved.

Permission to use, copy, modify, and distribute this software and its documentation for any purpose and without fee is hereby granted, provided that the above copyright notice appear in all copies and that both that copyright notice and this permission notice appear in supporting documentation, and that the name of Stichting Mathematisch Centrum or CWI not be used in advertising or publicity pertaining to distribution of the software without specific, written prior permission.

STICHTING MATHEMATISCH CENTRUM DISCLAIMS ALL WARRANTIES WITH REGARD TO THIS SOFTWARE, INCLUDING ALL IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS, IN NO EVENT SHALL STICHTING MATHEMATISCH CENTRUM BE LIABLE FOR ANY SPECIAL, INDIRECT OR CONSEQUENTIAL DAMAGES OR
ANY DAMAGES WHATSOEVER RESULTING FROM LOSS OF USE, DATA OR PROFITS, WHETHER IN AN ACTION OF CONTRACT, NEGLIGENCE OR OTHER TORTIOUS ACTION, ARISING OUT OF OR IN CONNECTION WITH THE USE OR PERFORMANCE OF THIS SOFTWARE.
C.3 Licenses and Acknowledgements for Incorporated Software

This section is an incomplete, but growing list of licenses and acknowledgements for third-party software incorporated in the Python distribution.

Subsections

- C.3.1 Mersenne Twister
- C.3.2 Sockets
- C.3.3 Floating point exception control
- C.3.4 MD5 message digest algorithm
- C.3.5 Asynchronous socket services
- C.3.6 Cookie management
- C.3.7 Profiling
- C.3.8 Execution tracing
- C.3.9 UUencode and UUdecode functions
- C.3.10 XML Remote Procedure Calls

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
C.3.1 Mersenne Twister

The _random module includes code based on a download from http://www.math.keio.ac.jp/~matumoto/MT2002/emt19937ar.html. The following are the verbatim comments from the original code:

A C-program for MT19937, with initialization improved 2002/1/26. Coded by Takuji Nishimura and Makoto Matsumoto.

Before using, initialize the state by using init_genrand(seed) or init_by_array(init_key, key_length).

Copyright (C) 1997 - 2002, Makoto Matsumoto and Takuji Nishimura, All rights reserved.

Redistribution and use in source and binary forms, with or without modification, are permitted provided that the following conditions are met:

1. Redistributions of source code must retain the above copyright notice, this list of conditions and the following disclaimer.

2. Redistributions in binary form must reproduce the above copyright notice, this list of conditions and the following disclaimer in documentation and/or other materials provided with the distribution.

3. The names of its contributors may not be used to endorse or promote products derived from this software without specific prior written permission.

THIS SOFTWARE IS PROVIDED BY THE COPYRIGHT HOLDERS AND CONTRIBUTORS "AS IS" AND ANY EXPRESS OR IMPLIED WARRANTIES, INCLUDING, BUT NOT LIMITED TO, THE IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS FOR A PARTICULAR PURPOSE ARE DISCLAIMED. IN NO EVENT SHALL THE COPYRIGHT HOLDERS AND CONTRIBUTORS BE LIABLE FOR ANY DIRECT, INDIRECT, INCIDENTAL, SPECIAL EXEMPLARY, OR CONSEQUENTIAL DAMAGES (INCLUDING, BUT NOT LIMITED TO, PROCUREMENT OF SUBSTITUTE GOODS OR SERVICES; LOSS OF USE, DATA, OR PROFITS; OR BUSINESS INTERRUPTION) HOWEVER CAUSED AND ON ANY THEORY LIABILITY, WHETHER IN CONTRACT, STRICT LIABILITY, OR TORT (INCLUDING NEGLIGENCE OR OTHERWISE) ARISING IN ANY WAY OUT OF THE USE OF THIS SOFTWARE, EVEN IF ADVISED OF THE POSSIBILITY OF SUCH DAMAGE.

Any feedback is very welcome.

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
C.3.2 Sockets

The socket module uses the functions, `getaddrinfo`, and `getnameinfo`, which are coded in separate source files from the WIDE Project, http://www.wide.ad.jp/about/index.html.

Copyright (C) 1995, 1996, 1997, and 1998 WIDE Project. All rights reserved.

Redistribution and use in source and binary forms, with or without modification, are permitted provided that the following conditions are met:

1. Redistributions of source code must retain the above copyright notice, this list of conditions and the following disclaimer.
2. Redistributions in binary form must reproduce the above copyright notice, this list of conditions and the following disclaimer in the documentation and/or other materials provided with the distribution.
3. Neither the name of the project nor the names of its contributors may be used to endorse or promote products derived from this software without specific prior written permission.

THIS SOFTWARE IS PROVIDED BY THE PROJECT AND CONTRIBUTORS "AS IS" AND ANY EXPRESS OR IMPLIED WARRANTIES, INCLUDING, BUT NOT LIMITED TO IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS FOR A PARTICULAR PURPOSE ARE DISCLAIMED. IN NO EVENT SHALL THE PROJECT OR CONTRIBUTORS BE LIABLE FOR ANY DIRECT, INDIRECT, INCIDENTAL, SPECIAL, EXEMPLARY, OR CONSEQUENTIAL DAMAGES (INCLUDING, BUT NOT LIMITED TO, PROCUREMENT OF SUBSTITUTE GOODS OR SERVICES; LOSS OF USE, DATA, OR PROFITS; OR BUSINESS INTERRUPTION) HOWEVER CAUSED AND ON ANY THEORY OF LIABILITY, WHETHER IN CONTRACT, STRICT LIABILITY, OR TORT (INCLUDING NEGLIGENCE OR OTHERWISE) ARISING IN ANY WAY OUT OF THE USE OF THIS SOFTWARE, EVEN IF ADVISED OF THE POSSIBILITY OF SUCH DAMAGE.
C.3.3 Floating point exception control

The source for the `fpectl` module includes the following notice:

```
/               Copyright (c) 1996.
                The Regents of the University of California.
                All rights reserved.

Permission to use, copy, modify, and distribute this software any purpose without fee is hereby granted, provided that this tire notice is included in all copies of any software which i includes a copy or modification of this software and in copies of the supporting documentation for such software.

This work was produced at the University of California, Lawr Livermore National Laboratory under contract no. W-7405-EN between the U.S. Department of Energy and The Regents of University of California for the operation of UC LLNL.

DISCLAIMER

This software was prepared as an account of work sponsored b agency of the United States Government. Neither the United St Government nor the University of California nor any of their ployees, makes any warranty, express or implied, or assumes liability or responsibility for the accuracy, completeness usefulness of any information, apparatus, product, or pro disclosed, or represents that its use would not infr privately-owned rights. Reference herein to any specific com rcial products, process, or service by trade name, trademark manufacturer, or otherwise, does not necessarily constitute imply its endorsement, recommendation, or favoring by the Un States Government or the University of California. The views opinions of authors expressed herein do not necessarily stat reflect those of the United States Government or the Univer of California, and shall not be used for advertising or pro endorsement purposes.
```
C.3.4 MD5 message digest algorithm

The source code for the `md5` module contains the following notice:

```
Copyright (C) 1999, 2002 Aladdin Enterprises. All rights reserved

This software is provided 'as-is', without any express or implied warranty. In no event will the authors be held liable for any damage arising from the use of this software.

Permission is granted to anyone to use this software for any purpose including commercial applications, and to alter it and redistribute it freely, subject to the following restrictions:

1. The origin of this software must not be misrepresented; you must claim that you wrote the original software. If you use this software in a product, an acknowledgment in the product documentation would be appreciated but is not required.
2. Altered source versions must be plainly marked as such, and not misrepresented as being the original software.
3. This notice may not be removed or altered from any source distribution.

L. Peter Deutsch
ghost@aladdin.com

Independent implementation of MD5 (RFC 1321).

This code implements the MD5 Algorithm defined in RFC 1321, whose text is available at
http://www.ietf.org/rfc/rfc1321.txt
The code is derived from the text of the RFC, including the test suite (section A.5) but excluding the rest of Appendix A. It does not include any code or documentation that is identified in the RFC as being copyrighted.

The original and principal author of `md5.h` is L. Peter Deutsch <ghost@aladdin.com>. Other authors are noted in the change history that follows (in reverse chronological order):

2002-04-13 lpd Removed support for non-ANSI compilers; removed references to Ghostscript; clarified derivation from RFC 132
now handles byte order either statically or dynamically.
1999-11-04 lpd Edited comments slightly for automatic TOC extraction
1999-10-18 lpd Fixed typo in header comment (ansi2knr rather than added conditionalization for C++ compilation from Martin Purschke <purschke@bnl.gov>.
1999-05-03 lpd Original version.
```
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
C.3.5 Asynchronous socket services

The `asynchat` and `asyncore` modules contain the following notice:

```
Copyright 1996 by Sam Rushing

All Rights Reserved

Permission to use, copy, modify, and distribute this software and its documentation for any purpose and without fee is hereby granted, provided that the above copyright notice appear in all copies and that both that copyright notice and this permission notice appear in supporting documentation, and that the name of Sam Rushing not be used in advertising or publicity pertaining to distribution of the software without specific, written prior permission.

SAM RUSHING DISCLAIMS ALL WARRANTIES WITH REGARD TO THIS SOFTWARE, INCLUDING ALL IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS, IN NO EVENT SHALL SAM RUSHING BE LIABLE FOR ANY SPECIAL, INDIRECT OR CONSEQUENTIAL DAMAGES OR ANY DAMAGES WHATSOEVER RESULTING FROM LOSS OF USE, DATA OR PROFITS, WHETHER IN AN ACTION OF CONTRACT, NEGLIGENCE OR OTHER TORTIOUS ACTION, ARISING OUT OF OR IN CONNECTION WITH THE USE OR PERFORMANCE OF THIS SOFTWARE.
```
C.3.6 Cookie management

The Cookie module contains the following notice:

Copyright 2000 by Timothy O'Malley <timo@alum.mit.edu>

All Rights Reserved

Permission to use, copy, modify, and distribute this software and its documentation for any purpose and without fee is hereby granted, provided that the above copyright notice appear in all copies and that both that copyright notice and this permission notice appear in supporting documentation, and that the name of Timothy O'Malley not be used in advertising or publicity pertaining to distribution of the software without specific, written prior permission.

Timothy O'Malley DISCLAIMS ALL WARRANTIES WITH REGARD TO THIS SOFTWARE, INCLUDING ALL IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS, IN NO EVENT SHALL Timothy O'Malley BE LIABLE FOR ANY SPECIAL, INDIRECT OR CONSEQUENTIAL DAMAGES OR ANY DAMAGES WHATSOEVER RESULTING FROM LOSS OF USE, DATA OR PROFITS, WHETHER IN AN ACTION OF CONTRACT, NEGLIGENCE OR OTHER TORTIOUS ACTION, ARISING OUT OF OR IN CONNECTION WITH THE USE OR PERFORMANCE OF THIS SOFTWARE.
C.3.7 Profiling

The profile and pstats modules contain the following notice:

Copyright 1994, by InfoSeek Corporation, all rights reserved. Written by James Roskind

Permission to use, copy, modify, and distribute this Python software and its associated documentation for any purpose (subject to the restriction in the following sentence) without fee is hereby granted provided that the above copyright notice appears in all copies, and that both that copyright notice and this permission notice appear in supporting documentation, and that the name of InfoSeek not be used advertising or publicity pertaining to distribution of the software without specific, written prior permission. This permission is explicitly restricted to the copying and modification of the software to remain in Python, compiled Python, or other languages (such as C wherein the modified or derived code is exclusively imported into a Python module.

INFOSEEK CORPORATION DISCLAIMS ALL WARRANTIES WITH REGARD TO THIS SOFTWARE, INCLUDING ALL IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS. IN NO EVENT SHALL INFOSEEK CORPORATION BE LIABLE FOR ANY SPECIAL, INDIRECT OR CONSEQUENTIAL DAMAGES OR ANY DAMAGES WHATSOEVER RESULTING FROM LOSS OF USE, DATA OR PROFITS, WHETHER IN AN ACTION OF CONTRACT, NEGLIGENCE OR OTHER TORTIOUS ACTION, ARISING OUT OF OR IN CONNECTION WITH THE USE OR PERFORMANCE OF THIS SOFTWARE.
C.3.8 Execution tracing

The `trace` module contains the following notice:

```
portions copyright 2001, Autonomous Zones Industries, Inc., all rig
erres... reserved and offered to the public under the terms of the
Python 2.2 license.
Author: Zooko O'Whielacronx
http://zooko.com/

Copyright 1991-1995, Stichting Mathematisch Centrum, all rights res
```

Permission to use, copy, modify, and distribute this Python software
its associated documentation for any purpose without fee is hereby
granted, provided that the above copyright notice appears in all co
and that both that copyright notice and this permission notice appe
supporting documentation, and that the name of neither Automatrix,
Bioreason or Mojam Media be used in advertising or publicity pertai
distribution of the software without specific, written prior permis
C.3.9 UUencode and UUdecode functions

The uu module contains the following notice:

Copyright 1994 by Lance Ellinghouse
Cathedral City, California Republic, United States of America.
All Rights Reserved
Permission to use, copy, modify, and distribute this software and its
documentation for any purpose and without fee is hereby granted,
provided that the above copyright notice appear in all copies and that
both that copyright notice and this permission notice appear in
supporting documentation, and that the name of Lance Ellinghouse
not be used in advertising or publicity pertaining to distribution
of the software without specific, written prior permission.
LANCE ELLINGHOUSE DISCLAIMS ALL WARRANTIES WITH REGARD TO
THIS SOFTWARE, INCLUDING ALL IMPLIED WARRANTIES OF MERCHANTABILITY
FITNESS, IN NO EVENT SHALL LANCE ELLINGHOUSE CENTRUM BE LIABLE
FOR ANY SPECIAL, INDIRECT OR CONSEQUENTIAL DAMAGES OR ANY DAMAGES
WHATSOEVER RESULTING FROM LOSS OF USE, DATA OR PROFITS, WHETHER IN
ACTION OF CONTRACT, NEGLIGENCE OR OTHER TORTIOUS ACTION, ARISING OUT
OF OR IN CONNECTION WITH THE USE OR PERFORMANCE OF THIS SOFTWARE.

Modified by Jack Jansen, CWI, July 1995:
- Use binascii module to do the actual line-by-line conversion
  between ascii and binary. This results in a 1000-fold speedup. Th
  version is still 5 times faster, though.
- Arguments more compliant with python standard
C.3.10 XML Remote Procedure Calls

The xmlrpclib module contains the following notice:

The XML-RPC client interface is

Copyright (c) 1999-2002 by Secret Labs AB
Copyright (c) 1999-2002 by Fredrik Lundh

By obtaining, using, and/or copying this software and/or its associated documentation, you agree that you have read, understood, and will comply with the following terms and conditions:

Permission to use, copy, modify, and distribute this software and its associated documentation for any purpose and without fee is hereby granted, provided that the above copyright notice appears in all copies, and that both that copyright notice and this permission notice appear in supporting documentation, and that the name of Secret Labs AB or the author not be used in advertising or publicit pertaining to distribution of the software without specific, written prior permission.

SECRET LABS AB AND THE AUTHOR DISCLAIMS ALL WARRANTIES WITH REGARD TO THIS SOFTWARE, INCLUDING ALL IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS. IN NO EVENT SHALL SECRET LABS AB OR THE AUTHOR BE LIABLE FOR ANY SPECIAL, INDIRECT OR CONSEQUENTIAL DAMAGES OR ANY DAMAGES WHATSOEVER RESULTING FROM LOSS OF USE, DATA OR PROFITS, WHETHER IN AN ACTION OF CONTRACT, NEGLIGENCE OR OTHER TORTIOUS ACTION, ARISING OUT OF OR IN CONNECTION WITH THE USE OR PERFORMANCE OF THIS SOFTWARE.

About this document...
1. Introduction

This reference manual describes the Python programming language. It is not intended as a tutorial.

While I am trying to be as precise as possible, I chose to use English rather than formal specifications for everything except syntax and lexical analysis. This should make the document more understandable to the average reader, but will leave room for ambiguities. Consequently, if you were coming from Mars and tried to re-implement Python from this document alone, you might have to guess things and in fact you would probably end up implementing quite a different language. On the other hand, if you are using Python and wonder what the precise rules about a particular area of the language are, you should definitely be able to find them here. If you would like to see a more formal definition of the language, maybe you could volunteer your time -- or invent a cloning machine :-).

It is dangerous to add too many implementation details to a language reference document -- the implementation may change, and other implementations of the same language may work differently. On the other hand, there is currently only one Python implementation in widespread use (although alternate implementations exist), and its particular quirks are sometimes worth being mentioned, especially where the implementation imposes additional limitations. Therefore, you'll find short ``implementation notes" sprinkled throughout the text.

Every Python implementation comes with a number of built-in and standard modules. These are not documented here, but in the separate Python Library Reference document. A few built-in modules are mentioned when they interact in a significant way with the language definition.

Subsections

- 1.1 Alternate Implementations
- 1.2 Notation
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
1.1 Alternate Implementations

Though there is one Python implementation which is by far the most popular, there are some alternate implementations which are of particular interest to different audiences.

Known implementations include:

**CPython**
This is the original and most-maintained implementation of Python, written in C. New language features generally appear here first.

**Jython**
Python implemented in Java. This implementation can be used as a scripting language for Java applications, or can be used to create applications using the Java class libraries. It is also often used to create tests for Java libraries. More information can be found at the Jython website.

**Python for .NET**
This implementation actually uses the CPython implementation, but is a managed .NET application and makes .NET libraries available. This was created by Brian Lloyd. For more information, see the Python for .NET home page.

**IronPython**
An alternate Python for .NET. Unlike Python.NET, this is a complete Python implementation that generates IL, and compiles Python code directly to .NET assemblies. It was created by Jim Hugunin, the original creator of Jython. For more information, see the IronPython website.

**PyPy**
An implementation of Python written in Python; even the bytecode interpreter is written in Python. This is executed using CPython as the underlying interpreter. One of the goals of the project is to encourage experimentation with the language itself by making it easier to modify the interpreter (since it is written in Python). Additional information is available on the PyPy project's home page.
Each of these implementations varies in some way from the language as documented in this manual, or introduces specific information beyond what's covered in the standard Python documentation. Please refer to the implementation-specific documentation to determine what else you need to know about the specific implementation you're using.
1.2 Notation

The descriptions of lexical analysis and syntax use a modified BNF grammar notation. This uses the following style of definition:

```plaintext
name ::= lc_letter (lc_letter | "_")*
lc_letter ::= "a"..."z"
```

The first line says that a `name` is an `lc_letter` followed by a sequence of zero or more `lc_letter`s and underscores. An `lc_letter` in turn is any of the single characters "a" through "z". (This rule is actually adhered to for the names defined in lexical and grammar rules in this document.)

Each rule begins with a name (which is the name defined by the rule) and `::=`. A vertical bar (`|`) is used to separate alternatives; it is the least binding operator in this notation. A star (`*`) means zero or more repetitions of the preceding item; likewise, a plus (`+`) means one or more repetitions, and a phrase enclosed in square brackets (`[ ]`) means zero or one occurrences (in other words, the enclosed phrase is optional). The * and + operators bind as tightly as possible; parentheses are used for grouping. Literal strings are enclosed in quotes. White space is only meaningful to separate tokens. Rules are normally contained on a single line; rules with many alternatives may be formatted alternatively with each line after the first beginning with a vertical bar.

In lexical definitions (as the example above), two more conventions are used: Two literal characters separated by three dots mean a choice of any single character in the given (inclusive) range of ASCII characters. A phrase between angular brackets (`<...>`) gives an informal description of the symbol defined; e.g., this could be used to describe the notion of `control character` if needed.

Even though the notation used is almost the same, there is a big difference between the meaning of lexical and syntactic definitions: a lexical definition operates on the individual characters of the input source, while a syntax definition operates on the stream of tokens generated by the lexical analysis. All uses of BNF in the next chapter (``Lexical Analysis``) are lexical definitions;
uses in subsequent chapters are syntactic definitions.
2. Lexical analysis

A Python program is read by a parser. Input to the parser is a stream of tokens, generated by the lexical analyzer. This chapter describes how the lexical analyzer breaks a file into tokens.

Python uses the 7-bit ASCII character set for program text. New in version 2.3: An encoding declaration can be used to indicate that string literals and comments use an encoding different from ASCII. For compatibility with older versions, Python only warns if it finds 8-bit characters; those warnings should be corrected by either declaring an explicit encoding, or using escape sequences if those bytes are binary data, instead of characters.

The run-time character set depends on the I/O devices connected to the program but is generally a superset of ASCII.

Future compatibility note: It may be tempting to assume that the character set for 8-bit characters is ISO Latin-1 (an ASCII superset that covers most western languages that use the Latin alphabet), but it is possible that in the future Unicode text editors will become common. These generally use the UTF-8 encoding, which is also an ASCII superset, but with very different use for the characters with ordinals 128-255. While there is no consensus on this subject yet, it is unwise to assume either Latin-1 or UTF-8, even though the current implementation appears to favor Latin-1. This applies both to the source character set and the run-time character set.

  2.4.5 Floating point literals
  2.4.6 Imaginary literals

2.5 Operators

2.6 Delimiters
2.1 Line structure

A Python program is divided into a number of *logical lines*.
2.1.1 Logical lines

The end of a logical line is represented by the token NEWLINE. Statements cannot cross logical line boundaries except where NEWLINE is allowed by the syntax (e.g., between statements in compound statements). A logical line is constructed from one or more physical lines by following the explicit or implicit line joining rules.
2.1.2 Physical lines

A physical line is a sequence of characters terminated by an end-of-line sequence. In source files, any of the standard platform line termination sequences can be used - the UNIX form using ASCII LF (linefeed), the Windows form using the ASCII sequence CR LF (return followed by linefeed), or the Macintosh form using the ASCII CR (return) character. All of these forms can be used equally, regardless of platform.

When embedding Python, source code strings should be passed to Python APIs using the standard C conventions for newline characters (the \n character, representing ASCII LF, is the line terminator).
2.1.3 Comments

A comment starts with a hash character (#) that is not part of a string literal, and ends at the end of the physical line. A comment signifies the end of the logical line unless the implicit line joining rules are invoked. Comments are ignored by the syntax; they are not tokens.
2.1.4 Encoding declarations

If a comment in the first or second line of the Python script matches the regular expression `coding[=:]\s*([-\w.]+)`, this comment is processed as an encoding declaration; the first group of this expression names the encoding of the source code file. The recommended forms of this expression are

```
# -*- coding: <encoding-name> -*-
```

which is recognized also by GNU Emacs, and

```
# vim:fileencoding=<encoding-name>
```

which is recognized by Bram Moolenaar's VIM. In addition, if the first bytes of the file are the UTF-8 byte-order mark (`\xef\xbb\xbf`), the declared file encoding is UTF-8 (this is supported, among others, by Microsoft's notepad).

If an encoding is declared, the encoding name must be recognized by Python. The encoding is used for all lexical analysis, in particular to find the end of a string, and to interpret the contents of Unicode literals. String literals are converted to Unicode for syntactical analysis, then converted back to their original encoding before interpretation starts. The encoding declaration must appear on a line of its own.
2.1.5 Explicit line joining

Two or more physical lines may be joined into logical lines using backslash characters (\), as follows: when a physical line ends in a backslash that is not part of a string literal or comment, it is joined with the following forming a single logical line, deleting the backslash and the following end-of-line character. For example:

```python
if 1900 < year < 2100 and 1 <= month <= 12 \
and 1 <= day <= 31 and 0 <= hour < 24 \
and 0 <= minute < 60 and 0 <= second < 60:    # Looks like a valid
    return 1
```

A line ending in a backslash cannot carry a comment. A backslash does not continue a comment. A backslash does not continue a token except for string literals (i.e., tokens other than string literals cannot be split across physical lines using a backslash). A backslash is illegal elsewhere on a line outside a string literal.
2.1.6 Implicit line joining

Expressions in parentheses, square brackets or curly braces can be split over more than one physical line without using backslashes. For example:

```python
code
month_names = ['Januari', 'Februari', 'Maart',]  # These are the
       [ 'April', 'Mei', 'Juni',]  # Dutch names
       [ 'Juli', 'Augustus', 'September',]  # for the months
       [ 'Oktober', 'November', 'December']  # of the year
```

Implicitly continued lines can carry comments. The indentation of the continuation lines is not important. Blank continuation lines are allowed. There is no NEWLINE token between implicit continuation lines. Implicitly continued lines can also occur within triple-quoted strings (see below); in that case they cannot carry comments.
2.1.7 Blank lines

A logical line that contains only spaces, tabs, formfeeds and possibly a comment, is ignored (i.e., no NEWLINE token is generated). During interactive input of statements, handling of a blank line may differ depending on the implementation of the read-eval-print loop. In the standard implementation, an entirely blank logical line (i.e. one containing not even whitespace or a comment) terminates a multi-line statement.
2.1.8 Indentation

Leading whitespace (spaces and tabs) at the beginning of a logical line is used to compute the indentation level of the line, which in turn is used to determine the grouping of statements.

First, tabs are replaced (from left to right) by one to eight spaces such that the total number of characters up to and including the replacement is a multiple of eight (this is intended to be the same rule as used by UNIX). The total number of spaces preceding the first non-blank character then determines the line's indentation. Indentation cannot be split over multiple physical lines using backslashes; the whitespace up to the first backslash determines the indentation.

**Cross-platform compatibility note:** because of the nature of text editors on non-UNIX platforms, it is unwise to use a mixture of spaces and tabs for the indentation in a single source file. It should also be noted that different platforms may explicitly limit the maximum indentation level.

A formfeed character may be present at the start of the line; it will be ignored for the indentation calculations above. Formfeed characters occurring elsewhere in the leading whitespace have an undefined effect (for instance, they may reset the space count to zero).

The indentation levels of consecutive lines are used to generate INDENT and DEDENT tokens, using a stack, as follows.

Before the first line of the file is read, a single zero is pushed on the stack; this will never be popped off again. The numbers pushed on the stack will always be strictly increasing from bottom to top. At the beginning of each logical line, the line's indentation level is compared to the top of the stack. If it is equal, nothing happens. If it is larger, it is pushed on the stack, and one INDENT token is generated. If it is smaller, it **must** be one of the numbers occurring on the stack; all numbers on the stack that are larger are popped off, and for each number popped off a DEDENT token is generated. At the end of the file, a DEDENT token is generated for each number remaining on the stack that is larger than zero.

Here is an example of a correctly (though confusingly) indented piece of Python
code:

```python
def perm(l):
    # Compute the list of all permutations of l
    if len(l) <= 1:
        return [l]
    r = []
    for i in range(len(l)):
        s = l[:i] + l[i+1:]
        p = perm(s)
        for x in p:
            r.append(l[i:i+1] + x)
    return r
```

The following example shows various indentation errors:

```python
def perm(l):
    for i in range(len(l)):
        s = l[:i] + l[i+1:]
        p = perm(l[:i] + l[i+1:])
        for x in p:
            r.append(l[i:i+1] + x)
    return r
```

(Actually, the first three errors are detected by the parser; only the last error is found by the lexical analyzer -- the indentation of `return r` does not match a level popped off the stack.)
2.1.9 Whitespace between tokens

Except at the beginning of a logical line or in string literals, the whitespace characters space, tab and formfeed can be used interchangeably to separate tokens. Whitespace is needed between two tokens only if their concatenation could otherwise be interpreted as a different token (e.g., ab is one token, but a b is two tokens).
2.2 Other tokens

Besides NEWLINE, INDENT and DEDENT, the following categories of tokens exist: identifiers, keywords, literals, operators, and delimiters. Whitespace characters (other than line terminators, discussed earlier) are not tokens, but serve to delimit tokens. Where ambiguity exists, a token comprises the longest possible string that forms a legal token, when read from left to right.
2.3 Identifiers and keywords

Identifiers (also referred to as names) are described by the following lexical definitions:

```
   identifier ::= (letter|"_") (letter  |  digit
                 |  "_")*

   letter ::= lowercase  |  uppercase

   lowercase ::= "a"..."z"

   uppercase ::= "A"..."Z"

   digit ::= "0"..."9"
```

Identifiers are unlimited in length. Case is significant.
2.3.2 Reserved classes of
2.3.1 Keywords

The following identifiers are used as reserved words, or *keywords* of the language, and cannot be used as ordinary identifiers. They must be spelled exactly as written here:

```
and  del  from  not  while
as   elif  global  or  with
assert  else  if  pass  yield
break  except  import  print
class  exec  in  raise
continue  finally  is  return
def  for  lambda  try
```

Changed in version 2.4: `None` became a constant and is now recognized by the compiler as a name for the built-in object `None`. Although it is not a keyword, you cannot assign a different object to it.

Changed in version 2.5: Both `as` and `with` are only recognized when the `with_statement` future feature has been enabled. It will always be enabled in Python 2.6. See section 7.5 for details. Note that using `as` and `with` as identifiers will always issue a warning, even when the `with_statement` future directive is not in effect.

---

*Release 2.5, documentation updated on 19th September, 2006.*

*See [About this document...](#) for information on suggesting changes.*
2.3.2 Reserved classes of identifiers

Certain classes of identifiers (besides keywords) have special meanings. These classes are identified by the patterns of leading and trailing underscore characters:

_ *

Not imported by "from module import *". The special identifier "_" is used in the interactive interpreter to store the result of the last evaluation; it is stored in the __builtin__ module. When not in interactive mode, "_" has no special meaning and is not defined. See section 6.12, ``The import statement."

Note: The name "_" is often used in conjunction with internationalization; refer to the documentation for the gettext module for more information on this convention.

__*_

System-defined names. These names are defined by the interpreter and its implementation (including the standard library); applications should not expect to define additional names using this convention. The set of names of this class defined by Python may be extended in future versions. See section 3.4, ``Special method names."

__*

Class-private names. Names in this category, when used within the context of a class definition, are re-written to use a mangled form to help avoid name clashes between "private" attributes of base and derived classes. See section 5.2.1, ``Identifiers (Names)."
2.4 Literals

Literals are notations for constant values of some built-in types.

Subsections

- 2.4.1 String literals
- 2.4.2 String literal concatenation
- 2.4.3 Numeric literals
- 2.4.4 Integer and long integer literals
- 2.4.5 Floating point literals
- 2.4.6 Imaginary literals
## 2.4.1 String literals

String literals are described by the following lexical definitions:

<table>
<thead>
<tr>
<th>Nonterminal</th>
<th>Production</th>
</tr>
</thead>
<tbody>
<tr>
<td>stringliteral</td>
<td>[ [stringprefix] (shortstring</td>
</tr>
<tr>
<td>stringprefix</td>
<td>&quot;r&quot;</td>
</tr>
<tr>
<td>shortstring</td>
<td>&quot;&quot;&quot;&quot; shortstringitem* &quot;&quot;&quot;&quot;</td>
</tr>
<tr>
<td>longstring</td>
<td>&quot;&quot;&quot;&quot; longstringitem* &quot;&quot;&quot;&quot;</td>
</tr>
<tr>
<td>shortstringitem</td>
<td>shortstringchar</td>
</tr>
<tr>
<td>longstringitem</td>
<td>longstringchar</td>
</tr>
<tr>
<td>shortstringchar</td>
<td>&lt;any source character except &quot;&quot; or newline or the quote&gt;</td>
</tr>
<tr>
<td>longstringchar</td>
<td>&lt;any source character except &quot;&quot;&gt;</td>
</tr>
<tr>
<td>escapeseq</td>
<td>&quot;&quot; &lt;any ASCII character&gt;</td>
</tr>
</tbody>
</table>

One syntactic restriction not indicated by these productions is that whitespace is not allowed between the stringprefix and the rest of the string literal. The source character set is defined by the encoding declaration; it is ASCII if no encoding declaration is given in the source file; see section 2.1.4.
In plain English: String literals can be enclosed in matching single quotes (' ) or double quotes (" ). They can also be enclosed in matching groups of three single or double quotes (these are generally referred to as *triple-quoted strings*). The backslash (\) character is used to escape characters that otherwise have a special meaning, such as newline, backslash itself, or the quote character. String literals may optionally be prefixed with a letter "r" or "R"; such strings are called *raw strings* and use different rules for interpreting backslash escape sequences. A prefix of "u" or "U" makes the string a Unicode string. Unicode strings use the Unicode character set as defined by the Unicode Consortium and ISO 10646. Some additional escape sequences, described below, are available in Unicode strings. The two prefix characters may be combined; in this case, "u" must appear before "r".

In triple-quoted strings, unescaped newlines and quotes are allowed (and are retained), except that three unescaped quotes in a row terminate the string. (A "`quote" is the character used to open the string, i.e. either ' or ".)

Unless an "r" or "R" prefix is present, escape sequences in strings are interpreted according to rules similar to those used by Standard C. The recognized escape sequences are:

<table>
<thead>
<tr>
<th>Escape Sequence</th>
<th>Meaning</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>\newline</td>
<td>Ignored</td>
<td></td>
</tr>
<tr>
<td>\  \</td>
<td>Backslash ()</td>
<td></td>
</tr>
<tr>
<td>\  '</td>
<td>Single quote (' )</td>
<td></td>
</tr>
<tr>
<td>\  &quot;</td>
<td>Double quote (&quot; )</td>
<td></td>
</tr>
<tr>
<td>\a</td>
<td>ASCII Bell (BEL)</td>
<td></td>
</tr>
<tr>
<td>\b</td>
<td>ASCII Backspace (BS)</td>
<td></td>
</tr>
<tr>
<td>\f</td>
<td>ASCII Formfeed (FF)</td>
<td></td>
</tr>
<tr>
<td>\n</td>
<td>ASCII Linefeed (LF)</td>
<td></td>
</tr>
<tr>
<td>\N{name}</td>
<td>Character named name in the Unicode database (Unicode only)</td>
<td></td>
</tr>
<tr>
<td>\r</td>
<td>ASCII Carriage Return (CR)</td>
<td></td>
</tr>
<tr>
<td>\t</td>
<td>ASCII Horizontal Tab (TAB)</td>
<td></td>
</tr>
<tr>
<td>\uxxxx</td>
<td>Character with 16-bit hex value xxxx (Unicode only)</td>
<td>(1)</td>
</tr>
<tr>
<td>\Uxxxxxxxx</td>
<td>Character with 32-bit hex value xxxxxxxxx (Unicode only)</td>
<td>(2)</td>
</tr>
<tr>
<td>-------------</td>
<td>----------------------------------------------------------</td>
<td>-----</td>
</tr>
<tr>
<td>\v</td>
<td>ASCII Vertical Tab (VT)</td>
<td></td>
</tr>
<tr>
<td>\ooo</td>
<td>Character with octal value ooo</td>
<td>(3,5)</td>
</tr>
<tr>
<td>\xhh</td>
<td>Character with hex value hh</td>
<td>(4,5)</td>
</tr>
</tbody>
</table>

Notes:

(1) Individual code units which form parts of a surrogate pair can be encoded using this escape sequence.

(2) Any Unicode character can be encoded this way, but characters outside the Basic Multilingual Plane (BMP) will be encoded using a surrogate pair if Python is compiled to use 16-bit code units (the default). Individual code units which form parts of a surrogate pair can be encoded using this escape sequence.

(3) As in Standard C, up to three octal digits are accepted.

(4) Unlike in Standard C, at most two hex digits are accepted.

(5) In a string literal, hexadecimal and octal escapes denote the byte with the given value; it is not necessary that the byte encodes a character in the source character set. In a Unicode literal, these escapes denote a Unicode character with the given value.

Unlike Standard C, all unrecognized escape sequences are left in the string unchanged, i.e., the backslash is left in the string. (This behavior is useful when debugging: if an escape sequence is mistyped, the resulting output is more easily recognized as broken.) It is also important to note that the escape sequences marked as ``(Unicode only)`` in the table above fall into the category of unrecognized escapes for non-Unicode string literals.

When an "r" or "R" prefix is present, a character following a backslash is included in the string without change, and all backslashes are left in the string. For example, the string literal r"\n" consists of two characters: a backslash and a lowercase "n". String quotes can be escaped with a backslash, but the
backslash remains in the string; for example, \"\" is a valid string literal consisting of two characters: a backslash and a double quote; \"\ is not a valid string literal (even a raw string cannot end in an odd number of backslashes). Specifically, a raw string cannot end in a single backslash (since the backslash would escape the following quote character). Note also that a single backslash followed by a newline is interpreted as those two characters as part of the string, not as a line continuation.

When an "r" or "R" prefix is used in conjunction with a "u" or "U" prefix, then the \uXXXX and \UXXXXXXXX escape sequences are processed while all other backslashes are left in the string. For example, the string literal ur"\u0062\n" consists of three Unicode characters: `LATIN SMALL LETTER B', `REVERSE SOLIDUS', and `LATIN SMALL LETTER N'. Backslashes can be escaped with a preceding backslash; however, both remain in the string. As a result, \uXXXX escape sequences are only recognized when there are an odd number of backslashes.

---

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
2.4.2 String literal concatenation

Multiple adjacent string literals (delimited by whitespace), possibly using different quoting conventions, are allowed, and their meaning is the same as their concatenation. Thus, "hello' world' is equivalent to "helloworld". This feature can be used to reduce the number of backslashes needed, to split long strings conveniently across long lines, or even to add comments to parts of strings, for example:

```
re.compile("[A-Za-z_]" # letter or underscore
          "[A-Za-z0-9_]"* # letter, digit or underscore
       )
```

Note that this feature is defined at the syntactical level, but implemented at compile time. The `+' operator must be used to concatenate string expressions at run time. Also note that literal concatenation can use different quoting styles for each component (even mixing raw strings and triple quoted strings).
2.4.3 Numeric literals

There are four types of numeric literals: plain integers, long integers, floating point numbers, and imaginary numbers. There are no complex literals (complex numbers can be formed by adding a real number and an imaginary number).

Note that numeric literals do not include a sign; a phrase like -1 is actually an expression composed of the unary operator `\-\' and the literal 1.
2.4.4 Integer and long integer literals

Integer and long integer literals are described by the following lexical definitions:

```
longinteger ::= integer ("l" | "L")
integer ::= decimalinteger | octinteger | hexinteger
decimalinteger ::= nonzerodigit digit* | "0"
octinteger ::= "0" octdigit+
hexinteger ::= "0" ("x" | "X") hexdigit+
nonzerodigit ::= "1"..."9"
octdigit ::= "0"..."7"
hexdigit ::= digit | "a"..."f" | "A"..."F"
```

Although both lower case "l" and upper case "L" are allowed as suffix for long integers, it is strongly recommended to always use "L", since the letter "l" looks too much like the digit "1".

Plain integer literals that are above the largest representable plain integer (e.g., 2147483647 when using 32-bit arithmetic) are accepted as if they were long integers instead. There is no limit for long integer literals apart from what can be stored in available memory.

Some examples of plain integer literals (first row) and long integer literals (second and third rows):

```
  7     2147483647                      0177
3L    79228162514264337593543950336L  0377L  0x1000000000L
  79228162514264337593543950336       0xdeadbeef
```
In versions of Python prior to 2.4, octal and hexadecimal literals in the range just above the largest representable plain integer but below the largest unsigned 32-bit number (on a machine using 32-bit arithmetic), 4294967296, were taken as the negative plain integer obtained by subtracting 4294967296 from their unsigned value.
## 2.4.5 Floating point literals

Floating point literals are described by the following lexical definitions:

```
floatnumber ::= pointfloat | exponentfloat
pointfloat ::= [intpart] fraction | intpart "." 
exponentfloat ::= (intpart | pointfloat) exponent
intpart ::= digit+
fraction ::= "." digit+
exponent ::= ("e" | "E") ["+" | "-"] digit+
```

Note that the integer and exponent parts of floating point numbers can look like octal integers, but are interpreted using radix 10. For example, "077e010" is legal, and denotes the same number as "77e10". The allowed range of floating point literals is implementation-dependent. Some examples of floating point literals:

- 3.14
- 10.
- .001
- 1e100
- 3.14e-10
- 0e0

Note that numeric literals do not include a sign; a phrase like -1 is actually an expression composed of the unary operator - and the literal 1.
2.4.6 Imaginary literals

Imaginary literals are described by the following lexical definitions:

```
imagnumber ::= (floatnumber | intpart) ("j" | "J")
```

An imaginary literal yields a complex number with a real part of 0.0. Complex numbers are represented as a pair of floating point numbers and have the same restrictions on their range. To create a complex number with a nonzero real part, add a floating point number to it, e.g., (3+4j). Some examples of imaginary literals:

```
3.14j  10.j  10j  .001j  1e100j  3.14e-10j
```

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
2.5 Operators

The following tokens are operators:

```
+  -  *  **  /  //  %
<<  >>  &  |  ^  ~
<  >  <=  >=  ==  !=  <>
```

The comparison operators <> and != are alternate spellings of the same operator. != is the preferred spelling; <> is obsolescent.
2.6 Delimiters

The following tokens serve as delimiters in the grammar:

```
(    )  [    ]  {    }   @
,    :    .    `    =    ;
+=   -=   *=   /=   //=   %=   &+=   |=   ^=   >>=   <<=   **=
```

The period can also occur in floating-point and imaginary literals. A sequence of three periods has a special meaning as an ellipsis in slices. The second half of the list, the augmented assignment operators, serve lexically as delimiters, but also perform an operation.

The following printing ASCII characters have special meaning as part of other tokens or are otherwise significant to the lexical analyzer:

```
'   "   #    \n```

The following printing ASCII characters are not used in Python. Their occurrence outside string literals and comments is an unconditional error:

```
$    ?
```
3. Data model

3.1 Objects, values and types

*Objects* are Python's abstraction for data. All data in a Python program is represented by objects or by relations between objects. (In a sense, and in conformance to Von Neumann's model of a ``stored program computer," code is also represented by objects.)

Every object has an identity, a type and a value. An object's *identity* never changes once it has been created; you may think of it as the object's address in memory. The `is' operator compares the identity of two objects; the `id()' function returns an integer representing its identity (currently implemented as its address). An object's *type* is also unchangeable. An object's type determines the operations that the object supports (e.g., ``does it have a length?'') and also defines the possible values for objects of that type. The `type()' function returns an object's type (which is an object itself). The value of some objects can change. Objects whose value can change are said to be *mutable*; objects whose value is unchangeable once they are created are called *immutable*. (The value of an immutable container object that contains a reference to a mutable object can change when the latter's value is changed; however the container is still considered immutable, because the collection of objects it contains cannot be changed. So, immutability is not strictly the same as having an unchangeable value, it is more subtle.) An object's mutability is determined by its type; for instance, numbers, strings and tuples are immutable, while dictionaries and lists are mutable.

Objects are never explicitly destroyed; however, when they become unreachable they may be garbage-collected. An implementation is allowed to postpone garbage collection or omit it altogether -- it is a matter of implementation quality how garbage collection is implemented, as long as no objects are collected that are still reachable. (Implementation note: the current implementation uses a reference-counting scheme with (optional) delayed detection of cyclically linked garbage, which collects most objects as soon as they become unreachable, but is not guaranteed to collect garbage containing circular references. See the Python Library Reference for information on controlling the collection of cyclic garbage.)

Note that the use of the implementation's tracing or debugging facilities may
keep objects alive that would normally be collectable. Also note that catching an exception with a `try...except' statement may keep objects alive.

Some objects contain references to ``external'' resources such as open files or windows. It is understood that these resources are freed when the object is garbage-collected, but since garbage collection is not guaranteed to happen, such objects also provide an explicit way to release the external resource, usually a `close()' method. Programs are strongly recommended to explicitly close such objects. The `try...finally' statement provides a convenient way to do this.

Some objects contain references to other objects; these are called containers. Examples of containers are tuples, lists and dictionaries. The references are part of a container's value. In most cases, when we talk about the value of a container, we imply the values, not the identities of the contained objects; however, when we talk about the mutability of a container, only the identities of the immediately contained objects are implied. So, if an immutable container (like a tuple) contains a reference to a mutable object, its value changes if that mutable object is changed.

Types affect almost all aspects of object behavior. Even the importance of object identity is affected in some sense: for immutable types, operations that compute new values may actually return a reference to any existing object with the same type and value, while for mutable objects this is not allowed. E.g., after "a = 1; b = 1", a and b may or may not refer to the same object with the value one, depending on the implementation, but after "c = []; d = []", c and d are guaranteed to refer to two different, unique, newly created empty lists. (Note that "c = d = []" assigns the same object to both c and d.)

Footnotes

... unchangeable.

Since Python 2.2, a gradual merging of types and classes has been started that makes this and a few other assertions made in this manual not 100% accurate and complete: for example, it is now possible in some cases to change an object's type, under certain controlled conditions. Until this
manual undergoes extensive revision, it must now be taken as authoritative only regarding `classic classes', that are still the default, for compatibility purposes, in Python 2.2 and 2.3. For more information, see http://www.python.org/doc/newstyle.html.
3.2 The standard type hierarchy

Below is a list of the types that are built into Python. Extension modules (written in C, Java, or other languages, depending on the implementation) can define additional types. Future versions of Python may add types to the type hierarchy (e.g., rational numbers, efficiently stored arrays of integers, etc.).

Some of the type descriptions below contain a paragraph listing `special attributes.' These are attributes that provide access to the implementation and are not intended for general use. Their definition may change in the future.

None
This type has a single value. There is a single object with this value. This object is accessed through the built-in name None. It is used to signify the absence of a value in many situations, e.g., it is returned from functions that don't explicitly return anything. Its truth value is false.

NotImplemented
This type has a single value. There is a single object with this value. This object is accessed through the built-in name NotImplemented. Numeric methods and rich comparison methods may return this value if they do not implement the operation for the operands provided. (The interpreter will then try the reflected operation, or some other fallback, depending on the operator.) Its truth value is true.

Ellipsis
This type has a single value. There is a single object with this value. This object is accessed through the built-in name Ellipsis. It is used to indicate the presence of the "..." syntax in a slice. Its truth value is true.

Numbers
These are created by numeric literals and returned as results by arithmetic operators and arithmetic built-in functions. Numeric objects are immutable; once created their value never changes. Python numbers are of course strongly related to mathematical numbers, but subject to the limitations of numerical representation in computers.
Python distinguishes between integers, floating point numbers, and complex numbers:

**Integers**
These represent elements from the mathematical set of integers (positive and negative).

There are three types of integers:

**Plain integers**
These represent numbers in the range \(-2147483648\) through \(2147483647\). (The range may be larger on machines with a larger natural word size, but not smaller.) When the result of an operation would fall outside this range, the result is normally returned as a long integer (in some cases, the exception `OverflowError` is raised instead). For the purpose of shift and mask operations, integers are assumed to have a binary, 2’s complement notation using 32 or more bits, and hiding no bits from the user (i.e., all \(4294967296\) different bit patterns correspond to different values).

**Long integers**
These represent numbers in an unlimited range, subject to available (virtual) memory only. For the purpose of shift and mask operations, a binary representation is assumed, and negative numbers are represented in a variant of 2’s complement which gives the illusion of an infinite string of sign bits extending to the left.

**Booleans**
These represent the truth values False and True. The two objects representing the values False and True are the only Boolean objects. The Boolean type is a subtype of plain integers, and Boolean values behave like the values 0 and 1, respectively, in almost all contexts, the exception being that when converted to a string, the strings "False" or "True" are returned, respectively.

The rules for integer representation are intended to give the most
meaningful interpretation of shift and mask operations involving negative integers and the least surprises when switching between the plain and long integer domains. Any operation except left shift, if it yields a result in the plain integer domain without causing overflow, will yield the same result in the long integer domain or when using mixed operands.

**Floating point numbers**
These represent machine-level double precision floating point numbers. You are at the mercy of the underlying machine architecture (and C or Java implementation) for the accepted range and handling of overflow. Python does not support single-precision floating point numbers; the savings in processor and memory usage that are usually the reason for using these is dwarfed by the overhead of using objects in Python, so there is no reason to complicate the language with two kinds of floating point numbers.

**Complex numbers**
These represent complex numbers as a pair of machine-level double precision floating point numbers. The same caveats apply as for floating point numbers. The real and imaginary parts of a complex number \( z \) can be retrieved through the read-only attributes \( z.real \) and \( z.imag \).

**Sequences**
These represent finite ordered sets indexed by non-negative numbers. The built-in function `len()` returns the number of items of a sequence. When the length of a sequence is \( n \), the index set contains the numbers 0, 1, ..., \( n-1 \). Item \( i \) of sequence \( a \) is selected by \( a[i] \).

Sequences also support slicing: \( a[i:j] \) selects all items with index \( k \) such that \( i <= k < j \). When used as an expression, a slice is a sequence of the same type. This implies that the index set is renumbered so that it starts at 0.

Some sequences also support ```extended slicing``" with a third ```step``" parameter: \( a[i:j:k] \) selects all items of \( a \) with index \( x \) where \( x = i + n*k \), \( n >= 0 \) and \( i <= x < j \).
Sequences are distinguished according to their mutability:

**Immutable sequences**
An object of an immutable sequence type cannot change once it is created. (If the object contains references to other objects, these other objects may be mutable and may be changed; however, the collection of objects directly referenced by an immutable object cannot change.)

The following types are immutable sequences:

**Strings**
The items of a string are characters. There is no separate character type; a character is represented by a string of one item. Characters represent (at least) 8-bit bytes. The built-in functions `chr()` and `ord()` convert between characters and nonnegative integers representing the byte values. Bytes with the values 0-127 usually represent the corresponding ASCII values, but the interpretation of values is up to the program. The string data type is also used to represent arrays of bytes, e.g., to hold data read from a file.

(On systems whose native character set is not ASCII, strings may use EBCDIC in their internal representation, provided the functions `chr()` and `ord()` implement a mapping between ASCII and EBCDIC, and string comparison preserves the ASCII order. Or perhaps someone can propose a better rule?)

**Unicode**
The items of a Unicode object are Unicode code units. A Unicode code unit is represented by a Unicode object of one item and can hold either a 16-bit or 32-bit value representing a Unicode ordinal (the maximum value for the ordinal is given in `sys.maxunicode`, and depends on how Python is configured at compile time). Surrogate pairs may be present in the Unicode object, and will be reported as two separate items. The built-in functions `unichr()` and `ord()` convert between code units and nonnegative integers representing the Unicode ordinals as defined in the Unicode Standard 3.0. Conversion from and to other encodings are possible through the Unicode method `encode()` and the built-in function `unicode()`.)
**Tuples**

The items of a tuple are arbitrary Python objects. Tuples of two or more items are formed by comma-separated lists of expressions. A tuple of one item (a `singleton`) can be formed by affixing a comma to an expression (an expression by itself does not create a tuple, since parentheses must be usable for grouping of expressions). An empty tuple can be formed by an empty pair of parentheses.

**Mutable sequences**

Mutable sequences can be changed after they are created. The subscription and slicing notations can be used as the target of assignment and `del` (delete) statements.

There is currently a single intrinsic mutable sequence type:

**Lists**

The items of a list are arbitrary Python objects. Lists are formed by placing a comma-separated list of expressions in square brackets. (Note that there are no special cases needed to form lists of length 0 or 1.)

The extension module `array` provides an additional example of a mutable sequence type.

**Mappings**

These represent finite sets of objects indexed by arbitrary index sets. The subscript notation `a[k]` selects the item indexed by `k` from the mapping `a`; this can be used in expressions and as the target of assignments or `del` statements. The built-in function `len()` returns the number of items in a mapping.

There is currently a single intrinsic mapping type:

**Dictionaries**

These represent finite sets of objects indexed by nearly arbitrary values. The only types of values not acceptable as keys are values containing lists or dictionaries or other mutable types that are compared by value rather than by object identity, the reason being that
the efficient implementation of dictionaries requires a key's hash value
to remain constant. Numeric types used for keys obey the normal rules
for numeric comparison: if two numbers compare equal (e.g., 1 and
1.0) then they can be used interchangeably to index the same
dictionary entry.

Dictionaries are mutable; they can be created by the \{ \ldots \} notation
(see section 5.2.6, "Dictionary Displays").

The extension modules dbm, gdbm, and bsddb provide additional
examples of mapping types.

**Callable types**
These are the types to which the function call operation (see section 5.3.4,
``Calls"") can be applied:

**User-defined functions**
A user-defined function object is created by a function definition (see
section 7.6, "Function definitions"). It should be called with an
argument list containing the same number of items as the function's
formal parameter list.

Special attributes:

<table>
<thead>
<tr>
<th>Attribute</th>
<th>Meaning</th>
<th>Writable</th>
</tr>
</thead>
<tbody>
<tr>
<td>func_doc</td>
<td>The function's documentation string, or None if unavailable</td>
<td></td>
</tr>
<tr>
<td><strong>doc</strong></td>
<td>Another way of spelling func_doc</td>
<td></td>
</tr>
<tr>
<td>func_name</td>
<td>The function's name</td>
<td></td>
</tr>
<tr>
<td><strong>name</strong></td>
<td>Another way of spelling func_name</td>
<td></td>
</tr>
<tr>
<td><strong>module</strong></td>
<td>The name of the module the function was defined in, or None if unavailable.</td>
<td></td>
</tr>
<tr>
<td>func_defaults</td>
<td>A tuple containing default argument values for those arguments that have defaults, or None if no arguments</td>
<td></td>
</tr>
<tr>
<td>Attribute</td>
<td>Description</td>
<td>Access</td>
</tr>
<tr>
<td>-----------------</td>
<td>-----------------------------------------------------------------------------</td>
<td>----------</td>
</tr>
<tr>
<td><code>func_code</code></td>
<td>The code object representing the compiled function body.</td>
<td>Writable</td>
</tr>
<tr>
<td><code>func_globals</code></td>
<td>A reference to the dictionary that holds the function's global variables -- the global namespace of the module in which the function was defined.</td>
<td>Read-only</td>
</tr>
<tr>
<td><code>func_dict</code></td>
<td>The namespace supporting arbitrary function attributes.</td>
<td>Writable</td>
</tr>
<tr>
<td><code>func_closure</code></td>
<td>None or a tuple of cells that contain bindings for the function's free variables.</td>
<td>Read-only</td>
</tr>
</tbody>
</table>

Most of the attributes labelled ``Writable`` check the type of the assigned value.

Changed in version 2.4: `func_name` is now writable.

Function objects also support getting and setting arbitrary attributes, which can be used, for example, to attach metadata to functions. Regular attribute dot-notation is used to get and set such attributes. *Note that the current implementation only supports function attributes on user-defined functions. Function attributes on built-in functions may be supported in the future.*

Additional information about a function's definition can be retrieved from its code object; see the description of internal types below.

**User-defined methods**

A user-defined method object combines a class, a class instance (or `None`) and any callable object (normally a user-defined function).

Special read-only attributes: `im_self` is the class instance object, `im_func` is the function object; `im_class` is the class of `im_self` for bound methods or the class that asked for the method for unbound methods; `__doc__` is the method's documentation (same as `im_func.__doc__`); `__name__` is the method name (same as
im_func.__name__); __module__ is the name of the module the method was defined in, or None if unavailable. Changed in version 2.2: im_self used to refer to the class that defined the method.

Methods also support accessing (but not setting) the arbitrary function attributes on the underlying function object.

User-defined method objects may be created when getting an attribute of a class (perhaps via an instance of that class), if that attribute is a user-defined function object, an unbound user-defined method object, or a class method object. When the attribute is a user-defined method object, a new method object is only created if the class from which it is being retrieved is the same as, or a derived class of, the class stored in the original method object; otherwise, the original method object is used as it is.

When a user-defined method object is created by retrieving a user-defined function object from a class, its im_self attribute is None and the method object is said to be unbound. When one is created by retrieving a user-defined function object from a class via one of its instances, its im_self attribute is the instance, and the method object is said to be bound. In either case, the new method's im_class attribute is the class from which the retrieval takes place, and its im_func attribute is the original function object.

When a user-defined method object is created by retrieving another method object from a class or instance, the behaviour is the same as for a function object, except that the im_func attribute of the new instance is not the original method object but its im_func attribute.

When a user-defined method object is created by retrieving a class method object from a class or instance, its im_self attribute is the class itself (the same as the im_class attribute), and its im_func attribute is the function object underlying the class method.

When an unbound user-defined method object is called, the underlying function (im_func) is called, with the restriction that the first argument must be an instance of the proper class (im_class) or of a
When a bound user-defined method object is called, the underlying function (im_func) is called, inserting the class instance (im_self) in front of the argument list. For instance, when C is a class which contains a definition for a function f(), and x is an instance of C, calling x.f(1) is equivalent to calling C.f(x, 1).

When a user-defined method object is derived from a class method object, the "class instance" stored in im_self will actually be the class itself, so that calling either x.f(1) or C.f(1) is equivalent to calling f(C, 1) where f is the underlying function.

Note that the transformation from function object to (unbound or bound) method object happens each time the attribute is retrieved from the class or instance. In some cases, a fruitful optimization is to assign the attribute to a local variable and call that local variable. Also notice that this transformation only happens for user-defined functions; other callable objects (and all non-callable objects) are retrieved without transformation. It is also important to note that user-defined functions which are attributes of a class instance are not converted to bound methods; this only happens when the function is an attribute of the class.

**Generator functions**

A function or method which uses the `yield` statement (see section 6.8, "The `yield` statement") is called a *generator function*. Such a function, when called, always returns an iterator object which can be used to execute the body of the function: calling the iterator's `next()` method will cause the function to execute until it provides a value using the `yield` statement. When the function executes a `return` statement or falls off the end, a `StopIteration` exception is raised and the iterator will have reached the end of the set of values to be returned.

**Built-in functions**

A built-in function object is a wrapper around a C function. Examples of built-in functions are `len()` and `math.sin()` (math is a standard built-in module). The number and type of the arguments are
determined by the C function. Special read-only attributes: __doc__ is the function's documentation string, or None if unavailable; __name__ is the function's name; __self__ is set to None (but see the next item); __module__ is the name of the module the function was defined in or None if unavailable.

Built-in methods
This is really a different disguise of a built-in function, this time containing an object passed to the C function as an implicit extra argument. An example of a built-in method is alist.append(), assuming alist is a list object. In this case, the special read-only attribute __self__ is set to the object denoted by list.

Class Types
Class types, or "new-style classes," are callable. These objects normally act as factories for new instances of themselves, but variations are possible for class types that override __new__( ). The arguments of the call are passed to __new__( ) and, in the typical case, to __init__( ) to initialize the new instance.

Classic Classes
Class objects are described below. When a class object is called, a new class instance (also described below) is created and returned. This implies a call to the class's __init__( ) method if it has one. Any arguments are passed on to the __init__( ) method. If there is no __init__( ) method, the class must be called without arguments.

Class instances
Class instances are described below. Class instances are callable only when the class has a __call__( ) method; x(arguments) is a shorthand for x.__call__(arguments).

Modules
Modules are imported by the import statement (see section 6.12, "The import statement"). A module object has a namespace implemented by a dictionary object (this is the dictionary referenced by the func_globals attribute of functions defined in the module). Attribute references are translated to lookups in this dictionary, e.g., m.x is equivalent to
__dict__['x']. A module object does not contain the code object used to initialize the module (since it isn't needed once the initialization is done).

Attribute assignment updates the module's namespace dictionary, e.g., "m.x = 1" is equivalent to "m.__dict__['x'] = 1".

Special read-only attribute: __dict__ is the module's namespace as a dictionary object.

Predefined (writable) attributes: __name__ is the module's name; __doc__ is the module's documentation string, or None if unavailable; __file__ is the pathname of the file from which the module was loaded, if it was loaded from a file. The __file__ attribute is not present for C modules that are statically linked into the interpreter; for extension modules loaded dynamically from a shared library, it is the pathname of the shared library file.

Classes

Class objects are created by class definitions (see section 7.7, ``Class definitions''). A class has a namespace implemented by a dictionary object. Class attribute references are translated to lookups in this dictionary, e.g., "C.x" is translated to "C.__dict__['x']". When the attribute name is not found there, the attribute search continues in the base classes. The search is depth-first, left-to-right in the order of occurrence in the base class list.

When a class attribute reference (for class C, say) would yield a user-defined function object or an unbound user-defined method object whose associated class is either C or one of its base classes, it is transformed into an unbound user-defined method object whose im_class attribute is C. When it would yield a class method object, it is transformed into a bound user-defined method object whose im_class and im_self attributes are both C. When it would yield a static method object, it is transformed into the object wrapped by the static method object. See section 3.4.2 for another way in which attributes retrieved from a class may differ from those actually contained in its __dict__.

Class attribute assignments update the class's dictionary, never the
dictionary of a base class.

A class object can be called (see above) to yield a class instance (see below).

Special attributes: `__name__` is the class name; `__module__` is the module name in which the class was defined; `__dict__` is the dictionary containing the class's namespace; `__bases__` is a tuple (possibly empty or a singleton) containing the base classes, in the order of their occurrence in the base class list; `__doc__` is the class's documentation string, or None if undefined.

**Class instances**

A class instance is created by calling a class object (see above). A class instance has a namespace implemented as a dictionary which is the first place in which attribute references are searched. When an attribute is not found there, and the instance's class has an attribute by that name, the search continues with the class attributes. If a class attribute is found that is a user-defined function object or an unbound user-defined method object whose associated class is the class (call it `C`) of the instance for which the attribute reference was initiated or one of its bases, it is transformed into a bound user-defined method object whose `im_class` attribute is `C` and whose `im_self` attribute is the instance. Static method and class method objects are also transformed, as if they had been retrieved from class `C`; see above under ``Classes``. See section 3.4.2 for another way in which attributes of a class retrieved via its instances may differ from the objects actually stored in the class's `__dict__`. If no class attribute is found, and the object's class has a `__getattr__()` method, that is called to satisfy the lookup.

Attribute assignments and deletions update the instance's dictionary, never a class's dictionary. If the class has a `__setattr__()` or `__delattr__()` method, this is called instead of updating the instance dictionary directly.

Class instances can pretend to be numbers, sequences, or mappings if they have methods with certain special names. See section 3.4, ``Special method names.
Special attributes: \_\_dict\_\_ is the attribute dictionary; \_\_class\_\_ is the instance's class.

Files
A file object represents an open file. File objects are created by the open() built-in function, and also by os.popen(), os.fdopen(), and the makefile() method of socket objects (and perhaps by other functions or methods provided by extension modules). The objects sys.stdin, sys.stdout and sys.stderr are initialized to file objects corresponding to the interpreter's standard input, output and error streams. See the Python Library Reference for complete documentation of file objects.

Internal types
A few types used internally by the interpreter are exposed to the user. Their definitions may change with future versions of the interpreter, but they are mentioned here for completeness.

Code objects
Code objects represent byte-compiled executable Python code, or bytecode. The difference between a code object and a function object is that the function object contains an explicit reference to the function's globals (the module in which it was defined), while a code object contains no context; also the default argument values are stored in the function object, not in the code object (because they represent values calculated at run-time). Unlike function objects, code objects are immutable and contain no references (directly or indirectly) to mutable objects.

Special read-only attributes: co\_name gives the function name; co\_argcount is the number of positional arguments (including arguments with default values); co\_nlocals is the number of local variables used by the function (including arguments); co\_varnames is a tuple containing the names of the local variables (starting with the argument names); co\_cellvars is a tuple containing the names of local variables that are referenced by nested functions; co\_freevars is a tuple containing the names of free variables; co\_code is a string representing the sequence of bytecode instructions; co\_consts is a tuple containing the literals used by the
bytecode; **co_names** is a tuple containing the names used by the bytecode; **co_filename** is the filename from which the code was compiled; **co_firstlineno** is the first line number of the function; **co_lnotab** is a string encoding the mapping from byte code offsets to line numbers (for details see the source code of the interpreter); **co_stacksize** is the required stack size (including local variables); **co_flags** is an integer encoding a number of flags for the interpreter.

The following flag bits are defined for **co_flags**: bit \(0x04\) is set if the function uses the "*arguments" syntax to accept an arbitrary number of positional arguments; bit \(0x08\) is set if the function uses the "**keywords" syntax to accept arbitrary keyword arguments; bit \(0x20\) is set if the function is a generator.

Future feature declarations ("from __future__ import division") also use bits in **co_flags** to indicate whether a code object was compiled with a particular feature enabled: bit \(0x2000\) is set if the function was compiled with future division enabled; bits \(0x10\) and \(0x1000\) were used in earlier versions of Python.

Other bits in **co_flags** are reserved for internal use.

If a code object represents a function, the first item in **co_consts** is the documentation string of the function, or **None** if undefined.

**Frame objects**
Frame objects represent execution frames. They may occur in traceback objects (see below).

Special read-only attributes: **f_back** is to the previous stack frame (towards the caller), or **None** if this is the bottom stack frame; **f_code** is the code object being executed in this frame; **f_locals** is the dictionary used to look up local variables; **f_globals** is used for global variables; **f_builtins** is used for built-in (intrinsic) names; **f_restricted** is a flag indicating whether the function is executing in restricted execution mode; **f_lasti** gives the precise instruction (this is an index into the bytecode string of the code
object).

Special writable attributes: `f_trace`, if not `None`, is a function called at the start of each source code line (this is used by the debugger); `f_exc_type`, `f_exc_value`, `f_exc_traceback` represent the last exception raised in the parent frame provided another exception was ever raised in the current frame (in all other cases they are `None`); `f_lineno` is the current line number of the frame -- writing to this from within a trace function jumps to the given line (only for the bottom-most frame). A debugger can implement a Jump command (aka Set Next Statement) by writing to `f_lineno`.

**Traceback objects**

Traceback objects represent a stack trace of an exception. A traceback object is created when an exception occurs. When the search for an exception handler unwinds the execution stack, at each unwound level a traceback object is inserted in front of the current traceback. When an exception handler is entered, the stack trace is made available to the program. (See section 7.4, "The try statement.") It is accessible as `sys.exc_traceback`, and also as the third item of the tuple returned by `sys.exc_info()`. The latter is the preferred interface, since it works correctly when the program is using multiple threads. When the program contains no suitable handler, the stack trace is written (nicely formatted) to the standard error stream; if the interpreter is interactive, it is also made available to the user as `sys.last_traceback`.

Special read-only attributes: `tb_next` is the next level in the stack trace (towards the frame where the exception occurred), or `None` if there is no next level; `tb_frame` points to the execution frame of the current level; `tb_lineno` gives the line number where the exception occurred; `tb_lasti` indicates the precise instruction. The line number and last instruction in the traceback may differ from the line number of its frame object if the exception occurred in a `try` statement with no matching except clause or with a finally clause.

**Slice objects**

Slice objects are used to represent slices when *extended slice syntax* is used. This is a slice using two colons, or multiple slices or ellipses
separated by commas, e.g., \texttt{a[i:j:step]}, \texttt{a[i:j, k:l]}, or \texttt{a[... , i:j]}. They are also created by the built-in \texttt{slice()} function.

Special read-only attributes: \texttt{start} is the lower bound; \texttt{stop} is the upper bound; \texttt{step} is the step value; each is \texttt{None} if omitted. These attributes can have any type.

Slice objects support one method:

\texttt{indices( self, length)}

This method takes a single integer argument \texttt{length} and computes information about the extended slice that the slice object would describe if applied to a sequence of \texttt{length} items. It returns a tuple of three integers; respectively these are the \texttt{start} and \texttt{stop} indices and the \texttt{step} or stride length of the slice. Missing or out-of-bounds indices are handled in a manner consistent with regular slices. New in version 2.3.

\textbf{Static method objects}

Static method objects provide a way of defeating the transformation of function objects to method objects described above. A static method object is a wrapper around any other object, usually a user-defined method object. When a static method object is retrieved from a class or a class instance, the object actually returned is the wrapped object, which is not subject to any further transformation. Static method objects are not themselves callable, although the objects they wrap usually are. Static method objects are created by the built-in \texttt{staticmethod()} constructor.

\textbf{Class method objects}

A class method object, like a static method object, is a wrapper around another object that alters the way in which that object is retrieved from classes and class instances. The behaviour of class method objects upon such retrieval is described above, under \texttt{``User-defined methods''}. Class method objects are created by the built-in \texttt{classmethod()} constructor.
Release 2.5, documentation updated on 19th September, 2006.  
See About this document... for information on suggesting changes.
3.3 New-style and classic classes

Classes and instances come in two flavors: old-style or classic, and new-style.

Up to Python 2.1, old-style classes were the only flavour available to the user. The concept of (old-style) class is unrelated to the concept of type: if \( x \) is an instance of an old-style class, then \( x.__class__ \) designates the class of \( x \), but \( \text{type}(x) \) is always \(<\text{type} \ '\text{instance}'>\). This reflects the fact that all old-style instances, independently of their class, are implemented with a single built-in type, called \text{instance}.

New-style classes were introduced in Python 2.2 to unify classes and types. A new-style class neither more nor less than a user-defined type. If \( x \) is an instance of a new-style class, then \( \text{type}(x) \) is the same as \( x.__class__ \).

The major motivation for introducing new-style classes is to provide a unified object model with a full meta-model. It also has a number of immediate benefits, like the ability to subclass most built-in types, or the introduction of "descriptors", which enable computed properties.

For compatibility reasons, classes are still old-style by default. New-style classes are created by specifying another new-style class (i.e. a type) as a parent class, or the "top-level type" \text{object} if no other parent is needed. The behaviour of new-style classes differs from that of old-style classes in a number of important details in addition to what \text{type} returns. Some of these changes are fundamental to the new object model, like the way special methods are invoked. Others are "fixes" that could not be implemented before for compatibility concerns, like the method resolution order in case of multiple inheritance.

This manual is not up-to-date with respect to new-style classes. For now, please see \url{http://www.python.org/doc/newstyle.html} for more information.

The plan is to eventually drop old-style classes, leaving only the semantics of new-style classes. This change will probably only be feasible in Python 3.0.
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
3.4 Special method names

A class can implement certain operations that are invoked by special syntax (such as arithmetic operations or subscripting and slicing) by defining methods with special names. This is Python's approach to operator overloading, allowing classes to define their own behavior with respect to language operators. For instance, if a class defines a method named \texttt{__getitem__}(), and \texttt{x} is an instance of this class, then \texttt{x[i]} is equivalent\footnote{3.2} to \texttt{x.__getitem__(i)}. Except where mentioned, attempts to execute an operation raise an exception when no appropriate method is defined.

When implementing a class that emulates any built-in type, it is important that the emulation only be implemented to the degree that it makes sense for the object being modelled. For example, some sequences may work well with retrieval of individual elements, but extracting a slice may not make sense. (One example of this is the \texttt{NodeList} interface in the W3C's Document Object Model.)

Footnotes

... equivalent\footnote{3.2}  
This, and other statements, are only roughly true for instances of new-style classes.

3.4.1 Basic customization

__new__( cls[, ...])

Called to create a new instance of class cls. __new__() is a static method (special-cased so you need not declare it as such) that takes the class of which an instance was requested as its first argument. The remaining arguments are those passed to the object constructor expression (the call to the class). The return value of __new__() should be the new object instance (usually an instance of cls).

Typical implementations create a new instance of the class by invoking the superclass's __new__() method using "super(currentclass, cls).__new__(cls[, ...])" with appropriate arguments and then modifying the newly-created instance as necessary before returning it.

If __new__() returns an instance of cls, then the new instance's __init__() method will be invoked like "__init__(self[, ...])", where self is the new instance and the remaining arguments are the same as were passed to __new__().

If __new__() does not return an instance of cls, then the new instance's __init__() method will not be invoked.

__new__() is intended mainly to allow subclasses of immutable types (like int, str, or tuple) to customize instance creation.

__init__( self[, ...])

Called when the instance is created. The arguments are those passed to the class constructor expression. If a base class has an __init__() method, the derived class's __init__() method, if any, must explicitly call it to ensure proper initialization of the base class part of the instance; for example: "BaseClass.__init__(self, [args...])". As a special constraint on constructors, no value may be returned; doing so will cause a TypeError to be raised at runtime.

__del__( self)
Called when the instance is about to be destroyed. This is also called a
destructor. If a base class has a __del__() method, the derived class's
__del__() method, if any, must explicitly call it to ensure proper
deletion of the base class part of the instance. Note that it is possible
(though not recommended!) for the __del__() method to postpone
destruction of the instance by creating a new reference to it. It may then be
called at a later time when this new reference is deleted. It is not guaranteed
that __del__() methods are called for objects that still exist when the
interpreter exits.

Note: "del x" doesn't directly call x.__del__() -- the
former decrements the reference count for x by one, and the
latter is only called when x's reference count reaches zero.
Some common situations that may prevent the reference
count of an object from going to zero include: circular
references between objects (e.g., a doubly-linked list or a
tree data structure with parent and child pointers); a
reference to the object on the stack frame of a function that
catched an exception (the traceback stored in
sys.exc_traceback keeps the stack frame alive); or a
reference to the object on the stack frame that raised an
unhandled exception in interactive mode (the traceback
stored in sys.last_traceback keeps the stack frame
alive). The first situation can only be remedied by explicitly
breaking the cycles; the latter two situations can be resolved
by storing None in sys.exc_traceback or
sys.last_traceback. Circular references which are
garbage are detected when the option cycle detector is
enabled (it's on by default), but can only be cleaned up if
there are no Python-level __del__() methods involved.
Refer to the documentation for the gc module for more
information about how __del__() methods are handled
by the cycle detector, particularly the description of the
garbage value.
**Warning:** Due to the precarious circumstances under which `__del__()` methods are invoked, exceptions that occur during their execution are ignored, and a warning is printed to `sys.stderr` instead. Also, when `__del__()` is invoked in response to a module being deleted (e.g., when execution of the program is done), other globals referenced by the `__del__()` method may already have been deleted. For this reason, `__del__() `methods should do the absolute minimum needed to maintain external invariants.

Starting with version 1.5, Python guarantees that globals whose name begins with a single underscore are deleted from their module before other globals are deleted; if no other references to such globals exist, this may help in assuring that imported modules are still available at the time when the `__del__() `method is called.

---

**`__repr__(self)`**

Called by the `repr()` built-in function and by string conversions (reverse quotes) to compute the "official" string representation of an object. If at all possible, this should look like a valid Python expression that could be used to recreate an object with the same value (given an appropriate environment). If this is not possible, a string of the form "<...some useful description...>" should be returned. The return value must be a string object. If a class defines `__repr__() `but not `__str__()`, then `__repr__() `is also used when an "informal" string representation of instances of that class is required.

This is typically used for debugging, so it is important that the representation is information-rich and unambiguous.

---

**`__str__(self)`**

Called by the `str()` built-in function and by the `print` statement to compute the "informal" string representation of an object. This differs from `__repr__() `in that it does not have to be a valid Python expression: a more convenient or concise representation may be used instead. The return value must be a string object.
__lt__(self, other)
__le__(self, other)
__eq__(self, other)
__ne__(self, other)
__gt__(self, other)
__ge__(self, other)

New in version 2.1. These are the so-called ``rich comparison'' methods, and are called for comparison operators in preference to __cmp__() below. The correspondence between operator symbols and method names is as follows: x<y calls x.__lt__(y), x<=y calls x.__le__(y), x==y calls x.__eq__(y), x!=y and x<>y call x.__ne__(y), x>y calls x.__gt__(y), and x>=y calls x.__ge__(y). These methods can return any value, but if the comparison operator is used in a Boolean context, the return value should be interpretable as a Boolean value, else a TypeError will be raised. By convention, False is used for false and True for true.

There are no implied relationships among the comparison operators. The truth of x==y does not imply that x!=y is false. Accordingly, when defining __eq__( ), one should also define __ne__( ) so that the operators will behave as expected.

There are no reflected (swapped-argument) versions of these methods (to be used when the left argument does not support the operation but the right argument does); rather, __lt__( ) and __gt__( ) are each other's reflection, __le__( ) and __ge__( ) are each other's reflection, and __eq__( ) and __ne__( ) are their own reflection.

Arguments to rich comparison methods are never coerced. A rich comparison method may return NotImplemented if it does not implement the operation for a given pair of arguments.

__cmp__(self, other)

Called by comparison operations if rich comparison (see above) is not defined. Should return a negative integer if self < other, zero if self == other, a positive integer if self > other. If no __cmp__( ), __eq__( ) or __ne__( ) operation is defined, class instances are
compared by object identity (``address''). See also the description of
\_\_hash\_\_( ) for some important notes on creating objects which support
custom comparison operations and are usable as dictionary keys. (Note: the
restriction that exceptions are not propagated by \_\_cmp\_\_( ) has been
removed since Python 1.5.)

\_\_rcmp\_\_( self, other)
Changed in version 2.1: No longer supported.

\_\_hash\_\_( self)
Called for the key object for dictionary operations, and by the built-in
function hash( ). Should return a 32-bit integer usable as a hash value for
dictionary operations. The only required property is that objects which
compare equal have the same hash value; it is advised to somehow mix
together (e.g., using exclusive or) the hash values for the components of the
object that also play a part in comparison of objects. If a class does not
define a \_\_cmp\_\_( ) method it should not define a \_\_hash\_\_( )
operation either; if it defines \_\_cmp\_\_( ) or \_\_eq\_\_( ) but not
\_\_hash\_\_( ), its instances will not be usable as dictionary keys. If a class
defines mutable objects and implements a \_\_cmp\_\_( ) or \_\_eq\_\_( )
method, it should not implement \_\_hash\_\_( ), since the dictionary
implementation requires that a key's hash value is immutable (if the object's
hash value changes, it will be in the wrong hash bucket).

Changed in version 2.5: \_\_hash\_\_( ) may now also return a long integer
object; the 32-bit integer is then derived from the hash of that object.

\_\_nonzero\_\_( self)
Called to implement truth value testing, and the built-in operation bool( );
should return False or True, or their integer equivalents 0 or 1. When
this method is not defined, \_\_len\_\_( ) is called, if it is defined (see
below). If a class defines neither \_\_len\_\_( ) nor \_\_nonzero\_\_( ), all
its instances are considered true.

\_\_unicode\_\_( self)
Called to implement unicode( ) builtin; should return a Unicode object.
When this method is not defined, string conversion is attempted, and the
result of string conversion is converted to Unicode using the system default encoding.
3.4.2 Customizing attribute access

The following methods can be defined to customize the meaning of attribute access (use of, assignment to, or deletion of x.name) for class instances.

__getattr__(self, name)
Called when an attribute lookup has not found the attribute in the usual places (i.e. it is not an instance attribute nor is it found in the class tree for self). name is the attribute name. This method should return the (computed) attribute value or raise an AttributeError exception.

Note that if the attribute is found through the normal mechanism, __getattr__() is not called. (This is an intentional asymmetry between __getattr__() and __setattr__().) This is done both for efficiency reasons and because otherwise __setattr__() would have no way to access other attributes of the instance. Note that at least for instance variables, you can fake total control by not inserting any values in the instance attribute dictionary (but instead inserting them in another object). See the __getattribute__() method below for a way to actually get total control in new-style classes.

__setattr__(self, name, value)
Called when an attribute assignment is attempted. This is called instead of the normal mechanism (i.e. store the value in the instance dictionary). name is the attribute name, value is the value to be assigned to it.

If __setattr__() wants to assign to an instance attribute, it should not simply execute "self.name = value" -- this would cause a recursive call to itself. Instead, it should insert the value in the dictionary of instance attributes, e.g., "self.__dict__[name] = value". For new-style classes, rather than accessing the instance dictionary, it should call the base class method with the same name, for example, "object.__setattr__(self, name, value)".

__delattr__(self, name)
Like __setattr__() but for attribute deletion instead of assignment.
This should only be implemented if "\texttt{del \ obj. name}" is meaningful for the object.

---

Subsections

- 3.4.2.1 More attribute access for new-style classes
- 3.4.2.2 Implementing Descriptors
- 3.4.2.3 Invoking Descriptors
- 3.4.2.4 \texttt{__slots__}

---

Release 2.5, documentation updated on 19th September, 2006.
See \texttt{About this document...} for information on suggesting changes.
3.4.3 Customizing class creation

By default, new-style classes are constructed using `type()`. A class definition is read into a separate namespace and the value of class name is bound to the result of `type(name, bases, dict).

When the class definition is read, if `__metaclass__` is defined then the callable assigned to it will be called instead of `type()`. The allows classes or functions to be written which monitor or alter the class creation process:

- Modifying the class dictionary prior to the class being created.
- Returning an instance of another class - essentially performing the role of a factory function.

`__metaclass__`

This variable can be any callable accepting arguments for `name`, `bases`, and `dict`. Upon class creation, the callable is used instead of the built-in `type()`. New in version 2.2.

The appropriate metaclass is determined by the following precedence rules:

- If `dict['__metaclass__']` exists, it is used.
- Otherwise, if there is at least one base class, its metaclass is used (this looks for a `__class__` attribute first and if not found, uses its type).
- Otherwise, if a global variable named `__metaclass__` exists, it is used.
- Otherwise, the old-style, classic metaclass (types.ClassType) is used.

The potential uses for metaclasses are boundless. Some ideas that have been explored including logging, interface checking, automatic delegation, automatic property creation, proxies, frameworks, and automatic resource locking/synchronization.
Emulating callable objects

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
3.4.4 Emulating callable objects

__call__( self[, args...])

Called when the instance is "called" as a function; if this method is defined, 
x(arg1, arg2, ...) is a shorthand for x.__call__(arg1, 
arg2, ...).
3.4.5 Emulating container types

The following methods can be defined to implement container objects. Containers usually are sequences (such as lists or tuples) or mappings (like dictionaries), but can represent other containers as well. The first set of methods is used either to emulate a sequence or to emulate a mapping; the difference is that for a sequence, the allowable keys should be the integers \( k \) for which \( 0 \leq k < N \) where \( N \) is the length of the sequence, or slice objects, which define a range of items. (For backwards compatibility, the method `__getslice__()` (see below) can also be defined to handle simple, but not extended slices.) It is also recommended that mappings provide the methods `keys()`, `values()`, `items()`, `has_key()`, `get()`, `clear()`, `setdefault()`, `iterkeys()`, `itervalues()`, `iteritems()`, `pop()`, `popitem()`, `copy()`, and `update()` behaving similar to those for Python's standard dictionary objects. The `UserDict` module provides a `DictMixin` class to help create those methods from a base set of `__getitem__()`, `__setitem__()`, `__delitem__()`, and `keys()`. Mutable sequences should provide methods `append()`, `count()`, `index()`, `extend()`, `insert()`, `pop()`, `remove()`, `reverse()` and `sort()`, like Python standard list objects. Finally, sequence types should implement addition (meaning concatenation) and multiplication (meaning repetition) by defining the methods `__add__()`, `__radd__()`, `__iadd__()`, `__mul__()`, `__rmul__()`, and `__imul__()` described below; they should not define `__coerce__()` or other numerical operators. It is recommended that both mappings and sequences implement the `__contains__()` method to allow efficient use of the `in` operator; for mappings, `in` should be equivalent of `has_key()`; for sequences, it should search through the values. It is further recommended that both mappings and sequences implement the `__iter__()` method to allow efficient iteration through the container; for mappings, `__iter__()` should be the same as `iterkeys()`; for sequences, it should iterate through the values.

`__len__(self)`

Called to implement the built-in function `len()`. Should return the length of the object, an integer \( \geq 0 \). Also, an object that doesn't define a `__nonzero__()` method and whose `__len__()` method returns zero is
considered to be false in a Boolean context.

__getitem__(self, key)
Called to implement evaluation of self[key]. For sequence types, the accepted keys should be integers and slice objects. Note that the special interpretation of negative indexes (if the class wishes to emulate a sequence type) is up to the __getitem__() method. If key is of an inappropriate type, TypeError may be raised; if of a value outside the set of indexes for the sequence (after any special interpretation of negative values), IndexError should be raised. For mapping types, if key is missing (not in the container), KeyError should be raised. Note: for loops expect that an IndexError will be raised for illegal indexes to allow proper detection of the end of the sequence.

__setitem__(self, key, value)
Called to implement assignment to self[key]. Same note as for __getitem__(). This should only be implemented for mappings if the objects support changes to the values for keys, or if new keys can be added, or for sequences if elements can be replaced. The same exceptions should be raised for improper key values as for the __getitem__() method.

__delitem__(self, key)
Called to implement deletion of self[key]. Same note as for __getitem__()(). This should only be implemented for mappings if the objects support removal of keys, or for sequences if elements can be removed from the sequence. The same exceptions should be raised for improper key values as for the __getitem__() method.

__iter__(self)
This method is called when an iterator is required for a container. This method should return a new iterator object that can iterate over all the objects in the container. For mappings, it should iterate over the keys of the container, and should also be made available as the method iterkeys().

Iterator objects also need to implement this method; they are required to return themselves. For more information on iterator objects, see "Iterator Types" in the Python Library Reference.
The membership test operators (in and not in) are normally implemented as an iteration through a sequence. However, container objects can supply the following special method with a more efficient implementation, which also does not require the object be a sequence.

__contains__( self, item)

Called to implement membership test operators. Should return true if item is in self, false otherwise. For mapping objects, this should consider the keys of the mapping rather than the values or the key-item pairs.
3.4.6 Additional methods for emulation of sequence types

The following optional methods can be defined to further emulate sequence objects. Immutable sequences methods should at most only define __getslice__(); mutable sequences might define all three methods.

__getslice__(self, i, j)

*Deprecated since release 2.0.* Support slice objects as parameters to the __getitem__() method.

Called to implement evaluation of self[i:j]. The returned object should be of the same type as self. Note that missing i or j in the slice expression are replaced by zero or sys.maxint, respectively. If negative indexes are used in the slice, the length of the sequence is added to that index. If the instance does not implement the __len__() method, an AttributeError is raised. No guarantee is made that indexes adjusted this way are not still negative. Indexes which are greater than the length of the sequence are not modified. If no __getslice__() is found, a slice object is created instead, and passed to __getitem__() instead.

__setslice__(self, i, j, sequence)

Called to implement assignment to self[i:j]. Same notes for i and j as for __getslice__().

This method is deprecated. If no __setslice__() is found, or for extended slicing of the form self[i:j:k], a slice object is created, and passed to __setitem__(), instead of __setslice__() being called.

__delslice__(self, i, j)

Called to implement deletion of self[i:j]. Same notes for i and j as for __getslice__(). This method is deprecated. If no __delslice__() is found, or for extended slicing of the form self[i:j:k], a slice object is created, and passed to __delitem__(), instead of __delslice__() being called.
Notice that these methods are only invoked when a single slice with a single colon is used, and the slice method is available. For slice operations involving extended slice notation, or in absence of the slice methods, __getitem__(), __setitem__() or __delitem__() is called with a slice object as argument.

The following example demonstrate how to make your program or module compatible with earlier versions of Python (assuming that methods __getitem__(), __setitem__() and __delitem__() support slice objects as arguments):

```python
class MyClass:
    ...
    def __getitem__(self, index):
        ...
    def __setitem__(self, index, value):
        ...
    def __delitem__(self, index):
        ...

    if sys.version_info < (2, 0):
        # They won't be defined if version is at least 2.0 final
        def __getslice__(self, i, j):
            return self[max(0, i):max(0, j):]
        def __setslice__(self, i, j, seq):
            self[max(0, i):max(0, j):] = seq
        def __delslice__(self, i, j):
            del self[max(0, i):max(0, j):]
    ...
```

Note the calls to max(); these are necessary because of the handling of negative indices before the ___*slice__() methods are called. When negative indexes are used, the ___*item__() methods receive them as provided, but the ___*slice__() methods get a ```cooked`` form of the index values. For each negative index value, the length of the sequence is added to the index before calling the method (which may still result in a negative index); this is the customary handling of negative indexes by the built-in sequence types, and the ___*item__() methods are expected to do this as well. However, since they should already be doing that, negative indexes cannot be passed in; they must be constrained to the bounds of the sequence before being passed to the ___*item__() methods. Calling max(0, i) conveniently returns the proper value.
3.4.7 Emulating numeric types

The following methods can be defined to emulate numeric objects. Methods corresponding to operations that are not supported by the particular kind of number implemented (e.g., bitwise operations for non-integral numbers) should be left undefined.

```
__add__(self, other)
__sub__(self, other)
__mul__(self, other)
__floordiv__(self, other)
__mod__(self, other)
__divmod__(self, other)
__pow__(self, other[, modulo])
__lshift__(self, other)
__rshift__(self, other)
__and__(self, other)
__xor__(self, other)
__or__(self, other)
```

These methods are called to implement the binary arithmetic operations (+, -, *, //, %, divmod(), pow(), **, <<, >>, &, ^, |). For instance, to evaluate the expression x+y, where x is an instance of a class that has an __add__() method, x.__add__(y) is called. The __divmod__() method should be the equivalent to using __floordiv__() and __mod__(); it should not be related to __truediv__() (described below). Note that __pow__() should be defined to accept an optional third argument if the ternary version of the built-in pow() function is to be supported.

If one of those methods does not support the operation with the supplied arguments, it should return NotImplemented.

```
__div__(self, other)
```
__truediv__( self, other)
The division operator (/) is implemented by these methods. The
__truediv__( ) method is used when __future__.division is in
effect, otherwise __div__( ) is used. If only one of these two methods is
defined, the object will not support division in the alternate context;
TypeError will be raised instead.

__radd__( self, other)
__rsub__( self, other)
__rmul__( self, other)
__rdiv__( self, other)
__rtruediv__( self, other)
__rfloordiv__( self, other)
__rmod__( self, other)
__rdivmod__( self, other)
__rpow__( self, other)
__rlshift__( self, other)
__rrshift__( self, other)
__rand__( self, other)
__rxor__( self, other)
__ror__( self, other)

These methods are called to implement the binary arithmetic operations (+, -,-, *, /, %, divmod(), pow(), **, <<, >>, & , ^, | ) with reflected
(swapped) operands. These functions are only called if the left operand does
not support the corresponding operation and the operands are of different
types. For instance, to evaluate the expression x - y, where y is an instance
of a class that has an __rsub__( ) method, y . __rsub__( x ) is called if
x . __sub__( y ) returns NotImplemented.

Note that ternary pow( ) will not try calling __rpow__( ) (the coercion
rules would become too complicated).

Note: If the right operand's type is a subclass of the left operand's type and
that subclass provides the reflected method for the operation, this method
will be called before the left operand's non-reflected method. This behavior allows subclasses to override their ancestors' operations.

```python
__iadd__(self, other)
__isub__(self, other)
__imul__(self, other)
__idiv__(self, other)
__itruediv__(self, other)
__ifloordiv__(self, other)
__imod__(self, other)
__ipow__(self, other[, modulo])
__ilshift__(self, other)
__irshift__(self, other)
__iand__(self, other)
__ixor__(self, other)
__ior__(self, other)
```

These methods are called to implement the augmented arithmetic operations (+=, -=, *=, /=, %=, **=, <<=, >=, &=, ^=, |=). These methods should attempt to do the operation in-place (modifying `self`) and return the result (which could be, but does not have to be, `self`). If a specific method is not defined, the augmented operation falls back to the normal methods. For instance, to evaluate the expression `x+=y`, where `x` is an instance of a class that has an `__iadd__()` method, `x.__iadd__(y)` is called. If `x` is an instance of a class that does not define a `__iadd__()` method, `x.__add__(y)` and `y.__radd__(x)` are considered, as with the evaluation of `x+y`.

```python
__neg__(self)
__pos__(self)
__abs__(self)
__invert__(self)
```

Called to implement the unary arithmetic operations (-, +, abs() and ~).
__complex__(self)
__int__(self)
__long__(self)
__float__(self)

Called to implement the built-in functions complex(), int(), long(), and float(). Should return a value of the appropriate type.

__oct__(self)
__hex__(self)

Called to implement the built-in functions oct() and hex(). Should return a string value.

__index__(self)

Called to implement operator.index(). Also called whenever Python needs an integer object (such as in slicing). Must return an integer (int or long). New in version 2.5.

__coerce__(self, other)

Called to implement "mixed-mode" numeric arithmetic. Should either return a 2-tuple containing self and other converted to a common numeric type, or None if conversion is impossible. When the common type would be the type of other, it is sufficient to return None, since the interpreter will also ask the other object to attempt a coercion (but sometimes, if the implementation of the other type cannot be changed, it is useful to do the conversion to the other type here). A return value of NotImplemented is equivalent to returning None.

Footnotes

... types.\textsuperscript{33}

For operands of the same type, it is assumed that if the non-reflected method (such as \_\_\_add\_\_( ) fails the operation is not supported, which is why the reflected method is not called.
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
3.4.8 Coercion rules

This section used to document the rules for coercion. As the language has evolved, the coercion rules have become hard to document precisely; documenting what one version of one particular implementation does is undesirable. Instead, here are some informal guidelines regarding coercion. In Python 3.0, coercion will not be supported.

- If the left operand of a % operator is a string or Unicode object, no coercion takes place and the string formatting operation is invoked instead.

- It is no longer recommended to define a coercion operation. Mixed-mode operations on types that don't define coercion pass the original arguments to the operation.

- New-style classes (those derived from object) never invoke the __coerce__() method in response to a binary operator; the only time __coerce__() is invoked is when the built-in function coerce() is called.

- For most intents and purposes, an operator that returns NotImplemented is treated the same as one that is not implemented at all.

- Below, __op__() and __rop__() are used to signify the generic method names corresponding to an operator; __iop__() is used for the corresponding in-place operator. For example, for the operator `+`, __add__() and __radd__() are used for the left and right variant of the binary operator, and __iadd__() for the in-place variant.

- For objects x and y, first x.__op__(y) is tried. If this is not implemented or returns NotImplemented, y.__rop__(x) is tried. If this is also not implemented or returns NotImplemented, a TypeError exception is raised. But see the following exception:

- Exception to the previous item: if the left operand is an instance of a built-in type or a new-style class, and the right operand is an instance of a proper subclass of that type or class and overrides the base's __rop__() method,
the right operand's __rop__( ) method is tried before the left operand's __op__( ) method.

This is done so that a subclass can completely override binary operators. Otherwise, the left operand's __op__( ) method would always accept the right operand: when an instance of a given class is expected, an instance of a subclass of that class is always acceptable.

- When either operand type defines a coercion, this coercion is called before that type's __op__( ) or __rop__( ) method is called, but no sooner. If the coercion returns an object of a different type for the operand whose coercion is invoked, part of the process is redone using the new object.

- When an in-place operator (like `+=`) is used, if the left operand implements __iop__( ), it is invoked without any coercion. When the operation falls back to __op__( ) and/or __rop__( ), the normal coercion rules apply.

- In x+y, if x is a sequence that implements sequence concatenation, sequence concatenation is invoked.

- In x*y, if one operator is a sequence that implements sequence repetition, and the other is an integer (int or long), sequence repetition is invoked.

- Rich comparisons (implemented by methods __eq__( ) and so on) never use coercion. Three-way comparison (implemented by __cmp__( )) does use coercion under the same conditions as other binary operations use it.

- In the current implementation, the built-in numeric types int, long and float do not use coercion; the type complex however does use it. The difference can become apparent when subclassing these types. Over time, the type complex may be fixed to avoid coercion. All these types implement a __coerce__( ) method, for use by the built-in coerce() function.

See About this document... for information on suggesting changes.

3.4.9 With Statement Context Managers

New in version 2.5.

A context manager is an object that defines the runtime context to be established when executing a `with` statement. The context manager handles the entry into, and the exit from, the desired runtime context for the execution of the block of code. Context managers are normally invoked using the `with` statement (described in section 7.5), but can also be used by directly invoking their methods.

Typical uses of context managers include saving and restoring various kinds of global state, locking and unlocking resources, closing opened files, etc.

For more information on context managers, see ``Context Types'' in the Python Library Reference.

``

```enter__(self)

Enter the runtime context related to this object. The `with` statement will bind this method's return value to the target(s) specified in the `as` clause of the statement, if any.

```exit__(self, exc_type, exc_value, traceback)

Exit the runtime context related to this object. The parameters describe the exception that caused the context to be exited. If the context was exited without an exception, all three arguments will be `None`.

If an exception is supplied, and the method wishes to suppress the exception (i.e., prevent it from being propagated), it should return a true value. Otherwise, the exception will be processed normally upon exit from this method.

Note that `__exit__` methods should not reraise the passed-in exception; this is the caller's responsibility.

4. Execution model

4.1.1 Interaction with dynamic
4.1 Naming and binding

Names refer to objects. Names are introduced by name binding operations. Each occurrence of a name in the program text refers to the binding of that name established in the innermost function block containing the use.

A block is a piece of Python program text that is executed as a unit. The following are blocks: a module, a function body, and a class definition. Each command typed interactively is a block. A script file (a file given as standard input to the interpreter or specified on the interpreter command line the first argument) is a code block. A script command (a command specified on the interpreter command line with the `-c` option) is a code block. The file read by the built-in function `execfile()` is a code block. The string argument passed to the built-in function `eval()` and to the `exec` statement is a code block. The expression read and evaluated by the built-in function `input()` is a code block.

A code block is executed in an execution frame. A frame contains some administrative information (used for debugging) and determines where and how execution continues after the code block's execution has completed.

A scope defines the visibility of a name within a block. If a local variable is defined in a block, its scope includes that block. If the definition occurs in a function block, the scope extends to any blocks contained within the defining one, unless a contained block introduces a different binding for the name. The scope of names defined in a class block is limited to the class block; it does not extend to the code blocks of methods.

When a name is used in a code block, it is resolved using the nearest enclosing scope. The set of all such scopes visible to a code block is called the block's environment.

If a name is bound in a block, it is a local variable of that block. If a name is bound at the module level, it is a global variable. (The variables of the module code block are local and global.) If a variable is used in a code block but not defined there, it is a free variable.

When a name is not found at all, a NameError exception is raised. If the name
refers to a local variable that has not been bound, a `UnboundLocalError` exception is raised. `UnboundLocalError` is a subclass of `NameError`.

The following constructs bind names: formal parameters to functions, `import` statements, class and function definitions (these bind the class or function name in the defining block), and targets that are identifiers if occurring in an assignment, `for` loop header, or in the second position of an `except` clause header. The `import` statement of the form ```from ...import *``` binds all names defined in the imported module, except those beginning with an underscore. This form may only be used at the module level.

A target occurring in a `del` statement is also considered bound for this purpose (though the actual semantics are to unbind the name). It is illegal to unbind a name that is referenced by an enclosing scope; the compiler will report a `SyntaxError`.

Each assignment or `import` statement occurs within a block defined by a class or function definition or at the module level (the top-level code block).

If a name binding operation occurs anywhere within a code block, all uses of the name within the block are treated as references to the current block. This can lead to errors when a name is used within a block before it is bound. This rule is subtle. Python lacks declarations and allows name binding operations to occur anywhere within a code block. The local variables of a code block can be determined by scanning the entire text of the block for name binding operations.

If the `global` statement occurs within a block, all uses of the name specified in the statement refer to the binding of that name in the top-level namespace. Names are resolved in the top-level namespace by searching the global namespace, i.e. the namespace of the module containing the code block, and the `builtin` namespace, the namespace of the module `__builtin__`. The global namespace is searched first. If the name is not found there, the `builtin` namespace is searched. The `global` statement must precede all uses of the name.

The built-in namespace associated with the execution of a code block is actually found by looking up the name `__builtins__` in its global namespace; this should be a dictionary or a module (in the latter case the module's dictionary is used). By default, when in the `__main__` module, `__builtins__` is the built-in module `__builtin__` (note: no `\`s); when in any other module,
__builtins__ is an alias for the dictionary of the __builtin__ module itself. __builtins__ can be set to a user-created dictionary to create a weak form of restricted execution.

**Note:** Users should not touch __builtins__; it is strictly an implementation detail. Users wanting to override values in the built-in namespace should import the __builtin__ (no `s`) module and modify its attributes appropriately.

The namespace for a module is automatically created the first time a module is imported. The main module for a script is always called __main__.

The global statement has the same scope as a name binding operation in the same block. If the nearest enclosing scope for a free variable contains a global statement, the free variable is treated as a global.

A class definition is an executable statement that may use and define names. These references follow the normal rules for name resolution. The namespace of the class definition becomes the attribute dictionary of the class. Names defined at the class scope are not visible in methods.

---

*Release 2.5, documentation updated on 19th September, 2006.*

*See [About this document...](#) for information on suggesting changes.*
4.1.1 Interaction with dynamic features

There are several cases where Python statements are illegal when used in conjunction with nested scopes that contain free variables.

If a variable is referenced in an enclosing scope, it is illegal to delete the name. An error will be reported at compile time.

If the wild card form of import -- "import *" -- is used in a function and the function contains or is a nested block with free variables, the compiler will raise a SyntaxError.

If exec is used in a function and the function contains or is a nested block with free variables, the compiler will raise a SyntaxError unless the exec explicitly specifies the local namespace for the exec. (In other words, "exec obj" would be illegal, but "exec obj in ns" would be legal.)

The eval(), execfile(), and input() functions and the exec statement do not have access to the full environment for resolving names. Names may be resolved in the local and global namespaces of the caller. Free variables are not resolved in the nearest enclosing namespace, but in the global namespace.4.1 The exec statement and the eval() and execfile() functions have optional arguments to override the global and local namespace. If only one namespace is specified, it is used for both.

Footnotes

... namespace.4.1

This limitation occurs because the code that is executed by these operations is not available at the time the module is compiled.
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
4.2 Exceptions

Exceptions are a means of breaking out of the normal flow of control of a code block in order to handle errors or other exceptional conditions. An exception is raised at the point where the error is detected; it may be handled by the surrounding code block or by any code block that directly or indirectly invoked the code block where the error occurred.

The Python interpreter raises an exception when it detects a run-time error (such as division by zero). A Python program can also explicitly raise an exception with the raise statement. Exception handlers are specified with the try ... except statement. The try ... finally statement specifies cleanup code which does not handle the exception, but is executed whether an exception occurred or not in the preceding code.

Python uses the "termination" model of error handling: an exception handler can find out what happened and continue execution at an outer level, but it cannot repair the cause of the error and retry the failing operation (except by re-entering the offending piece of code from the top).

When an exception is not handled at all, the interpreter terminates execution of the program, or returns to its interactive main loop. In either case, it prints a stack backtrace, except when the exception is SystemExit.

Exceptions are identified by class instances. The except clause is selected depending on the class of the instance: it must reference the class of the instance or a base class thereof. The instance can be received by the handler and can carry additional information about the exceptional condition.

Exceptions can also be identified by strings, in which case the except clause is selected by object identity. An arbitrary value can be raised along with the identifying string which can be passed to the handler.

**Deprecated since release 2.5.** String exceptions should not be used in new code. They will not be supported in a future version of Python. Old code should be rewritten to use class exceptions instead.
Warning: Messages to exceptions are not part of the Python API. Their contents may change from one version of Python to the next without warning and should not be relied on by code which will run under multiple versions of the interpreter.

See also the description of the `try` statement in section 7.4 and `raise` statement in section 6.9.
5. Expressions

This chapter explains the meaning of the elements of expressions in Python.

Syntax Notes: In this and the following chapters, extended BNF notation will be used to describe syntax, not lexical analysis. When (one alternative of) a syntax rule has the form

```
name ::= othername
```

and no semantics are given, the semantics of this form of name are the same as for othername.

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
5.1 Arithmetic conversions

When a description of an arithmetic operator below uses the phrase `the numeric arguments are converted to a common type," the arguments are coerced using the coercion rules listed at 3.4.8. If both arguments are standard numeric types, the following coercions are applied:

- If either argument is a complex number, the other is converted to complex;
- otherwise, if either argument is a floating point number, the other is converted to floating point;
- otherwise, if either argument is a long integer, the other is converted to long integer;
- otherwise, both must be plain integers and no conversion is necessary.

Some additional rules apply for certain operators (e.g., a string left argument to the `%` operator). Extensions can define their own coercions.
5.2 Atoms

Atoms are the most basic elements of expressions. The simplest atoms are identifiers or literals. Forms enclosed in reverse quotes or in parentheses, brackets or braces are also categorized syntactically as atoms. The syntax for atoms is:

```
atom ::= identifier  |  literal  |  enclosure

enclosure ::= parenth_form  |  list_display
             |  generator_expression  |  dict_display
             |  string_conversion
```

Subsections

- 5.2.1 Identifiers (Names)
- 5.2.2 Literals
- 5.2.3 Parenthesized forms
- 5.2.4 List displays
- 5.2.5 Generator expressions
- 5.2.6 Dictionary displays
- 5.2.7 String conversions
5.2.1 Identifiers (Names)

An identifier occurring as an atom is a name. See section 4.1 for documentation of naming and binding.

When the name is bound to an object, evaluation of the atom yields that object. When a name is not bound, an attempt to evaluate it raises a NameError exception.

**Private name mangling:** When an identifier that textually occurs in a class definition begins with two or more underscore characters and does not end in two or more underscores, it is considered a *private name* of that class. Private names are transformed to a longer form before code is generated for them. The transformation inserts the class name in front of the name, with leading underscores removed, and a single underscore inserted in front of the class name. For example, the identifier `__spam` occurring in a class named `Ham` will be transformed to `_Ham__spam`. This transformation is independent of the syntactical context in which the identifier is used. If the transformed name is extremely long (longer than 255 characters), implementation defined truncation may happen. If the class name consists only of underscores, no transformation is done.
5.2.2 Literals

Python supports string literals and various numeric literals:

\[
\text{literal ::= stringliteral | integer | longinteger | floatnumber | imagnumber}
\]

Evaluation of a literal yields an object of the given type (string, integer, long integer, floating point number, complex number) with the given value. The value may be approximated in the case of floating point and imaginary (complex) literals. See section 2.4 for details.

All literals correspond to immutable data types, and hence the object's identity is less important than its value. Multiple evaluations of literals with the same value (either the same occurrence in the program text or a different occurrence) may obtain the same object or a different object with the same value.
5.2.3 Parenthesized forms

A parenthesized form is an optional expression list enclosed in parentheses:

\[
\text{parenth\_form} ::= "(" [expression\_list] ")"
\]

A parenthesized expression list yields whatever that expression list yields: if the list contains at least one comma, it yields a tuple; otherwise, it yields the single expression that makes up the expression list.

An empty pair of parentheses yields an empty tuple object. Since tuples are immutable, the rules for literals apply (i.e., two occurrences of the empty tuple may or may not yield the same object).

Note that tuples are not formed by the parentheses, but rather by use of the comma operator. The exception is the empty tuple, for which parentheses are required -- allowing unparenthesized `nothing" in expressions would cause ambiguities and allow common typos to pass uncaught.
5.2.4 List displays

A list display is a possibly empty series of expressions enclosed in square brackets:

```
test ::= or_test | lambda_form

testlist ::= test ( "," test )* [ "," ]

list_display ::= "[" [listmaker] "]"

listmaker ::= expression ( list_for | ( "," expression )* ["","] )

list_iter ::= list_for | list_if

list_for ::= "for" expression_list "in" testlist [list_iter]

list_if ::= "if" test [list_iter]
```

A list display yields a new list object. Its contents are specified by providing either a list of expressions or a list comprehension. When a comma-separated list of expressions is supplied, its elements are evaluated from left to right and placed into the list object in that order. When a list comprehension is supplied, it consists of a single expression followed by at least one `for` clause and zero or more `for` or `if` clauses. In this case, the elements of the new list are those that would be produced by considering each of the `for` or `if` clauses a block, nesting from left to right, and evaluating the expression to produce a list element each time the innermost block is reached.

Footnotes

... reached 5.1

In Python 2.3, a list comprehension "leaks" the control variables of each "for" it contains into the containing scope. However, this behavior is
deprecated, and relying on it will not work once this bug is fixed in a future release
5.2.5 Generator expressions

A generator expression is a compact generator notation in parentheses:

```
generator_expression ::= "(" test
genexpr_for ")"
genexpr_for ::= "for"
expression_list
"in" test
[genexpr_iter]
genexpr_iter ::= genexpr_for | genexpr_if
genexpr_if ::= "if" test
[genexpr_iter]
```

A generator expression yields a new generator object. It consists of a single expression followed by at least one for clause and zero or more for or if clauses. The iterating values of the new generator are those that would be produced by considering each of the for or if clauses a block, nesting from left to right, and evaluating the expression to yield a value that is reached the innermost block for each iteration.

Variables used in the generator expression are evaluated lazily when the next() method is called for generator object (in the same fashion as normal generators). However, the leftmost for clause is immediately evaluated so that error produced by it can be seen before any other possible error in the code that handles the generator expression. Subsequent for clauses cannot be evaluated immediately since they may depend on the previous for loop. For example: "(x*y for x in range(10) for y in bar(x))".

The parentheses can be omitted on calls with only one argument. See section 5.3.4 for the detail.
5.2.6 Dictionary displays

A dictionary display is a possibly empty series of key/datum pairs enclosed in curly braces:

```
dict_display ::= "{" [key_datum_list] "}"  
key_datum_list ::= key_datum ("," key_datum)* [","]  
key_datum ::= expression ":" expression  
```

A dictionary display yields a new dictionary object.

The key/datum pairs are evaluated from left to right to define the entries of the dictionary: each key object is used as a key into the dictionary to store the corresponding datum.

Restrictions on the types of the key values are listed earlier in section 3.2. (To summarize, the key type should be hashable, which excludes all mutable objects.) Clashes between duplicate keys are not detected; the last datum (textually rightmost in the display) stored for a given key value prevails.
5.2.7 String conversions

A string conversion is an expression list enclosed in reverse (a.k.a. backward) quotes:

```
string_conversion ::= "\"" expression_list "\""
```

Download entire grammar as text.

A string conversion evaluates the contained expression list and converts the resulting object into a string according to rules specific to its type.

If the object is a string, a number, `None`, or a tuple, list or dictionary containing only objects whose type is one of these, the resulting string is a valid Python expression which can be passed to the built-in function `eval()` to yield an expression with the same value (or an approximation, if floating point numbers are involved).

(In particular, converting a string adds quotes around it and converts ``funny'' characters to escape sequences that are safe to print.)

Recursive objects (for example, lists or dictionaries that contain a reference to themselves, directly or indirectly) use "..." to indicate a recursive reference, and the result cannot be passed to `eval()` to get an equal value (`SyntaxError` will be raised instead).

The built-in function `repr()` performs exactly the same conversion in its argument as enclosing it in parentheses and reverse quotes does. The built-in function `str()` performs a similar but more user-friendly conversion.
5.3 Primaries

Primaries represent the most tightly bound operations of the language. Their syntax is:

```
primary ::= atom | attributeref | subscription | slicing | call
```

Download entire grammar as text.

Subsections

- 5.3.1 Attribute references
- 5.3.2 Subscriptions
- 5.3.3 Slicings
- 5.3.4 Calls

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
5.3.1 Attribute references

An attribute reference is a primary followed by a period and a name:

```
attributeref := primary "." identifier
```

The primary must evaluate to an object of a type that supports attribute references, e.g., a module, list, or an instance. This object is then asked to produce the attribute whose name is the identifier. If this attribute is not available, the exception `AttributeError` is raised. Otherwise, the type and value of the object produced is determined by the object. Multiple evaluations of the same attribute reference may yield different objects.

---

*Previous:* 5.3 Primaries  *Up:* 5.3 Primaries  *Next:* 5.3.2 Subscriptions

*Release 2.5, documentation updated on 19th September, 2006.*

*See* About this document... *for information on suggesting changes.*
5.3.2 Subscriptions

A subscription selects an item of a sequence (string, tuple or list) or mapping (dictionary) object:

```
subscription ::= primary "[" expression_list "]"
```

The primary must evaluate to an object of a sequence or mapping type.

If the primary is a mapping, the expression list must evaluate to an object whose value is one of the keys of the mapping, and the subscription selects the value in the mapping that corresponds to that key. (The expression list is a tuple except if it has exactly one item.)

If the primary is a sequence, the expression (list) must evaluate to a plain integer. If this value is negative, the length of the sequence is added to it (so that, e.g., `x[-1]` selects the last item of `x.`) The resulting value must be a nonnegative integer less than the number of items in the sequence, and the subscription selects the item whose index is that value (counting from zero).

A string's items are characters. A character is not a separate data type but a string of exactly one character.
5.3.3 Slicings

A slicing selects a range of items in a sequence object (e.g., a string, tuple or list). Slicings may be used as expressions or as targets in assignment or `del` statements. The syntax for a slicing:

```
slicing ::= simple_slicing | extended_slicing

simple_slicing ::= primary "[" short_slice "]"

extended_slicing ::= primary "[" slice_list "]"

slice_list ::= slice_item ("," slice_item)* [",",]

slice_item ::= expression | proper_slice | ellipsis

proper_slice ::= short_slice | long_slice

short_slice ::= [lower_bound] ":" [upper_bound]

long_slice ::= short_slice ":" [stride]

lower_bound ::= expression

upper_bound ::= expression

stride ::= expression

ellipsis ::= "..."
```

There is ambiguity in the formal syntax here: anything that looks like an expression list also looks like a slice list, so any subscription can be interpreted as a slicing. Rather than further complicating the syntax, this is disambiguated by defining that in this case the interpretation as a subscription takes priority over the interpretation as a slicing (this is the case if the slice list contains no
proper slice nor ellipses). Similarly, when the slice list has exactly one short slice and no trailing comma, the interpretation as a simple slicing takes priority over that as an extended slicing.

The semantics for a simple slicing are as follows. The primary must evaluate to a sequence object. The lower and upper bound expressions, if present, must evaluate to plain integers; defaults are zero and the \texttt{sys.maxint}, respectively. If either bound is negative, the sequence's length is added to it. The slicing now selects all items with index \( k \) such that \( i \leq k < j \) where \( i \) and \( j \) are the specified lower and upper bounds. This may be an empty sequence. It is not an error if \( i \) or \( j \) lie outside the range of valid indexes (such items don't exist so they aren't selected).

The semantics for an extended slicing are as follows. The primary must evaluate to a mapping object, and it is indexed with a key that is constructed from the slice list, as follows. If the slice list contains at least one comma, the key is a tuple containing the conversion of the slice items; otherwise, the conversion of the lone slice item is the key. The conversion of a slice item that is an expression is that expression. The conversion of an ellipsis slice item is the built-in \texttt{Ellipsis} object. The conversion of a proper slice is a slice object (see section 3.2) whose \texttt{start}, \texttt{stop} and \texttt{step} attributes are the values of the expressions given as lower bound, upper bound and stride, respectively, substituting \texttt{None} for missing expressions.
5.3.4 Calls

A call calls a callable object (e.g., a function) with a possibly empty series of arguments:

```
primary "([argument_list [","] | testgenexpr_for] ")"
call ::= primary "(" [argument_list [",",]] ")"
argument_list ::= positional_arguments [","
                  keyword_arguments [","
                                    "*" expression] [","
                                    "**" expression]
                        | keyword_arguments [","
                                        "*" expression]
                        | "*" expression [","
                                 "**" expression]
                        | "**" expression
positional_arguments ::= expression (","
                        expression)*
keyword_arguments ::= keyword_item (","
                        keyword_item)*
keyword_item ::= identifier "=" expression
```

A trailing comma may be present after the positional and keyword arguments but does not affect the semantics.

The primary must evaluate to a callable object (user-defined functions, built-in functions, methods of built-in objects, class objects, methods of class instances,
and certain class instances themselves are callable; extensions may define additional callable object types). All argument expressions are evaluated before the call is attempted. Please refer to section 7.6 for the syntax of formal parameter lists.

If keyword arguments are present, they are first converted to positional arguments, as follows. First, a list of unfilled slots is created for the formal parameters. If there are N positional arguments, they are placed in the first N slots. Next, for each keyword argument, the identifier is used to determine the corresponding slot (if the identifier is the same as the first formal parameter name, the first slot is used, and so on). If the slot is already filled, a TypeError exception is raised. Otherwise, the value of the argument is placed in the slot, filling it (even if the expression is None, it fills the slot). When all arguments have been processed, the slots that are still unfilled are filled with the corresponding default value from the function definition. (Default values are calculated, once, when the function is defined; thus, a mutable object such as a list or dictionary used as default value will be shared by all calls that don't specify an argument value for the corresponding slot; this should usually be avoided.) If there are any unfilled slots for which no default value is specified, a TypeError exception is raised. Otherwise, the list of filled slots is used as the argument list for the call.

If there are more positional arguments than there are formal parameter slots, a TypeError exception is raised, unless a formal parameter using the syntax "*identifier" is present; in this case, that formal parameter receives a tuple containing the excess positional arguments (or an empty tuple if there were no excess positional arguments).

If any keyword argument does not correspond to a formal parameter name, a TypeError exception is raised, unless a formal parameter using the syntax "**identifier" is present; in this case, that formal parameter receives a dictionary containing the excess keyword arguments (using the keywords as keys and the argument values as corresponding values), or a (new) empty dictionary if there were no excess keyword arguments.

If the syntax "*expression" appears in the function call, "expression" must evaluate to a sequence. Elements from this sequence are treated as if they were additional positional arguments; if there are positional arguments \(x_1,\ldots,x_N\), and "expression" evaluates to a sequence \(y_1,\ldots,y_M\), this is equivalent to a
call with M+N positional arguments $x_1,...,x_N,y_1,...,y_M$.

A consequence of this is that although the "*expression" syntax appears after any keyword arguments, it is processed before the keyword arguments (and the "**expression" argument, if any - see below). So:

```python
>>> def f(a, b):
...   print a, b
... >>> f(b=1, *(2,))
  2 1
>>> f(a=1, *(2,))
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
TypeError: f() got multiple values for keyword argument 'a'
>>> f(1, *(2,))
  1 2
```

It is unusual for both keyword arguments and the "*expression" syntax to be used in the same call, so in practice this confusion does not arise.

If the syntax "**expression" appears in the function call, "expression" must evaluate to a (subclass of) dictionary, the contents of which are treated as additional keyword arguments. In the case of a keyword appearing in both "expression" and as an explicit keyword argument, a TypeError exception is raised.

Formal parameters using the syntax "*identifier" or "**identifier" cannot be used as positional argument slots or as keyword argument names. Formal parameters using the syntax "(sublist)" cannot be used as keyword argument names; the outermost sublist corresponds to a single unnamed argument slot, and the argument value is assigned to the sublist using the usual tuple assignment rules after all other parameter processing is done.

A call always returns some value, possibly None, unless it raises an exception. How this value is computed depends on the type of the callable object.

If it is--

**a user-defined function:**

The code block for the function is executed, passing it the argument list. The first thing the code block will do is bind the formal parameters to the
arguments; this is described in section 7.6. When the code block executes a return statement, this specifies the return value of the function call.

a built-in function or method:
The result is up to the interpreter; see the Python Library Reference for the descriptions of built-in functions and methods.

a class object:
A new instance of that class is returned.

a class instance method:
The corresponding user-defined function is called, with an argument list that is one longer than the argument list of the call: the instance becomes the first argument.

a class instance:
The class must define a __call__() method; the effect is then the same as if that method was called.
5.4 The power operator

The power operator binds more tightly than unary operators on its left; it binds less tightly than unary operators on its right. The syntax is:

```
power ::= primary ["**" u_expr]
```

Thus, in an unparenthesized sequence of power and unary operators, the operators are evaluated from right to left (this does not constrain the evaluation order for the operands).

The power operator has the same semantics as the built-in `pow()` function, when called with two arguments: it yields its left argument raised to the power of its right argument. The numeric arguments are first converted to a common type. The result type is that of the arguments after coercion.

With mixed operand types, the coercion rules for binary arithmetic operators apply. For int and long int operands, the result has the same type as the operands (after coercion) unless the second argument is negative; in that case, all arguments are converted to float and a float result is delivered. For example, `10**2` returns `100`, but `10**-2` returns `0.01`. (This last feature was added in Python 2.2. In Python 2.1 and before, if both arguments were of integer types and the second argument was negative, an exception was raised).

Raising `0.0` to a negative power results in a `ZeroDivisionError`. Raising a negative number to a fractional power results in a `ValueError`.
5.5 Unary arithmetic operations

All unary arithmetic (and bit-wise) operations have the same priority:

\[
u_{-\text{expr}} ::= \text{power} | \text{"-"} u_{\text{expr}} | \text{"+"} u_{\text{expr}} | \text{"~"} u_{\text{expr}}
\]

Download entire grammar as text.

The unary - (minus) operator yields the negation of its numeric argument.

The unary + (plus) operator yields its numeric argument unchanged.

The unary ~ (invert) operator yields the bit-wise inversion of its plain or long integer argument. The bit-wise inversion of \(x\) is defined as \(- (x+1)\). It only applies to integral numbers.

In all three cases, if the argument does not have the proper type, a TypeError exception is raised.
5.6 Binary arithmetic operations

The binary arithmetic operations have the conventional priority levels. Note that some of these operations also apply to certain non-numeric types. Apart from the power operator, there are only two levels, one for multiplicative operators and one for additive operators:

```
m_expr ::= u_expr | m_expr "*" u_expr | m_expr "//" u_expr | m_expr "/" u_expr | m_expr "%" u_expr

a_expr ::= m_expr | a_expr "+" m_expr | a_expr "-" m_expr
```

The * (multiplication) operator yields the product of its arguments. The arguments must either both be numbers, or one argument must be an integer (plain or long) and the other must be a sequence. In the former case, the numbers are converted to a common type and then multiplied together. In the latter case, sequence repetition is performed; a negative repetition factor yields an empty sequence.

The / (division) and // (floor division) operators yield the quotient of their arguments. The numeric arguments are first converted to a common type. Plain or long integer division yields an integer of the same type; the result is that of mathematical division with the `floor` function applied to the result. Division by zero raises the `ZeroDivisionError` exception.

The % (modulo) operator yields the remainder from the division of the first argument by the second. The numeric arguments are first converted to a common type. A zero right argument raises the `ZeroDivisionError` exception. The arguments may be floating point numbers, e.g., `3.14%0.7` equals `0.34` (since `3.14` equals `4*0.7 + 0.34`). The modulo operator always yields a result with the same sign as its second operand (or zero); the absolute value of the result is strictly smaller than the absolute value of the second operand.
The integer division and modulo operators are connected by the following identity: \( x = (x/y) \times y + (x\%y) \). Integer division and modulo are also connected with the built-in function `divmod()`:

\[
\text{divmod}(x, y) = (x/y, x\%y)
\]

These identities don't hold for floating point numbers; there similar identities hold approximately where \( x/y \) is replaced by \( \text{floor}(x/y) \) or \( \text{floor}(x/y) - 1 \).

In addition to performing the modulo operation on numbers, the % operator is also overloaded by string and unicode objects to perform string formatting (also known as interpolation). The syntax for string formatting is described in the Python Library Reference, section ``Sequence Types''.

**Deprecated since release 2.3.** The floor division operator, the modulo operator, and the `divmod()` function are no longer defined for complex numbers. Instead, convert to a floating point number using the `abs()` function if appropriate.

The + (addition) operator yields the sum of its arguments. The arguments must either both be numbers or both sequences of the same type. In the former case, the numbers are converted to a common type and then added together. In the latter case, the sequences are concatenated.

The - (subtraction) operator yields the difference of its arguments. The numeric arguments are first converted to a common type.

---

**Footnotes**

... operand

While \( \text{abs}(x\%y) < \text{abs}(y) \) is true mathematically, for floats it may not be true numerically due to roundoff. For example, and assuming a platform on which a Python float is an IEEE 754 double-precision number, in order that \(-1e-100 \% 1e100\) have the same sign as \(1e100\), the computed result is \(-1e-100 + 1e100\), which is numerically exactly equal to \(1e100\). Function `fmod()` in the `math` module returns a result whose sign matches the sign of the first argument instead, and so returns \(-1e-100\) in
this case. Which approach is more appropriate depends on the application. 

If $x$ is very close to an exact integer multiple of $y$, it's possible for $\text{floor}(x/y)$ to be one larger than $(x - x\%y)/y$ due to rounding. In such cases, Python returns the latter result, in order to preserve that $\text{divmod}(x, y)[0] * y + x \% y$ be very close to $x$. 

Release 2.5, documentation updated on 19th September, 2006. 
See About this document... for information on suggesting changes.
5.7 Shifting operations

The shifting operations have lower priority than the arithmetic operations:

```
shift_expr ::= a_expr | shift_expr ( "<<" | ">>" ) a_expr
```

These operators accept plain or long integers as arguments. The arguments are converted to a common type. They shift the first argument to the left or right by the number of bits given by the second argument.

A right shift by \( n \) bits is defined as division by \( \text{pow}(2, n) \). A left shift by \( n \) bits is defined as multiplication with \( \text{pow}(2, n) \); for plain integers there is no overflow check so in that case the operation drops bits and flips the sign if the result is not less than \( \text{pow}(2, 31) \) in absolute value. Negative shift counts raise a `ValueError` exception.
5.8 Binary bit-wise operations

Each of the three bitwise operations has a different priority level:

```
and_expr ::= shift_expr | and_expr "&" shift_expr
xor_expr ::= and_expr | xor_expr "^" and_expr
or_expr ::= xor_expr | or_expr "|" xor_expr
```

The & operator yields the bitwise AND of its arguments, which must be plain or long integers. The arguments are converted to a common type.

The ^ operator yields the bitwise XOR (exclusive OR) of its arguments, which must be plain or long integers. The arguments are converted to a common type.

The | operator yields the bitwise (inclusive) OR of its arguments, which must be plain or long integers. The arguments are converted to a common type.
5.9 Comparisons

Unlike C, all comparison operations in Python have the same priority, which is lower than that of any arithmetic, shifting or bitwise operation. Also unlike C, expressions like \( a < b < c \) have the interpretation that is conventional in mathematics:

```
comparison ::= or_expr ( comp_operator
                        or_expr )*

comp_operator ::= 
                
                "<" | ">" | ">=\" | ">=" | 
                "<=\" | "><\" | ">!=\" |
                "is" ["not"] | ["not"]
                "in"
```

Comparisons yield boolean values: \texttt{True} or \texttt{False}.

Comparisons can be chained arbitrarily, e.g., \( x < y <= z \) is equivalent to \( x < y \) and \( y <= z \), except that \( y \) is evaluated only once (but in both cases \( z \) is not evaluated at all when \( x < y \) is found to be false).

Formally, if \( a, b, c, ..., y, z \) are expressions and \( opa, opb, ..., opy \) are comparison operators, then \( a opa b opb c ... y opy z \) is equivalent to \( a opa b \) and \( b opb c \) and ... \( y opy z \), except that each expression is evaluated at most once.

Note that \( a opa b opb c \) doesn't imply any kind of comparison between \( a \) and \( c \), so that, e.g., \( x < y > z \) is perfectly legal (though perhaps not pretty).

The forms \( <> \) and \( != \) are equivalent; for consistency with C, \( != \) is preferred; where \( != \) is mentioned below \( <> \) is also accepted. The \( <> \) spelling is considered obsolescent.

The operators \( <, >, ==, >=, <=, \) and \( != \) compare the values of two objects. The objects need not have the same type. If both are numbers, they are converted to a common type. Otherwise, objects of different types \textit{always} compare unequal, and are ordered consistently but arbitrarily. You can control comparison behavior
of objects of non-builtin types by defining a __cmp__ method or rich comparison methods like __gt__, described in section 3.4.

(This unusual definition of comparison was used to simplify the definition of operations like sorting and the in and not in operators. In the future, the comparison rules for objects of different types are likely to change.)

Comparison of objects of the same type depends on the type:

- Numbers are compared arithmetically.
- Strings are compared lexicographically using the numeric equivalents (the result of the built-in function ord()) of their characters. Unicode and 8-bit strings are fully interoperable in this behavior.
- Tuples and lists are compared lexicographically using comparison of corresponding elements. This means that to compare equal, each element must compare equal and the two sequences must be of the same type and have the same length.

If not equal, the sequences are ordered the same as their first differing elements. For example, cmp([1, 2, x], [1, 2, y]) returns the same as cmp(x, y). If the corresponding element does not exist, the shorter sequence is ordered first (for example, [1, 2] < [1, 2, 3]).

- Mappings (dictionaries) compare equal if and only if their sorted (key, value) lists compare equal. Outcomes other than equality are resolved consistently, but are not otherwise defined.

- Most other objects of builtin types compare unequal unless they are the same object; the choice whether one object is considered smaller or larger than another one is made arbitrarily but consistently within one execution of a program.

The operators in and not in test for set membership. x in s evaluates to true if x is a member of the set s, and false otherwise. x not in s returns the negation of x in s. The set membership test has traditionally been bound to sequences; an object is a member of a set if the set is a sequence and contains an element equal to that object. However, it is possible for an object to support
membership tests without being a sequence. In particular, dictionaries support membership testing as a nicer way of spelling `key in dict`; other mapping types may follow suit.

For the list and tuple types, `x in y` is true if and only if there exists an index `i` such that `x == y[i]` is true.

For the Unicode and string types, `x in y` is true if and only if `x` is a substring of `y`. An equivalent test is `y.find(x) != -1`. Note, `x` and `y` need not be the same type; consequently, `'ab' in 'abc'` will return `True`. Empty strings are always considered to be a substring of any other string, so `'' in ''abc''` will return `True`. Changed in version 2.3: Previously, `x` was required to be a string of length 1.

For user-defined classes which define the `__contains__()` method, `x in y` is true if and only if `y.__contains__(x)` is true.

For user-defined classes which do not define `__contains__()` and do define `__getitem__()`, `x in y` is true if and only if there is a non-negative integer index `i` such that `x == y[i]`, and all lower integer indices do not raise `IndexError` exception. (If any other exception is raised, it is as if `in` raised that exception).

The operator `not in` is defined to have the inverse true value of `in`.

The operators `is` and `is not` test for object identity: `x is y` is true if and only if `x` and `y` are the same object. `x is not y` yields the inverse truth value.

---

### Footnotes

... equal.\(^5.4\)

The implementation computes this efficiently, without constructing lists or sorting.

... defined.\(^5.5\)

Earlier versions of Python used lexicographic comparison of the sorted
(key, value) lists, but this was very expensive for the common case of comparing for equality. An even earlier version of Python compared dictionaries by identity only, but this caused surprises because people expected to be able to test a dictionary for emptiness by comparing it to `{}`.
5.10 Boolean operations

Boolean operations have the lowest priority of all Python operations:

```
expression ::= or_test [if or_test else test] | lambda_form
or_test ::= and_test | or_test "or" and_test
and_test ::= not_test | and_test "and" not_test
not_test ::= comparison | "not" not_test
```

In the context of Boolean operations, and also when expressions are used by control flow statements, the following values are interpreted as false: `False`, `None`, numeric zero of all types, and empty strings and containers (including strings, tuples, lists, dictionaries, sets and frozensets). All other values are interpreted as true.

The operator `not` yields `True` if its argument is false, `False` otherwise.

The expression `x if C else y` first evaluates `C (not x)`; if `C` is true, `x` is evaluated and its value is returned; otherwise, `y` is evaluated and its value is returned. New in version 2.5.

The expression `x and y` first evaluates `x`; if `x` is false, its value is returned; otherwise, `y` is evaluated and the resulting value is returned.

The expression `x or y` first evaluates `x`; if `x` is true, its value is returned; otherwise, `y` is evaluated and the resulting value is returned.

(Note that neither `and` nor `or` restrict the value and type they return to `False` and `True`, but rather return the last evaluated argument. This is sometimes useful, e.g., if `s` is a string that should be replaced by a default value if it is empty, the expression `s or 'foo'` yields the desired value. Because `not` has to invent a value anyway, it does not bother to return a value of the same type as
its argument, so e.g., not 'foo' yields False, not ''.)
5.11 Lambdas

\[
\text{lambda_form ::= "lambda" [parameter_list]: expression}
\]

Lambda forms (lambda expressions) have the same syntactic position as expressions. They are a shorthand to create anonymous functions; the expression \text{lambda arguments: expression} yields a function object. The unnamed object behaves like a function object defined with

\[
def \text{name(arguments): return expression}
\]

See section 7.6 for the syntax of parameter lists. Note that functions created with lambda forms cannot contain statements.
5.12 Expression lists

expression_list ::= expression ("," expression )* ["","]

An expression list containing at least one comma yields a tuple. The length of the tuple is the number of expressions in the list. The expressions are evaluated from left to right.

The trailing comma is required only to create a single tuple (a.k.a. a singleton); it is optional in all other cases. A single expression without a trailing comma doesn't create a tuple, but rather yields the value of that expression. (To create an empty tuple, use an empty pair of parentheses: ( ).)
5.13 Evaluation order

Python evaluates expressions from left to right. Notice that while evaluating an assignment, the right-hand side is evaluated before the left-hand side.

In the following lines, expressions will be evaluated in the arithmetic order of their suffixes:

```python
expr1, expr2, expr3, expr4
(expr1, expr2, expr3, expr4)
{expr1: expr2, expr3: expr4}
expr1 + expr2 * (expr3 - expr4)
func(expr1, expr2, *expr3, **expr4)
expr3, expr4 = expr1, expr2
```
5.14 Summary

The following table summarizes the operator precedences in Python, from lowest precedence (least binding) to highest precedence (most binding). Operators in the same box have the same precedence. Unless the syntax is explicitly given, operators are binary. Operators in the same box group left to right (except for comparisons, including tests, which all have the same precedence and chain from left to right -- see section 5.9 - and exponentiation, which groups from right to left).

6. Simple statements

Simple statements are comprised within a single logical line. Several simple statements may occur on a single line separated by semicolons. The syntax for simple statements is:

```
simple_stmt ::= expression_stmt
               | assert_stmt
               | assignment_stmt
               | augmented_assignment_stmt
               | pass_stmt
               | del_stmt
               | print_stmt
               | return_stmt
               | yield_stmt
               | raise_stmt
               | break_stmt
               | continue_stmt
               | import_stmt
               | global_stmt
               | exec_stmt
```

6.10 The `break` statement
6.11 The `continue` statement
6.12 The `import` statement
   - 6.12.1 Future statements
6.13 The `global` statement
6.14 The `exec` statement
6.1 Expression statements

Expression statements are used (mostly interactively) to compute and write a value, or (usually) to call a procedure (a function that returns no meaningful result; in Python, procedures return the value None). Other uses of expression statements are allowed and occasionally useful. The syntax for an expression statement is:

```
expression_stmt ::= expression_list
```

An expression statement evaluates the expression list (which may be a single expression).

In interactive mode, if the value is not None, it is converted to a string using the built-in `repr()` function and the resulting string is written to standard output (see section 6.6) on a line by itself. (Expression statements yielding None are not written, so that procedure calls do not cause any output.)
6.2 Assert statements

Assert statements are a convenient way to insert debugging assertions into a program:

```python
assert_stmt ::= "assert" expression ["," expression]
```

The simple form, "assert expression", is equivalent to

```python
if __debug__:
    if not expression: raise AssertionError
```

The extended form, "assert expression1, expression2", is equivalent to

```python
if __debug__:
    if not expression1: raise AssertionError, expression2
```

These equivalences assume that __debug__ and AssertionError refer to the built-in variables with those names. In the current implementation, the built-in variable __debug__ is True under normal circumstances, False when optimization is requested (command line option -O). The current code generator emits no code for an assert statement when optimization is requested at compile time. Note that it is unnecessary to include the source code for the expression that failed in the error message; it will be displayed as part of the stack trace.

Assignments to __debug__ are illegal. The value for the built-in variable is determined when the interpreter starts.
Augmented assignment statements
6.3 Assignment statements

Assignment statements are used to (re)bind names to values and to modify attributes or items of mutable objects:

\[
\text{assignment_stmt} ::= (\text{target_list } "=")+ \text{expression_list}
\]
\[
\text{target_list} ::= \text{target } ("," \text{target})* [","]
\]
\[
\text{target} ::= \text{identifier} \\
| "(" \text{target_list } ")"
| "[" \text{target_list } "]"
| \text{attributeref}
| \text{subscription}
| \text{slicing}
\]

(See section 5.3 for the syntax definitions for the last three symbols.)

An assignment statement evaluates the expression list (remember that this can be a single expression or a comma-separated list, the latter yielding a tuple) and assigns the single resulting object to each of the target lists, from left to right.

Assignment is defined recursively depending on the form of the target (list). When a target is part of a mutable object (an attribute reference, subscription or slicing), the mutable object must ultimately perform the assignment and decide about its validity, and may raise an exception if the assignment is unacceptable. The rules observed by various types and the exceptions raised are given with the definition of the object types (see section 3.2).

Assignment of an object to a target list is recursively defined as follows.

- If the target list is a single target: The object is assigned to that target.
- If the target list is a comma-separated list of targets: The object must be a
sequence with the same number of items as there are targets in the target list, and the items are assigned, from left to right, to the corresponding targets. (This rule is relaxed as of Python 1.5; in earlier versions, the object had to be a tuple. Since strings are sequences, an assignment like "a, b = "xy"" is now legal as long as the string has the right length.)

Assignment of an object to a single target is recursively defined as follows.

- If the target is an identifier (name):
  - If the name does not occur in a `global` statement in the current code block: the name is bound to the object in the current local namespace.
  - Otherwise: the name is bound to the object in the current global namespace.

The name is rebound if it was already bound. This may cause the reference count for the object previously bound to the name to reach zero, causing the object to be deallocated and its destructor (if it has one) to be called.

- If the target is a target list enclosed in parentheses or in square brackets:
The object must be a sequence with the same number of items as there are targets in the target list, and its items are assigned, from left to right, to the corresponding targets.

- If the target is an attribute reference: The primary expression in the reference is evaluated. It should yield an object with assignable attributes; if this is not the case, `TypeError` is raised. That object is then asked to assign the assigned object to the given attribute; if it cannot perform the assignment, it raises an exception (usually but not necessarily `AttributeError`).

- If the target is a subscription: The primary expression in the reference is evaluated. It should yield either a mutable sequence object (such as a list) or a mapping object (such as a dictionary). Next, the subscript expression is evaluated.

  If the primary is a mutable sequence object (such as a list), the subscript must yield a plain integer. If it is negative, the sequence's length is added to it. The resulting value must be a nonnegative integer less than the
sequence's length, and the sequence is asked to assign the assigned object to its item with that index. If the index is out of range, \texttt{IndexError} is raised (assignment to a subscripted sequence cannot add new items to a list).

If the primary is a mapping object (such as a dictionary), the subscript must have a type compatible with the mapping's key type, and the mapping is then asked to create a key/datum pair which maps the subscript to the assigned object. This can either replace an existing key/value pair with the same key value, or insert a new key/value pair (if no key with the same value existed).

- If the target is a slicing: The primary expression in the reference is evaluated. It should yield a mutable sequence object (such as a list). The assigned object should be a sequence object of the same type. Next, the lower and upper bound expressions are evaluated, insofar they are present; defaults are zero and the sequence's length. The bounds should evaluate to (small) integers. If either bound is negative, the sequence's length is added to it. The resulting bounds are clipped to lie between zero and the sequence's length, inclusive. Finally, the sequence object is asked to replace the slice with the items of the assigned sequence. The length of the slice may be different from the length of the assigned sequence, thus changing the length of the target sequence, if the object allows it.

(In the current implementation, the syntax for targets is taken to be the same as for expressions, and invalid syntax is rejected during the code generation phase, causing less detailed error messages.)

\textbf{WARNING:} Although the definition of assignment implies that overlaps between the left-hand side and the right-hand side are `safe' (for example "$a, \ b = \ b, \ a" swaps two variables), overlaps \textit{within} the collection of assigned-to variables are not safe! For instance, the following program prints "$[0, 2]":

\begin{verbatim}
x = [0, 1]
i = 0
i, x[i] = 1, 2
print x
\end{verbatim}
### 6.3.1 Augmented assignment statements

Augmented assignment is the combination, in a single statement, of a binary operation and an assignment statement:

```plaintext
augmented_assignment_stmt ::= target augop expression_list
```

```plaintext
augop ::= "+=" | "-=" | "*=" | "/=" | "%=" | "+=" | "**=" | ">>=" | "<<=" | "&=" | "^=" | "|="
```

(See section [5.3](#) for the syntax definitions for the last three symbols.)

An augmented assignment evaluates the target (which, unlike normal assignment statements, cannot be an unpacking) and the expression list, performs the binary operation specific to the type of assignment on the two operands, and assigns the result to the original target. The target is only evaluated once.

An augmented assignment expression like `x += 1` can be rewritten as `x = x + 1` to achieve a similar, but not exactly equal effect. In the augmented version, `x` is only evaluated once. Also, when possible, the actual operation is performed *in-place*, meaning that rather than creating a new object and assigning that to the target, the old object is modified instead.

With the exception of assigning to tuples and multiple targets in a single statement, the assignment done by augmented assignment statements is handled the same way as normal assignments. Similarly, with the exception of the possible *in-place* behavior, the binary operation performed by augmented assignment is the same as the normal binary operations.

For targets which are attribute references, the initial value is retrieved with a `getattr()` and the result is assigned with a `setattr()`. Notice that the two methods do not necessarily refer to the same variable. When `getattr()` refers
to a class variable, `setattr()` still writes to an instance variable. For example:

```python
class A:
    x = 3    # class variable
a = A()
a.x += 1  # writes a.x as 4 leaving A.x as 3
```
6.4 The pass statement

```
pass_stmt ::= "pass"
```

pass is a null operation -- when it is executed, nothing happens. It is useful as a placeholder when a statement is required syntactically, but no code needs to be executed, for example:

```
def f(arg): pass    # a function that does nothing (yet)

class C: pass       # a class with no methods (yet)
```
6.4 The pass statement

6. Simple statements

6.6 The print statement
6.5 The del statement

```
del_stmt ::= "del" target_list
```

Deletion is recursively defined very similar to the way assignment is defined. Rather than spelling it out in full details, here are some hints.

Deletion of a target list recursively deletes each target, from left to right.

Deletion of a name removes the binding of that name from the local or global namespace, depending on whether the name occurs in a `global` statement in the same code block. If the name is unbound, a `NameError` exception will be raised.

It is illegal to delete a name from the local namespace if it occurs as a free variable in a nested block.

Deletion of attribute references, subscriptions and slicings is passed to the primary object involved; deletion of a slicing is in general equivalent to assignment of an empty slice of the right type (but even this is determined by the sliced object).
6.6 The print statement

```
print_stmt ::= "print" ( [expression ("," expression)* [","]]
              | ">>" expression [(""," expression)+ [","]]
```

`print` evaluates each expression in turn and writes the resulting object to standard output (see below). If an object is not a string, it is first converted to a string using the rules for string conversions. The (resulting or original) string is then written. A space is written before each object is (converted and) written, unless the output system believes it is positioned at the beginning of a line. This is the case (1) when no characters have yet been written to standard output, (2) when the last character written to standard output is "\n", or (3) when the last write operation on standard output was not a `print` statement. (In some cases it may be functional to write an empty string to standard output for this reason.)

**Note:** Objects which act like file objects but which are not the built-in file objects often do not properly emulate this aspect of the file object's behavior, so it is best not to rely on this.

A "\n" character is written at the end, unless the `print` statement ends with a comma. This is the only action if the statement contains just the keyword `print`.

Standard output is defined as the file object named `stdout` in the built-in module `sys`. If no such object exists, or if it does not have a `write()` method, a `RuntimeError` exception is raised.

`print` also has an extended form, defined by the second portion of the syntax described above. This form is sometimes referred to as ``print chevron." In this form, the first expression after the `>>` must evaluate to a ``file-like" object, specifically an object that has a `write()` method as described above. With this extended form, the subsequent expressions are printed to this file object. If the first expression evaluates to `None`, then `sys.stdout` is used as the file for
output.
6.7 The return statement

```
return_stmt ::= "return" [expression_list]
```

The `return` statement may only occur syntactically nested in a function definition, not within a nested class definition.

If an expression list is present, it is evaluated, else `None` is substituted.

The `return` leaves the current function call with the expression list (or `None`) as return value.

When `return` passes control out of a `try` statement with a `finally` clause, that `finally` clause is executed before really leaving the function.

In a generator function, the `return` statement is not allowed to include an `expression_list`. In that context, a bare `return` indicates that the generator is done and will cause `StopIteration` to be raised.
6.8 The yield statement

yield_stmt ::= "yield" expression_list

The yield statement is only used when defining a generator function, and is only used in the body of the generator function. Using a yield statement in a function definition is sufficient to cause that definition to create a generator function instead of a normal function.

When a generator function is called, it returns an iterator known as a generator iterator, or more commonly, a generator. The body of the generator function is executed by calling the generator's `next()` method repeatedly until it raises an exception.

When a yield statement is executed, the state of the generator is frozen and the value of expression_list is returned to `next()`'s caller. By ``frozen'' we mean that all local state is retained, including the current bindings of local variables, the instruction pointer, and the internal evaluation stack: enough information is saved so that the next time `next()` is invoked, the function can proceed exactly as if the yield statement were just another external call.

As of Python version 2.5, the yield statement is now allowed in the try clause of a try ... finally construct. If the generator is not resumed before it is finalized (by reaching a zero reference count or by being garbage collected), the generator-iterator's `close()` method will be called, allowing any pending finally clauses to execute.

**Note:** In Python 2.2, the yield statement is only allowed when the generators feature has been enabled. It will always be enabled in Python 2.3. This `__future__` import statement can be used to enable the feature:

```python
from __future__ import generators
```
See Also:

The proposal for adding generators and the `yield` statement to Python.

**PEP 0342, Coroutines via Enhanced Generators**
The proposal that, among other generator enhancements, proposed allowing `yield` to appear inside a `try ... finally` block.
6.9 The raise statement

```python
raise_stmt ::= "raise" [expression ["," expression ["," expression]]]
```

If no expressions are present, `raise` re-raises the last exception that was active in the current scope. If no exception is active in the current scope, a `TypeError` exception is raised indicating that this is an error (if running under IDLE, a `Queue.Empty` exception is raised instead).

Otherwise, `raise` evaluates the expressions to get three objects, using `None` as the value of omitted expressions. The first two objects are used to determine the `type` and `value` of the exception.

If the first object is an instance, the type of the exception is the class of the instance, the instance itself is the value, and the second object must be `None`.

If the first object is a class, it becomes the type of the exception. The second object is used to determine the exception value: If it is an instance of the class, the instance becomes the exception value. If the second object is a tuple, it is used as the argument list for the class constructor; if it is `None`, an empty argument list is used, and any other object is treated as a single argument to the constructor. The instance so created by calling the constructor is used as the exception value.

If a third object is present and not `None`, it must be a traceback object (see section 3.2), and it is substituted instead of the current location as the place where the exception occurred. If the third object is present and not a traceback object or `None`, a `TypeError` exception is raised. The three-expression form of `raise` is useful to re-raise an exception transparently in an except clause, but `raise` with no expressions should be preferred if the exception to be re-raised was the most recently active exception in the current scope.

Additional information on exceptions can be found in section 4.2, and information about handling exceptions is in section 7.4.
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
6.10 The break statement

`break_stmt ::= "break"
``

`break` may only occur syntactically nested in a `for` or `while` loop, but not nested in a function or class definition within that loop.

It terminates the nearest enclosing loop, skipping the optional `else` clause if the loop has one.

If a `for` loop is terminated by `break`, the loop control target keeps its current value.

When `break` passes control out of a `try` statement with a `finally` clause, that `finally` clause is executed before really leaving the loop.
6.11 The continue statement

\[ \text{continue_stmt ::= "continue"} \]

```
continue may only occur syntactically nested in a for or while loop, but
not nested in a function or class definition or finally statement within that
loop. It continues with the next cycle of the nearest enclosing loop.
```

Footnotes

... loop. It may occur within an except or else clause. The restriction on
occuring in the try clause is implementor's laziness and will eventually be
lifted.
6.12 The import statement

Import statements are executed in two steps: (1) find a module, and initialize it if necessary; (2) define a name or names in the local namespace (of the scope where the import statement occurs). The first form (without from) repeats these steps for each identifier in the list. The form with from performs step (1) once, and then performs step (2) repeatedly.

In this context, to `initialize` a built-in or extension module means to call an initialization function that the module must provide for the purpose (in the reference implementation, the function's name is obtained by prepending string `init` to the module's name); to `initialize` a Python-coded module means to execute the module's body.

The system maintains a table of modules that have been or are being initialized, indexed by module name. This table is accessible as sys.modules. When a module name is found in this table, step (1) is finished. If not, a search for a module definition is started. When a module is found, it is loaded. Details of the module searching and loading process are implementation and platform specific. It generally involves searching for a `built-in` module with the given name and then searching a list of locations given as sys.path.
If a built-in module is found, its built-in initialization code is executed and step (1) is finished. If no matching file is found, ImportError is raised. If a file is found, it is parsed, yielding an executable code block. If a syntax error occurs, SyntaxError is raised. Otherwise, an empty module of the given name is created and inserted in the module table, and then the code block is executed in the context of this module. Exceptions during this execution terminate step (1).

When step (1) finishes without raising an exception, step (2) can begin.

The first form of import statement binds the module name in the local namespace to the module object, and then goes on to import the next identifier, if any. If the module name is followed by as, the name following as is used as the local name for the module.

The from form does not bind the module name: it goes through the list of identifiers, looks each one of them up in the module found in step (1), and binds the name in the local namespace to the object thus found. As with the first form of import, an alternate local name can be supplied by specifying "as localname". If a name is not found, ImportError is raised. If the list of identifiers is replaced by a star ("*"), all public names defined in the module are bound in the local namespace of the import statement..

The public names defined by a module are determined by checking the module's namespace for a variable named __all__; if defined, it must be a sequence of strings which are names defined or imported by that module. The names given in __all__ are all considered public and are required to exist. If __all__ is not defined, the set of public names includes all names found in the module's namespace which do not begin with an underscore character ("_"). __all__ should contain the entire public API. It is intended to avoid accidentally exporting items that are not part of the API (such as library modules which were imported and used within the module).

The from form with "*" may only occur in a module scope. If the wild card form of import -- "import *" -- is used in a function and the function contains or is a nested block with free variables, the compiler will raise a SyntaxError.

Hierarchical module names: when the module names contains one or more dots, the module search path is carried out differently. The sequence of
identifiers up to the last dot is used to find a ``package''; the final identifier is then searched inside the package. A package is generally a subdirectory of a directory on sys.path that has a file __init__.py. [XXX Can't be bothered to spell this out right now; see the URL http://www.python.org/doc/essays/packages.html for more details, also about how the module search works from inside a package.]

The built-in function __import__( ) is provided to support applications that determine which modules need to be loaded dynamically; refer to Built-in Functions in the Python Library Reference for additional information.

Subsections

- 6.12.1 Future statements

Python Reference Manual

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
6.12.1 Future statements

A future statement is a directive to the compiler that a particular module should be compiled using syntax or semantics that will be available in a specified future release of Python. The future statement is intended to ease migration to future versions of Python that introduce incompatible changes to the language. It allows use of the new features on a per-module basis before the release in which the feature becomes standard.

```
future_statement ::=  "from" "__future__" "import" feature ["as" name] ("," feature ["as" name])* 
| "from" "__future__" "import" "(" feature ["as" name] ("," feature ["as" name])* [",",] ")"
feature ::= identifier
name ::= identifier
```

A future statement must appear near the top of the module. The only lines that can appear before a future statement are:

- the module docstring (if any),
- comments,
- blank lines, and
- other future statements.

The features recognized by Python 2.3 are "generators", "division" and "nested_scopes". "generators" and "nested_scopes" are redundant in 2.3 because they are always enabled.

A future statement is recognized and treated specially at compile time: Changes to the semantics of core constructs are often implemented by generating different code. It may even be the case that a new feature introduces new incompatible
syntax (such as a new reserved word), in which case the compiler may need to parse the module differently. Such decisions cannot be pushed off until runtime.

For any given release, the compiler knows which feature names have been defined, and raises a compile-time error if a future statement contains a feature not known to it.

The direct runtime semantics are the same as for any import statement: there is a standard module `__future__`, described later, and it will be imported in the usual way at the time the future statement is executed.

The interesting runtime semantics depend on the specific feature enabled by the future statement.

Note that there is nothing special about the statement:

```python
import __future__ [as name]
```

That is not a future statement; it's an ordinary import statement with no special semantics or syntax restrictions.

Code compiled by an `exec` statement or calls to the built-in functions `compile()` and `execfile()` that occur in a module M containing a future statement will, by default, use the new syntax or semantics associated with the future statement. This can, starting with Python 2.2 be controlled by optional arguments to `compile()` -- see the documentation of that function in the *Python Library Reference* for details.

A future statement typed at an interactive interpreter prompt will take effect for the rest of the interpreter session. If an interpreter is started with the `-i` option, is passed a script name to execute, and the script includes a future statement, it will be in effect in the interactive session started after the script is executed.
6.13 The global statement

```
global_stmt ::= "global" identifier ("," identifier)*
```

The `global` statement is a declaration which holds for the entire current code block. It means that the listed identifiers are to be interpreted as globals. It would be impossible to assign to a global variable without `global`, although free variables may refer to globals without being declared global.

Names listed in a `global` statement must not be used in the same code block textually preceding that `global` statement.

Names listed in a `global` statement must not be defined as formal parameters or in a `for` loop control target, `class` definition, function definition, or `import` statement.

(The current implementation does not enforce the latter two restrictions, but programs should not abuse this freedom, as future implementations may enforce them or silently change the meaning of the program.)

**Programmer's note:** the `global` is a directive to the parser. It applies only to code parsed at the same time as the `global` statement. In particular, a `global` statement contained in an `exec` statement does not affect the code block containing the `exec` statement, and code contained in an `exec` statement is unaffected by `global` statements in the code containing the `exec` statement. The same applies to the `eval()`, `execfile()` and `compile()` functions.
This statement supports dynamic execution of Python code. The first expression should evaluate to either a string, an open file object, or a code object. If it is a string, the string is parsed as a suite of Python statements which is then executed (unless a syntax error occurs). If it is an open file, the file is parsed until EOF and executed. If it is a code object, it is simply executed. In all cases, the code that's executed is expected to be valid as file input (see section 8.2, ``File input''). Be aware that the return and yield statements may not be used outside of function definitions even within the context of code passed to the exec statement.

In all cases, if the optional parts are omitted, the code is executed in the current scope. If only the first expression after in is specified, it should be a dictionary, which will be used for both the global and the local variables. If two expressions are given, they are used for the global and local variables, respectively. If provided, locals can be any mapping object. Changed in version 2.4: formerly locals was required to be a dictionary.

As a side effect, an implementation may insert additional keys into the dictionaries given besides those corresponding to variable names set by the executed code. For example, the current implementation may add a reference to the dictionary of the built-in module __builtin__ under the key __builtins__(!).

**Programmer's hints:** dynamic evaluation of expressions is supported by the built-in function eval(). The built-in functions globals() and locals() return the current global and local dictionary, respectively, which may be useful to pass around for use by exec.
7. Compound statements

Compound statements contain (groups of) other statements; they affect or control the execution of those other statements in some way. In general, compound statements span multiple lines, although in simple incarnations a whole compound statement may be contained in one line.

The `if`, `while` and `for` statements implement traditional control flow constructs. `try` specifies exception handlers and/or cleanup code for a group of statements. Function and class definitions are also syntactically compound statements.

Compound statements consist of one or more `clauses.' A clause consists of a header and a `suite.' The clause headers of a particular compound statement are all at the same indentation level. Each clause header begins with a uniquely identifying keyword and ends with a colon. A suite is a group of statements controlled by a clause. A suite can be one or more semicolon-separated simple statements on the same line as the header, following the header's colon, or it can be one or more indented statements on subsequent lines. Only the latter form of suite can contain nested compound statements; the following is illegal, mostly because it wouldn't be clear to which `if` clause a following `else` clause would belong:

```
if test1: if test2: print x
```

Also note that the semicolon binds tighter than the colon in this context, so that in the following example, either all or none of the `print` statements are executed:

```
if x < y < z: print x; print y; print z
```

Summarizing:

```
compound_stmt ::= if_stmt
    | while_stmt
    | for_stmt
    | try_stmt
```
Note that statements always end in a `NEWLINE` possibly followed by a `DEDENT`. Also note that optional continuation clauses always begin with a keyword that cannot start a statement, thus there are no ambiguities (the `dangling else` problem is solved in Python by requiring nested `if` statements to be indented).

The formatting of the grammar rules in the following sections places each clause on a separate line for clarity.

Previous: 6.14 The **exec** statement  Up: Python Reference Manual  Next: 7.1 The **if** statement
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
The while statement
7.1 The if statement

The if statement is used for conditional execution:

```
if_stmt ::= "if" expression ":" suite
            ( "elif" expression ":" suite )*
            ["else" ":" suite]
```

It selects exactly one of the suites by evaluating the expressions one by one until one is found to be true (see section 5.10 for the definition of true and false); then that suite is executed (and no other part of the if statement is executed or evaluated). If all expressions are false, the suite of the else clause, if present, is executed.
7.2 The while statement

The `while` statement is used for repeated execution as long as an expression is true:

```
while_stmt ::= "while" expression "::=
            suite
            ["else" ::=" suite]
```

This repeatedly tests the expression and, if it is true, executes the first suite; if the expression is false (which may be the first time it is tested) the suite of the `else` clause, if present, is executed and the loop terminates.

A **break** statement executed in the first suite terminates the loop without executing the `else` clause's suite. A **continue** statement executed in the first suite skips the rest of the suite and goes back to testing the expression.
7.3 The for statement

The for statement is used to iterate over the elements of a sequence (such as a string, tuple or list) or other iterable object:

```
for_stmt ::=  "for" target_list "in"
expression_list ":" suite
["else" ":" suite]
```

The expression list is evaluated once; it should yield an iterable object. An iterator is created for the result of the expression_list. The suite is then executed once for each item provided by the iterator, in the order of ascending indices. Each item in turn is assigned to the target list using the standard rules for assignments, and then the suite is executed. When the items are exhausted (which is immediately when the sequence is empty), the suite in the else clause, if present, is executed, and the loop terminates.

A break statement executed in the first suite terminates the loop without executing the else clause's suite. A continue statement executed in the first suite skips the rest of the suite and continues with the next item, or with the else clause if there was no next item.

The suite may assign to the variable(s) in the target list; this does not affect the next item assigned to it.

The target list is not deleted when the loop is finished, but if the sequence is empty, it will not have been assigned to at all by the loop. Hint: the built-in function range() returns a sequence of integers suitable to emulate the effect of Pascal's for i := a to b do; e.g., range(3) returns the list [0, 1, 2].

**Warning:** There is a subtlety when the sequence is being modified by the loop (this can only occur for mutable sequences, i.e. lists). An internal counter is used to keep track of which item is used next, and this is incremented on each iteration. When this counter has reached the length of the sequence the loop
terminates. This means that if the suite deletes the current (or a previous) item from the sequence, the next item will be skipped (since it gets the index of the current item which has already been treated). Likewise, if the suite inserts an item in the sequence before the current item, the current item will be treated again the next time through the loop. This can lead to nasty bugs that can be avoided by making a temporary copy using a slice of the whole sequence, e.g.,

```python
for x in a[:]
    if x < 0: a.remove(x)
```
7.4 The `try` statement

The `try` statement specifies exception handlers and/or cleanup code for a group of statements:

```
try_stmt ::= try1_stmt | try2_stmt
try1_stmt ::= "try" ":" suite
             ("except" [expression ["," target]] ":" suite)+
             ["else" ":" suite]
             ["finally" ":" suite]
try2_stmt ::= "try" ":" suite
             "finally" ":" suite
```

Download entire grammar as text.

Changed in version 2.5: In previous versions of Python, `try...except...finally` did not work. `try...except` had to be nested in `try...finally`.

The `except` clause(s) specify one or more exception handlers. When no exception occurs in the `try` clause, no exception handler is executed. When an exception occurs in the `try` suite, a search for an exception handler is started. This search inspects the `except` clauses in turn until one is found that matches the exception. An expression-less `except` clause, if present, must be last; it matches any exception. For an `except` clause with an expression, that expression is evaluated, and the clause matches the exception if the resulting object is `"compatible"` with the exception. An object is compatible with an exception if it is the class or a base class of the exception object, a tuple containing an item compatible with the exception, or, in the (deprecated) case of string exceptions, is the raised string itself (note that the object identities must match, i.e. it must be the same string object, not just a string with the same value).

If no `except` clause matches the exception, the search for an exception handler continues in the surrounding code and on the invocation stack.
If the evaluation of an expression in the header of an except clause raises an exception, the original search for a handler is canceled and a search starts for the new exception in the surrounding code and on the call stack (it is treated as if the entire try statement raised the exception).

When a matching except clause is found, the exception is assigned to the target specified in that except clause, if present, and the except clause's suite is executed. All except clauses must have an executable block. When the end of this block is reached, execution continues normally after the entire try statement. (This means that if two nested handlers exist for the same exception, and the exception occurs in the try clause of the inner handler, the outer handler will not handle the exception.)

Before an except clause's suite is executed, details about the exception are assigned to three variables in the sys module: `sys.exc_type` receives the object identifying the exception; `sys.exc_value` receives the exception's parameter; `sys.exc_traceback` receives a traceback object (see section 3.2) identifying the point in the program where the exception occurred. These details are also available through the `sys.exc_info()` function, which returns a tuple `(exc_type, exc_value, exc_traceback)`. Use of the corresponding variables is deprecated in favor of this function, since their use is unsafe in a threaded program. As of Python 1.5, the variables are restored to their previous values (before the call) when returning from a function that handled an exception.

The optional else clause is executed if and when control flows off the end of the try clause. Exceptions in the else clause are not handled by the preceding except clauses.

If finally is present, it specifies a `cleanup' handler. The try clause is executed, including any except and else clauses. If an exception occurs in any of the clauses and is not handled, the exception is temporarily saved. The finally clause is executed. If there is a saved exception, it is re-raised at the end of the finally clause. If the finally clause raises another exception or executes a return or break statement, the saved exception is lost. The exception information is not available to the program during execution of the finally clause.

When a return, break or continue statement is executed in the try suite
of a `try...finally` statement, the `finally` clause is also executed `on the way out.' A `continue` statement is illegal in the `finally` clause. (The reason is a problem with the current implementation -- this restriction may be lifted in the future).

Additional information on exceptions can be found in section 4.2, and information on using the `raise` statement to generate exceptions may be found in section 6.9.

---

**Footnotes**

... stack.7.1

The exception is propogated to the invocation stack only if there is no `finally` clause that negates the exception.

... clause.7.2

Currently, control ``flows off the end'' except in the case of an exception or the execution of a `return`, `continue`, or `break` statement.

---

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
7.5 The with statement

New in version 2.5.

The with statement is used to wrap the execution of a block with methods defined by a context manager (see section 3.4.9). This allows common try...except...finally usage patterns to be encapsulated for convenient reuse.

```
with_stmt ::= "with" expression ["as" target] ":" suite
```

The execution of the with statement proceeds as follows:

1. The context expression is evaluated to obtain a context manager.

2. The context manager's __enter__() method is invoked.

3. If a target was included in the with statement, the return value from __enter__() is assigned to it.

   **Note:** The with statement guarantees that if the __enter__() method returns without an error, then __exit__() will always be called. Thus, if an error occurs during the assignment to the target list, it will be treated the same as an error occurring within the suite would be. See step 5 below.

4. The suite is executed.

5. The context manager's __exit__() method is invoked. If an exception caused the suite to be exited, its type, value, and traceback are passed as arguments to __exit__(). Otherwise, three None arguments are supplied.

   If the suite was exited due to an exception, and the return value from the __exit__() method was false, the exception is reraised. If the return value was true, the exception is suppressed, and execution continues with
the statement following the `with` statement.

If the suite was exited for any reason other than an exception, the return value from `__exit__()` is ignored, and execution proceeds at the normal location for the kind of exit that was taken.

**Note:** In Python 2.5, the `with` statement is only allowed when the `with_statement` feature has been enabled. It will always be enabled in Python 2.6. This `__future__` import statement can be used to enable the feature:

```
from __future__ import with_statement
```

The specification, background, and examples for the Python `with` statement.

---

Release 2.5, documentation updated on 19th September, 2006.
See *About this document...* for information on suggesting changes.
A function definition defines a user-defined function object (see section \[section 3.2\]):

A function definition is an executable statement. Its execution binds the function name in the current local namespace to a function object (a wrapper around the executable code for the function). This function object contains a reference to the current global namespace as the global namespace to be used when the function is called.
The function definition does not execute the function body; this gets executed only when the function is called.

A function definition may be wrapped by one or more decorator expressions. Decorator expressions are evaluated when the function is defined, in the scope that contains the function definition. The result must be a callable, which is invoked with the function object as the only argument. The returned value is bound to the function name instead of the function object. Multiple decorators are applied in nested fashion. For example, the following code:

```python
@f1(arg)
@f2
def func(): pass
```

is equivalent to:

```python
def func(): pass
func = f1(arg)(f2(func))
```

When one or more top-level parameters have the form `parameter = expression`, the function is said to have "default parameter values." For a parameter with a default value, the corresponding argument may be omitted from a call, in which case the parameter's default value is substituted. If a parameter has a default value, all following parameters must also have a default value -- this is a syntactic restriction that is not expressed by the grammar.

**Default parameter values are evaluated when the function definition is executed.** This means that the expression is evaluated once, when the function is defined, and that that same "pre-computed" value is used for each call. This is especially important to understand when a default parameter is a mutable object, such as a list or a dictionary: if the function modifies the object (e.g. by appending an item to a list), the default value is in effect modified. This is generally not what was intended. A way around this is to use `None` as the default, and explicitly test for it in the body of the function, e.g.:

```python
def whats_on_the_telly(penguin=None):
    if penguin is None:
        penguin = []
    penguin.append("property of the zoo")
    return penguin
```

Function call semantics are described in more detail in section 5.3.4. A function
call always assigns values to all parameters mentioned in the parameter list, either from position arguments, from keyword arguments, or from default values. If the form `"*identifier"` is present, it is initialized to a tuple receiving any excess positional parameters, defaulting to the empty tuple. If the form `"**identifier"` is present, it is initialized to a new dictionary receiving any excess keyword arguments, defaulting to a new empty dictionary.

It is also possible to create anonymous functions (functions not bound to a name), for immediate use in expressions. This uses lambda forms, described in section 5.11. Note that the lambda form is merely a shorthand for a simplified function definition; a function defined in a `"def"` statement can be passed around or assigned to another name just like a function defined by a lambda form. The `"def"` form is actually more powerful since it allows the execution of multiple statements.

**Programmer's note:** Functions are first-class objects. A `"def"` form executed inside a function definition defines a local function that can be returned or passed around. Free variables used in the nested function can access the local variables of the function containing the def. See section 4.1 for details.
7.7 Class definitions

A class definition defines a class object (see section 3.2):

```
classdef ::= "class" classname
           [inheritance] ":" suite
inheritance ::= "(" [expression_list] ")"
classname ::= identifier
```

A class definition is an executable statement. It first evaluates the inheritance list, if present. Each item in the inheritance list should evaluate to a class object or class type which allows subclassing. The class's suite is then executed in a new execution frame (see section 4.1), using a newly created local namespace and the original global namespace. (Usually, the suite contains only function definitions.) When the class's suite finishes execution, its execution frame is discarded but its local namespace is saved. A class object is then created using the inheritance list for the base classes and the saved local namespace for the attribute dictionary. The class name is bound to this class object in the original local namespace.

**Programmer's note:** Variables defined in the class definition are class variables; they are shared by all instances. To define instance variables, they must be given a value in the `__init__()` method or in another method. Both class and instance variables are accessible through the notation `\self\name`, and an instance variable hides a class variable with the same name when accessed in this way. Class variables with immutable values can be used as defaults for instance variables. For new-style classes, descriptors can be used to create instance variables with different implementation details.
See About this document... for information on suggesting changes.
8. Top-level components

The Python interpreter can get its input from a number of sources: from a script passed to it as standard input or as program argument, typed in interactively, from a module source file, etc. This chapter gives the syntax used in these cases.

Subsections

- 8.1 Complete Python programs
- 8.2 File input
- 8.3 Interactive input
- 8.4 Expression input

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
8.1 Complete Python programs

While a language specification need not prescribe how the language interpreter is invoked, it is useful to have a notion of a complete Python program. A complete Python program is executed in a minimally initialized environment: all built-in and standard modules are available, but none have been initialized, except for sys (various system services), __builtins__ (built-in functions, exceptions and None) and __main__. The latter is used to provide the local and global namespace for execution of the complete program.

The syntax for a complete Python program is that for file input, described in the next section.

The interpreter may also be invoked in interactive mode; in this case, it does not read and execute a complete program but reads and executes one statement (possibly compound) at a time. The initial environment is identical to that of a complete program; each statement is executed in the namespace of __main__.

Under Unix, a complete program can be passed to the interpreter in three forms: with the -c string command line option, as a file passed as the first command line argument, or as standard input. If the file or standard input is a tty device, the interpreter enters interactive mode; otherwise, it executes the file as a complete program.
Previous: 8.1 Complete Python programs  Up: 8. Top-level components  Next: 8.3 Interactive input
8.2 File input

All input read from non-interactive files has the same form:

\[
\text{file_input} ::= (\text{NEWLINE} \mid \text{statement})^*
\]

This syntax is used in the following situations:

- when parsing a complete Python program (from a file or from a string);
- when parsing a module;
- when parsing a string passed to the \texttt{exec} statement;

Release 2.5, documentation updated on 19th September, 2006.
See \texttt{About this document...} for information on suggesting changes.
8.3 Interactive input

Input in interactive mode is parsed using the following grammar:

```
interactive_input ::= [stmt_list] NEWLINE | compound_stmt NEWLINE
```

Download entire grammar as text.

Note that a (top-level) compound statement must be followed by a blank line in interactive mode; this is needed to help the parser detect the end of the input.
8.4 Expression input

There are two forms of expression input. Both ignore leading whitespace. The string argument to `eval()` must have the following form:

```
expr ::= expression_list NEWLINE*
```

The input line read by `input()` must have the following form:

```
expr ::= expression_list NEWLINE
```

Note: to read `raw' input line without interpretation, you can use the built-in function `raw_input()' or the `readline()' method of file objects.
A. History and License

Subsections

- A.1 History of the software
- A.2 Terms and conditions for accessing or otherwise using Python
- A.3 Licenses and Acknowledgements for Incorporated Software

A.1 History of the software

Python was created in the early 1990s by Guido van Rossum at Stichting Mathematisch Centrum (CWI, see http://www.cwi.nl/) in the Netherlands as a successor of a language called ABC. Guido remains Python's principal author, although it includes many contributions from others.

In 1995, Guido continued his work on Python at the Corporation for National Research Initiatives (CNRI, see http://www.cnri.reston.va.us/) in Reston, Virginia where he released several versions of the software.

In May 2000, Guido and the Python core development team moved to BeOpen.com to form the BeOpen PythonLabs team. In October of the same year, the PythonLabs team moved to Digital Creations (now Zope Corporation; see http://www.zope.com/). In 2001, the Python Software Foundation (PSF, see http://www.python.org/psf/) was formed, a non-profit organization created specifically to own Python-related Intellectual Property. Zope Corporation is a sponsoring member of the PSF.

All Python releases are Open Source (see http://www.opensource.org/ for the Open Source Definition). Historically, most, but not all, Python releases have also been GPL-compatible; the table below summarizes the various releases.

**Note:** GPL-compatible doesn't mean that we're distributing Python under the GPL. All Python licenses, unlike the GPL, let you distribute a modified version without making your changes open source. The GPL-compatible licenses make it possible to combine Python with other software that is released under the GPL; the others don't.

Thanks to the many outside volunteers who have worked under Guido's direction to make these releases possible.
A.2 Terms and conditions for accessing or otherwise using Python

PSF LICENSE AGREEMENT FOR PYTHON 2.5

1. This LICENSE AGREEMENT is between the Python Software Foundation (``PSF''), and the Individual or Organization (``Licensee'') accessing and otherwise using Python 2.5 software in source or binary form and its associated documentation.

2. Subject to the terms and conditions of this License Agreement, PSF hereby grants Licensee a nonexclusive, royalty-free, world-wide license to reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use Python 2.5 alone or in any derivative version, provided, however, that PSF's License Agreement and PSF's notice of copyright, i.e., ``Copyright © 2001-2006 Python Software Foundation; All Rights Reserved'' are retained in Python 2.5 alone or in any derivative version prepared by Licensee.

3. In the event Licensee prepares a derivative work that is based on or incorporates Python 2.5 or any part thereof, and wants to make the derivative work available to others as provided herein, then Licensee hereby agrees to include in any such work a brief summary of the changes made to Python 2.5.

4. PSF is making Python 2.5 available to Licensee on an ``AS IS'' basis. PSF MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT LIMITATION, PSF MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF PYTHON 2.5 WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.

5. PSF SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS
OF PYTHON 2.5 FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF MODIFYING, DISTRIBUTING, OR OTHERWISE USING PYTHON 2.5, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.

6. This License Agreement will automatically terminate upon a material breach of its terms and conditions.

7. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between PSF and Licensee. This License Agreement does not grant permission to use PSF trademarks or trade name in a trademark sense to endorse or promote products or services of Licensee, or any third party.

8. By copying, installing or otherwise using Python 2.5, Licensee agrees to be bound by the terms and conditions of this License Agreement.

BEOPEN.COM LICENSE AGREEMENT FOR PYTHON 2.0

BEOPEN PYTHON OPEN SOURCE LICENSE AGREEMENT VERSION 1

1. This LICENSE AGREEMENT is between BeOpen.com (``BeOpen''), having an office at 160 Saratoga Avenue, Santa Clara, CA 95051, and the Individual or Organization (``Licensee'') accessing and otherwise using this software in source or binary form and its associated documentation (``the Software'').

2. Subject to the terms and conditions of this BeOpen Python License Agreement, BeOpen hereby grants Licensee a non-exclusive, royalty-free, world-wide license to reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use the Software alone or in any derivative version, provided, however, that the BeOpen Python License is retained in the Software, alone or in any derivative version prepared by Licensee.

3. BeOpen is making the Software available to Licensee on an ``AS IS'' basis. BEOPEN MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT
LIMITATION, BEOPEN MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF THE SOFTWARE WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.

4. BEOPEN SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS OF THE SOFTWARE FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF USING, MODIFYING OR DISTRIBUTING THE SOFTWARE, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.

5. This License Agreement will automatically terminate upon a material breach of its terms and conditions.

6. This License Agreement shall be governed by and interpreted in all respects by the law of the State of California, excluding conflict of law provisions. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between BeOpen and Licensee. This License Agreement does not grant permission to use BeOpen trademarks or trade names in a trademark sense to endorse or promote products or services of Licensee, or any third party. As an exception, the "BeOpen Python" logos available at http://www.pythonlabs.com/logos.html may be used according to the permissions granted on that web page.

7. By copying, installing or otherwise using the software, Licensee agrees to be bound by the terms and conditions of this License Agreement.

**CNRI LICENSE AGREEMENT FOR PYTHON 1.6.1**

1. This LICENSE AGREEMENT is between the Corporation for National Research Initiatives, having an office at 1895 Preston White Drive, Reston, VA 20191 (``CNRI''), and the Individual or Organization (``Licensee'') accessing and otherwise using Python 1.6.1 software in source or binary form and its associated documentation.

2. Subject to the terms and conditions of this License Agreement, CNRI hereby grants Licensee a nonexclusive, royalty-free, world-wide license to
reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use Python 1.6.1 alone or in any derivative version, provided, however, that CNRI's License Agreement and CNRI's notice of copyright, i.e., "Copyright © 1995-2001 Corporation for National Research Initiatives; All Rights Reserved" are retained in Python 1.6.1 alone or in any derivative version prepared by Licensee. Alternately, in lieu of CNRI's License Agreement, Licensee may substitute the following text (omitting the quotes): ``Python 1.6.1 is made available subject to the terms and conditions in CNRI's License Agreement. This Agreement together with Python 1.6.1 may be located on the Internet using the following unique, persistent identifier (known as a handle): 1895.22/1013. This Agreement may also be obtained from a proxy server on the Internet using the following URL: http://hdl.handle.net/1895.22/1013."

3. In the event Licensee prepares a derivative work that is based on or incorporates Python 1.6.1 or any part thereof, and wants to make the derivative work available to others as provided herein, then Licensee hereby agrees to include in any such work a brief summary of the changes made to Python 1.6.1.

4. CNRI is making Python 1.6.1 available to Licensee on an "AS IS" basis. CNRI MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT LIMITATION, CNRI MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF PYTHON 1.6.1 WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.

5. CNRI SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS OF PYTHON 1.6.1 FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF MODIFYING, DISTRIBUTING, OR OTHERWISE USING PYTHON 1.6.1, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.

6. This License Agreement will automatically terminate upon a material breach of its terms and conditions.

7. This License Agreement shall be governed by the federal intellectual
property law of the United States, including without limitation the federal
copyright law, and, to the extent such U.S. federal law does not apply, by
the law of the Commonwealth of Virginia, excluding Virginia's conflict of
law provisions. Notwithstanding the foregoing, with regard to derivative
works based on Python 1.6.1 that incorporate non-separable material that
was previously distributed under the GNU General Public License (GPL),
the law of the Commonwealth of Virginia shall govern this License
Agreement only as to issues arising under or with respect to Paragraphs 4,
5, and 7 of this License Agreement. Nothing in this License Agreement
shall be deemed to create any relationship of agency, partnership, or joint
venture between CNRI and Licensee. This License Agreement does not
grant permission to use CNRI trademarks or trade name in a trademark
sense to endorse or promote products or services of Licensee, or any third

A.3 Licenses and Acknowledgements for Incorporated Software

This section is an incomplete, but growing list of licenses and acknowledgements for third-party software incorporated in the Python distribution.

Subsections

- A.3.1 Mersenne Twister
- A.3.2 Sockets
- A.3.3 Floating point exception control
- A.3.4 MD5 message digest algorithm
- A.3.5 Asynchronous socket services
- A.3.6 Cookie management
- A.3.7 Profiling
- A.3.8 Execution tracing
- A.3.9 UUencode and UUdecode functions
- A.3.10 XML Remote Procedure Calls
A.3.1 Mersenne Twister

The `_random` module includes code based on a download from http://www.math.keio.ac.jp/~matumoto/MT2002/emt19937ar.html. The following are the verbatim comments from the original code:

A C-program for MT19937, with initialization improved 2002/1/26. Coded by Takuji Nishimura and Makoto Matsumoto.

Before using, initialize the state by using init_genrand(seed) or init_by_array(init_key, key_length).

Copyright (C) 1997 - 2002, Makoto Matsumoto and Takuji Nishimura, All rights reserved.

Redistribution and use in source and binary forms, with or without modification, are permitted provided that the following conditions are met:

1. Redistributions of source code must retain the above copyright notice, this list of conditions and the following disclaimer.

2. Redistributions in binary form must reproduce the above copyright notice, this list of conditions and the following disclaimer in documentation and/or other materials provided with the distribution.

3. The names of its contributors may not be used to endorse or promote products derived from this software without specific prior written permission.

THIS SOFTWARE IS PROVIDED BY THE COPYRIGHT HOLDERS AND CONTRIBUTORS "AS IS" AND ANY EXPRESS OR IMPLIED WARRANTIES, INCLUDING, BUT NOT LIMITED TO, THE IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS FOR A PARTICULAR PURPOSE ARE DISCLAIMED. IN NO EVENT SHALL THE COPYRIGHT HOLDERS AND CONTRIBUTORS BE LIABLE FOR ANY DIRECT, INDIRECT, INCIDENTAL, SPECIAL EXEMPLARY, OR CONSEQUENTIAL DAMAGES (INCLUDING, BUT NOT LIMITED TO, PROCUREMENT OF SUBSTITUTE GOODS OR SERVICES; LOSS OF USE, DATA, OR PROFITS; OR BUSINESS INTERRUPTION) HOWEVER CAUSED AND ON ANY THEORY LIABILITY, WHETHER IN CONTRACT, STRICT LIABILITY, OR TORT (INCLUDING NEGLIGENCE OR OTHERWISE) ARISING IN ANY WAY OUT OF THE USE OF THIS SOFTWARE, EVEN IF ADVISED OF THE POSSIBILITY OF SUCH DAMAGE.

Any feedback is very welcome.

email: matumoto@math.keio.ac.jp
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
A.3.2 Sockets

The socket module uses the functions, `getaddrinfo`, and `getnameinfo`, which are coded in separate source files from the WIDE Project, http://www.wide.ad.jp/about/index.html.

Copyright (C) 1995, 1996, 1997, and 1998 WIDE Project. All rights reserved.

Redistribution and use in source and binary forms, with or without modification, are permitted provided that the following conditions are met:

1. Redistributions of source code must retain the above copyright notice, this list of conditions and the following disclaimer.
2. Redistributions in binary form must reproduce the above copyright notice, this list of conditions and the following disclaimer in the documentation and/or other materials provided with the distribution.
3. Neither the name of the project nor the names of its contributors may be used to endorse or promote products derived from this software without specific prior written permission.

THIS SOFTWARE IS PROVIDED BY THE PROJECT AND CONTRIBUTORS ``AS IS'' AND GAI ANY EXPRESS OR IMPLIED WARRANTIES, INCLUDING, BUT NOT LIMITED TO IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS FOR A PARTICULAR PURPOSE ARE DISCLAIMED. IN NO EVENT SHALL THE PROJECT OR CONTRIBUTORS BE LIABLE FOR GAI ANY DIRECT, INDIRECT, INCIDENTAL, SPECIAL, EXEMPLARY, OR CONSEQUENTIAL DAMAGES (INCLUDING, BUT NOT LIMITED TO, PROCUREMENT OF SUBSTITUTE GOODS OR SERVICES; LOSS OF USE, DATA, OR PROFITS; OR BUSINESS INTERRUPTION HOWEVER CAUSED AND ON GAI ANY THEORY OF LIABILITY, WHETHER IN CONTRA LIABILITY, OR TORT (INCLUDING NEGLIGENCE OR OTHERWISE) ARISING IN GAI OUT OF THE USE OF THIS SOFTWARE, EVEN IF ADVISED OF THE POSSIBILITY SUCH DAMAGE.
A.3.3 Floating point exception control

The source for the fpectl1 module includes the following notice:

```
/                              Copyright (c) 1996.
|                              The Regents of the University of California.
|                              All rights reserved.
|                              Permission to use, copy, modify, and distribute this software
|                              any purpose without fee is hereby granted, provided that this
|                              tire notice is included in all copies of any software which i
|                              includes a copy or modification of this software and in
|                              copies of the supporting documentation for such software.

Python Reference Manual

Previous: A.3.2 Sockets  Up: A.3 Licenses and Acknowledgements  Next: A.3.4 MD5 message digest

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
A.3.4 MD5 message digest algorithm

The source code for the md5 module contains the following notice:

Copyright (C) 1999, 2002 Aladdin Enterprises. All rights reserved

This software is provided 'as-is', without any express or implied warranty. In no event will the authors be held liable for any damages arising from the use of this software.

Permission is granted to anyone to use this software for any purpose including commercial applications, and to alter it and redistribute it freely, subject to the following restrictions:

1. The origin of this software must not be misrepresented; you must claim that you wrote the original software. If you use this software in a product, an acknowledgment in the product documentation would be appreciated but is not required.
2. Altered source versions must be plainly marked as such, and not misrepresented as being the original software.
3. This notice may not be removed or altered from any source distribution.

L. Peter Deutsch
ghost@aladdin.com

Independent implementation of MD5 (RFC 1321).

This code implements the MD5 Algorithm defined in RFC 1321, whose text is available at
http://www.ietf.org/rfc/rfc1321.txt
The code is derived from the text of the RFC, including the test suite (section A.5) but excluding the rest of Appendix A. It does not include any code or documentation that is identified in the RFC as being copyrighted.

The original and principal author of md5.h is L. Peter Deutsch <ghost@aladdin.com>. Other authors are noted in the change history that follows (in reverse chronological order):

2002-04-13 lpd Removed support for non-ANSI compilers; removed references to Ghostscript; clarified derivation from RFC 132
1999-11-04 lpd Edited comments slightly for automatic TOC extracti
1999-10-18 lpd Fixed typo in header comment (ansi2knr rather than added conditionalization for C++ compilation from Martin
Purschke <purschke@bnl.gov>.
1999-05-03 lpd Original version.
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
A.3.5 Asynchronous socket services

The asynchat and asyncore modules contain the following notice:

Copyright 1996 by Sam Rushing

All Rights Reserved

Permission to use, copy, modify, and distribute this software and its documentation for any purpose and without fee is hereby granted, provided that the above copyright notice appear in all copies and that both that copyright notice and this permission notice appear in supporting documentation, and that the name of Sam Rushing not be used in advertising or publicity pertaining to distribution of the software without specific, written prior permission.

SAM RUSHING DISCLAIMS ALL WARRANTIES WITH REGARD TO THIS SOFTWARE, INCLUDING ALL IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS, IN NO EVENT SHALL SAM RUSHING BE LIABLE FOR ANY SPECIAL, INDIRECT OR CONSEQUENTIAL DAMAGES OR ANY DAMAGES WHATSOEVER RESULTING FROM LOSS OF USE, DATA OR PROFITS, WHETHER IN AN ACTION OF CONTRACT, NEGLIGENCE OR OTHER TORTIOUS ACTION, ARISING OUT OF OR IN CONNECTION WITH THE USE OR PERFORMANCE OF THIS SOFTWARE.
A.3.6 Cookie management

The Cookie module contains the following notice:

Copyright 2000 by Timothy O'Malley <timo@alum.mit.edu>

All Rights Reserved

Permission to use, copy, modify, and distribute this software and its documentation for any purpose and without fee is hereby granted, provided that the above copyright notice appear in all copies and that both that copyright notice and this permission notice appear in supporting documentation, and that the name of Timothy O'Malley not be used in advertising or publicity pertaining to distribution of the software without specific, written prior permission.

Timothy O'Malley DISCLAIMS ALL WARRANTIES WITH REGARD TO THIS SOFTWARE, INCLUDING ALL IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS, IN NO EVENT SHALL Timothy O'Malley BE LIABLE FOR ANY SPECIAL, INDIRECT OR CONSEQUENTIAL DAMAGES OR ANY DAMAGES WHATSOEVER RESULTING FROM LOSS OF USE, DATA OR PROFITS, WHETHER IN AN ACTION OF CONTRACT, NEGLIGENCE OR OTHER TORTIOUS ACTION, ARISING OUT OF OR IN CONNECTION WITH THE USE OR PERFORMANCE OF THIS SOFTWARE.
A.3.7 Profiling

The profile and pstats modules contain the following notice:

Copyright 1994, by InfoSeek Corporation, all rights reserved.
Written by James Roskind

Permission to use, copy, modify, and distribute this Python software and its associated documentation for any purpose (subject to the restriction in the following sentence) without fee is hereby granted provided that the above copyright notice appears in all copies, and that both that copyright notice and this permission notice appear in supporting documentation, and that the name of InfoSeek not be used advertising or publicity pertaining to distribution of the software without specific, written prior permission. This permission is explicitly restricted to the copying and modification of the software to remain in Python, compiled Python, or other languages (such as C wherein the modified or derived code is exclusively imported into a Python module.

INFOSEEK CORPORATION DISCLAIMS ALL WARRANTIES WITH REGARD TO THIS SOFTWARE, INCLUDING ALL IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS. IN NO EVENT SHALL INFOSEEK CORPORATION BE LIABLE FOR ANY SPECIAL, INDIRECT OR CONSEQUENTIAL DAMAGES OR ANY DAMAGES WHATSOEVER RESULTING FROM LOSS OF USE, DATA OR PROFITS, WHETHER IN AN ACTION OF CONTRACT, NEGLIGENCE OR OTHER TORTIOUS ACTION, ARISING OUT OF OR IN CONNECTION WITH THE USE OR PERFORMANCE OF THIS SOFTWARE.
A.3.8 Execution tracing

The `trace` module contains the following notice:

```
portions copyright 2001, Autonomous Zones Industries, Inc., all rig
err... reserved and offered to the public under the terms of the
Python 2.2 license.

```

Permission to use, copy, modify, and distribute this Python software
and its associated documentation for any purpose without fee is hereby
granted, provided that the above copyright notice appears in all co
files and that both that copyright notice and this permission notice ap
supporting documentation, and that the name of neither Automatrix,
Bioreason or Mojam Media be used in advertising or publicity pertai
distribution of the software without specific, written prior permis

---

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
A.3.9 UUencode and UUdecode functions

The uu module contains the following notice:

```
Copyright 1994 by Lance Ellinghouse
Cathedral City, California Republic, United States of America.
All Rights Reserved
Permission to use, copy, modify, and distribute this software and documentation for any purpose and without fee is hereby granted, provided that the above copyright notice appear in all copies and both that copyright notice and this permission notice appear in supporting documentation, and that the name of Lance Ellinghouse not be used in advertising or publicity pertaining to distribution of the software without specific, written prior permission.
LANCE ELLINGHOUSE DISCLAIMS ALL WARRANTIES WITH REGARD TO THIS SOFTWARE, INCLUDING ALL IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS, IN NO EVENT SHALL LANCE ELLINGHOUSE CENTRUM BE LIABLE FOR ANY SPECIAL, INDIRECT OR CONSEQUENTIAL DAMAGES OR ANY DAMAGES WHATSOEVER RESULTING FROM LOSS OF USE, DATA OR PROFITS, WHETHER IN ACTION OF CONTRACT, NEGLIGENCE OR OTHER TORTIOUS ACTION, ARISING OUT OF OR IN CONNECTION WITH THE USE OR PERFORMANCE OF THIS SOFTWARE.
```

Modified by Jack Jansen, CWI, July 1995:
- Use binascii module to do the actual line-by-line conversion between ascii and binary. This results in a 1000-fold speedup. Th version is still 5 times faster, though.
- Arguments more compliant with python standard
A.3.10 XML Remote Procedure Calls

The xmlrpclib module contains the following notice:

The XML-RPC client interface is

Copyright (c) 1999-2002 by Secret Labs AB
Copyright (c) 1999-2002 by Fredrik Lundh

By obtaining, using, and/or copying this software and/or its associated documentation, you agree that you have read, understood, and will comply with the following terms and conditions:

Permission to use, copy, modify, and distribute this software and its associated documentation for any purpose and without fee is hereby granted, provided that the above copyright notice appears in all copies, and that both that copyright notice and this permission notice appear in supporting documentation, and that the name of Secret Labs AB or the author not be used in advertising or publiccit pertaining to distribution of the software without specific, written prior permission.

SECRET LABS AB AND THE AUTHOR DISCLAIMS ALL WARRANTIES WITH REGARD TO THIS SOFTWARE, INCLUDING ALL IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS. IN NO EVENT SHALL SECRET LABS AB OR THE AUTHOR BE LIABLE FOR ANY SPECIAL, INDIRECT OR CONSEQUENTIAL DAMAGES OR ANY DAMAGES WHATSOEVER RESULTING FROM LOSS OF USE, DATA OR PROFITS, WHETHER IN AN ACTION OF CONTRACT, NEGLIGENCE OR OTHER TORTIOUS ACTION, ARISING OUT OF OR IN CONNECTION WITH THE USE OR PERFORMANCE OF THIS SOFTWARE.

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
1. Using Python on a Macintosh

Python on a Macintosh running Mac OS X is in principle very similar to Python on any other UNIX platform, but there are a number of additional features such as the IDE and the Package Manager that are worth pointing out.

Python on Mac OS 9 or earlier can be quite different from Python on UNIX or Windows, but is beyond the scope of this manual, as that platform is no longer supported, starting with Python 2.4. See http://www.cwi.nl/~jack/macpython for installers for the latest 2.3 release for Mac OS 9 and related documentation.

Subsections

- **1.1 Getting and Installing MacPython**
  - 1.1.1 How to run a Python script
  - 1.1.2 Running scripts with a GUI
  - 1.1.3 configuration
- **1.2 The IDE**
  - 1.2.1 Using the `Python Interactive` window
  - 1.2.2 Writing a Python Script
  - 1.2.3 Executing a script from within the IDE
  - 1.2.4 ``Save as'' versus ``Save as Applet"
- **1.3 The Package Manager**
1.1 Getting and Installing MacPython

Mac OS X 10.3 comes with Python 2.3 pre-installed by Apple. This installation does not come with the IDE and other additions, however, so to get these you need to install the MacPython for Panther additions from the MacPython website, http://www.cwi.nl/~jack/macpython.

For MacPython 2.4, or for any MacPython on earlier releases of Mac OS X, you need to install a full distribution from the same website.

What you get after installing is a number of things:

- A MacPython-2.3 folder in your Applications folder. In here you find the PythonIDE Integrated Development Environment; PythonLauncher, which handles double-clicking Python scripts from the Finder; and the Package Manager.

- A fairly standard UNIX commandline Python interpreter in /usr/local/bin/python, but without the usual /usr/local/lib/python.

- A framework /Library/Frameworks/Python.framework, where all the action really is, but which you usually do not have to be aware of.

To uninstall MacPython you can simply remove these three things.

If you use the ``additions'' installer to install on top of an existing Apple-Python you will not get the framework and the commandline interpreter, as they have been installed by Apple already, in /System/Library/Frameworks/Python.framework and /usr/bin/python, respectively. You should in principle never modify or delete these, as they are Apple-controlled and may be used by Apple- or third-party software.

PythonIDE contains an Apple Help Viewer book called "MacPython Help" which you can access through its help menu. If you are completely new to Python you should start reading the IDE introduction in that document.

If you are familiar with Python on other UNIX platforms you should read the section on running Python scripts from the UNIX shell.
Subsections

- 1.1.1 How to run a Python script
- 1.1.2 Running scripts with a GUI
- 1.1.3 configuration

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
1.1.1 How to run a Python script

Your best way to get started with Python on Mac OS X is through the PythonIDE integrated development environment, see section 1.2 and use the Help menu when the IDE is running.

If you want to run Python scripts from the Terminal window command line or from the Finder you first need an editor to create your script. Mac OS X comes with a number of standard UNIX command line editors, vim and emacs among them. If you want a more Mac-like editor BBEdit or TextWrangler from Bare Bones Software (see http://www.barebones.com/products/bbedit/index.shtml) are good choices. AppleWorks or any other word processor that can save files in ASCII is also a possibility, including TextEdit which is included with OS X.

To run your script from the Terminal window you must make sure that /usr/local/bin is in your shell search path.

To run your script from the Finder you have two options:

- Drag it to PythonLauncher
- Select PythonLauncher as the default application to open your script (or any .py script) through the finder Info window and double-click it.

PythonLauncher has various preferences to control how your script is launched. Option-dragging allows you to change these for one invocation, or use its Preferences menu to change things globally.
1.1.2 Running scripts with a GUI

There is one Mac OS X quirk that you need to be aware of: programs that talk to
the Aqua window manager (in other words, anything that has a GUI) need to be
run in a special way. Use `pythonw` instead of `python` to start such scripts.
1.1.3 configuration

MacPython honours all standard UNIX environment variables such as PYTHONPATH, but setting these variables for programs started from the Finder is non-standard as the Finder does not read your .profile or .cshrc at startup. You need to create a file ~/.MacOSX/environment.plist. See Apple's Technical Document QA1067 for details.

Installing additional Python packages is most easily done through the Package Manager, see the MacPython Help Book for details.
1.2 The IDE

The **Python IDE** (Integrated Development Environment) is a separate application that acts as a text editor for your Python code, a class browser, a graphical debugger, and more.

The online Python Help contains a quick walkthrough of the IDE that shows the major features and how to use them.

---

**Subsections**

- 1.2.1 Using the ``Python Interactive'' window
- 1.2.2 Writing a Python Script
- 1.2.3 Executing a script from within the IDE
- 1.2.4 ``Save as" versus ``Save as Applet"

---

*Macintosh Library Modules*

Previous: 1.1.3 configuration  Up: 1. Using Python on  Next: 1.2.1 Using the ``Python"

*Release 2.5, documentation updated on 19th September, 2006.*

*See [About this document...](About this document...) for information on suggesting changes.*
1.2.1 Using the ``Python Interactive'' window

Use this window like you would use a normal UNIX command line interpreter.
1.2.2 Writing a Python Script

In addition to using the Python IDE interactively, you can also type out a complete Python program, saving it incrementally, and execute it or smaller selections of it.

You can create a new script, open a previously saved script, and save your currently open script by selecting the appropriate item in the "File" menu. Dropping a Python script onto the Python IDE will open it for editing.

When the Python IDE saves a script, it uses the creator code settings which are available by clicking on the small black triangle on the top right of the document window, and selecting "save options". The default is to save the file with the Python IDE as the creator, this means that you can open the file for editing by simply double-clicking on its icon. You might want to change this behaviour so that it will be opened by the PythonLauncher, and run. To do this simply choose "PythonLauncher" from the "save options". Note that these options are associated with the file not the application.

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
1.2.3 Executing a script from within the IDE

You can run the script in the frontmost window of the Python IDE by hitting the run all button. You should be aware, however that if you use the Python convention "if __name__ == "__main__":" the script will not be `__main__` by default. To get that behaviour you must select the `Run as __main__` option from the small black triangle on the top right of the document window. Note that this option is associated with the file not the application. It will stay active after a save, however; to shut this feature off simply select it again.
1.2.4 ``Save as'' versus ``Save as Applet''

When you are done writing your Python script you have the option of saving it as an ``applet'' (by selecting ``Save as applet'' from the ``File'' menu). This has a significant advantage in that you can drop files or folders onto it, to pass them to the applet the way command-line users would type them onto the command-line to pass them as arguments to the script. However, you should make sure to save the applet as a separate file, do not overwrite the script you are writing, because you will not be able to edit it again.

Accessing the items passed to the applet via ``drag-and-drop'' is done using the standard `sys.argv` mechanism. See the general documentation for more.

Note that saving a script as an applet will not make it runnable on a system without a Python installation.
1.3 The Package Manager

Historically MacPython came with a number of useful extension packages included, because most Macintosh users do not have access to a development environment and C compiler. For Mac OS X that bundling is no longer done, but a new mechanism has been made available to allow easy access to extension packages.

The Python Package Manager helps you installing additional packages that enhance Python. It determines the exact MacOS version and Python version you have and uses that information to download a database that has packages that are tested and tried on that combination. In other words: if something is in your Package Manager window but does not work you are free to blame the database maintainer.

PackageManager then checks which of the packages you have installed and which ones are not. This should also work when you have installed packages outside of PackageManager. You can select packages and install them, and PackageManager will work out the requirements and install these too.

Often PackageManager will list a package in two flavors: binary and source. Binary should always work, source will only work if you have installed the Apple Developer Tools. PackageManager will warn you about this, and also about other external dependencies.

PackageManager is available as a separate application and also as a function of the IDE, through the File->Package Manager menu entry.
2. MacPython Modules

The following modules are only available on the Macintosh, and are documented here:

- **macpath**: MacOS path manipulation functions.
- **macfs**: Support for FSSpec, the Alias Manager, **finder** aliases, and the Standard File package.
- **ic**: Access to Internet Config.
- **MacOS**: Access to Mac OS-specific interpreter features.
- **macostools**: Convenience routines for file manipulation.
- **findertools**: Wrappers around the **finder**'s Apple Events interface.
- **EasyDialogs**: Basic Macintosh dialogs.
- **FrameWork**: Interactive application framework.
- **autoGIL**: Global Interpreter Lock handling in event loops.

---

*Release 2.5, documentation updated on 19th September, 2006.*

See [About this document...](#) for information on suggesting changes.
2.1 macpath -- MacOS path manipulation functions

This module is the Mac OS 9 (and earlier) implementation of the `os.path` module. It can be used to manipulate old-style Macintosh pathnames on Mac OS X (or any other platform). Refer to the [Python Library Reference](#) for documentation of `os.path`.

The following functions are available in this module: `normcase()`, `normpath()`, `isabs()`, `join()`, `split()`, `isdir()`, `isfile()`, `walk()`, `exists()`. For other functions available in `os.path` dummy counterparts are available.
2.2 macfs -- Various file system services

Availability: Macintosh.

**Deprecated since release 2.3.** The macfs module should be considered obsolete. For FSSpec, FSRef and Alias handling use the Carbon.File or Carbon.Folder module. For file dialogs use the EasyDialogs module. Also, this module is known to not work correctly with UFS partitions.

This module provides access to Macintosh FSSpec handling, the Alias Manager, finder aliases and the Standard File package.

Whenever a function or method expects a file argument, this argument can be one of three things: (1) a full or partial Macintosh pathname, (2) an FSSpec object or (3) a 3-tuple \((\text{wdRefNum}, \text{parID}, \text{name})\) as described in *Inside Macintosh: Files*. An FSSpec can point to a non-existing file, as long as the folder containing the file exists. Under MacPython the same is true for a pathname, but not under UNIX-Python because of the way pathnames and FSRefs works. See Apple's documentation for details.

A description of aliases and the Standard File package can also be found there.

**FSSpec**(*file*)

Create an FSSpec object for the specified file.

**RawFSSpec**(*data*)

Create an FSSpec object given the raw data for the C structure for the FSSpec as a string. This is mainly useful if you have obtained an FSSpec structure over a network.

**RawAlias**(*data*)

Create an Alias object given the raw data for the C structure for the alias as a string. This is mainly useful if you have obtained an FSSpec structure over a network.
**FInfo()**

Create a zero-filled FInfo object.

**ResolveAliasFile(file)**

Resolve an alias file. Returns a 3-tuple \((\text{fsspec}, \text{isfolder}, \text{aliased})\) where \(\text{fsspec}\) is the resulting FSSpec object, \(\text{isfolder}\) is true if \(\text{fsspec}\) points to a folder and \(\text{aliased}\) is true if the file was an alias in the first place (otherwise the FSSpec object for the file itself is returned).

**StandardGetFile([type, ...])**

Present the user with a standard ```open input file``` dialog. Optionally, you can pass up to four 4-character file types to limit the files the user can choose from. The function returns an FSSpec object and a flag indicating that the user completed the dialog without cancelling.

**PromptGetFile(prompt[, type, ...])**

Similar to **StandardGetFile()** but allows you to specify a prompt which will be displayed at the top of the dialog.

**StandardPutFile(prompt[, default])**

Present the user with a standard ```open output file``` dialog. \(\text{prompt}\) is the prompt string, and the optional \(\text{default}\) argument initializes the output file name. The function returns an FSSpec object and a flag indicating that the user completed the dialog without cancelling.

**GetDirectory([prompt])**

Present the user with a non-standard ```select a directory``` dialog. You have to first open the directory before clicking on the ```select current directory``` button. \(\text{prompt}\) is the prompt string which will be displayed at the top of the dialog. Return an FSSpec object and a success-indicator.

**SetFolder([fsspec])**

Set the folder that is initially presented to the user when one of the file selection dialogs is presented. \(\text{fsspec}\) should point to a file in the folder, not the folder itself (the file need not exist, though). If no argument is passed the folder will be set to the current directory, i.e. what \(\text{os.getcwd()}\)
returns.

Note that starting with System 7.5 the user can change Standard File behaviour with the "general controls" control panel, thereby making this call inoperative.

**FindFolder( where, which, create)**

Locates one of the "special" folders that Mac OS knows about, such as the trash or the Preferences folder. *where* is the disk to search, *which* is the 4-character string specifying which folder to locate. Setting *create* causes the folder to be created if it does not exist. Returns a *(vrefnum, dirid)* tuple.

The constants for *where* and *which* can be obtained from the standard module *Carbon.Folders*.

**NewAliasMinimalFromFullPath( pathname)**

Return a minimal *alias* object that points to the given file, which must be specified as a full pathname. This is the only way to create an *Alias* pointing to a non-existing file.

**FindApplication( creator)**

Locate the application with 4-character creator code *creator*. The function returns an *FSSpec* object pointing to the application.
2.2.1 FSSpec Objects

data
The raw data from the FSSpec object, suitable for passing to other applications, for instance.

as_pathname()
Return the full pathname of the file described by the FSSpec object.

as_tuple()
Return the \((wdRefNum, parID, name)\) tuple of the file described by the FSSpec object.

NewAlias([file])
Create an Alias object pointing to the file described by this FSSpec. If the optional \(file\) parameter is present the alias will be relative to that file, otherwise it will be absolute.

NewAliasMinimal()
Create a minimal alias pointing to this file.

GetCreatorType()
Return the 4-character creator and type of the file.

SetCreatorType(creator, type)
Set the 4-character creator and type of the file.

GetFInfo()
Return a FInfo object describing the finder info for the file.

SetFInfo(finfo)
Set the finder info for the file to the values given as \(finfo\) (an FInfo object).

GetDates()
Return a tuple with three floating point values representing the creation date, modification date and backup date of the file.

**SetDates** (crdate, moddate, backupdate)

Set the creation, modification and backup date of the file. The values are in the standard floating point format used for times throughout Python.
2.2.2 Alias Objects

**data**

The raw data for the Alias record, suitable for storing in a resource or transmitting to other programs.

**Resolve([file])**

Resolve the alias. If the alias was created as a relative alias you should pass the file relative to which it is. Return the FSSpec for the file pointed to and a flag indicating whether the Alias object itself was modified during the search process. If the file does not exist but the path leading up to it does exist a valid fsspec is returned.

**GetInfo( num)**

An interface to the C routine GetAliasInfo().

**Update( file[ , file2])**

Update the alias to point to the file given. If file2 is present a relative alias will be created.

Note that it is currently not possible to directly manipulate a resource as an Alias object. Hence, after calling Update() or after Resolve() indicates that the alias has changed the Python program is responsible for getting the data value from the Alias object and modifying the resource.
2.2.3 FInfo Objects

See Inside Macintosh: Files for a complete description of what the various fields mean.

**Creator**
The 4-character creator code of the file.

**Type**
The 4-character type code of the file.

**Flags**
The finder flags for the file as 16-bit integer. The bit values in Flags are defined in standard module MACFS.

**Location**
A Point giving the position of the file's icon in its folder.

**Fldr**
The folder the file is in (as an integer).
2.3 ic -- Access to Internet Config

Availability: Macintosh.

This module provides access to various internet-related preferences set through System Preferences or the Finder.

There is a low-level companion module icglue which provides the basic Internet Config access functionality. This low-level module is not documented, but the docstrings of the routines document the parameters and the routine names are the same as for the Pascal or C API to Internet Config, so the standard IC programmers' documentation can be used if this module is needed.

The ic module defines the error exception and symbolic names for all error codes Internet Config can produce; see the source for details.

**exception error**

Exception raised on errors in the ic module.

The ic module defines the following class and function:

**class IC([signature[, ic]])**

Create an Internet Config object. The signature is a 4-character creator code of the current application (default 'Pyth') which may influence some of ICs settings. The optional ic argument is a low-level icglue.icinstance created beforehand, this may be useful if you want to get preferences from a different config file, etc.

**launchurl(url[, hint])**

**parseurl(data[, start[, end[, hint]]])**

**mapfile(file)**

**maptypecreator(type, creator[, filename])**

**settypecreator(file)**

These functions are ``shortcuts'' to the methods of the same name, described below.
2.3.1 IC Objects

IC objects have a mapping interface, hence to obtain the mail address you simply get `ic['MailAddress']`. Assignment also works, and changes the option in the configuration file.

The module knows about various datatypes, and converts the internal IC representation to a "logical" Python data structure. Running the `ic` module standalone will run a test program that lists all keys and values in your IC database, this will have to serve as documentation.

If the module does not know how to represent the data it returns an instance of the `ICOpaqueData` type, with the raw data in its `data` attribute. Objects of this type are also acceptable values for assignment.

Besides the dictionary interface, IC objects have the following methods:

**launchurl**( `url[, hint]` )

Parse the given URL, launch the correct application and pass it the URL. The optional `hint` can be a scheme name such as `'mailto:'`, in which case incomplete URLs are completed with this scheme. If `hint` is not provided, incomplete URLs are invalid.

**parseurl**( `data[, start[, end[, hint]]]` )

Find an URL somewhere in `data` and return start position, end position and the URL. The optional `start` and `end` can be used to limit the search, so for instance if a user clicks in a long text field you can pass the whole text field and the click-position in `start` and this routine will return the whole URL in which the user clicked. As above, `hint` is an optional scheme used to complete incomplete URLs.

**mapfile**( `file` )

Return the mapping entry for the given `file`, which can be passed as either a filename or an `FSSpec()` result, and which need not exist.

The mapping entry is returned as a tuple `(version, type, creator,`
postcreator, flags, extension, appname, postappname, mimetype, entryname), where version is the entry version number, type is the 4-character filetype, creator is the 4-character creator type, postcreator is the 4-character creator code of an optional application to post-process the file after downloading, flags are various bits specifying whether to transfer in binary or ascii and such, extension is the filename extension for this file type, appname is the printable name of the application to which this file belongs, postappname is the name of the postprocessing application, mimetype is the MIME type of this file and entryname is the name of this entry.

maptypecreator(type, creator[, filename])

Return the mapping entry for files with given 4-character type and creator codes. The optional filename may be specified to further help finding the correct entry (if the creator code is '????', for instance).

The mapping entry is returned in the same format as for mapfile.

settypecreator(file)

Given an existing file, specified either as a filename or as an FSSpec() result, set its creator and type correctly based on its extension. The finder is told about the change, so the finder icon will be updated quickly.
2.4 MacOS -- Access to Mac OS interpreter features

Availability: Macintosh.

This module provides access to MacOS specific functionality in the Python interpreter, such as how the interpreter eventloop functions and the like. Use with care.

Note the capitalization of the module name; this is a historical artifact.

**runtimemodel**
Always 'mačo', from Python 2.4 on. In earlier versions of Python the value could also be 'ppc' for the classic Mac OS 8 runtime model or 'carbon' for the Mac OS 9 runtime model.

**linkmodel**
The way the interpreter has been linked. As extension modules may be incompatible between linking models, packages could use this information to give more decent error messages. The value is one of 'static' for a statically linked Python, 'framework' for Python in a Mac OS X framework, 'shared' for Python in a standard UNIX shared library. Older Pythons could also have the value 'cfm' for Mac OS 9-compatible Python.

**exception Error**
This exception is raised on MacOS generated errors, either from functions in this module or from other mac-specific modules like the toolbox interfaces. The arguments are the integer error code (the OSErr value) and a textual description of the error code. Symbolic names for all known error codes are defined in the standard module macerrors.

**GetErrorString**(*errno*)
Return the textual description of MacOS error code *errno*. 
**DebugStr**( message [, object])

On Mac OS X the string is simply printed to stderr (on older Mac OS systems more elaborate functionality was available), but it provides a convenient location to attach a breakpoint in a low-level debugger like **gdb**.

**SysBeep**( )

Ring the bell.

**GetTicks**( )

Get the number of clock ticks (1/60th of a second) since system boot.

**GetCreatorAndType**( file)

Return the file creator and file type as two four-character strings. The *file* parameter can be a pathname or an **FSSpec** or **FSRef** object.

**SetCreatorAndType**( file, creator, type)

Set the file creator and file type. The *file* parameter can be a pathname or an **FSSpec** or **FSRef** object. *creator* and *type* must be four character strings.

**openrf**( name [, mode])

Open the resource fork of a file. Arguments are the same as for the built-in function **open**( ). The object returned has file-like semantics, but it is not a Python file object, so there may be subtle differences.

**WMAvailable**( )

Checks whether the current process has access to the window manager. The method will return **False** if the window manager is not available, for instance when running on Mac OS X Server or when logged in via ssh, or when the current interpreter is not running from a fullblown application bundle. A script runs from an application bundle either when it has been started with **pythonw** instead of **python** or when running as an applet.
See About this document... for information on suggesting changes.
2.5 macostools -- Convenience routines for file manipulation

Availability: Macintosh.

This module contains some convenience routines for file-manipulation on the Macintosh. All file parameters can be specified as pathnames, FSRef or FSSpec objects. This module expects a filesystem which supports forked files, so it should not be used on UFS partitions.

The macostools module defines the following functions:

**copy** (src, dst[, createpath[, copytimes]])
Copy file src to dst. If createpath is non-zero the folders leading to dst are created if necessary. The method copies data and resource fork and some finder information (creator, type, flags) and optionally the creation, modification and backup times (default is to copy them). Custom icons, comments and icon position are not copied.

**copytree** (src, dst)
Recursively copy a file tree from src to dst, creating folders as needed. src and dst should be specified as pathnames.

**mkalias** (src, dst)
Create a finder alias dst pointing to src.

**touched** (dst)
Tell the finder that some bits of finder-information such as creator or type for file dst has changed. The file can be specified by pathname or fsspec. This call should tell the finder to redraw the files icon.

**BUFSIZ**
The buffer size for copy, default 1 megabyte.

Note that the process of creating finder aliases is not specified in the Apple
documentation. Hence, aliases created with `mkalias()` could conceivably have incompatible behaviour in some cases.
2.6 findertools -- The finder's Apple Events interface

Availability: Macintosh.

This module contains routines that give Python programs access to some functionality provided by the finder. They are implemented as wrappers around the AppleEvent interface to the finder.

All file and folder parameters can be specified either as full pathnames, or as FSRef or FSSpec objects.

The findertools module defines the following functions:

`launch(file)`
Tell the finder to launch file. What launching means depends on the file: applications are started, folders are opened and documents are opened in the correct application.

`Print(file)`
Tell the finder to print a file. The behaviour is identical to selecting the file and using the print command in the finder's file menu.

`copy(file, destdir)`
Tell the finder to copy a file or folder file to folder destdir. The function returns an Alias object pointing to the new file.

`move(file, destdir)`
Tell the finder to move a file or folder file to folder destdir. The function returns an Alias object pointing to the new file.

`sleep()`
Tell the finder to put the Macintosh to sleep, if your machine supports it.

`restart()`
Tell the finder to perform an orderly restart of the machine.

```
shutdown()
```

Tell the finder to perform an orderly shutdown of the machine.

*Release 2.5, documentation updated on 19th September, 2006.*

*See [About this document...](#) for information on suggesting changes.*
2.7 EasyDialogs -- Basic Macintosh dialogs

Availability: Macintosh.

The EasyDialogs module contains some simple dialogs for the Macintosh. All routines take an optional resource ID parameter id with which one can override the DLOG resource used for the dialog, provided that the dialog items correspond (both type and item number) to those in the default DLOG resource. See source code for details.

The EasyDialogs module defines the following functions:

**Message**(str[, id[, ok]])
Displays a modal dialog with the message text str, which should be at most 255 characters long. The button text defaults to ``OK``, but is set to the string argument ok if the latter is supplied. Control is returned when the user clicks the ``OK`` button.

**AskString**(prompt[, default[, id[, ok[, cancel]]]])
Asks the user to input a string value via a modal dialog. prompt is the prompt message, and the optional default supplies the initial value for the string (otherwise "" is used). The text of the ``OK`` and ``Cancel`` buttons can be changed with the ok and cancel arguments. All strings can be at most 255 bytes long. AskString() returns the string entered or None in case the user cancelled.

**AskPassword**(prompt[, default[, id[, ok[, cancel]]]])
Asks the user to input a string value via a modal dialog. Like AskString(), but with the text shown as bullets. The arguments have the same meaning as for AskString().

**AskYesNoCancel**(question[, default[, yes[, no[, cancel[, id]]]]])
Presents a dialog with prompt question and three buttons labelled ``Yes``,
``No'', and ``Cancel''. Returns 1 for ``Yes'', 0 for ``No'' and -1 for 
``Cancel''. The value of default (or 0 if default is not supplied) is returned 
when the RETURN key is pressed. The text of the buttons can be changed 
with the yes, no, and cancel arguments; to prevent a button from appearing, 
supply "" for the corresponding argument.

**ProgressBar([title[, maxval[, label[, id]]]])**

Displays a modeless progress-bar dialog. This is the constructor for the 
**ProgressBar** class described below. title is the text string displayed 
(default ``Working...''), maxval is the value at which progress is complete 
(default 0, indicating that an indeterminate amount of work remains to be 
done), and label is the text that is displayed above the progress bar itself.

**GetArgv([optionlist[ commandlist[, addoldfile[, addnewfile[, addfolder[, id]]]]]])**

Displays a dialog which aids the user in constructing a command-line 
argument list. Returns the list in sys.argv format, suitable for passing as 
an argument to getopt.getopt(). addoldfile, addnewfile, and 
addfolder are boolean arguments. When nonzero, they enable the user to 
insert into the command line paths to an existing file, a (possibly) not-yet-
extistent file, and a folder, respectively. (Note: Option arguments must 
appear in the command line before file and folder arguments in order to be 
recognized by getopt.getopt().) Arguments containing spaces can be 
specified by enclosing them within single or double quotes. A 
SystemExit exception is raised if the user presses the ``Cancel'' button.

optionlist is a list that determines a popup menu from which the allowed 
options are selected. Its items can take one of two forms: optstr or (optstr, 
descr). When present, descr is a short descriptive string that is displayed in 
the dialog while this option is selected in the popup menu. The 
correspondence between optstrs and command-line arguments is:

<table>
<thead>
<tr>
<th>optstr format</th>
<th>Command-line format</th>
</tr>
</thead>
<tbody>
<tr>
<td>x</td>
<td>-x (short option)</td>
</tr>
<tr>
<td>x: or x=</td>
<td>-x (short option with value)</td>
</tr>
<tr>
<td>xyz</td>
<td>--xyz (long option)</td>
</tr>
<tr>
<td>xyz: or xyz=</td>
<td>--xyz (long option with value)</td>
</tr>
</tbody>
</table>
commandlist is a list of items of the form cmdstr or (cmdstr, descr), where descr is as above. The cmdstrs will appear in a popup menu. When chosen, the text of cmdstr will be appended to the command line as is, except that a trailing " : " or " = " (if present) will be trimmed off.

New in version 2.0.

Post a dialog asking the user for a file to open, and return the file selected or None if the user cancelled. message is a text message to display, typeList is a list of 4-char filetypes allowable, defaultLocation is the pathname, FSSpec or FSRef of the folder to show initially, location is the (x, y) position on the screen where the dialog is shown, actionButtonLabel is a string to show instead of "Open" in the OK button, cancelButtonLabel is a string to show instead of "Cancel" in the cancel button, wanted is the type of value wanted as a return: str, unicode, FSSpec, FSRef and subtypes thereof are acceptable.

For a description of the other arguments please see the Apple Navigation Services documentation and the EasyDialogs source code.

Post a dialog asking the user for a file to save to, and return the file selected or None if the user cancelled. savedFileName is the default for the file name to save to (the return value). See AskFileForOpen( ) for a description of the other arguments.
AskFolder([, clientId[, windowTitle][, actionButtonLabel][, cancelButtonLabel][, preferenceKey][, popupExtension][, eventProc][, filterProc][, wanted])

Post a dialog asking the user to select a folder, and return the folder selected or None if the user cancelled. See AskFileForOpen() for a description of the arguments.

- 2.7.1 ProgressBar Objects

Macintosh Library Modules

Previous: 2.6 findertools  Up: 2. MacPython Modules  Next: 2.7.1 ProgressBar Objects

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
2.7.1 ProgressBar Objects

ProgressBar objects provide support for modeless progress-bar dialogs. Both determinate (thermometer style) and indeterminate (barber-pole style) progress bars are supported. The bar will be determinate if its maximum value is greater than zero; otherwise it will be indeterminate. Changed in version 2.2: Support for indeterminate-style progress bars was added.

The dialog is displayed immediately after creation. If the dialog's `Cancel` button is pressed, or if `Cmd-.` or `ESC` is typed, the dialog window is hidden and `KeyboardInterrupt` is raised (but note that this response does not occur until the progress bar is next updated, typically via a call to `inc()` or `set()`). Otherwise, the bar remains visible until the `ProgressBar` object is discarded.

`ProgressBar` objects possess the following attributes and methods:

**curval**
- The current value (of type integer or long integer) of the progress bar. The normal access methods coerce `curval` between 0 and `maxval`. This attribute should not be altered directly.

**maxval**
- The maximum value (of type integer or long integer) of the progress bar; the progress bar (thermometer style) is full when `curval` equals `maxval`. If `maxval` is 0, the bar will be indeterminate (barber-pole). This attribute should not be altered directly.

**title([newstr])**
- Sets the text in the title bar of the progress dialog to `newstr`.

**label([newstr])**
- Sets the text in the progress box of the progress dialog to `newstr`.

**set(value[, max])**
- Sets the progress bar's `curval` to `value`, and also `maxval` to `max` if the latter is provided. `value` is first coerced between 0 and `maxval`. The
thermometer bar is updated to reflect the changes, including a change from indeterminate to determinate or vice versa.

\texttt{inc([n])}

Increments the progress bar's \texttt{curval} by \texttt{n}, or by \texttt{1} if \texttt{n} is not provided. (Note that \texttt{n} may be negative, in which case the effect is a decrement.) The progress bar is updated to reflect the change. If the bar is indeterminate, this causes one ``spin'' of the barber pole. The resulting \texttt{curval} is coerced between 0 and \texttt{maxval} if incrementing causes it to fall outside this range.
2.8 FrameWork -- Interactive application framework

Availability: Macintosh.

The FrameWork module contains classes that together provide a framework for an interactive Macintosh application. The programmer builds an application by creating subclasses that override various methods of the bases classes, thereby implementing the functionality wanted. Overriding functionality can often be done on various different levels, i.e. to handle clicks in a single dialog window in a non-standard way it is not necessary to override the complete event handling.

Work on the FrameWork has pretty much stopped, now that PyObjC is available for full Cocoa access from Python, and the documentation describes only the most important functionality, and not in the most logical manner at that. Examine the source or the examples for more details. The following are some comments posted on the MacPython newsgroup about the strengths and limitations of FrameWork:

The strong point of FrameWork is that it allows you to break into the control-flow at many different places. W, for instance, uses a different way to enable/disable menus and that plugs right in leaving the rest intact. The weak points of FrameWork are that it has no abstract command interface (but that shouldn't be difficult), that its dialog support is minimal and that its control/toolbar support is non-existent.

The FrameWork module defines the following functions:

Application()
An object representing the complete application. See below for a description of the methods. The default __init__() routine creates an empty window dictionary and a menu bar with an apple menu.

MenuBar()
An object representing the menubar. This object is usually not created by
the user.

**Menu**(*bar, title[, after]*)

An object representing a menu. Upon creation you pass the MenuBar the menu appears in, the *title* string and a position (1-based) *after* where the menu should appear (default: at the end).

**MenuItem**(*menu, title[, shortcut, callback]*)

Create a menu item object. The arguments are the menu to create, the item title string and optionally the keyboard shortcut and a callback routine. The callback is called with the arguments menu-id, item number within menu (1-based), current front window and the event record.

Instead of a callable object the callback can also be a string. In this case menu selection causes the lookup of a method in the topmost window and the application. The method name is the callback string with 'domenu_' prepended.

Calling the MenuBar fixmenudimstate() method sets the correct dimming for all menu items based on the current front window.

**Separator**(*menu*)

Add a separator to the end of a menu.

**SubMenu**(*menu, label*)

Create a submenu named *label* under menu *menu*. The menu object is returned.

**Window**(*parent*)

Creates a (modeless) window. *Parent* is the application object to which the window belongs. The window is not displayed until later.

**DialogWindow**(*parent*)

Creates a modeless dialog window.

**windowbounds**(*width, height*)

Return a (*left, top, right, bottom*) tuple suitable for creation of a
window of given width and height. The window will be staggered with respect to previous windows, and an attempt is made to keep the whole window on-screen. However, the window will however always be the exact size given, so parts may be offscreen.

**setwatchcursor()**
Set the mouse cursor to a watch.

**setarrowcursor()**
Set the mouse cursor to an arrow.

---

Release 2.5, documentation updated on 19th September, 2006.
See [About this document...](#) for information on suggesting changes.
2.8.1 Application Objects

Application objects have the following methods, among others:

**makeusermenus()**
Override this method if you need menus in your application. Append the menus to the attribute `menubar`.

**getabouttext()**
Override this method to return a text string describing your application. Alternatively, override the `do_about()` method for more elaborate ```about``` messages.

**mainloop([`mask`, `wait`])**
This routine is the main event loop, call it to set your application rolling. `Mask` is the mask of events you want to handle, `wait` is the number of ticks you want to leave to other concurrent application (default 0, which is probably not a good idea). While raising `self` to exit the mainloop is still supported it is not recommended: call `self._quit()` instead.

The event loop is split into many small parts, each of which can be overridden. The default methods take care of dispatching events to windows and dialogs, handling drags and resizes, Apple Events, events for non-FrameWork windows, etc.

In general, all event handlers should return 1 if the event is fully handled and 0 otherwise (because the front window was not a FrameWork window, for instance). This is needed so that update events and such can be passed on to other windows like the Sioux console window. Calling `MacOS.HandleEvent()` is not allowed within `our_dispatch` or its callees, since this may result in an infinite loop if the code is called through the Python inner-loop event handler.

**asyncevents(`onoff`)**
Call this method with a nonzero parameter to enable asynchronous event handling. This will tell the inner interpreter loop to call the application
event handler *async_dispatch* whenever events are available. This will cause FrameWork window updates and the user interface to remain working during long computations, but will slow the interpreter down and may cause surprising results in non-reentrant code (such as FrameWork itself). By default *async_dispatch* will immediately call *our_dispatch* but you may override this to handle only certain events asynchronously. Events you do not handle will be passed to Sioux and such.

The old on/off value is returned.

**_quit()**

Terminate the running *mainloop()* call at the next convenient moment.

**do_char**(c, *event*)

The user typed character *c*. The complete details of the event can be found in the *event* structure. This method can also be provided in a *Window* object, which overrides the application-wide handler if the window is frontmost.

**do_dialogevent**(event)

Called early in the event loop to handle modeless dialog events. The default method simply dispatches the event to the relevant dialog (not through the *DialogWindow* object involved). Override if you need special handling of dialog events (keyboard shortcuts, etc).

**idle**(event)

Called by the main event loop when no events are available. The null-event is passed (so you can look at mouse position, etc).
2.8.2 Window Objects

Window objects have the following methods, among others:

**open()**
Override this method to open a window. Store the MacOS window-id in `self.wid` and call the `do_postopen()` method to register the window with the parent application.

**close()**
Override this method to do any special processing on window close. Call the `do_postclose()` method to cleanup the parent state.

**do_postresize(width, height, macoswindowid)**
Called after the window is resized. Override if more needs to be done than calling `InvalRect`.

**do_contentclick(local, modifiers, event)**
The user clicked in the content part of a window. The arguments are the coordinates (window-relative), the key modifiers and the raw event.

**do_update(macoswindowid, event)**
An update event for the window was received. Redraw the window.

**do_activate(activate, event)**
The window was activated (`activate == 1`) or deactivated (`activate == 0`). Handle things like focus highlighting, etc.
2.8.3 ControlsWindow Object

ControlsWindow objects have the following methods besides those of Window objects:

\textbf{do\_controlhit}( window, control, pcode, event)

Part \textit{pcode} of control \textit{control} was hit by the user. Tracking and such has already been taken care of.
2.8.4 ScrolledWindow Object

ScrolledWindow objects are ControlsWindow objects with the following extra methods:

**scrollbars**([wantx[, wanty]])
Create (or destroy) horizontal and vertical scrollbars. The arguments specify which you want (default: both). The scrollbars always have minimum 0 and maximum 32767.

**getscrollbarvalues()**
You must supply this method. It should return a tuple \((x, y)\) giving the current position of the scrollbars (between 0 and 32767). You can return None for either to indicate the whole document is visible in that direction.

**updatescrollbars()**
Call this method when the document has changed. It will call getscrollbarvalues() and update the scrollbars.

**scrollbar_callback**(which, what, value)
Supplied by you and called after user interaction. which will be 'x' or 'y', what will be '-', '--', 'set', '++' or '+'. For 'set', value will contain the new scrollbar position.

**scalebarvalues**(absmin, absmax, curmin, curmax)
Auxiliary method to help you calculate values to return from getscrollbarvalues(). You pass document minimum and maximum value and topmost (leftmost) and bottommost (rightmost) visible values and it returns the correct number or None.

**do_activate**(onoff, event)
Takes care of dimming/highlighting scrollbars when a window becomes frontmost. If you override this method, call this one at the end of your method.

**do_postresize**(width, height, window)
Moves scrollbars to the correct position. Call this method initially if you override it.

**do_controlhit** *(window, control, pcode, event)*

Handles scrollbar interaction. If you override it call this method first, a nonzero return value indicates the hit was in the scrollbars and has been handled.
2.8.5 DialogWindow Objects

DialogWindow objects have the following methods besides those of Window objects:

**open***( resid)  
Create the dialog window, from the DLOG resource with id resid. The dialog object is stored in self.wid.

**do_itemhit**( item, event)  
Item number item was hit. You are responsible for redrawing toggle buttons, etc.
2.9 autoGIL -- Global Interpreter Lock handling in event loops

Availability: Macintosh.

The autoGIL module provides a function installAutoGIL that automatically locks and unlocks Python's Global Interpreter Lock when running an event loop.

**exception AutoGILError**

Raised if the observer callback cannot be installed, for example because the current thread does not have a run loop.

**installAutoGIL()**

Install an observer callback in the event loop (CFRunLoop) for the current thread, that will lock and unlock the Global Interpreter Lock (GIL) at appropriate times, allowing other Python threads to run while the event loop is idle.

Availability: OSX 10.1 or later.
3. MacPython OSA Modules

This chapter describes the current implementation of the Open Scripting Architecture (OSA, also commonly referred to as AppleScript) for Python, allowing you to control scriptable applications from your Python program, and with a fairly pythonic interface. Development on this set of modules has stopped, and a replacement is expected for Python 2.5.

For a description of the various components of AppleScript and OSA, and to get an understanding of the architecture and terminology, you should read Apple's documentation. The "Applescript Language Guide" explains the conceptual model and the terminology, and documents the standard suite. The "Open Scripting Architecture" document explains how to use OSA from an application programmers point of view. In the Apple Help Viewer these books are located in the Developer Documentation, Core Technologies section.

As an example of scripting an application, the following piece of AppleScript will get the name of the frontmost Finder window and print it:

```applescript
tell application "Finder"
    get name of window 1
end tell
```

In Python, the following code fragment will do the same:

```python
import Finder

f = Finder.Finder()
print f.get(f.window(1).name)
```

As distributed the Python library includes packages that implement the standard suites, plus packages that interface to a small number of common applications.

To send AppleEvents to an application you must first create the Python package interfacing to the terminology of the application (what Script Editor calls the "Dictionary"). This can be done from within the PythonIDE or by running the gensuitemodule.py module as a standalone program from the command line.

The generated output is a package with a number of modules, one for every suite
used in the program plus an `__init__` module to glue it all together. The Python inheritance graph follows the AppleScript inheritance graph, so if a program's dictionary specifies that it includes support for the Standard Suite, but extends one or two verbs with extra arguments then the output suite will contain a module `Standard_Suite` that imports and re-exports everything from `StdSuites.Standard_Suite` but overrides the methods that have extra functionality. The output of `gensuitemodule` is pretty readable, and contains the documentation that was in the original AppleScript dictionary in Python docstrings, so reading it is a good source of documentation.

The output package implements a main class with the same name as the package which contains all the AppleScript verbs as methods, with the direct object as the first argument and all optional parameters as keyword arguments. AppleScript classes are also implemented as Python classes, as are comparisons and all the other thingies.

The main Python class implementing the verbs also allows access to the properties and elements declared in the AppleScript class "application". In the current release that is as far as the object orientation goes, so in the example above we need to use `f.get(f.window(1).name)` instead of the more Pythonic `f.window(1).name.get()`.

If an AppleScript identifier is not a Python identifier the name is mangled according to a small number of rules:

- spaces are replaced with underscores
- other non-alphanumeric characters are replaced with `_xx_` where `xx` is the hexadecimal character value
- any Python reserved word gets an underscore appended

Python also has support for creating scriptable applications in Python, but The following modules are relevant to MacPython AppleScript support:

- `gensuitemodule` Create a stub package from an OSA dictionary
- `aetools` Basic support for sending Apple Events
- `aepack` Conversion between Python variables and AppleEvent data containers.
- `aetypes` Python representation of the Apple Event Object Model.
MiniAEFrame

Support to act as an Open Scripting Architecture (OSA) server (``Apple Events '').

In addition, support modules have been pre-generated for Finder, Terminal, Explorer, Netscape, CodeWarrior, SystemEvents and StdSuites.
3.1 gensuitemodule -- Generate OSA stub packages

Availability: Macintosh.

The gensuitemodule module creates a Python package implementing stub code for the AppleScript suites that are implemented by a specific application, according to its AppleScript dictionary.

It is usually invoked by the user through the PythonIDE, but it can also be run as a script from the command line (pass --help for help on the options) or imported from Python code. For an example of its use see Mac/scripts/genallsuites.py in a source distribution, which generates the stub packages that are included in the standard library.

It defines the following public functions:

is_scriptable( application)

Returns true if application, which should be passed as a pathname, appears to be scriptable. Take the return value with a grain of salt: Internet Explorer appears not to be scriptable but definitely is.

processfile( application[, output, basepkgname, edit_modnames, creatorsignature, dump, verbose])

Create a stub package for application, which should be passed as a full pathname. For a .app bundle this is the pathname to the bundle, not to the executable inside the bundle; for an unbundled CFM application you pass the filename of the application binary.

This function asks the application for its OSA terminology resources, decodes these resources and uses the resultant data to create the Python code for the package implementing the client stubs.

output is the pathname where the resulting package is stored, if not specified a standard "save file as" dialog is presented to the user.
basepkgname is the base package on which this package will build, and defaults to StdSuites. Only when generating StdSuites itself do you need to specify this. edit_modnames is a dictionary that can be used to change modulenames that are too ugly after name mangling. creator_signature can be used to override the 4-char creator code, which is normally obtained from the PkgInfo file in the package or from the CFM file creator signature. When dump is given it should refer to a file object, and processfile will stop after decoding the resources and dump the Python representation of the terminology resources to this file. verbose should also be a file object, and specifying it will cause processfile to tell you what it is doing.

\[
\text{application}[, \text{output, basepkgname,}}
\]

\text{processfile_fromresource(} \text{edit_modnames, creatorsignature, dump,}
\]

\text{verbose])

This function does the same as processfile, except that it uses a different method to get the terminology resources. It opens application as a resource file and reads all "aete" and "aeut" resources from this file.
3.2 aetools -- OSA client support

Availability: Macintosh.

The aetools module contains the basic functionality on which Python AppleScript client support is built. It also imports and re-exports the core functionality of the aetypes and aepack modules. The stub packages generated by gensuitemodule import the relevant portions of aetools, so usually you do not need to import it yourself. The exception to this is when you cannot use a generated suite package and need lower-level access to scripting.

The aetools module itself uses the AppleEvent support provided by the Carbon.AE module. This has one drawback: you need access to the window manager, see section 1.1.2 for details. This restriction may be lifted in future releases.

The aetools module defines the following functions:

packevent( ae, parameters, attributes)

Stores parameters and attributes in a pre-created Carbon.AE.AEDesc object. parameters and attributes are dictionaries mapping 4-character OSA parameter keys to Python objects. The objects are packed using aepack.pack().

unpackevent( ae[, formodulename])

Recursively unpacks a Carbon.AE.AEDesc event to Python objects. The function returns the parameter dictionary and the attribute dictionary. The formodulename argument is used by generated stub packages to control where AppleScript classes are looked up.

keysubst( arguments, keydict)

Converts a Python keyword argument dictionary arguments to the format required by packevent by replacing the keys, which are Python identifiers, by the four-character OSA keys according to the mapping specified in keydict. Used by the generated suite packages.
enumsubst( arguments, key, edict)

If the arguments dictionary contains an entry for key convert the value for that entry according to dictionary edict. This converts human-readable Python enumeration names to the OSA 4-character codes. Used by the generated suite packages.

The aetools module defines the following class:

class TalkTo([signature=None, start=0, timeout=0])

Base class for the proxy used to talk to an application. signature overrides the class attribute _signature (which is usually set by subclasses) and is the 4-char creator code defining the application to talk to. start can be set to true to enable running the application on class instantiation. timeout can be specified to change the default timeout used while waiting for an AppleEvent reply.

_start()

Test whether the application is running, and attempt to start it if not.

send( code, subcode[, parameters, attributes])

Create the AppleEvent Carbon.AE.AEDesc for the verb with the OSA designation code, subcode (which are the usual 4-character strings), pack the parameters and attributes into it, send it to the target application, wait for the reply, unpack the reply with unpackevent and return the reply appleevent, the unpacked return values as a dictionary and the return attributes.
3.3 aepack -- Conversion between Python variables and AppleEvent data containers

Availability: Macintosh.

The aepack module defines functions for converting (packing) Python variables to AppleEvent descriptors and back (unpacking). Within Python the AppleEvent descriptor is handled by Python objects of built-in type AEDesc, defined in module Carbon.AE.

The aepack module defines the following functions:

`pack(x[, forctype])`

Returns an AEDesc object containing a conversion of Python value x. If forctype is provided it specifies the descriptor type of the result. Otherwise, a default mapping of Python types to Apple Event descriptor types is used, as follows:

<table>
<thead>
<tr>
<th>Python type</th>
<th>descriptor type</th>
</tr>
</thead>
<tbody>
<tr>
<td>FSSpec</td>
<td>typeFSS</td>
</tr>
<tr>
<td>FSRef</td>
<td>typeFSRef</td>
</tr>
<tr>
<td>Alias</td>
<td>typeAlias</td>
</tr>
<tr>
<td>integer</td>
<td>typeLong (32 bit integer)</td>
</tr>
<tr>
<td>float</td>
<td>typeFloat (64 bit floating point)</td>
</tr>
<tr>
<td>string</td>
<td>typeText</td>
</tr>
<tr>
<td>unicode</td>
<td>typeUnicodeText</td>
</tr>
<tr>
<td>list</td>
<td>typeAEList</td>
</tr>
<tr>
<td>dictionary</td>
<td>typeAERecord</td>
</tr>
<tr>
<td>instance</td>
<td>see below</td>
</tr>
</tbody>
</table>

If x is a Python instance then this function attempts to call an `__aepack__()` method. This method should return an AEDesc object.
If the conversion $x$ is not defined above, this function returns the Python string representation of a value (the `repr()` function) encoded as a text descriptor.

**unpack**(*$x$, *formodulename*)

$x$ must be an object of type `AEDesc`. This function returns a Python object representation of the data in the Apple Event descriptor $x$. Simple AppleEvent data types (integer, text, float) are returned as their obvious Python counterparts. Apple Event lists are returned as Python lists, and the list elements are recursively unpacked. Object references (ex. line 3 of document 1) are returned as instances of `aetypes.ObjectSpecifier`, unless `formodulename` is specified. AppleEvent descriptors with descriptor type typeFSS are returned as `FSSpec` objects. AppleEvent record descriptors are returned as Python dictionaries, with 4-character string keys and elements recursively unpacked.

The optional `formodulename` argument is used by the stub packages generated by `gensuitemodule`, and ensures that the OSA classes for object specifiers are looked up in the correct module. This ensures that if, say, the Finder returns an object specifier for a window you get an instance of `Finder.Window` and not a generic `aetypes.Window`. The former knows about all the properties and elements a window has in the Finder, while the latter knows no such things.

**See Also:**

Module **Carbon.AE**:

Built-in access to Apple Event Manager routines.

Module **aetypes**:

Python definitions of codes for Apple Event descriptor types.

*Inside Macintosh: Interapplication Communication*

Information about inter-process communications on the Macintosh.
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
3.4 aetypes -- AppleEvent objects

Availability: Macintosh.

The aetypes defines classes used to represent Apple Event data descriptors and Apple Event object specifiers.

Apple Event data is contained in descriptors, and these descriptors are typed. For many descriptors the Python representation is simply the corresponding Python type: typeText in OSA is a Python string, typeFloat is a float, etc. For OSA types that have no direct Python counterpart this module declares classes. Packing and unpacking instances of these classes is handled automatically by aepack.

An object specifier is essentially an address of an object implemented in a Apple Event server. An Apple Event specifier is used as the direct object for an Apple Event or as the argument of an optional parameter. The aetypes module contains the base classes for OSA classes and properties, which are used by the packages generated by gensuitemodule to populate the classes and properties in a given suite.

For reasons of backward compatibility, and for cases where you need to script an application for which you have not generated the stub package this module also contains object specifiers for a number of common OSA classes such as Document, Window, Character, etc.

The AEObjects module defines the following classes to represent Apple Event descriptor data:

**class Unknown** (type, data)

The representation of OSA descriptor data for which the aepack and aetypes modules have no support, i.e. anything that is not represented by the other classes here and that is not equivalent to a simple Python value.

**class Enum** (enum)

An enumeration value with the given 4-character string value.
class InsertionLoc( of, pos)
    Position pos in object of.

class Boolean( bool)
    A boolean.

class StyledText( style, text)
    Text with style information (font, face, etc) included.

class AEText( script, style, text)
    Text with script system and style information included.

class IntlText( script, language, text)
    Text with script system and language information included.

class IntlWritingCode( script, language)
    Script system and language information.

class QDPoint( v, h)
    A quickdraw point.

class QDRectangle( v0, h0, v1, h1)
    A quickdraw rectangle.

class RGBColor( r, g, b)
    A color.

class Type( type)
    An OSA type value with the given 4-character name.

class Keyword( name)
    An OSA keyword with the given 4-character name.

class Range( start, stop)
    A range.
**class Ordinal**( abso)

Non-numeric absolute positions, such as "**firs**", first, or "**midd**", middle.

**class Logical**( logc, term)

The logical expression of applying operator logc to term.

**class Comparison**( obj1, relo, obj2)

The comparison relo of obj1 to obj2.

The following classes are used as base classes by the generated stub packages to represent AppleScript classes and properties in Python:

**class ComponentItem**( which[, fr])

Abstract baseclass for an OSA class. The subclass should set the class attribute want to the 4-character OSA class code. Instances of subclasses of this class are equivalent to AppleScript Object Specifiers. Upon instantiation you should pass a selector in which, and optionally a parent object in fr.

**class NProperty**( fr)

Abstract baseclass for an OSA property. The subclass should set the class attributes want and which to designate which property we are talking about. Instances of subclasses of this class are Object Specifiers.

**class ObjectSpecifier**( want, form, seld[, fr])

Base class of ComponentItem and NProperty, a general OSA Object Specifier. See the Apple Open Scripting Architecture documentation for the parameters. Note that this class is not abstract.
3.5 MiniAEFrame -- Open Scripting Architecture server support

Availability: **Macintosh.**

The module MiniAEFrame provides a framework for an application that can function as an Open Scripting Architecture (OSA) server, i.e. receive and process AppleEvents. It can be used in conjunction with [FrameWork](#) or standalone. As an example, it is used in [PythonCGISlave](#).

The MiniAEFrame module defines the following classes:

**class AEServer()**

A class that handles AppleEvent dispatch. Your application should subclass this class together with either MiniApplication or FrameWork.Application. Your `__init__()` method should call the `__init__()` method for both classes.

**class MiniApplication()**

A class that is more or less compatible with FrameWork.Application but with less functionality. Its event loop supports the apple menu, command-dot and AppleEvents; other events are passed on to the Python interpreter and/or Sioux. Useful if your application wants to use AEServer but does not provide its own windows, etc.
See About this document... for information on suggesting changes.
3.5.1 AEServer Objects

installaehandler(classe, type, callback)
Installs an AppleEvent handler. classe and type are the four-character OSA Class and Type designators, '****' wildcards are allowed. When a matching AppleEvent is received the parameters are decoded and your callback is invoked.

callback(_object, **kwargs)
Your callback is called with the OSA Direct Object as first positional parameter. The other parameters are passed as keyword arguments, with the 4-character designator as name. Three extra keyword parameters are passed: _class and _type are the Class and Type designators and _attributes is a dictionary with the AppleEvent attributes.

The return value of your method is packed with aetools.packevent() and sent as reply.

Note that there are some serious problems with the current design. AppleEvents which have non-identifier 4-character designators for arguments are not implementable, and it is not possible to return an error to the originator. This will be addressed in a future release.
4. MacOS Toolbox Modules

There are a set of modules that provide interfaces to various MacOS toolboxes. If applicable the module will define a number of Python objects for the various structures declared by the toolbox, and operations will be implemented as methods of the object. Other operations will be implemented as functions in the module. Not all operations possible in C will also be possible in Python (callbacks are often a problem), and parameters will occasionally be different in Python (input and output buffers, especially). All methods and functions have a `__doc__` string describing their arguments and return values, and for additional description you are referred to *Inside Macintosh* or similar works.

These modules all live in a package called Carbon. Despite that name they are not all part of the Carbon framework: CF is really in the CoreFoundation framework and Qt is in the QuickTime framework. The normal use pattern is

```python
from Carbon import AE
```

**Warning!** These modules are not yet documented. If you wish to contribute documentation of any of these modules, please get in touch with docs@python.org.

- **Carbon.AE**: Interface to the Apple Events toolbox.
- **Carbon.AH**: Interface to the Apple Help manager.
- **Carbon.App**: Interface to the Appearance Manager.
- **Carbon.CF**: Interface to the Core Foundation.
- **Carbon.CG**: Interface to the Component Manager.
- **Carbon.CarOnEvt**: Interface to the Carbon Event Manager.
- **Carbon.Cm**: Interface to the Component Manager.
- **Carbon.Ctl**: Interface to the Control Manager.
- **Carbon.Dlg**: Interface to the Dialog Manager.
- **Carbon.Evt**: Interface to the classic Event Manager.
- **Carbon.Fm**: Interface to the Font Manager.
- **Carbon.Folder**: Interface to the Folder Manager.
- **Carbon.Help**: Interface to the Carbon Help Manager.
Carbon.List  Interface to the List Manager.
Carbon.Menu  Interface to the Menu Manager.
Carbon.Mlte  Interface to the MultiLingual Text Editor.
Carbon.Qd  Interface to the QuickDraw toolbox.
Carbon.Qdoffs  Interface to the QuickDraw Offscreen APIs.
Carbon.Qt  Interface to the QuickTime toolbox.
Carbon.Scrap  Interface to the Carbon Scrap Manager.
Carbon.Snd  Interface to the Sound Manager.
Carbon.TE  Interface to TextEdit.
Carbon.Win  Interface to the Window Manager.
ColorPicker  Interface to the standard color selection dialog.

Macintosh Library Modules

Previous: 3.5.1 AEServer Objects  Up: Macintosh Library Modules  Next: 4.1 Carbon.AE

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
4.1 Carbon.AE -- Apple Events

Availability: Macintosh.

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
4.2 Carbon.AH -- Apple Help

Availability: Macintosh.

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
4.3 Carbon.App -- Appearance Manager

Availability: Macintosh.

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
4.4 Carbon.CF -- Core Foundation

Availability: Macintosh.

The CFBaset, CFArray, CFData, CFDictionary, CFString and CFURL objects are supported, some only partially.
4.5 Carbon.CG -- Core Graphics

Availability: Macintosh.
4.6 Carbon.CarbonEvt -- Carbon Event Manager

Availability: Macintosh.

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
4.7 Carbon.Cm -- Component Manager

Availability: Macintosh.

Release 2.5, documentation updated on 19th September, 2006. 
See About this document... for information on suggesting changes.
4.8 Carbon.Ctl -- Control Manager

Availability: Macintosh.

Release 2.5, documentation updated on 19th September, 2006. See About this document... for information on suggesting changes.
4.9 Carbon.Dlg -- Dialog Manager

Availability: **Macintosh**.

Release 2.5, documentation updated on 19th September, 2006.
See [About this document...](#) for information on suggesting changes.
4.10 Carbon.Evt -- Event Manager

Availability: Macintosh.

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
4.11 Carbon.Fm -- Font Manager

Availability: Macintosh.

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
4.12 Carbon.Folder -- Folder Manager

Availability: Macintosh.

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
4.13 Carbon.Help -- Help Manager

Availability: Macintosh.

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
4.14 Carbon.List -- List Manager

Availability: Macintosh.

Release 2.5, documentation updated on 19th September, 2006. See About this document... for information on suggesting changes.
4.15 Carbon.Menu -- Menu Manager

Availability: Macintosh.

Release 2.5, documentation updated on 19th September, 2006. 
See About this document... for information on suggesting changes.
4.16 Carbon.Mlte -- MultiLingual Text Editor

Availability: Macintosh.
4.17 Carbon.Qd -- QuickDraw

Availability: Macintosh.
4.18 Carbon.Qdoffs -- QuickDraw Offscreen

Availability: Macintosh.
4.19 Carbon.Qt -- QuickTime

Availability: Macintosh.

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
4.20 Carbon.Res -- Resource Manager and Handles

Availability: Macintosh.
4.21 Carbon.Scrap -- Scrap Manager

Availability: Macintosh.

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
4.22 Carbon.Snd -- Sound Manager

Availability: Macintosh.

Release 2.5, documentation updated on 19th September, 2006. See About this document... for information on suggesting changes.
4.23 Carbon . TE -- TextEdit

Availability: Macintosh.

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
4.24 Carbon.Win -- Window Manager

Availability: Macintosh.

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
4.25 ColorPicker -- Color selection dialog

Availability: Macintosh.

The ColorPicker module provides access to the standard color picker dialog.

**GetColor**(prompt, rgb)

Show a standard color selection dialog and allow the user to select a color. The user is given instruction by the prompt string, and the default color is set to rgb. rgb must be a tuple giving the red, green, and blue components of the color. GetColor() returns a tuple giving the user’s selected color and a flag indicating whether they accepted the selection of cancelled.

---

Release 2.5, documentation updated on 19th September, 2006.

See [About this document...](#) for information on suggesting changes.
5. Undocumented Modules

The modules in this chapter are poorly documented (if at all). If you wish to contribute documentation of any of these modules, please get in touch with docs@python.org.

- **applesingle**: Rudimentary decoder for AppleSingle format files.
- **buildtools**: Helper module for BuildApplet, BuildApplication and macfreeze.
- **cfmfile**: Code Fragment Resource module.
- **icopen**: Internet Config replacement for `open()`.
- **macerrors**: Constant definitions for many Mac OS error codes.
- **macresource**: Locate script resources.
- **Nav**: Interface to Navigation Services.
- **PixMapWrapper**: Wrapper for PixMap objects.
- **videoreader**: Read QuickTime movies frame by frame for further processing.
- **W**: Widgets for the Mac, built on top of **Framework**.
5.1 applesingle -- AppleSingle decoder

Availability: Macintosh.

Release 2.5, documentation updated on 19th September, 2006. See About this document... for information on suggesting changes.
5.2 buildtools -- Helper module for BuildApplet and Friends

Availability: Macintosh.

Deprecated since release 2.4. <

P>
5.3 cfmyfile -- Code Fragment Resource module

Availability: Macintosh.

cfmyfile is a module that understands Code Fragments and the accompanying `cfrg` resources. It can parse them and merge them, and is used by BuildApplication to combine all plugin modules to a single executable.

Deprecated since release 2.4. <

P>
5.4 icopen -- Internet Config replacement for open()

Availability: Macintosh.

Importing icopen will replace the built-in open() with a version that uses Internet Config to set file type and creator for new files.

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
5.5 macerrors -- Mac OS Errors

Availability: Macintosh.

macerrors contains constant definitions for many Mac OS error codes.

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
5.6 macresource -- Locate script resources

Availability: Macintosh.

macresource helps scripts finding their resources, such as dialogs and menus, without requiring special case code for when the script is run under MacPython, as a MacPython applet or under OSX Python.
5.7 Nav -- NavServices calls

Availability: Macintosh.

A low-level interface to Navigation Services.
5.8 PixMapWrapper -- Wrapper for PixMap objects

Availability: Macintosh.

PixMapWrapper wraps a PixMap object with a Python object that allows access to the fields by name. It also has methods to convert to and from PIL images.
5.9 videoreader -- Read QuickTime movies

Availability: Macintosh.

videoreader reads and decodes QuickTime movies and passes a stream of images to your program. It also provides some support for audio tracks.
5.10 W -- Widgets built on FrameWork

Availability: **Macintosh**.

The W widgets are used extensively in the **IDE**.

A.1 History of the software

Python was created in the early 1990s by Guido van Rossum at Stichting Mathematisch Centrum (CWI, see http://www.cwi.nl/) in the Netherlands as a successor of a language called ABC. Guido remains Python's principal author, although it includes many contributions from others.

In 1995, Guido continued his work on Python at the Corporation for National Research Initiatives (CNRI, see http://www.cnri.reston.va.us/) in Reston, Virginia where he released several versions of the software.

In May 2000, Guido and the Python core development team moved to BeOpen.com to form the BeOpen PythonLabs team. In October of the same year, the PythonLabs team moved to Digital Creations (now Zope Corporation; see http://www.zope.com/). In 2001, the Python Software Foundation (PSF, see http://www.python.org/psf/) was formed, a non-profit organization created specifically to own Python-related Intellectual Property. Zope Corporation is a sponsoring member of the PSF.

All Python releases are Open Source (see http://www.opensource.org/ for the Open Source Definition). Historically, most, but not all, Python releases have also been GPL-compatible; the table below summarizes the various releases.

<table>

**Note:** GPL-compatible doesn't mean that we're distributing Python under the GPL. All Python licenses, unlike the GPL, let you distribute a modified version without making your changes open source. The GPL-compatible licenses make it possible to combine Python with other software that is released under the GPL; the others don't.

Thanks to the many outside volunteers who have worked under Guido's direction to make these releases possible.
A.2 Terms and conditions for accessing or otherwise using Python

PSF LICENSE AGREEMENT FOR PYTHON 2.5

1. This LICENSE AGREEMENT is between the Python Software Foundation ("PSF"), and the Individual or Organization ("Licensee") accessing and otherwise using Python 2.5 software in source or binary form and its associated documentation.

2. Subject to the terms and conditions of this License Agreement, PSF hereby grants Licensee a nonexclusive, royalty-free, world-wide license to reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use Python 2.5 alone or in any derivative version, provided, however, that PSF's License Agreement and PSF's notice of copyright, i.e., "Copyright © 2001-2006 Python Software Foundation; All Rights Reserved" are retained in Python 2.5 alone or in any derivative version prepared by Licensee.

3. In the event Licensee prepares a derivative work that is based on or incorporates Python 2.5 or any part thereof, and wants to make the derivative work available to others as provided herein, then Licensee hereby agrees to include in any such work a brief summary of the changes made to Python 2.5.

4. PSF is making Python 2.5 available to Licensee on an "AS IS" basis. PSF MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT LIMITATION, PSF MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF PYTHON 2.5 WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.

5. PSF SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS
OF PYTHON 2.5 FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF MODIFYING, DISTRIBUTING, OR OTHERWISE USING PYTHON 2.5, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.

6. This License Agreement will automatically terminate upon a material breach of its terms and conditions.

7. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between PSF and Licensee. This License Agreement does not grant permission to use PSF trademarks or trade name in a trademark sense to endorse or promote products or services of Licensee, or any third party.

8. By copying, installing or otherwise using Python 2.5, Licensee agrees to be bound by the terms and conditions of this License Agreement.

BEOPEN.COM LICENSE AGREEMENT FOR PYTHON 2.0

BEOPEN PYTHON OPEN SOURCE LICENSE AGREEMENT VERSION 1

1. This LICENSE AGREEMENT is between BeOpen.com (``BeOpen''), having an office at 160 Saratoga Avenue, Santa Clara, CA 95051, and the Individual or Organization (``Licensee'') accessing and otherwise using this software in source or binary form and its associated documentation (``the Software '').

2. Subject to the terms and conditions of this BeOpen Python License Agreement, BeOpen hereby grants Licensee a non-exclusive, royalty-free, world-wide license to reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use the Software alone or in any derivative version, provided, however, that the BeOpen Python License is retained in the Software, alone or in any derivative version prepared by Licensee.

3. BeOpen is making the Software available to Licensee on an ``AS IS'' basis. BEOPEN MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT
LIMITATION, BEOPEN MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF THE SOFTWARE WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.

4. BEOPEN SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS OF THE SOFTWARE FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF USING, MODIFYING OR DISTRIBUTING THE SOFTWARE, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.

5. This License Agreement will automatically terminate upon a material breach of its terms and conditions.

6. This License Agreement shall be governed by and interpreted in all respects by the law of the State of California, excluding conflict of law provisions. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between BeOpen and Licensee. This License Agreement does not grant permission to use BeOpen trademarks or trade names in a trademark sense to endorse or promote products or services of Licensee, or any third party. As an exception, the ``BeOpen Python'' logos available at http://www.pythonlabs.com/logos.html may be used according to the permissions granted on that web page.

7. By copying, installing or otherwise using the software, Licensee agrees to be bound by the terms and conditions of this License Agreement.

CNRI LICENSE AGREEMENT FOR PYTHON 1.6.1

1. This LICENSE AGREEMENT is between the Corporation for National Research Initiatives, having an office at 1895 Preston White Drive, Reston, VA 20191 (``CNRI''), and the Individual or Organization (``Licensee'') accessing and otherwise using Python 1.6.1 software in source or binary form and its associated documentation.

2. Subject to the terms and conditions of this License Agreement, CNRI hereby grants Licensee a nonexclusive, royalty-free, world-wide license to
reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use Python 1.6.1 alone or in any derivative version, provided, however, that CNRI's License Agreement and CNRI's notice of copyright, i.e., "Copyright © 1995-2001 Corporation for National Research Initiatives; All Rights Reserved" are retained in Python 1.6.1 alone or in any derivative version prepared by Licensee. Alternately, in lieu of CNRI's License Agreement, Licensee may substitute the following text (omitting the quotes): ``Python 1.6.1 is made available subject to the terms and conditions in CNRI's License Agreement. This Agreement together with Python 1.6.1 may be located on the Internet using the following unique, persistent identifier (known as a handle): 1895.22/1013. This Agreement may also be obtained from a proxy server on the Internet using the following URL: http://hdl.handle.net/1895.22/1013.''

3. In the event Licensee prepares a derivative work that is based on or incorporates Python 1.6.1 or any part thereof, and wants to make the derivative work available to others as provided herein, then Licensee hereby agrees to include in any such work a brief summary of the changes made to Python 1.6.1.

4. CNRI is making Python 1.6.1 available to Licensee on an ``AS IS'' basis. CNRI MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT LIMITATION, CNRI MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF PYTHON 1.6.1 WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.

5. CNRI SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS OF PYTHON 1.6.1 FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF MODIFYING, DISTRIBUTING, OR OTHERWISE USING PYTHON 1.6.1, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.

6. This License Agreement will automatically terminate upon a material breach of its terms and conditions.

7. This License Agreement shall be governed by the federal intellectual
property law of the United States, including without limitation the federal copyright law, and, to the extent such U.S. federal law does not apply, by the law of the Commonwealth of Virginia, excluding Virginia's conflict of law provisions. Notwithstanding the foregoing, with regard to derivative works based on Python 1.6.1 that incorporate non-separable material that was previously distributed under the GNU General Public License (GPL), the law of the Commonwealth of Virginia shall govern this License Agreement only as to issues arising under or with respect to Paragraphs 4, 5, and 7 of this License Agreement. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between CNRI and Licensee. This License Agreement does not grant permission to use CNRI trademarks or trade name in a trademark sense to endorse or promote products or services of Licensee, or any third party.

8. By clicking on the ``ACCEPT" button where indicated, or by copying, installing or otherwise using Python 1.6.1, Licensee agrees to be bound by the terms and conditions of this License Agreement.

ACCEPT

CWI LICENSE AGREEMENT FOR PYTHON 0.9.0 THROUGH 1.2

A.3 Licenses and Acknowledgements for Incorporated Software

This section is an incomplete, but growing list of licenses and acknowledgements for third-party software incorporated in the Python distribution.

Subsections

- A.3.1 Mersenne Twister
- A.3.2 Sockets
- A.3.3 Floating point exception control
- A.3.4 MD5 message digest algorithm
- A.3.5 Asynchronous socket services
- A.3.6 Cookie management
- A.3.7 Profiling
- A.3.8 Execution tracing
- A.3.9 UUencode and UUdecode functions
- A.3.10 XML Remote Procedure Calls

Macintosh Library Modules

Previous: A.2 Terms and conditions Up: A. History and License Next: A.3.1 Mersenne Twister

Release 2.5, documentation updated on 19th September, 2006.
See About this document.. for information on suggesting changes.
A.3.1 Mersenne Twister

The _random module includes code based on a download from http://www.math.keio.ac.jp/~matumoto/MT2002/emt19937ar.html. The following are the verbatim comments from the original code:

A C-program for MT19937, with initialization improved 2002/1/26. Coded by Takuji Nishimura and Makoto Matsumoto.

Before using, initialize the state by using init_genrand(seed) or init_by_array(init_key, key_length).

Copyright (C) 1997 - 2002, Makoto Matsumoto and Takuji Nishimura, All rights reserved.

Redistribution and use in source and binary forms, with or without modification, are permitted provided that the following conditions are met:

1. Redistributions of source code must retain the above copyright notice, this list of conditions and the following disclaimer.

2. Redistributions in binary form must reproduce the above copyright notice, this list of conditions and the following disclaimer in documentation and/or other materials provided with the distribution.

3. The names of its contributors may not be used to endorse or promote products derived from this software without specific prior written permission.

THIS SOFTWARE IS PROVIDED BY THE COPYRIGHT HOLDERS AND CONTRIBUTORS "AS IS" AND ANY EXPRESS OR IMPLIED WARRANTIES, INCLUDING, BUT NOT LIMITED TO, THE IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS FOR A PARTICULAR PURPOSE ARE DISCLAIMED. IN NO EVENT SHALL THE COPYRIGHT CONTRIBUTORS BE LIABLE FOR ANY DIRECT, INDIRECT, INCIDENTAL, SPECIAL EXEMPLARY, OR CONSEQUENTIAL DAMAGES (INCLUDING, BUT NOT LIMITED TO, PROCUREMENT OF SUBSTITUTE GOODS OR SERVICES; LOSS OF USE, DATA, OR PROFITS; OR BUSINESS INTERRUPTION) HOWEVER CAUSED AND ON ANY THEORY LIABILITY, WHETHER IN CONTRACT, STRICT LIABILITY, OR TORT (INCLUDING NEGLIGENCE OR OTHERWISE) ARISING IN ANY WAY OUT OF THE USE OF THIS SOFTWARE, EVEN IF ADVISED OF THE POSSIBILITY OF SUCH DAMAGE.

Any feedback is very welcome.

email: matumoto@math.keio.ac.jp
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
A.3.2 Sockets

The socket module uses the functions, `getaddrinfo`, and `getnameinfo`, which are coded in separate source files from the WIDE Project, [http://www.wide.ad.jp/about/index.html](http://www.wide.ad.jp/about/index.html).

All rights reserved.

Redistribution and use in source and binary forms, with or without modification, are permitted provided that the following conditions are met:
1. Redistributions of source code must retain the above copyright notice, this list of conditions and the following disclaimer.
2. Redistributions in binary form must reproduce the above copyright notice, this list of conditions and the following disclaimer in the documentation and/or other materials provided with the distribution.
3. Neither the name of the project nor the names of its contributors may be used to endorse or promote products derived from this software without specific prior written permission.

THIS SOFTWARE IS PROVIDED BY THE PROJECT AND CONTRIBUTORS "AS IS" AND ANY EXPRESS OR IMPLIED WARRANTIES, INCLUDING, BUT NOT LIMITED TO IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS FOR A PARTICULAR PURPOSE ARE DISCLAIMED. IN NO EVENT SHALL THE PROJECT OR CONTRIBUTORS BE LIABLE FOR ANY DIRECT, INDIRECT, INCIDENTAL, SPECIAL, EXEMPLARY, OR CONSEQUENTIAL DAMAGES (INCLUDING, BUT NOT LIMITED TO, PROCUREMENT OF SUBSTITUTE GOODS OR SERVICES; LOSS OF USE, DATA, OR PROFITS; OR BUSINESS INTERRUPTION) HOWEVER CAUSED AND ON ANY THEORY OF LIABILITY, WHETHER IN CONTRACT, STRICT LIABILITY, OR TORT (INCLUDING NEGLIGENCE OR OTHERWISE) ARISING IN ANY WAY OUT OF THE USE OF THIS SOFTWARE, EVEN IF ADVISED OF THE POSSIBILITY OF SUCH DAMAGE.
A.3.3 Floating point exception control

The source for the fpectl module includes the following notice:

---------------------------------------------------------------------
/ Copyright (c) 1996.
The Regents of the University of California.
All rights reserved.

Permission to use, copy, modify, and distribute this software
any purpose without fee is hereby granted, provided that this
tire notice is included in all copies of any software which i
cludes a copy or modification of this software and in
copies of the supporting documentation for such software.

This work was produced at the University of California, Lawr
Livermore National Laboratory under contract no. W-7405-EN
between the U.S. Department of Energy and The Regents of
University of California for the operation of UC LLNL.

MD5 message digest

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
A.3.4 MD5 message digest algorithm

The source code for the md5 module contains the following notice:

Copyright (C) 1999, 2002 Aladdin Enterprises. All rights reserved

This software is provided 'as-is', without any express or implied warranty. In no event will the authors be held liable for any damages arising from the use of this software.

Permission is granted to anyone to use this software for any purpose including commercial applications, and to alter it and redistribute it freely, subject to the following restrictions:

1. The origin of this software must not be misrepresented; you must claim that you wrote the original software. If you use this software in a product, an acknowledgment in the product documentation would be appreciated but is not required.
2. Altered source versions must be plainly marked as such, and must not be misrepresented as being the original software.
3. This notice may not be removed or altered from any source distribution.

L. Peter Deutsch
ghost@aladdin.com

Independent implementation of MD5 (RFC 1321).

This code implements the MD5 Algorithm defined in RFC 1321, whose text is available at

http://www.ietf.org/rfc/rfc1321.txt

The code is derived from the text of the RFC, including the test suite (section A.5) but excluding the rest of Appendix A. It does not include any code or documentation that is identified in the RFC as being copyrighted.

The original and principal author of md5.h is L. Peter Deutsch <ghost@aladdin.com>. Other authors are noted in the change history that follows (in reverse chronological order):

2002-04-13 lpd Removed support for non-ANSI compilers; removed references to Ghostscript; clarified derivation from RFC 132.
2001-12-08 lpd Fixed typo in header comment (ansi2knr rather than ansi2knr).
2000-10-18 lpd Fixed typo in header comment (ansi2knr rather than ansi2knr).
1999-11-04 lpd Edited comments slightly for automatic TOC extraction.
1999-10-18 lpd Added conditionalization for C++ compilation from Martin Purschke <purschke@bnl.gov>.
1999-05-03 lpd Original version.
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
A.3.5 Asynchronous socket services

The asynchat and asyncore modules contain the following notice:

Copyright 1996 by Sam Rushing

All Rights Reserved

Permission to use, copy, modify, and distribute this software and its documentation for any purpose and without fee is hereby granted, provided that the above copyright notice appear in all copies and that both that copyright notice and this permission notice appear in supporting documentation, and that the name of Sam Rushing not be used in advertising or publicity pertaining to distribution of the software without specific, written prior permission.

SAM RUSHING DISCLAIMS ALL WARRANTIES WITH REGARD TO THIS SOFTWARE, INCLUDING ALL IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS, IN NO EVENT SHALL SAM RUSHING BE LIABLE FOR ANY SPECIAL, INDIRECT OR CONSEQUENTIAL DAMAGES OR ANY DAMAGES WHATSOEVER RESULTING FROM LOSS OF USE, DATA OR PROFITS, WHETHER IN AN ACTION OF CONTRACT, NEGLIGENCE OR OTHER TORTIOUS ACTION, ARISING OUT OF OR IN CONNECTION WITH THE USE OR PERFORMANCE OF THIS SOFTWARE.
A.3.6 Cookie management

The Cookie module contains the following notice:

Copyright 2000 by Timothy O'Malley <timo@alum.mit.edu>

All Rights Reserved

Permission to use, copy, modify, and distribute this software and its documentation for any purpose and without fee is hereby granted, provided that the above copyright notice appear in all copies and that both that copyright notice and this permission notice appear in supporting documentation, and that the name of Timothy O'Malley not be used in advertising or publicity pertaining to distribution of the software without specific, written prior permission.

Timothy O'Malley DISCLAIMS ALL WARRANTIES WITH REGARD TO THIS SOFTWARE, INCLUDING ALL IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS, IN NO EVENT SHALL Timothy O'Malley BE LIABLE FOR ANY SPECIAL, INDIRECT OR CONSEQUENTIAL DAMAGES OR ANY DAMAGES WHATSOEVER RESULTING FROM LOSS OF USE, DATA OR PROFITS, WHETHER IN AN ACTION OF CONTRACT, NEGLIGENCE OR OTHER TORTIOUS ACTION, ARISING OUT OF OR IN CONNECTION WITH THE USE OR PERFORMANCE OF THIS SOFTWARE.
A.3.7 Profiling

The profile and pstats modules contain the following notice:

Copyright 1994, by InfoSeek Corporation, all rights reserved.
Written by James Roskind

Permission to use, copy, modify, and distribute this Python software and its associated documentation for any purpose (subject to the restriction in the following sentence) without fee is hereby granted provided that the above copyright notice appears in all copies, and that both that copyright notice and this permission notice appear supporting documentation, and that the name of InfoSeek not be used advertising or publicity pertaining to distribution of the software without specific, written prior permission. This permission is explicitly restricted to the copying and modification of the software to remain in Python, compiled Python, or other languages (such as C wherein the modified or derived code is exclusively imported into a Python module.

INFOSEEK CORPORATION DISCLAIMS ALL WARRANTIES WITH REGARD TO THIS SOFTWARE, INCLUDING ALL IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS. IN NO EVENT SHALL INFOSEEK CORPORATION BE LIABLE FOR ANY SPECIAL, INDIRECT OR CONSEQUENTIAL DAMAGES OR ANY DAMAGES WHATSOEVER RESULTING FROM LOSS OF USE, DATA OR PROFITS, WHETHER IN AN ACTION OF CONTRACT, NEGLIGENCE OR OTHER TORTIOUS ACTION, ARISING OUT OF OR IN CONNECTION WITH THE USE OR PERFORMANCE OF THIS SOFTWARE.
A.3.8 Execution tracing

The `trace` module contains the following notice:

```python
portions copyright 2001, Autonomous Zones Industries, Inc., all rig
err... reserved and offered to the public under the terms of the
Python 2.2 license.
Author: Zooko O'Whielacronx
http://zooko.com/

```

Permission to use, copy, modify, and distribute this Python softwar
its associated documentation for any purpose without fee is hereby
ganted, provided that the above copyright notice appears in all co
and that both that copyright notice and this permission notice appe
supporting documentation, and that the name of neither Automatrix,
Bioreason or Mojam Media be used in advertising or publicity pertai
distribution of the software without specific, written prior permis
A.3.9 UUencode and UUdecode functions

The uu module contains the following notice:

Copyright 1994 by Lance Ellinghouse
Cathedral City, California Republic, United States of America.
All Rights Reserved
Permission to use, copy, modify, and distribute this software and its documentation for any purpose and without fee is hereby granted, provided that the above copyright notice appear in all copies and both that copyright notice and this permission notice appear in supporting documentation, and that the name of Lance Ellinghouse not be used in advertising or publicity pertaining to distribution of the software without specific, written prior permission.
LANCE ELLINGHOUSE DISCLAIMS ALL WARRANTIES WITH REGARD TO
THIS SOFTWARE, INCLUDING ALL IMPLIED WARRANTIES OF MERCHANTABILITY
FITNESS, IN NO EVENT SHALL LANCE ELLINGHOUSE CENTRUM BE LIABLE
FOR ANY SPECIAL, INDIRECT OR CONSEQUENTIAL DAMAGES OR ANY DAMAGES
 WHATSOEVER RESULTING FROM LOSS OF USE, DATA OR PROFITS, WHETHER IN
ACTION OF CONTRACT, NEGLIGENCE OR OTHER TORTIOUS ACTION, ARISING OUT
OF OR IN CONNECTION WITH THE USE OR PERFORMANCE OF THIS SOFTWARE.

Modified by Jack Jansen, CWI, July 1995:
- Use binascii module to do the actual line-by-line conversion
  between ascii and binary. This results in a 1000-fold speedup. Th
  version is still 5 times faster, though.
- Arguments more compliant with python standard
A.3.10 XML Remote Procedure Calls

The xmlrpclib module contains the following notice:

The XML-RPC client interface is

Copyright (c) 1999-2002 by Secret Labs AB
Copyright (c) 1999-2002 by Fredrik Lundh

By obtaining, using, and/or copying this software and/or its associated documentation, you agree that you have read, understood, and will comply with the following terms and conditions:

Permission to use, copy, modify, and distribute this software and its associated documentation for any purpose and without fee is hereby granted, provided that the above copyright notice appears in all copies, and that both that copyright notice and this permission notice appear in supporting documentation, and that the name of Secret Labs AB or the author not be used in advertising or publicit pertaining to distribution of the software without specific, written prior permission.

SECRET LABS AB AND THE AUTHOR DISCLAIMS ALL WARRANTIES WITH REGARD TO THIS SOFTWARE, INCLUDING ALL IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS. IN NO EVENT SHALL SECRET LABS AB OR THE AUTHOR BE LIABLE FOR ANY SPECIAL, INDIRECT OR CONSEQUENTIAL DAMAGES OR ANY DAMAGES WHATSOEVER RESULTING FROM LOSS OF USE, DATA OR PROFITS, WHETHER IN AN ACTION OF CONTRACT, NEGLIGENCE OR OTHER TORTIOUS ACTION, ARISING OUT OF OR IN CONNECTION WITH THE USE OR PERFORMANCE OF THIS SOFTWARE.

1. Extending Python with C or C++

It is quite easy to add new built-in modules to Python, if you know how to program in C. Such extension modules can do two things that can't be done directly in Python: they can implement new built-in object types, and they can call C library functions and system calls.

To support extensions, the Python API (Application Programmers Interface) defines a set of functions, macros and variables that provide access to most aspects of the Python run-time system. The Python API is incorporated in a C source file by including the header "Python.h".

The compilation of an extension module depends on its intended use as well as on your system setup; details are given in later chapters.

See About this document... for information on suggesting changes.
1.1 A Simple Example

Let's create an extension module called "spam" (the favorite food of Monty Python fans...) and let's say we want to create a Python interface to the C library function `system()`. This function takes a null-terminated character string as argument and returns an integer. We want this function to be callable from Python as follows:

```python
>>> import spam
>>> status = spam.system("ls -l")
```

Begin by creating a file `spammodule.c`. (Historically, if a module is called "spam", the C file containing its implementation is called `spammodule.c`; if the module name is very long, like "spammify", the module name can be just `spammify.c`.)

The first line of our file can be:

```c
#include <Python.h>
```

which pulls in the Python API (you can add a comment describing the purpose of the module and a copyright notice if you like).

**Warning:** Since Python may define some pre-processor definitions which affect the standard headers on some systems, you must include `Python.h` before any standard headers are included.

All user-visible symbols defined by `Python.h` have a prefix of "Py" or "PY", except those defined in standard header files. For convenience, and since they are used extensively by the Python interpreter, "Python.h" includes a few standard header files: `<stdio.h>`, `<string.h>`, `<errno.h>`, and `<stdlib.h>`. If the latter header file does not exist on your system, it declares the functions `malloc()`, `free()` and `realloc()` directly.

The next thing we add to our module file is the C function that will be called
when the Python expression "spam.system(string)" is evaluated (we'll see shortly how it ends up being called):

```c
static PyObject *
spam_system(PyObject *self, PyObject *args)
{
    const char *command;
    int sts;

    if (!PyArg_ParseTuple(args, "s", &command))
        return NULL;
    sts = system(command);
    return Py_BuildValue("i", sts);
}
```

There is a straightforward translation from the argument list in Python (for example, the single expression "ls -l") to the arguments passed to the C function. The C function always has two arguments, conventionally named `self` and `args`.

The `self` argument is only used when the C function implements a built-in method, not a function. In the example, `self` will always be a NULL pointer, since we are defining a function, not a method. (This is done so that the interpreter doesn't have to understand two different types of C functions.)

The `args` argument will be a pointer to a Python tuple object containing the arguments. Each item of the tuple corresponds to an argument in the call's argument list. The arguments are Python objects -- in order to do anything with them in our C function we have to convert them to C values. The function `PyArg_ParseTuple() ` in the Python API checks the argument types and converts them to C values. It uses a template string to determine the required types of the arguments as well as the types of the C variables into which to store the converted values. More about this later.

`PyArg_ParseTuple() ` returns true (nonzero) if all arguments have the right type and its components have been stored in the variables whose addresses are passed. It returns false (zero) if an invalid argument list was passed. In the latter case it also raises an appropriate exception so the calling function can return NULL immediately (as we saw in the example).
Footnotes

...system().\footnote{1.1}

An interface for this function already exists in the standard module os -- it was chosen as a simple and straightforward example.
1.2 Intermezzo: Errors and Exceptions

An important convention throughout the Python interpreter is the following: when a function fails, it should set an exception condition and return an error value (usually a NULL pointer). Exceptions are stored in a static global variable inside the interpreter; if this variable is NULL no exception has occurred. A second global variable stores the “associated value” of the exception (the second argument to raise). A third variable contains the stack traceback in case the error originated in Python code. These three variables are the C equivalents of the Python variables sys.exc_type, sys.exc_value and sys.exc_traceback (see the section on module sys in the Python Library Reference). It is important to know about them to understand how errors are passed around.

The Python API defines a number of functions to set various types of exceptions.

The most common one is PyErr_SetString(). Its arguments are an exception object and a C string. The exception object is usually a predefined object like PyExc_ZeroDivisionError. The C string indicates the cause of the error and is converted to a Python string object and stored as the “associated value” of the exception.

Another useful function is PyErr_SetFromErrno(), which only takes an exception argument and constructs the associated value by inspection of the global variable errno. The most general function is PyErr_SetObject(), which takes two object arguments, the exception and its associated value. You don't need to Py_INCREF() the objects passed to any of these functions.

You can test non-destructively whether an exception has been set with PyErr_Occurred(). This returns the current exception object, or NULL if no exception has occurred. You normally don't need to call PyErr_Occurred() to see whether an error occurred in a function call, since you should be able to tell from the return value.

When a function \( f \) that calls another function \( g \) detects that the latter fails, \( f \)
should itself return an error value (usually NULL or -1). It should not call one of
the PyErr_*() functions -- one has already been called by g. f's caller is then
supposed to also return an error indication to its caller, again without calling
PyErr_*(), and so on -- the most detailed cause of the error was already
reported by the function that first detected it. Once the error reaches the Python
interpreter's main loop, this aborts the currently executing Python code and tries
to find an exception handler specified by the Python programmer.

(There are situations where a module can actually give a more detailed error
message by calling another PyErr_*() function, and in such cases it is fine to
do so. As a general rule, however, this is not necessary, and can cause
information about the cause of the error to be lost: most operations can fail for a
variety of reasons.)

To ignore an exception set by a function call that failed, the exception condition
must be cleared explicitly by calling PyErr_Clear(). The only time C code
should call PyErr_Clear() is if it doesn't want to pass the error on to the
interpreter but wants to handle it completely by itself (possibly by trying
something else, or pretending nothing went wrong).

Every failing malloc() call must be turned into an exception -- the direct
caller of malloc() (or realloc()) must call PyErr_NoMemory() and
return a failure indicator itself. All the object-creating functions (for example,
PyInt_FromLong()) already do this, so this note is only relevant to those
who call malloc() directly.

Also note that, with the important exception of PyArg_ParseTuple() and
friends, functions that return an integer status usually return a positive value or
zero for success and -1 for failure, like UNIX system calls.

Finally, be careful to clean up garbage (by making Py_XDECREF() or
Py_DECREF() calls for objects you have already created) when you return an
error indicator!

The choice of which exception to raise is entirely yours. There are predeclared C
objects corresponding to all built-in Python exceptions, such as
PyExc_ZeroDivisionError, which you can use directly. Of course, you
should choose exceptions wisely -- don't use PyExc_TypeError to mean that
a file couldn't be opened (that should probably be PyExc_IOError). If
something's wrong with the argument list, the PyArg_ParseTuple() function usually raises PyExc_TypeError. If you have an argument whose value must be in a particular range or must satisfy other conditions, PyExc_ValueError is appropriate.

You can also define a new exception that is unique to your module. For this, you usually declare a static object variable at the beginning of your file:

```c
static PyObject *SpamError;
```

and initialize it in your module's initialization function (initspam()) with an exception object (leaving out the error checking for now):

```c
PyMODINIT_FUNC
initspam(void)
{
    PyObject *m;

    m = Py_InitModule("spam", SpamMethods);
    SpamError = PyErr_NewException("spam.error", NULL, NULL);
    Py_INCREF(SpamError);
    PyModule_AddObject(m, "error", SpamError);
}
```

Note that the Python name for the exception object is spam.error. The PyErr_NewException() function may create a class with the base class being Exception (unless another class is passed in instead of NULL), described in the Python Library Reference under ```Built-in Exceptions.''

Note also that the SpamError variable retains a reference to the newly created exception class; this is intentional! Since the exception could be removed from the module by external code, an owned reference to the class is needed to ensure that it will not be discarded, causing SpamError to become a dangling pointer. Should it become a dangling pointer, C code which raises the exception could cause a core dump or other unintended side effects.

We discuss the use of PyMODINIT_FUNC as a function return type later in this sample.
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
1.3 Back to the Example

Going back to our example function, you should now be able to understand this statement:

```c
if (!PyArg_ParseTuple(args, "s", &command))
    return NULL;
```

It returns NULL (the error indicator for functions returning object pointers) if an error is detected in the argument list, relying on the exception set by `PyArg_ParseTuple()`. Otherwise the string value of the argument has been copied to the local variable `command`. This is a pointer assignment and you are not supposed to modify the string to which it points (so in Standard C, the variable `command` should properly be declared as "const char *command").

The next statement is a call to the UNIX function `system()`, passing it the string we just got from `PyArg_ParseTuple()`:

```c
sts = system(command);
```

Our `spam.system()` function must return the value of `sts` as a Python object. This is done using the function `Py_BuildValue()`, which is something like the inverse of `PyArg_ParseTuple()`: it takes a format string and an arbitrary number of C values, and returns a new Python object. More info on `Py_BuildValue()` is given later.

```c
return Py_BuildValue("i", sts);
```

In this case, it will return an integer object. (Yes, even integers are objects on the heap in Python!)

If you have a C function that returns no useful argument (a function returning `void`), the corresponding Python function must return `None`. You need this idiom to do so (which is implemented by the `Py_RETURN_NONE` macro):

```c
Py_INCREF(Py_None);
return Py_None;
```
Py_None is the C name for the special Python object None. It is a genuine Python object rather than a NULL pointer, which means ``error'' in most contexts, as we have seen.
1.4 The Module's Method Table and Initialization Function

I promised to show how spam_system() is called from Python programs. First, we need to list its name and address in a `method table`:

```c
static PyMethodDef SpamMethods[] = {
    ...
    {"system", spam_system, METH_VARARGS,
    "Execute a shell command."},
    ...
    {NULL, NULL, 0, NULL} /* Sentinel */
};
```

Note the third entry ("METH_VARARGS"). This is a flag telling the interpreter the calling convention to be used for the C function. It should normally always be "METH_VARARGS" or "METH_VARARGS | METH_KEYWORDS"; a value of 0 means that an obsolete variant of PyArg_ParseTuple() is used.

When using only "METH_VARARGS", the function should expect the Python-level parameters to be passed in as a tuple acceptable for parsing via PyArg_ParseTuple(); more information on this function is provided below.

The METH_KEYWORDS bit may be set in the third field if keyword arguments should be passed to the function. In this case, the C function should accept a third "PyObject **" parameter which will be a dictionary of keywords. Use PyArg_ParseTupleAndKeywords() to parse the arguments to such a function.

The method table must be passed to the interpreter in the module's initialization function. The initialization function must be named initname(), where name is the name of the module, and should be the only non-static item defined in the module file:

```c
PyMODINIT_FUNC
initspam(void)
{
    (void) Py_InitModule("spam", SpamMethods);
}
```
Note that PyMODINIT_FUNC declares the function as void return type, declares any special linkage declarations required by the platform, and for C++ declares the function as extern "C".

When the Python program imports module spam for the first time, \texttt{initspam()} is called. (See below for comments about embedding Python.) It calls \texttt{Py_InitModule()}, which creates a ``module object'' (which is inserted in the dictionary \texttt{sys.modules} under the key "spam"), and inserts built-in function objects into the newly created module based upon the table (an array of \texttt{PyMethodDef} structures) that was passed as its second argument. \texttt{Py_InitModule()} returns a pointer to the module object that it creates (which is unused here). It aborts with a fatal error if the module could not be initialized satisfactorily, so the caller doesn't need to check for errors.

When embedding Python, the \texttt{initspam()} function is not called automatically unless there's an entry in the \_\texttt{PyImport_Inittab} table. The easiest way to handle this is to statically initialize your statically-linked modules by directly calling \texttt{initspam()} after the call to \texttt{Py_Initialize()}:

```c
int main(int argc, char *argv[])
{
    /* Pass argv[0] to the Python interpreter */
    Py_SetProgramName(argv[0]);

    /* Initialize the Python interpreter. Required. */
    Py_Initialize();

    /* Add a static module */
    initspam();
}
```

An example may be found in the file \texttt{Demo/embed/demo.c} in the Python source distribution.

\textbf{Note:} Removing entries from \texttt{sys.modules} or importing compiled modules into multiple interpreters within a process (or following a \texttt{fork()} without an intervening \texttt{exec()}) can create problems for some extension modules. Extension module authors should exercise caution when initializing internal data structures. Note also that the \texttt{reload()} function can be used with extension modules, and will call the module initialization function (\texttt{initspam()} in the example), but will not load the module again if it was loaded from a dynamically
loadable object file (.so on UNIX, .dll on Windows).

A more substantial example module is included in the Python source distribution as Modules/xxmodule.c. This file may be used as a template or simply read as an example. The modulator.py script included in the source distribution or Windows install provides a simple graphical user interface for declaring the functions and objects which a module should implement, and can generate a template which can be filled in. The script lives in the Tools/modulator/ directory; see the README file there for more information.
1.5 Compilation and Linkage

There are two more things to do before you can use your new extension: compiling and linking it with the Python system. If you use dynamic loading, the details may depend on the style of dynamic loading your system uses; see the chapters about building extension modules (chapter 3) and additional information that pertains only to building on Windows (chapter 4) for more information about this.

If you can't use dynamic loading, or if you want to make your module a permanent part of the Python interpreter, you will have to change the configuration setup and rebuild the interpreter. Luckily, this is very simple on UNIX: just place your file (spammodule.c for example) in the Modules/ directory of an unpacked source distribution, add a line to the file Modules/Setup.local describing your file:

```
spam spammodule.o
```

and rebuild the interpreter by running `make` in the toplevel directory. You can also run `make` in the Modules/ subdirectory, but then you must first rebuild Makefile there by running `make Makefile`. (This is necessary each time you change the Setup file.)

If your module requires additional libraries to link with, these can be listed on the line in the configuration file as well, for instance:

```
spam spammodule.o -lX11
```
1.6 Calling Python Functions from C

So far we have concentrated on making C functions callable from Python. The reverse is also useful: calling Python functions from C. This is especially the case for libraries that support so-called ``callback'' functions. If a C interface makes use of callbacks, the equivalent Python often needs to provide a callback mechanism to the Python programmer; the implementation will require calling the Python callback functions from a C callback. Other uses are also imaginable.

Fortunately, the Python interpreter is easily called recursively, and there is a standard interface to call a Python function. (I won't dwell on how to call the Python parser with a particular string as input -- if you're interested, have a look at the implementation of the -c command line option in Python/pythonmain.c from the Python source code.)

Calling a Python function is easy. First, the Python program must somehow pass you the Python function object. You should provide a function (or some other interface) to do this. When this function is called, save a pointer to the Python function object (be careful to Py_INCREF() it!) in a global variable -- or wherever you see fit. For example, the following function might be part of a module definition:

```c
static PyObject *my_callback = NULL;

static PyObject *
my_set_callback(PyObject *dummy, PyObject *args)
{
    PyObject *result = NULL;
    PyObject *temp;

    if (PyArg_ParseTuple(args, "O:set_callback", &temp)) {
        if (!PyCallable_Check(temp)) {
            PyErr_SetString(PyExc_TypeError, "parameter must be callable");
            return NULL;
        }
        Py_XINCREF(temp); /* Add a reference to new callback
        Py_XDECREF(my_callback); /* Dispose of previous callback */
        my_callback = temp; /* Remember new callback */
        /* Boilerplate to return "None" */
        Py_INCREF(Py_None);
        result = Py_None;
    }
    return result;
}
```
return result;
}

This function must be registered with the interpreter using the METH_VARARGS flag; this is described in section 1.4, "The Module's Method Table and Initialization Function." The PyArg_ParseTuple() function and its arguments are documented in section 1.7, "Extracting Parameters in Extension Functions."

The macros Py_XINCREF() and Py_XDECREF() increment/decrement the reference count of an object and are safe in the presence of NULL pointers (but note that temp will not be NULL in this context). More info on them in section 1.10, "Reference Counts."

Later, when it is time to call the function, you call the C function PyEval_CallObject(). This function has two arguments, both pointers to arbitrary Python objects: the Python function, and the argument list. The argument list must always be a tuple object, whose length is the number of arguments. To call the Python function with no arguments, pass an empty tuple; to call it with one argument, pass a singleton tuple. Py_BuildValue() returns a tuple when its format string consists of zero or more format codes between parentheses. For example:

```c
int arg;
PyObject *arglist;
PyObject *result;
...
arg = 123;
...
/* Time to call the callback */
arglist = Py_BuildValue("(i)", arg);
result = PyEval_CallObject(my_callback, arglist);
Py_DECREF(arglist);
```

PyEval_CallObject() returns a Python object pointer: this is the return value of the Python function. PyEval_CallObject() is "reference-count-neutral" with respect to its arguments. In the example a new tuple was created to serve as the argument list, which is Py_DECREF()--ed immediately after the call.

The return value of PyEval_CallObject() is "new": either it is a brand new object, or it is an existing object whose reference count has been
incremented. So, unless you want to save it in a global variable, you should somehow `Py_DECREF()` the result, even (especially!) if you are not interested in its value.

Before you do this, however, it is important to check that the return value isn't `NULL`. If it is, the Python function terminated by raising an exception. If the C code that called `PyEval_CallObject()` is called from Python, it should now return an error indication to its Python caller, so the interpreter can print a stack trace, or the calling Python code can handle the exception. If this is not possible or desirable, the exception should be cleared by calling `PyErr_Clear()`. For example:

```c
if (result == NULL)
    return NULL; /* Pass error back */
...use result...
Py_DECREF(result);
```

Depending on the desired interface to the Python callback function, you may also have to provide an argument list to `PyEval_CallObject()`. In some cases the argument list is also provided by the Python program, through the same interface that specified the callback function. It can then be saved and used in the same manner as the function object. In other cases, you may have to construct a new tuple to pass as the argument list. The simplest way to do this is to call `Py_BuildValue()`. For example, if you want to pass an integral event code, you might use the following code:

```c
PyObject *arglist;
...arglist = Py_BuildValue("(l)", eventcode);
result = PyEval_CallObject(my_callback, arglist);
Py_DECREF(arglist);
if (result == NULL)
    return NULL; /* Pass error back */ /* Here maybe use the result */
Py_DECREF(result);
```

Note the placement of "`Py_DECREF(arglist)`" immediately after the call, before the error check! Also note that strictly spoken this code is not complete: `Py_BuildValue()` may run out of memory, and this should be checked.
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
1.7 Extracting Parameters in Extension Functions

The `PyArg_ParseTuple()` function is declared as follows:

```c
int PyArg_ParseTuple(PyObject *arg, char *format, ...);
```

The `arg` argument must be a tuple object containing an argument list passed from Python to a C function. The `format` argument must be a format string, whose syntax is explained in “Parsing arguments and building values” in the Python/C API Reference Manual. The remaining arguments must be addresses of variables whose type is determined by the format string.

Note that while `PyArg_ParseTuple()` checks that the Python arguments have the required types, it cannot check the validity of the addresses of C variables passed to the call: if you make mistakes there, your code will probably crash or at least overwrite random bits in memory. So be careful!

Note that any Python object references which are provided to the caller are borrowed references; do not decrement their reference count!

Some example calls:

```c
int ok;
int i, j;
long k, l;
const char *s;
int size;

ok = PyArg_ParseTuple(args, ""); /* No arguments */
     /* Python call: f() */

ok = PyArg_ParseTuple(args, "s", &s); /* A string */
     /* Possible Python call: f('whoops!') */

ok = PyArg_ParseTuple(args, "lls", &k, &l, &s); /* Two longs and */
     /* Possible Python call: f(1, 2, 'three') */

ok = PyArg_ParseTuple(args, "(ii)s#", &i, &j, &s, &size);
     /* A pair of ints and a string, whose size is also returned */
     /* Possible Python call: f((1, 2), 'three') */
```
const char *file;
const char *mode = "r";
int bufsize = 0;
ok = PyArg_ParseTuple(args, "s|si", &file, &mode, &bufsize);
/* A string, and optionally another string and an integer */
/* Possible Python calls:
   f('spam')
   f('spam', 'w')
   f('spam', 'wb', 100000) */
}

int left, top, right, bottom, h, v;
ok = PyArg_ParseTuple(args, "((ii)(ii))(ii)",
&left, &top, &right, &bottom, &h, &v);
/* A rectangle and a point */
/* Possible Python call:
   f(((0, 0), (400, 300)), (10, 10)) */
}

Py_complex c;
ok = PyArg_ParseTuple(args, "D:myfunction", &c);
/* a complex, also providing a function name for errors */
/* Possible Python call: myfunction(1+2j) */
1.8 Keyword Parameters for Extension Functions

The `PyArg_ParseTupleAndKeywords()` function is declared as follows:

```c
int PyArg_ParseTupleAndKeywords(PyObject *arg, PyObject *kwdict, char *format, char *kwlist[], ...);
```

The `arg` and `format` parameters are identical to those of the `PyArg_ParseTuple()` function. The `kwdict` parameter is the dictionary of keywords received as the third parameter from the Python runtime. The `kwlist` parameter is a NULL-terminated list of strings which identify the parameters; the names are matched with the type information from `format` from left to right. On success, `PyArg_ParseTupleAndKeywords()` returns true, otherwise it returns false and raises an appropriate exception.

**Note:** Nested tuples cannot be parsed when using keyword arguments! Keyword parameters passed in which are not present in the `kwlist` will cause `TypeError` to be raised.

Here is an example module which uses keywords, based on an example by Geoff Philbrick (philbrick@hks.com):

```c
#include "Python.h"

static PyObject *
keywdarg_parrot(PyObject *self, PyObject *args, PyObject *keywds)
{
    int voltage;
    char *state = "a stiff";
    char *action = "voom";
    char *type = "Norwegian Blue";

    static char *kwlist[] = {"voltage", "state", "action", "type", NULL};

    if (!PyArg_ParseTupleAndKeywords(args, keywds, "i|sss", kwlist, &voltage, &state, &action, &type))
        return NULL;

    printf("-- This parrot wouldn't %s if you put %i Volts through it.
           action, voltage);
    printf("-- Lovely plumage, the %s -- It's %s!
           type, state);
```
Py_INCREF(Py_None);
return Py_None;
}

static PyMethodDef keywdarg_methods[] = {
    /* The cast of the function is necessary since PyCFunction values
     * only take two PyObject* parameters, and keywdarg_parrot() takes
     * three.
     */
    {"parrot", (PyCFunction)keywdarg_parrot, METH_VARARGS | METH_KEYWORDS,
    "Print a lovely skit to standard output."},
    {NULL, NULL, 0, NULL} /* sentinel */
};

void
initkeywdarg(void)
{
    /* Create the module and add the functions */
    Py_InitModule("keywdarg", keywdarg_methods);
}
1.9 Building Arbitrary Values

This function is the counterpart to PyArg_ParseTuple(). It is declared as follows:

```
PyObject *Py_BuildValue(char *format, ...);
```

It recognizes a set of format units similar to the ones recognized by PyArg_ParseTuple(), but the arguments (which are input to the function, not output) must not be pointers, just values. It returns a new Python object, suitable for returning from a C function called from Python.

One difference with PyArg_ParseTuple(): while the latter requires its first argument to be a tuple (since Python argument lists are always represented as tuples internally), Py_BuildValue() does not always build a tuple. It builds a tuple only if its format string contains two or more format units. If the format string is empty, it returns None; if it contains exactly one format unit, it returns whatever object is described by that format unit. To force it to return a tuple of size 0 or one, parenthesize the format string.

Examples (to the left the call, to the right the resulting Python value):

```
Py_BuildValue(""")           None
Py_BuildValue("i", 123)      123
Py_BuildValue("iii", 123, 456, 789) (123, 456, 789)
Py_BuildValue("s", "hello")  "hello"
Py_BuildValue("ss", "hello", "world") ('hello', 'world')
Py_BuildValue("s#", "hello", 4)  'hell'
Py_BuildValue("()")          ()
Py_BuildValue("(i)", 123)     (123,)
Py_BuildValue("(ii)", 123, 456) (123, 456)
Py_BuildValue("(i,i)", 123, 456) (123, 456)
Py_BuildValue("[i,i]", 123, 456) [123, 456]
Py_BuildValue("{s,i:s:i}",  
     "abc", 123, "def", 456)  {'abc': 123, 'def': 456}
Py_BuildValue("((ii)(ii)) (ii)",
     1, 2, 3, 4, 5, 6)          (((1, 2), (3, 4)), (5, 6))
```

Extending and Embedding the Python Interpreter

1.10 Reference Counts

In languages like C or C++, the programmer is responsible for dynamic allocation and deallocation of memory on the heap. In C, this is done using the functions `malloc()` and `free()`. In C++, the operators `new` and `delete` are used with essentially the same meaning and we'll restrict the following discussion to the C case.

Every block of memory allocated with `malloc()` should eventually be returned to the pool of available memory by exactly one call to `free()`. It is important to call `free()` at the right time. If a block's address is forgotten but `free()` is not called for it, the memory it occupies cannot be reused until the program terminates. This is called a memory leak. On the other hand, if a program calls `free()` for a block and then continues to use the block, it creates a conflict with re-use of the block through another `malloc()` call. This is called using freed memory. It has the same bad consequences as referencing uninitialized data -- core dumps, wrong results, mysterious crashes.

Common causes of memory leaks are unusual paths through the code. For instance, a function may allocate a block of memory, do some calculation, and then free the block again. Now a change in the requirements for the function may add a test to the calculation that detects an error condition and can return prematurely from the function. It's easy to forget to free the allocated memory block when taking this premature exit, especially when it is added later to the code. Such leaks, once introduced, often go undetected for a long time: the error exit is taken only in a small fraction of all calls, and most modern machines have plenty of virtual memory, so the leak only becomes apparent in a long-running process that uses the leaking function frequently. Therefore, it's important to prevent leaks from happening by having a coding convention or strategy that minimizes this kind of errors.

Since Python makes heavy use of `malloc()` and `free()`, it needs a strategy to avoid memory leaks as well as the use of freed memory. The chosen method is called reference counting. The principle is simple: every object contains a counter, which is incremented when a reference to the object is stored somewhere, and which is decremented when a reference to it is deleted. When the counter reaches zero, the last reference to the object has been deleted and the
object is freed.

An alternative strategy is called *automatic garbage collection*. (Sometimes, reference counting is also referred to as a garbage collection strategy, hence my use of ``automatic'' to distinguish the two.) The big advantage of automatic garbage collection is that the user doesn't need to call `free()` explicitly. (Another claimed advantage is an improvement in speed or memory usage -- this is no hard fact however.) The disadvantage is that for C, there is no truly portable automatic garbage collector, while reference counting can be implemented portably (as long as the functions `malloc()` and `free()` are available -- which the C Standard guarantees). Maybe some day a sufficiently portable automatic garbage collector will be available for C. Until then, we'll have to live with reference counts.

While Python uses the traditional reference counting implementation, it also offers a cycle detector that works to detect reference cycles. This allows applications to not worry about creating direct or indirect circular references; these are the weakness of garbage collection implemented using only reference counting. Reference cycles consist of objects which contain (possibly indirect) references to themselves, so that each object in the cycle has a reference count which is non-zero. Typical reference counting implementations are not able to reclaim the memory belonging to any objects in a reference cycle, or referenced from the objects in the cycle, even though there are no further references to the cycle itself.

The cycle detector is able to detect garbage cycles and can reclaim them so long as there are no finalizers implemented in Python (`__del__()` methods). When there are such finalizers, the detector exposes the cycles through the `gc` module (specifically, the `garbage` variable in that module). The `gc` module also exposes a way to run the detector (the `collect()` function), as well as configuration interfaces and the ability to disable the detector at runtime. The cycle detector is considered an optional component; though it is included by default, it can be disabled at build time using the `--without-cycle-gc` option to the `configure` script on UNIX platforms (including Mac OS X) or by removing the definition of `WITH_CYCLE_GC` in the `pyconfig.h` header on other platforms. If the cycle detector is disabled in this way, the `gc` module will not be available.
1.10.1 Reference Counting in Python
1.10.2 Ownership Rules
1.10.3 Thin Ice
1.10.4 NULL Pointers

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
1.10.1 Reference Counting in Python

There are two macros, `Py_INCREF(x)` and `Py_DECREF(x)`, which handle the incrementing and decrementing of the reference count. `Py_DECREF()` also frees the object when the count reaches zero. For flexibility, it doesn't call `free()` directly -- rather, it makes a call through a function pointer in the object's type object. For this purpose (and others), every object also contains a pointer to its type object.

The big question now remains: when to use `Py_INCREF(x)` and `Py_DECREF(x)`? Let's first introduce some terms. Nobody "owns" an object; however, you can own a reference to an object. An object's reference count is now defined as the number of owned references to it. The owner of a reference is responsible for calling `Py_DECREF()` when the reference is no longer needed. Ownership of a reference can be transferred. There are three ways to dispose of an owned reference: pass it on, store it, or call `Py_DECREF()`. Forgetting to dispose of an owned reference creates a memory leak.

It is also possible to borrow a reference to an object. The borrower of a reference should not call `Py_DECREF()`. The borrower must not hold on to the object longer than the owner from which it was borrowed. Using a borrowed reference after the owner has disposed of it risks using freed memory and should be avoided completely.

The advantage of borrowing over owning a reference is that you don't need to take care of disposing of the reference on all possible paths through the code -- in other words, with a borrowed reference you don't run the risk of leaking when a premature exit is taken. The disadvantage of borrowing over leaking is that there are some subtle situations where in seemingly correct code a borrowed reference can be used after the owner from which it was borrowed has in fact disposed of it.

A borrowed reference can be changed into an owned reference by calling `Py_INCREF()`. This does not affect the status of the owner from which the reference was borrowed -- it creates a new owned reference, and gives full owner responsibilities (the new owner must dispose of the reference properly, as well as the previous owner).
Footnotes

...borrow\(^1\)\(^2\)

The metaphor of ``borrowing'' a reference is not completely correct: the owner still has a copy of the reference.

... completely.\(^1\)\(^3\)

Checking that the reference count is at least 1 does not work -- the reference count itself could be in freed memory and may thus be reused for another object!
1.10.2 Ownership Rules

Whenever an object reference is passed into or out of a function, it is part of the function's interface specification whether ownership is transferred with the reference or not.

Most functions that return a reference to an object pass on ownership with the reference. In particular, all functions whose function it is to create a new object, such as `PyInt_FromLong()` and `Py_BuildValue()`, pass ownership to the receiver. Even if the object is not actually new, you still receive ownership of a new reference to that object. For instance, `PyInt_FromLong()` maintains a cache of popular values and can return a reference to a cached item.

Many functions that extract objects from other objects also transfer ownership with the reference, for instance `PyObject_GetAttrString()`. The picture is less clear here, however, since a few common routines are exceptions: `PyTuple_GetItem()`, `PyList_GetItem()`, `PyDict_GetItem()`, and `PyDict_GetItemString()` all return references that you borrow from the tuple, list or dictionary.

The function `PyImport_AddModule()` also returns a borrowed reference, even though it may actually create the object it returns: this is possible because an owned reference to the object is stored in `sys.modules`.

When you pass an object reference into another function, in general, the function borrows the reference from you -- if it needs to store it, it will use `Py_INCREF()` to become an independent owner. There are exactly two important exceptions to this rule: ` PyTuple_SetItem()` and `PyList_SetItem()`. These functions take over ownership of the item passed to them -- even if they fail! (Note that `PyDict_SetItem()` and friends don't take over ownership -- they are ``normal."

When a C function is called from Python, it borrows references to its arguments from the caller. The caller owns a reference to the object, so the borrowed reference's lifetime is guaranteed until the function returns. Only when such a borrowed reference must be stored or passed on, it must be turned into an owned reference by calling `Py_INCREF()`.
The object reference returned from a C function that is called from Python must be an owned reference -- ownership is transferred from the function to its caller.
1.10.3 Thin Ice

There are a few situations where seemingly harmless use of a borrowed reference can lead to problems. These all have to do with implicit invocations of the interpreter, which can cause the owner of a reference to dispose of it.

The first and most important case to know about is using `Py_DECREF()` on an unrelated object while borrowing a reference to a list item. For instance:

```c
void
bug(PyObject *list)
{
    PyObject *item = PyList_GetItem(list, 0);
    PyList_SetItem(list, 1, PyInt_FromLong(0L));
    PyObject_Print(item, stdout, 0); /* BUG! */
}
```

This function first borrows a reference to `list[0]`, then replaces `list[1]` with the value 0, and finally prints the borrowed reference. Looks harmless, right? But it's not!

Let's follow the control flow into `PyList_SetItem()`. The list owns references to all its items, so when item 1 is replaced, it has to dispose of the original item 1. Now let's suppose the original item 1 was an instance of a user-defined class, and let's further suppose that the class defined a `__del__()` method. If this class instance has a reference count of 1, disposing of it will call its `__del__()` method.

Since it is written in Python, the `__del__()` method can execute arbitrary Python code. Could it perhaps do something to invalidate the reference to `item` in `bug()`? You bet! Assuming that the list passed into `bug()` is accessible to the `__del__()` method, it could execute a statement to the effect of `del list[0]`, and assuming this was the last reference to that object, it would free the memory associated with it, thereby invalidating `item`.

The solution, once you know the source of the problem, is easy: temporarily increment the reference count. The correct version of the function reads:

```c
void
```c
no_bug(PyObject *list)
{
    PyObject *item = PyList_GetItem(list, 0);
    Py_INCREF(item);
    PyList_SetItem(list, 1, PyInt_FromLong(0L));
    PyObject_Print(item, stdout, 0);
    Py_DECREF(item);
}
```

This is a true story. An older version of Python contained variants of this bug and someone spent a considerable amount of time in a C debugger to figure out why his `__del__()` methods would fail...

The second case of problems with a borrowed reference is a variant involving threads. Normally, multiple threads in the Python interpreter can't get in each other's way, because there is a global lock protecting Python's entire object space. However, it is possible to temporarily release this lock using the macro `Py_BEGIN_ALLOW_THREADS`, and to re-acquire it using `Py_END_ALLOW_THREADS`. This is common around blocking I/O calls, to let other threads use the processor while waiting for the I/O to complete. Obviously, the following function has the same problem as the previous one:

```c
void bug(PyObject *list)
{
    PyObject *item = PyList_GetItem(list, 0);
    Py_BEGIN_ALLOW_THREADS
    ...some blocking I/O call...
    Py_END_ALLOW_THREADS
    PyObject_Print(item, stdout, 0); /* BUG! */
}
```
1.10.4 NULL Pointers

In general, functions that take object references as arguments do not expect you to pass them NULL pointers, and will dump core (or cause later core dumps) if you do so. Functions that return object references generally return NULL only to indicate that an exception occurred. The reason for not testing for NULL arguments is that functions often pass the objects they receive on to other function -- if each function were to test for NULL, there would be a lot of redundant tests and the code would run more slowly.

It is better to test for NULL only at the "source:" when a pointer that may be NULL is received, for example, from `malloc()` or from a function that may raise an exception.

The macros `Py_INCREF()` and `Py_DECREF()` do not check for NULL pointers -- however, their variants `Py_XINCREF()` and `Py_XDECREF()` do.

The macros for checking for a particular object type (`Pytype_Check()`) don't check for NULL pointers -- again, there is much code that calls several of these in a row to test an object against various different expected types, and this would generate redundant tests. There are no variants with NULL checking.

The C function calling mechanism guarantees that the argument list passed to C functions (args in the examples) is never NULL -- in fact it guarantees that it is always a tuple.\footnote{1.4}

It is a severe error to ever let a NULL pointer `"escape" to the Python user.

Footnotes

\footnote{1.4}{These guarantees don't hold when you use the "old" style calling convention -- this is still found in much existing code.}
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
1.11 Writing Extensions in C++

It is possible to write extension modules in C++. Some restrictions apply. If the main program (the Python interpreter) is compiled and linked by the C compiler, global or static objects with constructors cannot be used. This is not a problem if the main program is linked by the C++ compiler. Functions that will be called by the Python interpreter (in particular, module initialization functions) have to be declared using `extern "C"`. It is unnecessary to enclose the Python header files in `extern "C" { ... }` -- they use this form already if the symbol "__cplusplus" is defined (all recent C++ compilers define this symbol).
1.12 Providing a C API for an Extension Module

Many extension modules just provide new functions and types to be used from Python, but sometimes the code in an extension module can be useful for other extension modules. For example, an extension module could implement a type `collection` which works like lists without order. Just like the standard Python list type has a C API which permits extension modules to create and manipulate lists, this new collection type should have a set of C functions for direct manipulation from other extension modules.

At first sight this seems easy: just write the functions (without declaring them static, of course), provide an appropriate header file, and document the C API. And in fact this would work if all extension modules were always linked statically with the Python interpreter. When modules are used as shared libraries, however, the symbols defined in one module may not be visible to another module. The details of visibility depend on the operating system; some systems use one global namespace for the Python interpreter and all extension modules (Windows, for example), whereas others require an explicit list of imported symbols at module link time (AIX is one example), or offer a choice of different strategies (most Unices). And even if symbols are globally visible, the module whose functions one wishes to call might not have been loaded yet!

Portability therefore requires not to make any assumptions about symbol visibility. This means that all symbols in extension modules should be declared static, except for the module's initialization function, in order to avoid name clashes with other extension modules (as discussed in section 1.4). And it means that symbols that should be accessible from other extension modules must be exported in a different way.

Python provides a special mechanism to pass C-level information (pointers) from one extension module to another one: CObjects. A CObject is a Python data type which stores a pointer (void *). CObjects can only be created and accessed via their C API, but they can be passed around like any other Python object. In particular, they can be assigned to a name in an extension module's namespace. Other extension modules can then import this module, retrieve the
value of this name, and then retrieve the pointer from the CObject.

There are many ways in which CObjects can be used to export the C API of an extension module. Each name could get its own CObject, or all C API pointers could be stored in an array whose address is published in a CObject. And the various tasks of storing and retrieving the pointers can be distributed in different ways between the module providing the code and the client modules.

The following example demonstrates an approach that puts most of the burden on the writer of the exporting module, which is appropriate for commonly used library modules. It stores all C API pointers (just one in the example!) in an array of void pointers which becomes the value of a CObject. The header file corresponding to the module provides a macro that takes care of importing the module and retrieving its C API pointers; client modules only have to call this macro before accessing the C API.

The exporting module is a modification of the spam module from section 1.1. The function spam.system() does not call the C library function system() directly, but a function PySpam_System(), which would of course do something more complicated in reality (such as adding ```spam``` to every command). This function PySpam_System() is also exported to other extension modules.

The function PySpam_System() is a plain C function, declared static like everything else:

```c
static int
PySpam_System(const char *command)
{
    return system(command);
}
```

The function spam_system() is modified in a trivial way:

```c
static PyObject *
spam_system(PyObject *self, PyObject *args)
{
    const char *command;
    int sts;

    if (!PyArg_ParseTuple(args, "s", &command))
        return NULL;
    sts = PySpam_System(command);
```
return Py_BuildValue("i", sts);
}

In the beginning of the module, right after the line

#include "Python.h"

two more lines must be added:

#define SPAM_MODULE
#include "spammodule.h"

The #define is used to tell the header file that it is being included in the
exporting module, not a client module. Finally, the module's initialization
function must take care of initializing the C API pointer array:

PyMODINIT_FUNC
initspam(void)
{
    PyObject *m;
    static void *PySpam_API[PySpam_API_pointers];
    PyObject *c_api_object;
    m = Py_InitModule("spam", SpamMethods);

    /* Initialize the C API pointer array */
    PySpam_API[PySpam_System_NUM] = (void *)PySpam_System;

    /* Create a CObject containing the API pointer array's address *
    c_api_object = PyCObject_FromVoidPtr((void *)PySpam_API, NULL);

    if (c_api_object != NULL)
        PyModule_AddObject(m, "_C_API", c_api_object);
}

Note that PySpam_API is declared static; otherwise the pointer array would
disappear when initspam() terminates!

The bulk of the work is in the header file spammodule.h, which looks like this:

#ifndef Py_SPAMMODULE_H
#define Py_SPAMMODULE_H
#ifdef __cplusplus
extern "C" {
#endif

/* Header file for spammodule */
/* C API functions */
#define PySpam_System_NUM 0
#define PySpam_System_RETURN int
#define PySpam_System_PROTO (const char *command)

/* Total number of C API pointers */
#define PySpam_API_pointers 1

#ifdef SPAM_MODULE
/* This section is used when compiling spammodule.c */
static PySpam_System_RETURN PySpam_System PySpam_System_PROTO;
#else
/* This section is used in modules that use spammodule's API */
static void **PySpam_API;
#endif
#define PySpam_System
(*(PySpam_System_RETURN (*)PySpam_System_PROTO) PySpam_API[PySpam_System_NUM])

/* Return -1 and set exception on error, 0 on success. */
static int import_spam(void)
{
    PyObject *module = PyImport_ImportModule("spam");

    if (module != NULL) {
        PyObject *c_api_object = PyObject_GetAttrString(module, ".C_
        if (c_api_object == NULL)
            return -1;
        if (PyCObject_Check(c_api_object))
            PySpam_API = (void **)PyCObject_AsVoidPtr(c_api_object);
        Py_DECREF(c_api_object);
    }
    return 0;
}
#endif

#ifdef __cplusplus
}
#endif
#endif /*!defined(Py_SPAMMODULE_H) */

All that a client module must do in order to have access to the function PySpam_System() is to call the function (or rather macro) import_spam() in its initialization function:
PyMODINIT_FUNC
initclient(void)
{
    PyObject *m;

    Py_InitModule("client", ClientMethods);
    if (import_spam() < 0)
        return;
    /* additional initialization can happen here */
}

The main disadvantage of this approach is that the file `spammodule.h` is rather complicated. However, the basic structure is the same for each function that is exported, so it has to be learned only once.

Finally it should be mentioned that CObjects offer additional functionality, which is especially useful for memory allocation and deallocation of the pointer stored in a CObject. The details are described in the `Python/C API Reference Manual` in the section ``CObjects`` and in the implementation of CObjects (files Include/cobject.h and Objects/cobject.c in the Python source code distribution).
2. Defining New Types

As mentioned in the last chapter, Python allows the writer of an extension module to define new types that can be manipulated from Python code, much like strings and lists in core Python.

This is not hard; the code for all extension types follows a pattern, but there are some details that you need to understand before you can get started.

Note: The way new types are defined changed dramatically (and for the better) in Python 2.2. This document documents how to define new types for Python 2.2 and later. If you need to support older versions of Python, you will need to refer to older versions of this documentation.

Subsections

- 2.1 The Basics
  - 2.1.1 Adding data and methods to the Basic example
  - 2.1.2 Providing finer control over data attributes
  - 2.1.3 Supporting cyclic garbage collection

- 2.2 Type Methods
  - 2.2.1 Finalization and De-allocation
  - 2.2.2 Object Presentation
  - 2.2.3 Attribute Management
    - 2.2.3.1 Generic Attribute Management
    - 2.2.3.2 Type-specific Attribute Management
  - 2.2.4 Object Comparison
  - 2.2.5 Abstract Protocol Support
  - 2.2.6 Weak Reference Support
  - 2.2.7 More Suggestions

Adding data and
2.1 The Basics

The Python runtime sees all Python objects as variables of type `PyObject*`. A `PyObject` is not a very magnificent object - it just contains the refcount and a pointer to the object's ```type object```. This is where the action is; the type object determines which (C) functions get called when, for instance, an attribute gets looked up on an object or it is multiplied by another object. These C functions are called ```type methods``" to distinguish them from things like `[ ] . append` (which we call ```object methods``").

So, if you want to define a new object type, you need to create a new type object.

This sort of thing can only be explained by example, so here's a minimal, but complete, module that defines a new type:

```c
#include <Python.h>

typedef struct {
    PyObject_HEAD
    /* Type-specific fields go here. */
} noddy_NoddyObject;

static PyTypeObject noddy_NoddyType = {
    PyObject_HEAD_INIT(NULL)
    0,          /*ob_size*/
    "noddy.Noddy", /*tp_name*/
    sizeof(noddy_NoddyObject), /*tp_basicsize*/
    0,          /*tp_itemsize*/
    0,          /*tp_dealloc*/
    0,          /*tp_print*/
    0,          /*tp_getattr*/
    0,          /*tp_setattr*/
    0,          /*tp_compare*/
    0,          /*tp_repr*/
    0,          /*tp_as_number*/
    0,          /*tp_as_sequence*/
    0,          /*tp_as_mapping*/
    0,          /*tp_hash */
    0,          /*tp_call*/
    0,          /*tp_str*/
    0,          /*tp_getattro*/
    0,          /*tp_setattro*/
    0,          /*tp_as_buffer*/
    Py_TPFLAGS_DEFAULT, /*tp_flags*/
    "Noddy objects",  /* tp_doc */
};
```
Now that's quite a bit to take in at once, but hopefully bits will seem familiar from the last chapter.

The first bit that will be new is:

```c
typedef struct {
    PyObject_HEAD
} noddy_NoddyObject;
```

This is what a Noddy object will contain—in this case, nothing more than every Python object contains, namely a refcount and a pointer to a type object. These are the fields the PyObject_HEAD macro brings in. The reason for the macro is to standardize the layout and to enable special debugging fields in debug builds. Note that there is no semicolon after the PyObject_HEAD macro; one is included in the macro definition. Be wary of adding one by accident; it's easy to do from habit, and your compiler might not complain, but someone else's probably will! (On Windows, MSVC is known to call this an error and refuse to compile the code.)
For contrast, let's take a look at the corresponding definition for standard Python integers:

```c
typedef struct {
    PyObject_HEAD
    long ob_ival;
} PyIntObject;
```

Moving on, we come to the crunch -- the type object.

```c
static PyTypeObject noddy_NoddyType = {
    PyObject_HEAD_INIT(NULL)
    0,    /*ob_size*/
    "noddy.Noddy", /*tp_name*/
    sizeof(noddy_NoddyObject), /*tp_basicsize*/
    0, /*tp_itemsize*/
    0, /*tp_dealloc*/
    0, /*tp_print*/
    0, /*tp_getattr*/
    0, /*tp_setattr*/
    0, /*tp_compare*/
    0, /*tp_repr*/
    0, /*tp_as_number*/
    0, /*tp_as_sequence*/
    0, /*tp_as_mapping*/
    0, /*tp_hash */
    0, /*tp_call*/
    0, /*tp_str*/
    0, /*tp_getattro*/
    0, /*tp_setattro*/
    0, /*tp_as_buffer*/
    Py_TPFLAGS_DEFAULT, /*tp_flags*/
    "Noddy objects", /* tp_doc */
};
```

Now if you go and look up the definition of PyTypeObject in object.h you'll see that it has many more fields that the definition above. The remaining fields will be filled with zeros by the C compiler, and it's common practice to not specify them explicitly unless you need them.

This is so important that we're going to pick the top of it apart still further:

```c
PyObject_HEAD_INIT(NULL)
```

This line is a bit of a wart; what we'd like to write is:

```c
PyObject_HEAD_INIT(&PyType_Type)
```
as the type of a type object is ``type'', but this isn't strictly conforming C and some compilers complain. Fortunately, this member will be filled in for us by PyType_Ready().

    0, /* ob_size */

The ob_size field of the header is not used; its presence in the type structure is a historical artifact that is maintained for binary compatibility with extension modules compiled for older versions of Python. Always set this field to zero.

    "noddy.Noddy", /* tp_name */

The name of our type. This will appear in the default textual representation of our objects and in some error messages, for example:

    >>> "" + noddy.new_noddy()
    Traceback (most recent call last):
      File "<stdin>", line 1, in ?
    TypeError: cannot add type "noddy.Noddy" to string

Note that the name is a dotted name that includes both the module name and the name of the type within the module. The module in this case is noddy and the type is Noddy, so we set the type name to noddy.Noddy.

    sizeof(noddy_NoddyObject), /* tp_basicsize */

This is so that Python knows how much memory to allocate when you call PyObject_New().

**Note:** If you want your type to be subclassable from Python, and your type has the same tp_basicsize as its base type, you may have problems with multiple inheritance. A Python subclass of your type will have to list your type first in its __bases__, or else it will not be able to call your type's __new__ method without getting an error. You can avoid this problem by ensuring that your type has a larger value for tp_basicsize than its base type does. Most of the time, this will be true anyway, because either your base type will be object, or else you will be adding data members to your base type, and therefore increasing its size.

    0, /* tp_itemsize */

This has to do with variable length objects like lists and strings. Ignore this for
now.

Skipping a number of type methods that we don't provide, we set the class flags to Py_TPFLAGS_DEFAULT.

    Py_TPFLAGS_DEFAULT,     /*tp_flags*/

All types should include this constant in their flags. It enables all of the members defined by the current version of Python.

We provide a doc string for the type in tp_doc.

    "Noddy objects",       /* tp_doc */

Now we get into the type methods, the things that make your objects different from the others. We aren't going to implement any of these in this version of the module. We'll expand this example later to have more interesting behavior.

For now, all we want to be able to do is to create new Noddy objects. To enable object creation, we have to provide a tp_new implementation. In this case, we can just use the default implementation provided by the API function PyType_GenericNew(). We'd like to just assign this to the tp_new slot, but we can't, for portability sake, On some platforms or compilers, we can't statically initialize a structure member with a function defined in another C module, so, instead, we'll assign the tp_new slot in the module initialization function just before calling PyType_Ready():

    noddy_NoddyType.tp_new = PyType_GenericNew;
    if (PyType_Ready(&noddy_NoddyType) < 0)
        return;

All the other type methods are NULL, so we'll go over them later -- that's for a later section!

Everything else in the file should be familiar, except for some code in initnoddy():

    if (PyType_Ready(&noddy_NoddyType) < 0)
        return;

This initializes the Noddy type, filing in a number of members, including ob_type that we initially set to NULL.
PyModule_AddObject(m, "Noddy", (PyObject *)&noddy_NoddyType);

This adds the type to the module dictionary. This allows us to create Noddy instances by calling the Noddy class:

```python
>>> import noddy
>>> mynoddy = noddy.Noddy()
```

That's it! All that remains is to build it; put the above code in a file called noddy.c and

```python
from distutils.core import setup, Extension
setup(name="noddy", version="1.0",
      ext_modules=[Extension("noddy", ["noddy.c"])]
)
```

in a file called setup.py; then typing

```bash
$ python setup.py build
```

at a shell should produce a file `noddy.so` in a subdirectory; move to that directory and fire up Python -- you should be able to `import noddy` and play around with Noddy objects.

That wasn't so hard, was it?

Of course, the current Noddy type is pretty uninteresting. It has no data and doesn't do anything. It can't even be subclassed.

2.1.1 Adding data and methods to the Basic example

Let's expend the basic example to add some data and methods. Let's also make
the type usable as a base class. We'll create a new module, noddy2 that adds
these capabilities:

```c
#include <Python.h>
#include "structmember.h"

typedef struct {
    PyObject_HEAD
    PyObject *first; /* first name */
    PyObject *last;  /* last name */
    int number;
} Noddy;

static void
Noddy_dealloc(Noddy* self)
{
    Py_XDECREF(self->first);
    Py_XDECREF(self->last);
    self->ob_type->tp_free((PyObject*)self);
}

static PyObject *
Noddy_new(PyTypeObject *type,
         PyObject *args,
         PyObject *kwds)
{
    Noddy *self;

    self = (Noddy *)type->tp_alloc(type, 0);
    if (self != NULL) {
        self->first = PyString_FromString("");
        if (self->first == NULL) {
            Py_DECREF(self);
            return NULL;
        }
        self->last = PyString_FromString("");
        if (self->last == NULL) {
            Py_DECREF(self);
            return NULL;
        }
        self->number = 0;
    }
    return self;
}
```
return (PyObject *)self;
}

static int
Noddy_init(Noddy *self, PyObject *args, PyObject *kwds)
{
    PyObject *first=NULL, *last=NULL, *tmp;

    static char *kwlist[] = {"first", "last", "number", NULL};

    if (!PyArg_ParseTupleAndKeywords(args, kwds, |OOi|, kwlist, &first, &last, &self->number))
        return -1;

    if (first) {
        tmp = self->first;
        Py_INCREF(first);
        self->first = first;
        Py_XDECREF(tmp);
    }

    if (last) {
        tmp = self->last;
        Py_INCREF(last);
        self->last = last;
        Py_XDECREF(tmp);
    }

    return 0;
}

static PyMemberDef Noddy_members[] = {
    {"first", T_OBJECT_EX, offsetof(Noddy, first), 0,
        "first name"},
    {"last", T_OBJECT_EX, offsetof(Noddy, last), 0,
        "last name"},
    {"number", T_INT, offsetof(Noddy, number), 0,
        "noddy number"},
    {NULL} /* Sentinel */
};

static PyObject *
Noddy_name(Noddy* self)
{
    static PyObject *format = NULL;
    PyObject *args, *result;

    if (format == NULL) {
        format = PyString_FromString("%s %s");
    }

    return (PyObject *)self;
}
if (format == NULL)
    return NULL;

if (self->first == NULL) {
    PyErr_SetString(PyExc_AttributeError, "first");
    return NULL;
}

if (self->last == NULL) {
    PyErr_SetString(PyExc_AttributeError, "last");
    return NULL;
}

args = Py_BuildValue("OO", self->first, self->last);
if (args == NULL)
    return NULL;

result = PyString_Format(format, args);
Py_DECREF(args);
return result;

static PyMethodDef Noddy_methods[] = {
    {"name", (PyCFunction)Noddy_name, METH_NOARGS,
     "Return the name, combining the first and last name"},
    {NULL} /* Sentinel */
};

static PyTypeObject NoddyType = {
    PyObject_HEAD_INIT(NULL)
    0,                  /*ob_size*/
    "noddy.Noddy",     /*tp_name*/
    sizeof(Noddy),     /*tp_basicsize*/
    0,                  /*tp_itemsize*/
    (destructor)Noddy_dealloc, /*tp_dealloc*/
    0,                  /*tp_print*/
    0,                  /*tp_getattr*/
    0,                  /*tp_setattr*/
    0,                  /*tp_compare*/
    0,                  /*tp_repr*/
    0,                  /*tp_as_number*/
    0,                  /*tp_as_sequence*/
    0,                  /*tp_as_mapping*/
    0,                  /*tp_hash */
    0,                  /*tp_call*/
    0,                  /*tp_str*/
    0,                  /*tp_getattro*/
    0,                  /*tp_setattro*/
    0,                  /*tp_as_buffer*/
};
This version of the module has a number of changes.

We've added an extra include:
#include "structmember.h"

This include provides declarations that we use to handle attributes, as described a bit later.

The name of the Noddy object structure has been shortened to Noddy. The type object name has been shortened to NoddyType.

The Noddy type now has three data attributes, first, last, and number. The first and last variables are Python strings containing first and last names. The number attribute is an integer.

The object structure is updated accordingly:

```c
typedef struct {
    PyObject_HEAD
    PyObject *first;
    PyObject *last;
    int number;
} Noddy;
```

Because we now have data to manage, we have to be more careful about object allocation and deallocation. At a minimum, we need a deallocation method:

```c
static void Noddy_dealloc(Noddy* self)
{
    Py_XDECREF(self->first);
    Py_XDECREF(self->last);
    self->ob_type->tp_free((PyObject*)self);
}
```

which is assigned to the tp_dealloc member:

```c
(destructor)Noddy_dealloc, /*tp_dealloc*/
```

This method decrements the reference counts of the two Python attributes. We use Py_XDECREF() here because the first and last members could be NULL. It then calls the tp_free member of the object's type to free the object's memory. Note that the object's type might not be NoddyType, because the object may be an instance of a subclass.

We want to make sure that the first and last names are initialized to empty strings, so we provide a new method:
static PyObject *
Noddy_new(PyTypeObject *type, PyObject *args, PyObject *kwds)
{
    Noddy *self;

    self = (Noddy *)type->tp_alloc(type, 0);
    if (self != NULL) {
        self->first = PyString_FromString("");
        if (self->first == NULL) {
            Py_DECREF(self);
            return NULL;
        }

        self->last = PyString_FromString("");
        if (self->last == NULL) {
            Py_DECREF(self);
            return NULL;
        }

        self->number = 0;
    }

    return (PyObject *)self;
}

and install it in the tp_new member:

    Noddy_new,            /* tp_new */

The new member is responsible for creating (as opposed to initializing) objects of the type. It is exposed in Python as the __new__( ) method. See the paper titled "Unifying types and classes in Python" for a detailed discussion of the __new__( ) method. One reason to implement a new method is to assure the initial values of instance variables. In this case, we use the new method to make sure that the initial values of the members first and last are not NULL. If we didn't care whether the initial values were NULL, we could have used PyType_GenericNew() as our new method, as we did before. PyType_GenericNew() initializes all of the instance variable members to NULL.

The new method is a static method that is passed the type being instantiated and any arguments passed when the type was called, and that returns the new object created. New methods always accept positional and keyword arguments, but they often ignore the arguments, leaving the argument handling to initializer
methods. Note that if the type supports subclassing, the type passed may not be the type being defined. The new method calls the tp_alloc slot to allocate memory. We don't fill the tp_alloc slot ourselves. Rather PyType_Ready() fills it for us by inheriting it from our base class, which is object by default. Most types use the default allocation.

**Note:** If you are creating a co-operative tp_new (one that calls a base type's tp_new or __new__), you must not try to determine what method to call using method resolution order at runtime. Always statically determine what type you are going to call, and call its tp_new directly, or via type->tp_base->tp_new. If you do not do this, Python subclasses of your type that also inherit from other Python-defined classes may not work correctly. (Specifically, you may not be able to create instances of such subclasses without getting a TypeError.)

We provide an initialization function:

```c
static int Noddy_init(Noddy *self, PyObject *args, PyObject *kwds)
{
    PyObject *first=NULL, *last=NULL, *tmp;

    static char *kwlist[] = {"first", "last", "number", NULL};

    if (!PyArg_ParseTupleAndKeywords(args, kwds, "|OOi", kwlist,
        &first, &last, &self->number))
        return -1;

    if (first) {
        tmp = self->first;
        Py_INCREF(first);
        self->first = first;
        Py_XINCREF(tmp);
    }

    if (last) {
        tmp = self->last;
        Py_INCREF(last);
        self->last = last;
        Py_XINCREF(tmp);
    }

    return 0;
}
```
by filling the `tp_init` slot.

```
(initproc)Noddy_init,       /* tp_init */
```

The `tp_init` slot is exposed in Python as the `__init__()` method. It is used to initialize an object after it's created. Unlike the new method, we can't guarantee that the initializer is called. The initializer isn't called when unpickling objects and it can be overridden. Our initializer accepts arguments to provide initial values for our instance. Initializers always accept positional and keyword arguments.

Initializers can be called multiple times. Anyone can call the `__init__()` method on our objects. For this reason, we have to be extra careful when assigning the new values. We might be tempted, for example to assign the `first` member like this:

```
if (first) {
    Py_XDECREF(self->first);
    Py_INCREF(first);
    self->first = first;
}
```

But this would be risky. Our type doesn't restrict the type of the `first` member, so it could be any kind of object. It could have a destructor that causes code to be executed that tries to access the `first` member. To be paranoid and protect ourselves against this possibility, we almost always reassign members before decrementing their reference counts. When don't we have to do this?

- when we absolutely know that the reference count is greater than 1
- when we know that deallocation of the object\(^{2,1}\) will not cause any calls back into our type's code
- when decrementing a reference count in a `tp_dealloc` handler when garbage-collections is not supported\(^{2,2}\)

We want to want to expose our instance variables as attributes. There are a number of ways to do that. The simplest way is to define member definitions:

```
static PyMemberDef Noddy_members[] = {
    {"first", T_OBJECT_EX, offsetof(Noddy, first), 0,
     "first name"},
    {"last", T_OBJECT_EX, offsetof(Noddy, last), 0,
```
"last name"},
{"number", T_INT, offsetof(Noddy, number), 0,
 "noddy number"},
{NULL} /* Sentinel */
}

and put the definitions in the tp_members slot:

Noddy_members,       /* tp_members */

Each member definition has a member name, type, offset, access flags and documentation string. See the "Generic Attribute Management" section below for details.

A disadvantage of this approach is that it doesn't provide a way to restrict the types of objects that can be assigned to the Python attributes. We expect the first and last names to be strings, but any Python objects can be assigned. Further, the attributes can be deleted, setting the C pointers to NULL. Even though we can make sure the members are initialized to non-NULL values, the members can be set to NULL if the attributes are deleted.

We define a single method, name, that outputs the objects name as the concatenation of the first and last names.

```c
static PyObject *
Noddy_name(Noddy* self)
{
    static PyObject *format = NULL;
    PyObject *args, *result;

    if (format == NULL) {
        format = PyString_FromString("%s %s");
        if (format == NULL)
            return NULL;
    }

    if (self->first == NULL) {
        PyErr_SetString(PyExc_AttributeError, "first");
        return NULL;
    }

    if (self->last == NULL) {
        PyErr_SetString(PyExc_AttributeError, "last");
        return NULL;
    }

    args = Py_BuildValue("OO", self->first, self->last);

```
if (args == NULL)
    return NULL;

result = PyString_Format(format, args);
Py_DECREF(args);

return result;
}

The method is implemented as a C function that takes a Noddy (or Noddy subclass) instance as the first argument. Methods always take an instance as the first argument. Methods often take positional and keyword arguments as well, but in this case we don't take any and don't need to accept a positional argument tuple or keyword argument dictionary. This method is equivalent to the Python method:

    def name(self):
        return "%s %s" % (self.first, self.last)

Note that we have to check for the possibility that our first and last members are NULL. This is because they can be deleted, in which case they are set to NULL. It would be better to prevent deletion of these attributes and to restrict the attribute values to be strings. We'll see how to do that in the next section.

Now that we've defined the method, we need to create an array of method definitions:

    static PyMethodDef Noddy_methods[] = {
        {"name", (PyCFunction)Noddy_name, METH_NOARGS, "Return the name, combining the first and last name"},
        {NULL} /* Sentinel */
    };

and assign them to the tp_methods slot:

    Noddy_methods, /* tp_methods */

Note that we used the METH_NOARGS flag to indicate that the method is passed no arguments.

Finally, we'll make our type usable as a base class. We've written our methods carefully so far so that they don't make any assumptions about the type of the
object being created or used, so all we need to do is to add the
Py_TPFLAGS_BASETYPE to our class flag definition:

    Py_TPFLAGS_DEFAULT | Py_TPFLAGS_BASETYPE, /*tp_flags*/

We rename initnoddy() to initnoddy2() and update the module name
passed to Py_InitModule3().

Finally, we update our setup.py file to build the new module:

    from distutils.core import setup, Extension
    setup(name="noddy", version="1.0",
          ext_modules=[
            Extension("noddy", ["noddy.c"],
                       Extension("noddy2", ["noddy2.c"],
                       )
          ])"

---

**Footnotes**

... object\(^2.1\)

This is true when we know that the object is a basic type, like a string or a
float.

... supported\(^2.2\)

We relied on this in the tp_dealloc handler in this example, because our
type doesn't support garbage collection. Even if a type supports garbage
collection, there are calls that can be made to \``untrack\" the object from
garbage collection, however, these calls are advanced and not covered here.
2.1.2 Providing finer control over data attributes

In this section, we'll provide finer control over how the first and last attributes are set in the Noddy example. In the previous version of our module, the instance variables first and last could be set to non-string values or even deleted. We want to make sure that these attributes always contain strings.

```c
#include <Python.h>
#include "structmember.h"

typedef struct {
   PyObject_HEAD
   PyObject *first;
   PyObject *last;
   int number;
} Noddy;

static void
Noddy_dealloc(Noddy* self)
{
   Py_XDECREF(self->first);
   Py_XDECREF(self->last);
   self->ob_type->tp_free((PyObject*)self);
}

static PyObject *
Noddy_new(PyTypeObject *type, PyObject *args, PyObject *kwds)
{
   Noddy *self;

   self = (Noddy *)type->tp_alloc(type, 0);
   if (self != NULL) {
      self->first = PyString_FromString("" );
      if (self->first == NULL) {
         Py_DECREF(self);
         return NULL;
      }
      self->last = PyString_FromString(""");
      if (self->last == NULL) {
         Py_DECREF(self);
         return NULL;
      }
      self->number = 0;
   }
   return (PyObject *)self;
}
```
return (PyObject *)self;
}

static int
Noddy_init(Noddy *self, PyObject *args, PyObject *kwds)
{
    PyObject *first=NULL, *last=NULL, *tmp;
    static char *kwlist[]={"first", "last", "number", NULL};

    if (!PyArg_ParseTupleAndKeywords(args, kwds, "|SSi", kwlist,
                                    &first, &last,
                                    &self->number))
        return -1;

    if (first) {
        tmp = self->first;
        Py_INCREF(first);
        self->first = first;
        Py_DECREF(tmp);
    }

    if (last) {
        tmp = self->last;
        Py_INCREF(last);
        self->last = last;
        Py_DECREF(tmp);
    }

    return 0;
}

static PyMemberDef Noddy_members[] = {
    {"number", T_INT, offsetof(Noddy, number), 0,
     "noddy number"},
    {NULL} /* Sentinel */
};

static PyObject *
Noddy_getfirst(Noddy *self, void *closure)
{
    Py_INCREF(self->first);
    return self->first;
}

static int
Noddy_setfirst(Noddy *self, PyObject *value, void *closure)
{
    if (value == NULL) {
        PyErr_SetString(PyExc_TypeError, "Cannot delete the first attrib
        return -1;
    }
if (!PyString_Check(value)) {

    Py_DECREF(args);
    return result;
}

static PyMethodDef Noddy_methods[] = {
    {"name", (PyCFunction)Noddy_name, METH_NOARGS,
     "Return the name, combining the first and last name"},
    {NULL} /* Sentinel */
};

static PyTypeObject NoddyType = {
    PyObject_HEAD_INIT(NULL)
    0, /*ob_size*/
    "noddy.Noddy", /*tp_name*/
    sizeof(Noddy), /*tp_basicsize*/
    0, /*tp_itemsize*/
    (destructor)Noddy_dealloc, /*tp_dealloc*/
    0, /*tp_print*/
    0, /*tp_getattr*/
    0, /*tp_setattr*/
    0, /*tp_compare*/
    0, /*tp_repr*/
    0, /*tp_as_number*/
    0, /*tp_as_sequence*/
    0, /*tp_as_mapping*/
    0, /*tp_hash */
    0, /*tp_call*/
    0, /*tp_str*/
    0, /*tp_getattro*/
    0, /*tp_setattro*/
};
To provide greater control, over the first and last attributes, we'll use custom getter and setter functions. Here are the functions for getting and setting
the first attribute:

```c
Noddy_getfirst(Noddy *self, void *closure)
{
    Py_INCREF(self->first);
    return self->first;
}
```

```c
static int
Noddy_setfirst(Noddy *self, PyObject *value, void *closure)
{
    if (value == NULL) {
        PyErr_SetString(PyExc_TypeError, "Cannot delete the first attribute");
        return -1;
    }
    if (! PyString_Check(value)) {
        PyErr_SetString(PyExc_TypeError, "The first attribute value must be a string");
        return -1;
    }
    Py_DECREF(self->first);
    Py_INCREF(value);
    self->first = value;
    return 0;
}
```

The getter function is passed a Noddy object and a ``closure'', which is void pointer. In this case, the closure is ignored. (The closure supports an advanced usage in which definition data is passed to the getter and setter. This could, for example, be used to allow a single set of getter and setter functions that decide the attribute to get or set based on data in the closure.)

The setter function is passed the Noddy object, the new value, and the closure. The new value may be NULL, in which case the attribute is being deleted. In our setter, we raise an error if the attribute is deleted or if the attribute value is not a string.

We create an array of PyGetSetDef structures:

```c
static PyGetSetDef Noddy_getseters[] = {
    "first",
    (getter)Noddy_getfirst, (setter)Noddy_setfirst,
    "first name",
    NULL,
};
```
The last item in a `PyGetSetDef` structure is the closure mentioned above. In this case, we aren't using the closure, so we just pass `NULL`.

We also remove the member definitions for these attributes:

```c
static PyMemberDef Noddy_members[] = {
    {"number", T_INT, offsetof(Noddy, number), 0,
     "noddy number"},
    {NULL} /* Sentinel */
};
```

We also need to update the `tp_init` handler to only allow strings to be passed:

```c
static int Noddy_init(Noddy *self, PyObject *args, PyObject *kwds)
{
    PyObject *first=NULL, *last=NULL, *tmp;
    static char *kwlist[] = {"first", "last", "number", NULL};
    if (!PyArg_ParseTupleAndKeywords(args, kwds, "|SSi", kwlist, &first, &last, &self->number))
        return -1;
    if (first) {
        tmp = self->first;
        Py_INCREF(first);
        self->first = first;
        Py_DECREF(tmp);
    }
    if (last) {
        tmp = self->last;
        Py_INCREF(last);
        self->last = last;
        Py_DECREF(tmp);
    }
    return 0;
}
```
Py_INCREF(last);
    self->last = last;
    Py_DECREF(tmp);
}
    return 0;
}

With these changes, we can assure that the first and last members are never NULL so we can remove checks for NULL values in almost all cases. This means that most of the Py_XDECREF() calls can be converted to Py_DECREF() calls. The only place we can't change these calls is in the deallocator, where there is the possibility that the initialization of these members failed in the constructor.

We also rename the module initialization function and module name in the initialization function, as we did before, and we add an extra definition to the setup.py file.

Footnotes

... strings

We now know that the first and last members are strings, so perhaps we could be less careful about decrementing their reference counts, however, we accept instances of string subclasses. Even though deallocating normal strings won't call back into our objects, we can't guarantee that deallocating an instance of a string subclass won't. call back into out objects.
2.1.3 Supporting cyclic garbage collection

Python has a cyclic-garbage collector that can identify unneeded objects even when their reference counts are not zero. This can happen when objects are involved in cycles. For example, consider:

```python
>>> l = []
>>> l.append(l)
>>> del l
```

In this example, we create a list that contains itself. When we delete it, it still has a reference from itself. Its reference count doesn't drop to zero. Fortunately, Python's cyclic-garbage collector will eventually figure out that the list is garbage and free it.

In the second version of the Noddy example, we allowed any kind of object to be stored in the `first` or `last` attributes. This means that Noddy objects can participate in cycles:

```python
>>> import noddy2
>>> n = noddy2.Noddy()
>>> l = [n]
>>> n.first = l
```

This is pretty silly, but it gives us an excuse to add support for the cyclic-garbage collector to the Noddy example. To support cyclic garbage collection, types need to fill two slots and set a class flag that enables these slots:

```c
#include <Python.h>
#include "structmember.h"

typedef struct {
    PyObject_HEAD
    PyObject *first;
    PyObject *last;
    int number;
} Noddy;

static int
Noddy_traverse(Noddy *self, visitproc visit, void *arg)
{
    int vret;
    if (self->first) {
```
vret = visit(self->first, arg);
    if (vret != 0)
        return vret;
}
if (self->last) {
    vret = visit(self->last, arg);
    if (vret != 0)
        return vret;
}
return 0;
}

static int
Noddy_clear(Noddy *self)
{
    PyObject *tmp;

    tmp = self->first;
    self->first = NULL;
    Py_XDECREF(tmp);
    tmp = self->last;
    self->last = NULL;
    Py_XDECREF(tmp);
    return 0;
}

static void
Noddy_dealloc(Noddy* self)
{
    Noddy_clear(self);
    self->ob_type->tp_free((PyObject*)self);
}

static PyObject *
Noddy_new(PyTypeObject *type, PyObject *args, PyObject *kwds)
{
    Noddy *self;

    self = (Noddy *)type->tp_alloc(type, 0);
    if (self != NULL) {
        self->first = PyString_FromString("");
        if (self->first == NULL)
            return NULL;
    }

    self->last = PyString_FromString("");
    if (self->last == NULL)
```c
{  
    Py_DECREF(self);  
    return NULL;  
}
self->number = 0;
return (PyObject *)self;
}
static int Noddy_init(Noddy *self, PyObject *args, PyObject *kwds) {
    PyObject *first=NULL, *last=NULL, *tmp;
    static char *kwlist[] = {"first", "last", "number", NULL};
    if (!PyArg_ParseTupleAndKeywords(args, kwds, "|OOi", kwlist, 
                                      &first, &last, 
                                      &self->number))
        return -1;
    if (first) {
        tmp = self->first;

0,       /* tp_base */
0,       /* tp_dict */
0,       /* tp_descr_get */
0,       /* tp_descr_set */
0,       /* tp_dictoffset */
(initproc)Noddy_init,    /* tp_init */
0,       /* tp_alloc */
Noddy_new,        /* tp_new */
};

static PyMethodDef module_methods[] = {
   {NULL}  /* Sentinel */
};

#ifndef PyMODINIT_FUNC  /* declarations for DLL import/export */
#define PyMODINIT_FUNC void
#endif
PyMODINIT_FUNC
initnoddy4(void)
{
    PyObject* m;

    if (PyType_Ready(&NoddyType) < 0)
        return;

    m = Py_InitModule3("noddy4", module_methods,
                      "Example module that creates an extension typ
                      
if (m == NULL)
            return;

    Py_INCREF(&NoddyType);
    PyModule_AddObject(m, "Noddy", (PyObject *)&NoddyType);
}
The traversal method provides access to subobjects that could participate in cycles:

```c
static int
Noddy_traverse(Noddy *self, visitproc visit, void *arg)
{
    int vret;
    if (self->first) {
        vret = visit(self->first, arg);
        if (vret != 0)
            return vret;
    }
    if (self->last) {
        vret = visit(self->last, arg);
        if (vret != 0)
            return vret;
    }
    return 0;
}
```

For each subobject that can participate in cycles, we need to call the `visit()` function, which is passed to the traversal method. The `visit()` function takes as arguments the subobject and the extra argument `arg` passed to the traversal method. It returns an integer value that must be returned if it is non-zero.

Python 2.4 and higher provide a `Py_VISIT()` macro that automates calling visit functions. With `Py_VISIT()`, `Noddy_traverse()` can be simplified:

```c
static int
Noddy_traverse(Noddy *self, visitproc visit, void *arg)
{
    Py_VISIT(self->first);
    Py_VISIT(self->last);
    return 0;
}
```

**Note:** Note that the `tp_traverse` implementation must name its arguments exactly `visit` and `arg` in order to use `Py_VISIT()`. This is to encourage uniformity across these boring implementations.

We also need to provide a method for clearing any subobjects that can participate in cycles. We implement the method and reimplement the deallocator to use it:
Notice the use of a temporary variable in `Noddy_clear()`. We use the temporary variable so that we can set each member to NULL before decrementing its reference count. We do this because, as was discussed earlier, if the reference count drops to zero, we might cause code to run that calls back into the object. In addition, because we now support garbage collection, we also have to worry about code being run that triggers garbage collection. If garbage collection is run, our `tp_traverse` handler could get called. We can't take a chance of having `Noddy_traverse()` called when a member's reference count has dropped to zero and its value hasn't been set to NULL.

Python 2.4 and higher provide a `Py_CLEAR()` that automates the careful decrementing of reference counts. With `Py_CLEAR()`, the `Noddy_clear()` function can be simplified:

```c
static int
Noddy_clear(Noddy *self)
{
    Py_CLEAR(self->first);
    Py_CLEAR(self->last);
    return 0;
}
```

Finally, we add the `Py_TPFLAGS_HAVE_GC` flag to the class flags:
That's pretty much it. If we had written custom `tp_alloc` or `tp_free` slots, we'd need to modify them for cyclic-garbage collection. Most extensions will use the versions automatically provided.

---

Footnotes

... attributes.\textsuperscript{2.4}

Even in the third version, we aren't guaranteed to avoid cycles. Instances of string subclasses are allowed and string subclasses could allow cycles even if normal strings don't.
2.2 Type Methods

This section aims to give a quick fly-by on the various type methods you can implement and what they do.

Here is the definition of `PyTypeObject`, with some fields only used in debug builds omitted:

```c
typedef struct _typeobject {
    PyObject_VAR_HEAD
    char *tp_name; /* For printing, in format "<module>.<name>" */
    int tp_basicsize, tp_itemsize; /* For allocation */

    /* Methods to implement standard operations */
    destructor tp_dealloc;
    printfunc tp_print;
   getattrfunc tp_getattr;
   setattrfunc tp_setattr;
    cmpfunc tp_compare;
    reprfunc tp_repr;

    /* Method suites for standard classes */
    PyNumberMethods *tp_as_number;
    PySequenceMethods *tp_as_sequence;
    PyMappingMethods *tp_as_mapping;

    /* More standard operations (here for binary compatibility) */
    hashfunc tp_hash;
    ternaryfunc tp_call;
    reprfunc tp_str;
    getattrofunc tp_getattro;
    setattrofunc tp_setattro;

    /* Functions to access object as input/output buffer */
    PyBufferProcs *tp_as_buffer;

    /* Flags to define presence of optional/expanded features */
    long tp_flags;

    char *tp_doc; /* Documentation string */

    /* Assigned meaning in release 2.0 */
    /* call function for all accessible objects */
    traverseproc tp_traverse;
}
```
Now that's a lot of methods. Don't worry too much though - if you have a type you want to define, the chances are very good that you will only implement a handful of these.

As you probably expect by now, we're going to go over this and give more information about the various handlers. We won't go in the order they are defined in the structure, because there is a lot of historical baggage that impacts the ordering of the fields; be sure your type initialization keeps the fields in the right order! It's often easiest to find an example that includes all the fields you
need (even if they're initialized to 0) and then change the values to suit your new type.

```c
char *tp_name; /* For printing */
```

The name of the type - as mentioned in the last section, this will appear in various places, almost entirely for diagnostic purposes. Try to choose something that will be helpful in such a situation!

```c
int tp_basicsize, tp_itemsize; /* For allocation */
```

These fields tell the runtime how much memory to allocate when new objects of this type are created. Python has some built-in support for variable length structures (think: strings, lists) which is where the `tp_itemsize` field comes in. This will be dealt with later.

```c
char *tp_doc;
```

Here you can put a string (or its address) that you want returned when the Python script references `obj.__doc__` to retrieve the doc string.

Now we come to the basic type methods--the ones most extension types will implement.

2.2.1 Finalization and De-allocation

destructor tp_dealloc;

This function is called when the reference count of the instance of your type is reduced to zero and the Python interpreter wants to reclaim it. If your type has memory to free or other clean-up to perform, put it here. The object itself needs to be freed here as well. Here is an example of this function:

```c
static void
newdatatype_dealloc(newdatatypeobject * obj)
{
    free(obj->obj_UnderlyingDatatypePtr);
    obj->ob_type->tp_free(obj);
}
```

One important requirement of the deallocator function is that it leaves any pending exceptions alone. This is important since deallocators are frequently called as the interpreter unwinds the Python stack; when the stack is unwound due to an exception (rather than normal returns), nothing is done to protect the deallocators from seeing that an exception has already been set. Any actions which a deallocator performs which may cause additional Python code to be executed may detect that an exception has been set. This can lead to misleading errors from the interpreter. The proper way to protect against this is to save a pending exception before performing the unsafe action, and restoring it when done. This can be done using the PyErr_Fetch() and PyErr_Restore() functions:

```c
static void
my_dealloc(PyObject *obj)
{
    MyObject *self = (MyObject *) obj;
    PyObject *cbresult;

    if (self->my_callback != NULL) {
        PyObject *err_type, *err_value, *err_traceback;
        int have_error = PyErr_Occurred() ? 1 : 0;

        if (have_error)
            PyErr_Fetch(&err_type, &err_value, &err_traceback);

        cbresult = PyObject_CallObject(self->my_callback, NULL);
        if (cbresult == NULL)
            PyErr_WriteUnraisable(self->my_callback);
```
else
    Py_DECREF(cbresult);

    if (have_error)
        PyErr_Restore(err_type, err_value, err_traceback);

    Py_DECREF(self->my_callback);
}
obj->ob_type->tp_free((PyObject*)self);
2.2.2 Object Presentation

In Python, there are three ways to generate a textual representation of an object: the `repr()` function (or equivalent back-tick syntax), the `str()` function, and the `print` statement. For most objects, the `print` statement is equivalent to the `str()` function, but it is possible to special-case printing to a `FILE*` if necessary; this should only be done if efficiency is identified as a problem and profiling suggests that creating a temporary string object to be written to a file is too expensive.

These handlers are all optional, and most types at most need to implement the `tp_str` and `tp_repr` handlers.

```c
reprfunc tp_repr;
reprfunc tp_str;
printfunc tp_print;
```

The `tp_repr` handler should return a string object containing a representation of the instance for which it is called. Here is a simple example:

```c
static PyObject *
newdatatype_repr(newdatatypeobject * obj)
{
    return PyString_FromFormat("Repr-ified_newdatatype{{size:\%d}}", obj->obj_UnderlyingDatatypePtr->size);
}
```

If no `tp_repr` handler is specified, the interpreter will supply a representation that uses the type's `tp_name` and a uniquely-identifying value for the object.

The `tp_str` handler is to `str()` what the `tp_repr` handler described above is to `repr()`; that is, it is called when Python code calls `str()` on an instance of your object. Its implementation is very similar to the `tp_repr` function, but the resulting string is intended for human consumption. If `tp_str` is not specified, the `tp_repr` handler is used instead.

Here is a simple example:

```c
static PyObject *
newdatatype_str(newdatatypeobject * obj)
{
```
The print function will be called whenever Python needs to "print" an instance of the type. For example, if 'node' is an instance of type TreeNode, then the print function is called when Python code calls:

```
print node
```

There is a flags argument and one flag, Py_PRINT_RAW, and it suggests that you print without string quotes and possibly without interpreting escape sequences.

The print function receives a file object as an argument. You will likely want to write to that file object.

Here is a sample print function:

```
static int
newdatatype_print(newdatatypeobject *obj, FILE *fp, int flags)
{
    if (flags & Py_PRINT_RAW) {
        fprintf(fp, "<{newdatatype object--size: %d}>",
                obj->obj_UnderlyingDatatypePtr->size);
    } else {
        fprintf(fp, ""{"<newdatatype object--size: %d}>"",
                obj->obj_UnderlyingDatatypePtr->size);
    }
    return 0;
}
```
2.2.3 Attribute Management

For every object which can support attributes, the corresponding type must provide the functions that control how the attributes are resolved. There needs to be a function which can retrieve attributes (if any are defined), and another to set attributes (if setting attributes is allowed). Removing an attribute is a special case, for which the new value passed to the handler is NULL.

Python supports two pairs of attribute handlers; a type that supports attributes only needs to implement the functions for one pair. The difference is that one pair takes the name of the attribute as a char*, while the other accepts a PyObject*. Each type can use whichever pair makes more sense for the implementation's convenience.

```c
getattrfunc   tp_getattr;    /* char * version */
setattrfunc    tp_setattr;
/* ... */
gettattrofunc  tp_getattrofunc;   /* PyObject * version */
setattrofunc  tp_setattrofunc;
```

If accessing attributes of an object is always a simple operation (this will be explained shortly), there are generic implementations which can be used to provide the PyObject* version of the attribute management functions. The actual need for type-specific attribute handlers almost completely disappeared starting with Python 2.2, though there are many examples which have not been updated to use some of the new generic mechanism that is available.

Release 2.5, documentation updated on 19th September, 2006. See About this document... for information on suggesting changes.
## 2.2.4 Object Comparison

```c
    cmpfunc tp_compare;
```

The `tp_compare` handler is called when comparisons are needed and the object does not implement the specific rich comparison method which matches the requested comparison. (It is always used if defined and the `PyObject_Compare()` or `PyObject_Cmp()` functions are used, or if `cmp()` is used from Python.) It is analogous to the `__cmp__()` method. This function should return -1 if `obj1` is less than `obj2`, 0 if they are equal, and 1 if `obj1` is greater than `obj2`. (It was previously allowed to return arbitrary negative or positive integers for less than and greater than, respectively; as of Python 2.2, this is no longer allowed. In the future, other return values may be assigned a different meaning.)

A `tp_compare` handler may raise an exception. In this case it should return a negative value. The caller has to test for the exception using `PyErr_Occurred()`.

Here is a sample implementation:

```c
    static int newdatatype_compare(newdatatypeobject * obj1, newdatatypeobject * ob
    { long result;

    if (obj1->obj_UnderlyingDatatypePtr->size <
          obj2->obj_UnderlyingDatatypePtr->size) {
            result = -1;
    }
    else if (obj1->obj_UnderlyingDatatypePtr->size >
          obj2->obj_UnderlyingDatatypePtr->size) {
            result = 1;
    }
    else {
            result = 0;
    }
    return result;
    }
```

---

**Extending and Embedding the Python**
2.2.5 Abstract Protocol Support

Python supports a variety of abstract `protocols;' the specific interfaces provided to use these interfaces are documented in the *Python/C API Reference Manual* in the chapter ``Abstract Objects Layer.''

A number of these abstract interfaces were defined early in the development of the Python implementation. In particular, the number, mapping, and sequence protocols have been part of Python since the beginning. Other protocols have been added over time. For protocols which depend on several handler routines from the type implementation, the older protocols have been defined as optional blocks of handlers referenced by the type object. For newer protocols there are additional slots in the main type object, with a flag bit being set to indicate that the slots are present and should be checked by the interpreter. (The flag bit does not indicate that the slot values are non-NULL. The flag may be set to indicate the presence of a slot, but a slot may still be unfilled.)

```c
PyNumberMethods tp_as_number;
PySequenceMethods tp_as_sequence;
PyMappingMethods tp_as_mapping;
```

If you wish your object to be able to act like a number, a sequence, or a mapping object, then you place the address of a structure that implements the C type PyNumberMethods, PySequenceMethods, or PyMappingMethods, respectively. It is up to you to fill in this structure with appropriate values. You can find examples of the use of each of these in the Objects directory of the Python source distribution.

```c
hashfunc tp_hash;
```

This function, if you choose to provide it, should return a hash number for an instance of your data type. Here is a moderately pointless example:

```c
static long
newdatatypenumberobject_hash(newdatatypenumberobject *obj)
{
    long result;
    result = obj->obj_UnderlyingDatatypePtr->size;
    result = result * 3;
    return result;
}
```
ternaryfunc tp_call;

This function is called when an instance of your data type is "called", for example, if obj1 is an instance of your data type and the Python script contains obj1('hello'), the tp_call handler is invoked.

This function takes three arguments:

1. arg1 is the instance of the data type which is the subject of the call. If the call is obj1('hello'), then arg1 is obj1.

2. arg2 is a tuple containing the arguments to the call. You can use PyArg_ParseTuple() to extract the arguments.

3. arg3 is a dictionary of keyword arguments that were passed. If this is non-NULL and you support keyword arguments, use PyArg_ParseTupleAndKeywords() to extract the arguments. If you do not want to support keyword arguments and this is non-NULL, raise a TypeError with a message saying that keyword arguments are not supported.

Here is a desultory example of the implementation of the call function.

```c
/* Implement the call function.
 * obj1 is the instance receiving the call.
 * obj2 is a tuple containing the arguments to the call, in this case 3 strings.
 */
static PyObject *
newdatatype_call(newdatatypeobject *obj, PyObject *args, PyObject *other)
{
    PyObject *result;
    char *arg1;
    char *arg2;
    char *arg3;

    if (!PyArg_ParseTuple(args, "sss:call", &arg1, &arg2, &arg3)) {
        return NULL;
    }
    result = PyString_FromFormat(
        " obj->obj_UnderlyingDatatypePtr->size, arg1, arg2, arg3);
    printf("%s", PyString_AS_STRING(result));
    return result;
```
XXX some fields need to be added here...

    /* Added in release 2.2 */
    /* Iterators */
    getiterfunc tp_iter;
    iternextfunc tp_iternext;

These functions provide support for the iterator protocol. Any object which
wishes to support iteration over its contents (which may be generated during
iteration) must implement the tp_iter handler. Objects which are returned by
a tp_iter handler must implement both the tp_iter and tp_iternext
handlers. Both handlers take exactly one parameter, the instance for which they
are being called, and return a new reference. In the case of an error, they should
set an exception and return NULL.

For an object which represents an iterable collection, the tp_iter handler
must return an iterator object. The iterator object is responsible for maintaining
the state of the iteration. For collections which can support multiple iterators
which do not interfere with each other (as lists and tuples do), a new iterator
should be created and returned. Objects which can only be iterated over once
(usually due to side effects of iteration) should implement this handler by
returning a new reference to themselves, and should also implement the
tp_iternext handler. File objects are an example of such an iterator.

Iterator objects should implement both handlers. The tp_iter handler should
return a new reference to the iterator (this is the same as the tp_iter handler
for objects which can only be iterated over destructively). The tp_iternext
handler should return a new reference to the next object in the iteration if there is
one. If the iteration has reached the end, it may return NULL without setting an
exception or it may set StopIteration; avoiding the exception can yield
slightly better performance. If an actual error occurs, it should set an exception
and return NULL.
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
2.2.6 Weak Reference Support

One of the goals of Python's weak-reference implementation is to allow any type to participate in the weak reference mechanism without incurring the overhead on those objects which do not benefit by weak referencing (such as numbers).

For an object to be weakly referencable, the extension must include a PyObject* field in the instance structure for the use of the weak reference mechanism; it must be initialized to NULL by the object's constructor. It must also set the tp_weaklistoffset field of the corresponding type object to the offset of the field. For example, the instance type is defined with the following structure:

```
typedef struct {
    PyObject_HEAD
    PyClassObject *in_class;  /* The class object */
    PyObject * in_dict;     /* A dictionary */
    PyObject * in_weakreflist; /* List of weak references */
} PyInstanceObject;
```

The statically-declared type object for instances is defined this way:

```
PyTypeObject PyInstance_Type = {
    PyObject_HEAD_INIT(&PyType_Type)
    0,
    "module.instance",
    /* Lots of stuff omitted for brevity... */
    Py_TPFLAGS_DEFAULT,       /* tp_flags */
    0,                        /* tp_doc */
    0,                        /* tp_traverse */
    0,                        /* tp_clear */
    0,                        /* tp_richcompare */
    offsetof(PyInstanceObject, in_weakreflist), /* tp_weaklistoffset */
};
```

The type constructor is responsible for initializing the weak reference list to NULL:

```
static PyObject *
instance_new() {
    /* Other initialization stuff omitted for brevity */
```
The only further addition is that the destructor needs to call the weak reference manager to clear any weak references. This should be done before any other parts of the destruction have occurred, but is only required if the weak reference list is non-NULL:

```c
static void
instance_dealloc(PyInstanceObject *inst)
{
    /* Allocate temporaries if needed, but do not begin
destruction just yet. */

    if (inst->in_weakreflist != NULL)
        PyObject_ClearWeakRefs((PyObject *) inst);

    /* Proceed with object destruction normally. */
}
```

Extending and Embedding the Python Interpreter

Previous: 2.2.5 Abstract Protocol Support  Up: 2.2 Type Methods  Next: 2.2.7

More Suggestions

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
2.2.7 More Suggestions

Remember that you can omit most of these functions, in which case you provide 0 as a value. There are type definitions for each of the functions you must provide. They are in object.h in the Python include directory that comes with the source distribution of Python.

In order to learn how to implement any specific method for your new data type, do the following: Download and unpack the Python source distribution. Go the Objects directory, then search the C source files for tp_ plus the function you want (for example, tp_print or tp_compare). You will find examples of the function you want to implement.

When you need to verify that an object is an instance of the type you are implementing, use the PyObject_TypeCheck function. A sample of its use might be something like the following:

```c
if (!PyObject_TypeCheck(some_object, &MyType)) {
    PyErr_SetString(PyExc_TypeError, "arg #1 not a mything");
    return NULL;
}
```

---

Release 2.5, documentation updated on 19th September, 2006.  
See About this document... for information on suggesting changes.
3. Building C and C++ Extensions with distutils

Starting in Python 1.4, Python provides, on UNIX, a special make file for building make files for building dynamically-linked extensions and custom interpreters. Starting with Python 2.0, this mechanism (known as related to Makefile.pre.in, and Setup files) is no longer supported. Building custom interpreters was rarely used, and extension modules can be built using distutils.

Building an extension module using distutils requires that distutils is installed on the build machine, which is included in Python 2.x and available separately for Python 1.5. Since distutils also supports creation of binary packages, users don't necessarily need a compiler and distutils to install the extension.

A distutils package contains a driver script, setup.py. This is a plain Python file, which, in the most simple case, could look like this:

```python
from distutils.core import setup, Extension

module1 = Extension('demo',
                      sources = ['demo.c'])

setup (name = 'PackageName',
       version = '1.0',
       description = 'This is a demo package',
       ext_modules = [module1])
```

With this setup.py, and a file demo.c, running

```bash
python setup.py build
```

will compile demo.c, and produce an extension module named "demo" in the build directory. Depending on the system, the module file will end up in a subdirectory build/lib.system, and may have a name like demo.so or demo.pyd.

In the setup.py, all execution is performed by calling the "setup" function. This takes a variable number of keyword arguments, of which the example above uses only a subset. Specifically, the example specifies meta-information to
build packages, and it specifies the contents of the package. Normally, a package will contain of addition modules, like Python source modules, documentation, subpackages, etc. Please refer to the distutils documentation in *Distributing Python Modules* to learn more about the features of distutils; this section explains building extension modules only.

It is common to pre-compute arguments to `setup`, to better structure the driver script. In the example above, the "ext_modules" argument to `setup` is a list of extension modules, each of which is an instance of the `Extension`. In the example, the instance defines an extension named "demo" which is build by compiling a single source file, demo.c.

In many cases, building an extension is more complex, since additional preprocessor defines and libraries may be needed. This is demonstrated in the example below.

```python
from distutils.core import setup, Extension

module1 = Extension('demo',
    define_macros = [('MAJOR_VERSION', '1'),
                     ('MINOR_VERSION', '0')],
    include_dirs = ['/usr/local/include'],
    libraries = ['tcl83'],
    library_dirs = ['/usr/local/lib'],
    sources = ['demo.c'])

setup (name = 'PackageName',
    version = '1.0',
    description = 'This is a demo package',
    author = 'Martin v. Loewis',
    author_email = 'martin@v.loewis.de',
    url = 'http://www.python.org/doc/current/ext/building.html',
    long_description = '''
This is really just a demo package.
''',
    ext_modules = [module1])
```

In this example, `setup` is called with additional meta-information, which is recommended when distribution packages have to be built. For the extension itself, it specifies preprocessor defines, include directories, library directories, and libraries. Depending on the compiler, distutils passes this information in different ways to the compiler. For example, on UNIX, this may result in the compilation commands

```bash
gcc -DNDEBUG -g -O3 -Wall -Wstrict-prototypes -fPIC -DMAJOR_VERSION=
```
gcc -shared build/temp.linux-i686-2.2/demo.o -L/usr/local/lib -ltcl8

These lines are for demonstration purposes only; distutils users should trust that distutils gets the invocations right.

Subsections

- 3.1 Distributing your extension modules

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
3.1 Distributing your extension modules

When an extension has been successfully build, there are three ways to use it.

End-users will typically want to install the module, they do so by running

    python setup.py install

Module maintainers should produce source packages; to do so, they run

    python setup.py sdist

In some cases, additional files need to be included in a source distribution; this is done through a MANIFEST.in file; see the distutils documentation for details.

If the source distribution has been build successfully, maintainers can also create binary distributions. Depending on the platform, one of the following commands can be used to do so.

    python setup.py bdist_wininst
    python setup.py bdist_rpm
    python setup.py bdist_dumb

4. Building C and C++ Extensions on Windows

This chapter briefly explains how to create a Windows extension module for Python using Microsoft Visual C++, and follows with more detailed background information on how it works. The explanatory material is useful for both the Windows programmer learning to build Python extensions and the UNIX programmer interested in producing software which can be successfully built on both UNIX and Windows.

Module authors are encouraged to use the distutils approach for building extension modules, instead of the one described in this section. You will still need the C compiler that was used to build Python; typically Microsoft Visual C++.

Note: This chapter mentions a number of filenames that include an encoded Python version number. These filenames are represented with the version number shown as "XY"; in practice, "X" will be the major version number and "Y" will be the minor version number of the Python release you're working with. For example, if you are using Python 2.2.1, "XY" will actually be "22".

Subsections

- 4.1 A Cookbook Approach
- 4.2 Differences Between UNIX and Windows
- 4.3 Using DLLs in Practice

Extending and Embedding the Python Interpreter
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
4.1 A Cookbook Approach

There are two approaches to building extension modules on Windows, just as there are on UNIX: use the distutils package to control the build process, or do things manually. The distutils approach works well for most extensions; documentation on using distutils to build and package extension modules is available in Distributing Python Modules. This section describes the manual approach to building Python extensions written in C or C++.

To build extensions using these instructions, you need to have a copy of the Python sources of the same version as your installed Python. You will need Microsoft Visual C++ "Developer Studio"; project files are supplied for VC++ version 7.1, but you can use older versions of VC++. Notice that you should use the same version of VC++ that was used to build Python itself. The example files described here are distributed with the Python sources in the PC\example_nt directory.

1. **Copy the example files**
   The example_nt directory is a subdirectory of the PC directory, in order to keep all the PC-specific files under the same directory in the source distribution. However, the example_nt directory can't actually be used from this location. You first need to copy or move it up one level, so that example_nt is a sibling of the PC and Include directories. Do all your work from within this new location.

2. **Open the project**
   From VC++, use the File > Open Solution dialog (not File > Open!). Navigate to and select the file example.sln, in the copy of the example_nt directory you made above. Click Open.

3. **Build the example DLL**
   In order to check that everything is set up right, try building:

   1. Select a configuration. This step is optional. Choose Build > Configuration Manager > Active Solution Configuration and select either Release or Debug. If you skip this step, VC++ will use the Debug configuration by default.
2. Build the DLL. Choose Build > Build Solution. This creates all intermediate and result files in a subdirectory called either Debug or Release, depending on which configuration you selected in the preceding step.

4. Testing the debug-mode DLL
Once the Debug build has succeeded, bring up a DOS box, and change to the example_nt\Debug directory. You should now be able to repeat the following session (C> is the DOS prompt, >>> is the Python prompt; note that build information and various debug output from Python may not match this screen dump exactly):

```
C> ..\.\PCbuild\python_d
Adding parser accelerators ...
Done.
Python 2.2 (#28, Dec 19 2001, 23:26:37) [MSC 32 bit (Intel)] on
Type "copyright", "credits" or "license" for more information.
>>> import example
[4897 refs]
>>> example.foo()
Hello, world
[4903 refs]
>>>
```

Congratulations! You've successfully built your first Python extension module.

5. Creating your own project
Choose a name and create a directory for it. Copy your C sources into it. Note that the module source file name does not necessarily have to match the module name, but the name of the initialization function should match the module name -- you can only import a module spam if its initialization function is called initspam(), and it should call Py_InitModule() with the string "spam" as its first argument (use the minimal example.c in this directory as a guide). By convention, it lives in a file called spam.c or spammodule.c. The output file should be called spam.dll or spam.pyd (the latter is supported to avoid confusion with a system library spam.dll to which your module could be a Python interface) in Release mode, or spam_d.dll or spam_d.pyd in Debug mode.

Now your options are:
1. Copy `example.sln` and `example.vcproj`, rename them to `spam.*`, and edit them by hand, or
2. Create a brand new project; instructions are below.

In either case, copy `example nt\example.def` to `spam\spam.def`, and edit the new `spam.def` so its second line contains the string `\initspam`. If you created a new project yourself, add the file `spam.def` to the project now. (This is an annoying little file with only two lines. An alternative approach is to forget about the `.def` file, and add the option `/export:initspam` somewhere to the Link settings, by manually editing the setting in Project Properties dialog).

6. **Creating a brand new project**
   Use the File > New > Project dialog to create a new Project Workspace. Select Visual C++ Projects/Win32/ Win32 Project, enter the name ("spam"), and make sure the Location is set to parent of the spam directory you have created (which should be a direct subdirectory of the Python build tree, a sibling of `Include` and `PC`). Select Win32 as the platform (in my version, this is the only choice). Make sure the Create new workspace radio button is selected. Click OK.

   You should now create the file `spam.def` as instructed in the previous section. Add the source files to the project, using Project > Add Existing Item. Set the pattern to *. * and select both `spam.c` and `spam.def` and click OK. (Inserting them one by one is fine too.)

   Now open the Project > spam properties dialog. You only need to change a few settings. Make sure All Configurations is selected from the Settings for: dropdown list. Select the C/C++ tab. Choose the General category in the popup menu at the top. Type the following text in the entry box labeled Additional Include Directories:

   ```
   ..\Include, ..\PC
   ```

   Then, choose the General category in the Linker tab, and enter

   ```
   ..\PCbuild
   ```

   in the text box labelled Additional library Directories.
Now you need to add some mode-specific settings:

Select Release in the Configuration dropdown list. Choose the Link tab, choose the Input category, and append `pythonXY.lib` to the list in the Additional Dependencies box.

Select Debug in the Configuration dropdown list, and append `pythonXY_d.lib` to the list in the Additional Dependencies box. Then click the C/C++ tab, select Code Generation, and select Multi-threaded Debug DLL from the Runtime library dropdown list.

Select Release again from the Configuration dropdown list. Select Multi-threaded DLL from the Runtime library dropdown list.

If your module creates a new type, you may have trouble with this line:

```c
PyObject_HEAD_INIT(&PyType_Type)
```

Change it to:

```c
PyObject_HEAD_INIT(NULL)
```

and add the following to the module initialization function:

```c
MyObject_Type.ob_type = &PyType_Type;
```

Refer to section 3 of the [Python FAQ](#) for details on why you must do this.
4.2 Differences Between **UNIX** and **Windows**

**UNIX** and Windows use completely different paradigms for run-time loading of code. Before you try to build a module that can be dynamically loaded, be aware of how your system works.

In **UNIX**, a shared object (.so) file contains code to be used by the program, and also the names of functions and data that it expects to find in the program. When the file is joined to the program, all references to those functions and data in the file's code are changed to point to the actual locations in the program where the functions and data are placed in memory. This is basically a link operation.

In Windows, a dynamic-link library (.dll) file has no dangling references. Instead, an access to functions or data goes through a lookup table. So the DLL code does not have to be fixed up at runtime to refer to the program's memory; instead, the code already uses the DLL's lookup table, and the lookup table is modified at runtime to point to the functions and data.

In **UNIX**, there is only one type of library file (.a) which contains code from several object files (.o). During the link step to create a shared object file (.so), the linker may find that it doesn't know where an identifier is defined. The linker will look for it in the object files in the libraries; if it finds it, it will include all the code from that object file.

In Windows, there are two types of library, a static library and an import library (both called .lib). A static library is like a **UNIX** .a file; it contains code to be included as necessary. An import library is basically used only to reassure the linker that a certain identifier is legal, and will be present in the program when the DLL is loaded. So the linker uses the information from the import library to build the lookup table for using identifiers that are not included in the DLL. When an application or a DLL is linked, an import library may be generated, which will need to be used for all future DLLs that depend on the symbols in the application or DLL.

Suppose you are building two dynamic-load modules, B and C, which should
share another block of code A. On UNIX, you would *not* pass A.a to the linker for B.so and C.so; that would cause it to be included twice, so that B and C would each have their own copy. In Windows, building A.dll will also build A.lib. You *do* pass A.lib to the linker for B and C. A.lib does not contain code; it just contains information which will be used at runtime to access A's code.

In Windows, using an import library is sort of like using "import spam"; it gives you access to spam's names, but does not create a separate copy. On UNIX, linking with a library is more like "from spam import *"; it does create a separate copy.
4.3 Using DLLs in Practice

Windows Python is built in Microsoft Visual C++; using other compilers may or may not work (though Borland seems to). The rest of this section is MSVC++ specific.

When creating DLLs in Windows, you must pass pythonXY.lib to the linker. To build two DLLs, spam and ni (which uses C functions found in spam), you could use these commands:

```
cl /LD /I/python/include spam.c ../libs/pythonXY.lib
cl /LD /I/python/include ni.c spam.lib ../libs/pythonXY.lib
```

The first command created three files: spam.obj, spam.dll and spam.lib. Spam.dll does not contain any Python functions (such as PyArg_ParseTuple()), but it does know how to find the Python code thanks to pythonXY.lib.

The second command created ni.dll (and .obj and .lib), which knows how to find the necessary functions from spam, and also from the Python executable.

Not every identifier is exported to the lookup table. If you want any other modules (including Python) to be able to see your identifiers, you have to say "declspec(dllexport)", as in "void _declspec(dllexport) initspam(void)" or "PyObject _declspec(dllexport) * NiGetSpamData(void)".

Developer Studio will throw in a lot of import libraries that you do not really need, adding about 100K to your executable. To get rid of them, use the Project Settings dialog, Link tab, to specify ignore default libraries. Add the correct msvcrxx.lib to the list of libraries.
Release 2.5, documentation updated on 19th September, 2006. See About this document... for information on suggesting changes.
5. Embedding Python in Another Application

The previous chapters discussed how to extend Python, that is, how to extend the functionality of Python by attaching a library of C functions to it. It is also possible to do it the other way around: enrich your C/C++ application by embedding Python in it. Embedding provides your application with the ability to implement some of the functionality of your application in Python rather than C or C++. This can be used for many purposes; one example would be to allow users to tailor the application to their needs by writing some scripts in Python. You can also use it yourself if some of the functionality can be written in Python more easily.

Embedding Python is similar to extending it, but not quite. The difference is that when you extend Python, the main program of the application is still the Python interpreter, while if you embed Python, the main program may have nothing to do with Python -- instead, some parts of the application occasionally call the Python interpreter to run some Python code.

So if you are embedding Python, you are providing your own main program. One of the things this main program has to do is initialize the Python interpreter. At the very least, you have to call the function `Py_Initialize()` (on Mac OS, call `PyMac_Initialize()` instead). There are optional calls to pass command line arguments to Python. Then later you can call the interpreter from any part of the application.

There are several different ways to call the interpreter: you can pass a string containing Python statements to `PyRun_SimpleString()`, or you can pass a stdio file pointer and a file name (for identification in error messages only) to `PyRun_SimpleFile()`. You can also call the lower-level operations described in the previous chapters to construct and use Python objects.

A simple demo of embedding Python can be found in the directory `Demo/embed/` of the source distribution.

5.1 Very High Level Embedding

The simplest form of embedding Python is the use of the very high level interface. This interface is intended to execute a Python script without needing to interact with the application directly. This can for example be used to perform some operation on a file.

```c
#include <Python.h>

int main(int argc, char *argv[])
{
    Py_Initialize();
    PyRun_SimpleString("from time import time,ctime\n":
                 "print 'Today is',ctime(time())\n");
    Py_Finalize();
    return 0;
}
```

The above code first initializes the Python interpreter with `Py_Initialize()`, followed by the execution of a hard-coded Python script that print the date and time. Afterwards, the `Py_Finalize()` call shuts the interpreter down, followed by the end of the program. In a real program, you may want to get the Python script from another source, perhaps a text-editor routine, a file, or a database. Getting the Python code from a file can better be done by using the `PyRun_SimpleFile()` function, which saves you the trouble of allocating memory space and loading the file contents.
5.2 Beyond Very High Level Embedding: An overview

The high level interface gives you the ability to execute arbitrary pieces of Python code from your application, but exchanging data values is quite cumbersome to say the least. If you want that, you should use lower level calls. At the cost of having to write more C code, you can achieve almost anything.

It should be noted that extending Python and embedding Python is quite the same activity, despite the different intent. Most topics discussed in the previous chapters are still valid. To show this, consider what the extension code from Python to C really does:

1. Convert data values from Python to C,
2. Perform a function call to a C routine using the converted values, and
3. Convert the data values from the call from C to Python.

When embedding Python, the interface code does:

1. Convert data values from C to Python,
2. Perform a function call to a Python interface routine using the converted values, and
3. Convert the data values from the call from Python to C.

As you can see, the data conversion steps are simply swapped to accommodate the different direction of the cross-language transfer. The only difference is the routine that you call between both data conversions. When extending, you call a C routine, when embedding, you call a Python routine.

This chapter will not discuss how to convert data from Python to C and vice versa. Also, proper use of references and dealing with errors is assumed to be understood. Since these aspects do not differ from extending the interpreter, you can refer to earlier chapters for the required information.
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
The first program aims to execute a function in a Python script. Like in the section about the very high level interface, the Python interpreter does not directly interact with the application (but that will change in the next section).

The code to run a function defined in a Python script is:

```c
#include <Python.h>

int
main(int argc, char *argv[])
{
    PyObject *pName, *pModule, *pDict, *pFunc;
    PyObject *pArgs, *pValue;
    int i;

    if (argc < 3) {
        fprintf(stderr,"Usage: call pythonfile funcname [args]\n");
        return 1;
    }

    Py_Initialize();
    pName = PyString_FromString(argv[1]);
    /* Error checking of pName left out */

    pModule = PyImport_Import(pName);
    Py_DECREF(pName);

    if (pModule != NULL) {
        pFunc = PyObject_GetAttrString(pModule, argv[2]);
        /* pFunc is a new reference */

        if (pFunc && PyCallable_Check(pFunc)) {
            pArgs = PyTuple_New(argc - 3);
            for (i = 0; i < argc - 3; ++i) {
                pValue = PyInt_FromLong(atoi(argv[i + 3]));
                if (!pValue) {
                    Py_DECREF(pArgs);
                    Py_DECREF(pModule);
                    fprintf(stderr, "Cannot convert argument\n");
                    return 1;
                }
                /* pValue reference stolen here: */
                PyTuple_SetItem(pArgs, i, pValue);
            }
            /* pValue reference stolen here: */
            PyObject_CallObject(pFunc, pArgs);
        }
    }
    pValue = PyObject_CallObject(pFunc, pArgs);
}```
Py_DECREF(pArgs);
if (pValue != NULL) {
    printf("Result of call: %ld\n", PyInt_AsLong(pValue))
    Py_DECREF(pValue);
} else {
    Py_DECREF(pFunc);
    Py_DECREF(pModule);
    PyErr_Print();
    fprintf(stderr,"Call failed\n");
    return 1;
}
} else {
    if (PyErr_Occurred())
        PyErr_Print();
    fprintf(stderr, "Cannot find function "\%s"\n", argv[2]);
    Py_XDECREF(pFunc);
    Py_DECREF(pModule);
} else {
    PyErr_Print();
    fprintf(stderr, "Failed to load "\%s"\n", argv[1]);
    return 1;
}
Py_Finalize();
return 0;

Download as text (original file name: run-func.c).

This code loads a Python script using argv[1], and calls the function named in argv[2]. Its integer arguments are the other values of the argv array. If you compile and link this program (let's call the finished executable call), and use it to execute a Python script, such as:

```python
def multiply(a,b):
    print "Will compute", a, "times", b
    c = 0
    for i in range(0, a):
        c = c + b
    return c
```

then the result should be:

```
$ call multiply multiply 3 2
Will compute 3 times 2
Result of call: 6
```
Although the program is quite large for its functionality, most of the code is for data conversion between Python and C, and for error reporting. The interesting part with respect to embedding Python starts with

```c
Py_Initialize();
pName = PyString_FromString(argv[1]);
/* Error checking of pName left out */
pModule = PyImport_Import(pName);
```

After initializing the interpreter, the script is loaded using `PyImport_Import()`. This routine needs a Python string as its argument, which is constructed using the `PyString_FromString()` data conversion routine.

```c
pFunc = PyObject_GetAttrString(pModule, argv[2]);
/* pFunc is a new reference */
if (pFunc && PyCallable_Check(pFunc)) {
    ...
}
Py_XDECREF(pFunc);
```

Once the script is loaded, the name we're looking for is retrieved using `PyObject_GetAttrString()`. If the name exists, and the object returned is callable, you can safely assume that it is a function. The program then proceeds by constructing a tuple of arguments as normal. The call to the Python function is then made with:

```c
pValue = PyObject_CallObject(pFunc, pArgs);
```

Upon return of the function, `pValue` is either `NULL` or it contains a reference to the return value of the function. Be sure to release the reference after examining the value.
5.4 Extending Embedded Python

Until now, the embedded Python interpreter had no access to functionality from the application itself. The Python API allows this by extending the embedded interpreter. That is, the embedded interpreter gets extended with routines provided by the application. While it sounds complex, it is not so bad. Simply forget for a while that the application starts the Python interpreter. Instead, consider the application to be a set of subroutines, and write some glue code that gives Python access to those routines, just like you would write a normal Python extension. For example:

```c
static int numargs=0;

/* Return the number of arguments of the application command line */
static PyObject*
emb_numargs(PyObject *self, PyObject *args)
{
    if(!PyArg_ParseTuple(args, ":numargs"))
        return NULL;
    return Py_BuildValue("i", numargs);
}

static PyMethodDef EmbMethods[] = {
    {"numargs", emb_numargs, METH_VARARGS,
     "Return the number of arguments received by the process."},
    {NULL, NULL, 0, NULL}
};
```

Insert the above code just above the `main()` function. Also, insert the following two statements directly after `Py_Initialize()`:

```c
numargs = argc;
Py_InitModule("emb", EmbMethods);
```

These two lines initialize the `numargs` variable, and make the `emb.numargs()` function accessible to the embedded Python interpreter. With these extensions, the Python script can do things like

```python
import emb
print "Number of arguments", emb.numargs()
```

In a real application, the methods will expose an API of the application to
Python.
5.5 Embedding Python in C++

It is also possible to embed Python in a C++ program; precisely how this is done will depend on the details of the C++ system used; in general you will need to write the main program in C++, and use the C++ compiler to compile and link your program. There is no need to recompile Python itself using C++.
5.6 Linking Requirements

While the `configure` script shipped with the Python sources will correctly build Python to export the symbols needed by dynamically linked extensions, this is not automatically inherited by applications which embed the Python library statically, at least on UNIX. This is an issue when the application is linked to the static runtime library (`libpython.a`) and needs to load dynamic extensions (implemented as .so files).

The problem is that some entry points are defined by the Python runtime solely for extension modules to use. If the embedding application does not use any of these entry points, some linkers will not include those entries in the symbol table of the finished executable. Some additional options are needed to inform the linker not to remove these symbols.

Determining the right options to use for any given platform can be quite difficult, but fortunately the Python configuration already has those values. To retrieve them from an installed Python interpreter, start an interactive interpreter and have a short session like this:

```python
>>> import distutils.sysconfig
>>> distutils.sysconfig.get_config_var('LINKFORSHARED')
'-Xlinker -export-dynamic'
```

The contents of the string presented will be the options that should be used. If the string is empty, there's no need to add any additional options. The `LINKFORSHARED` definition corresponds to the variable of the same name in Python's top-level `Makefile`. 

---

**Extending and Embedding the Python Interpreter**

*Previous: 5.5 Embedding Python in*  
*Up: 5. Embedding Python in*  
*Next: A. Reporting Bugs*

*Release 2.5, documentation updated on 19th September, 2006.*  
*See [About this document...](#) for information on suggesting changes.*
A. Reporting Bugs

Python is a mature programming language which has established a reputation for stability. In order to maintain this reputation, the developers would like to know of any deficiencies you find in Python or its documentation.

Before submitting a report, you will be required to log into SourceForge; this will make it possible for the developers to contact you for additional information if needed. It is not possible to submit a bug report anonymously.

All bug reports should be submitted via the Python Bug Tracker on SourceForge (http://sourceforge.net/bugs/?group_id=5470). The bug tracker offers a Web form which allows pertinent information to be entered and submitted to the developers.

The first step in filing a report is to determine whether the problem has already been reported. The advantage in doing so, aside from saving the developers time, is that you learn what has been done to fix it; it may be that the problem has already been fixed for the next release, or additional information is needed (in which case you are welcome to provide it if you can!). To do this, search the bug database using the search box on the left side of the page.

If the problem you're reporting is not already in the bug tracker, go back to the Python Bug Tracker (http://sourceforge.net/bugs/?group_id=5470). Select the ``Submit a Bug'' link at the top of the page to open the bug reporting form.

The submission form has a number of fields. The only fields that are required are the ``Summary'' and ``Details'' fields. For the summary, enter a very short description of the problem; less than ten words is good. In the Details field, describe the problem in detail, including what you expected to happen and what did happen. Be sure to include the version of Python you used, whether any extension modules were involved, and what hardware and software platform you were using (including version information as appropriate).

The only other field that you may want to set is the ``Category'' field, which allows you to place the bug report into a broad category (such as ``Documentation'' or ``Library'').
Each bug report will be assigned to a developer who will determine what needs to be done to correct the problem. You will receive an update each time action is taken on the bug.

B.1 History of the software

Python was created in the early 1990s by Guido van Rossum at Stichting Mathematisch Centrum (CWI, see [http://www.cwi.nl/](http://www.cwi.nl/)) in the Netherlands as a successor of a language called ABC. Guido remains Python's principal author, although it includes many contributions from others.

In 1995, Guido continued his work on Python at the Corporation for National Research Initiatives (CNRI, see [http://www.cnri.reston.va.us/](http://www.cnri.reston.va.us/)) in Reston, Virginia where he released several versions of the software.

In May 2000, Guido and the Python core development team moved to BeOpen.com to form the BeOpen PythonLabs team. In October of the same year, the PythonLabs team moved to Digital Creations (now Zope Corporation; see [http://www.zope.com/](http://www.zope.com/)). In 2001, the Python Software Foundation (PSF, see [http://www.python.org/psf/](http://www.python.org/psf/)) was formed, a non-profit organization created specifically to own Python-related Intellectual Property. Zope Corporation is a sponsoring member of the PSF.

All Python releases are Open Source (see [http://www.opensource.org/](http://www.opensource.org/) for the Open Source Definition). Historically, most, but not all, Python releases have also been GPL-compatible; the table below summarizes the various releases.

**Note:** GPL-compatible doesn't mean that we're distributing Python under the GPL. All Python licenses, unlike the GPL, let you distribute a modified version without making your changes open source. The GPL-compatible licenses make it possible to combine Python with other software that is released under the GPL; the others don't.

Thanks to the many outside volunteers who have worked under Guido's direction to make these releases possible.
B.2 Terms and conditions for accessing or otherwise using Python

PSF LICENSE AGREEMENT FOR PYTHON 2.5

1. This LICENSE AGREEMENT is between the Python Software Foundation (``PSF''), and the Individual or Organization (``Licensee'') accessing and otherwise using Python 2.5 software in source or binary form and its associated documentation.

2. Subject to the terms and conditions of this License Agreement, PSF hereby grants Licensee a nonexclusive, royalty-free, world-wide license to reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use Python 2.5 alone or in any derivative version, provided, however, that PSF's License Agreement and PSF's notice of copyright, i.e., ``Copyright © 2001-2006 Python Software Foundation; All Rights Reserved'' are retained in Python 2.5 alone or in any derivative version prepared by Licensee.

3. In the event Licensee prepares a derivative work that is based on or incorporates Python 2.5 or any part thereof, and wants to make the derivative work available to others as provided herein, then Licensee hereby agrees to include in any such work a brief summary of the changes made to Python 2.5.

4. PSF is making Python 2.5 available to Licensee on an ``AS IS'' basis. PSF MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT LIMITATION, PSF MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF PYTHON 2.5 WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.

5. PSF SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS
OF PYTHON 2.5 FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF MODIFYING, DISTRIBUTING, OR OTHERWISE USING PYTHON 2.5, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.

6. This License Agreement will automatically terminate upon a material breach of its terms and conditions.

7. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between PSF and Licensee. This License Agreement does not grant permission to use PSF trademarks or trade name in a trademark sense to endorse or promote products or services of Licensee, or any third party.

8. By copying, installing or otherwise using Python 2.5, Licensee agrees to be bound by the terms and conditions of this License Agreement.

BEOPEN.COM LICENSE AGREEMENT FOR PYTHON 2.0

BEOPEN PYTHON OPEN SOURCE LICENSE AGREEMENT VERSION 1

1. This LICENSE AGREEMENT is between BeOpen.com (``BeOpen''), having an office at 160 Saratoga Avenue, Santa Clara, CA 95051, and the Individual or Organization (``Licensee'') accessing and otherwise using this software in source or binary form and its associated documentation (``the Software'').

2. Subject to the terms and conditions of this BeOpen Python License Agreement, BeOpen hereby grants Licensee a non-exclusive, royalty-free, world-wide license to reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use the Software alone or in any derivative version, provided, however, that the BeOpen Python License is retained in the Software, alone or in any derivative version prepared by Licensee.

3. BeOpen is making the Software available to Licensee on an ``AS IS'' basis. BEOPEN MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT
LIMITATION, BEOPEN MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF THE SOFTWARE WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.

4. BEOPEN SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS OF THE SOFTWARE FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF USING, MODIFYING OR DISTRIBUTING THE SOFTWARE, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.

5. This License Agreement will automatically terminate upon a material breach of its terms and conditions.

6. This License Agreement shall be governed by and interpreted in all respects by the law of the State of California, excluding conflict of law provisions. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between BeOpen and Licensee. This License Agreement does not grant permission to use BeOpen trademarks or trade names in a trademark sense to endorse or promote products or services of Licensee, or any third party. As an exception, the ``BeOpen Python'' logos available at http://www.pythonlabs.com/logos.html may be used according to the permissions granted on that web page.

7. By copying, installing or otherwise using the software, Licensee agrees to be bound by the terms and conditions of this License Agreement.

**CNRI LICENSE AGREEMENT FOR PYTHON 1.6.1**

1. This LICENSE AGREEMENT is between the Corporation for National Research Initiatives, having an office at 1895 Preston White Drive, Reston, VA 20191 (``CNRI''), and the Individual or Organization (``Licensee'') accessing and otherwise using Python 1.6.1 software in source or binary form and its associated documentation.

2. Subject to the terms and conditions of this License Agreement, CNRI hereby grants Licensee a nonexclusive, royalty-free, world-wide license to
reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use Python 1.6.1 alone or in any derivative version, provided, however, that CNRI's License Agreement and CNRI's notice of copyright, i.e., ``Copyright © 1995-2001 Corporation for National Research Initiatives; All Rights Reserved" are retained in Python 1.6.1 alone or in any derivative version prepared by Licensee. Alternately, in lieu of CNRI's License Agreement, Licensee may substitute the following text (omitting the quotes): ``Python 1.6.1 is made available subject to the terms and conditions in CNRI's License Agreement. This Agreement together with Python 1.6.1 may be located on the Internet using the following unique, persistent identifier (known as a handle): 1895.22/1013. This Agreement may also be obtained from a proxy server on the Internet using the following URL: http://hdl.handle.net/1895.22/1013."

3. In the event Licensee prepares a derivative work that is based on or incorporates Python 1.6.1 or any part thereof, and wants to make the derivative work available to others as provided herein, then Licensee hereby agrees to include in any such work a brief summary of the changes made to Python 1.6.1.

4. CNRI is making Python 1.6.1 available to Licensee on an ``AS IS'' basis. CNRI MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT LIMITATION, CNRI MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF PYTHON 1.6.1 WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.

5. CNRI SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS OF PYTHON 1.6.1 FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF MODIFYING, DISTRIBUTING, OR OTHERWISE USING PYTHON 1.6.1, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.

6. This License Agreement will automatically terminate upon a material breach of its terms and conditions.

7. This License Agreement shall be governed by the federal intellectual
property law of the United States, including without limitation the federal copyright law, and, to the extent such U.S. federal law does not apply, by the law of the Commonwealth of Virginia, excluding Virginia's conflict of law provisions. Notwithstanding the foregoing, with regard to derivative works based on Python 1.6.1 that incorporate non-separable material that was previously distributed under the GNU General Public License (GPL), the law of the Commonwealth of Virginia shall govern this License Agreement only as to issues arising under or with respect to Paragraphs 4, 5, and 7 of this License Agreement. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between CNRI and Licensee. This License Agreement does not grant permission to use CNRI trademarks or trade name in a trademark sense to endorse or promote products or services of Licensee, or any third party.

8. By clicking on the "``ACCEPT"" button where indicated, or by copying, installing or otherwise using Python 1.6.1, Licensee agrees to be bound by the terms and conditions of this License Agreement.

ACCEPT

B.3.4 MD5 message digest algorithm

The source code for the md5 module contains the following notice:

Copyright (C) 1999, 2002 Aladdin Enterprises. All rights reserved

This software is provided 'as-is', without any express or implied warranty. In no event will the authors be held liable for any damages arising from the use of this software.

Permission is granted to anyone to use this software for any purpose including commercial applications, and to alter it and redistribute it freely, subject to the following restrictions:

1. The origin of this software must not be misrepresented; you must claim that you wrote the original software. If you use this software in a product, an acknowledgment in the product documentation would be appreciated but is not required.
2. Altered source versions must be plainly marked as such, and not misrepresented as being the original software.
3. This notice may not be removed or altered from any source distribution.

L. Peter Deutsch
ghost@aladdin.com

Independent implementation of MD5 (RFC 1321).

This code implements the MD5 Algorithm defined in RFC 1321, whose text is available at

http://www.ietf.org/rfc/rfc1321.txt

The code is derived from the text of the RFC, including the test suite (section A.5) but excluding the rest of Appendix A. It does not include any code or documentation that is identified in the RFC as being copyrighted.

The original and principal author of md5.h is L. Peter Deutsch <ghost@aladdin.com>. Other authors are noted in the change history that follows (in reverse chronological order):

2002-04-13 lpd Removed support for non-ANSI compilers; removed references to Ghostscript; clarified derivation from RFC 132
now handles byte order either statically or dynamically.
1999-11-04 lpd Edited comments slightly for automatic TOC extraction
1999-10-18 lpd Fixed typo in header comment (ans12knr rather than
added conditionalization for C++ compilation from Martin
Purschke <purschke@bnl.gov>.
1999-05-03 lpd Original version.
B.3.5 Asynchronous socket services

The asynchat and asyncore modules contain the following notice:

Copyright 1996 by Sam Rushing

All Rights Reserved

Permission to use, copy, modify, and distribute this software and its documentation for any purpose and without fee is hereby granted, provided that the above copyright notice appear in all copies and that both that copyright notice and this permission notice appear in supporting documentation, and that the name of Sam Rushing not be used in advertising or publicity pertaining to distribution of the software without specific, written prior permission.

SAM RUSHING DISCLAIMS ALL WARRANTIES WITH REGARD TO THIS SOFTWARE, INCLUDING ALL IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS, IN NO EVENT SHALL SAM RUSHING BE LIABLE FOR ANY SPECIAL, INDIRECT OR CONSEQUENTIAL DAMAGES OR ANY DAMAGES WHATSOEVER RESULTING FROM LOSS OF USE, DATA OR PROFITS, WHETHER IN AN ACTION OF CONTRACT, NEGLIGENCE OR OTHER TORTIOUS ACTION, ARISING OUT OF OR IN CONNECTION WITH THE USE OR PERFORMANCE OF THIS SOFTWARE.

Release 2.5, documentation updated on 19th September, 2006.

About this document...
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
1. Introduction

The Application Programmer's Interface to Python gives C and C++ programmers access to the Python interpreter at a variety of levels. The API is equally usable from C++, but for brevity it is generally referred to as the Python/C API. There are two fundamentally different reasons for using the Python/C API. The first reason is to write extension modules for specific purposes; these are C modules that extend the Python interpreter. This is probably the most common use. The second reason is to use Python as a component in a larger application; this technique is generally referred to as embedding Python in an application.

Writing an extension module is a relatively well-understood process, where a "cookbook" approach works well. There are several tools that automate the process to some extent. While people have embedded Python in other applications since its early existence, the process of embedding Python is less straightforward than writing an extension.

Many API functions are useful independent of whether you're embedding or extending Python; moreover, most applications that embed Python will need to provide a custom extension as well, so it's probably a good idea to become familiar with writing an extension before attempting to embed Python in a real application.

1.1 Include Files

All function, type and macro definitions needed to use the Python/C API are included in your code by the following line:

```c
#include "Python.h"
```

This implies inclusion of the following standard headers: `<stdio.h>`, `<string.h>`, `<errno.h>`, `<limits.h>`, and `<stdlib.h>` (if available).

**Warning:** Since Python may define some pre-processor definitions which affect the standard headers on some systems, you must include `Python.h` before any standard headers are included.

All user visible names defined by `Python.h` (except those defined by the included standard headers) have one of the prefixes "Py" or "_Py". Names beginning with "_Py" are for internal use by the Python implementation and should not be used by extension writers. Structure member names do not have a reserved prefix.

**Important:** user code should never define names that begin with "Py" or "_Py". This confuses the reader, and jeopardizes the portability of the user code to future Python versions, which may define additional names beginning with one of these prefixes.

The header files are typically installed with Python. On UNIX, these are located in the directories `prefix/include/pythonversion/` and `exec_prefix/include/pythonversion/`, where `prefix` and `exec_prefix` are defined by the corresponding parameters to Python's `configure` script and `version` is `sys.version[:3]`. On Windows, the headers are installed in `prefix/include`, where `prefix` is the installation directory specified to the installer.

To include the headers, place both directories (if different) on your compiler's search path for includes. Do not place the parent directories on the search path.
and then use "#include <python2.5/Python.h>"; this will break on multi-platform builds since the platform independent headers under prefix include the platform specific headers from exec_prefix.

C++ users should note that though the API is defined entirely using C, the header files do properly declare the entry points to be extern "C", so there is no need to do anything special to use the API from C++.
1.2 Objects, Types and Reference Counts

Most Python/C API functions have one or more arguments as well as a return value of type PyObject*. This type is a pointer to an opaque data type representing an arbitrary Python object. Since all Python object types are treated the same way by the Python language in most situations (e.g., assignments, scope rules, and argument passing), it is only fitting that they should be represented by a single C type. Almost all Python objects live on the heap: you never declare an automatic or static variable of type PyObject, only pointer variables of type PyObject* can be declared. The sole exception are the type objects; since these must never be deallocated, they are typically static PyTypeObject objects.

All Python objects (even Python integers) have a type and a reference count. An object's type determines what kind of object it is (e.g., an integer, a list, or a user-defined function; there are many more as explained in the Python Reference Manual). For each of the well-known types there is a macro to check whether an object is of that type; for instance, "PyList_Check(a)" is true if (and only if) the object pointed to by a is a Python list.

Subsections

- 1.2.1 Reference Counts
  - 1.2.1.1 Reference Count Details
- 1.2.2 Types
1.2.1 Reference Counts

The reference count is important because today's computers have a finite (and often severely limited) memory size; it counts how many different places there are that have a reference to an object. Such a place could be another object, or a global (or static) C variable, or a local variable in some C function. When an object's reference count becomes zero, the object is deallocated. If it contains references to other objects, their reference count is decremented. Those other objects may be deallocated in turn, if this decrement makes their reference count become zero, and so on. (There's an obvious problem with objects that reference each other here; for now, the solution is ``don't do that.''

Reference counts are always manipulated explicitly. The normal way is to use the macro Py_INCREF() to increment an object's reference count by one, and Py_DECREF() to decrement it by one. The Py_DECREF() macro is considerably more complex than the incref one, since it must check whether the reference count becomes zero and then cause the object's deallocator to be called. The deallocator is a function pointer contained in the object's type structure. The type-specific deallocator takes care of decrementing the reference counts for other objects contained in the object if this is a compound object type, such as a list, as well as performing any additional finalization that's needed. There's no chance that the reference count can overflow; at least as many bits are used to hold the reference count as there are distinct memory locations in virtual memory (assuming sizeof(long) >= sizeof(char*)). Thus, the reference count increment is a simple operation.

It is not necessary to increment an object's reference count for every local variable that contains a pointer to an object. In theory, the object's reference count goes up by one when the variable is made to point to it and it goes down by one when the variable goes out of scope. However, these two cancel each other out, so at the end the reference count hasn't changed. The only real reason to use the reference count is to prevent the object from being deallocated as long as our variable is pointing to it. If we know that there is at least one other reference to the object that lives at least as long as our variable, there is no need to increment the reference count temporarily. An important situation where this arises is in objects that are passed as arguments to C functions in an extension module that are called from Python; the call mechanism guarantees to hold a
reference to every argument for the duration of the call.

However, a common pitfall is to extract an object from a list and hold on to it for a while without incrementing its reference count. Some other operation might conceivably remove the object from the list, decrementing its reference count and possible deallocating it. The real danger is that innocent-looking operations may invoke arbitrary Python code which could do this; there is a code path which allows control to flow back to the user from a `Py_DECREF()`, so almost any operation is potentially dangerous.

A safe approach is to always use the generic operations (functions whose name begins with "PyObject_", "PyNumber_", "PySequence_" or "PyMapping_"'). These operations always increment the reference count of the object they return. This leaves the caller with the responsibility to call `Py_DECREF()` when they are done with the result; this soon becomes second nature.

---

**Subsections**

- [1.2.1.1 Reference Count Details](#)

---

Release 2.5, documentation updated on 19th September, 2006.
See [About this document...](#) for information on suggesting changes.
1.2.2 Types

There are few other data types that play a significant role in the Python/C API; most are simple C types such as `int`, `long`, `double` and `char*`. A few structure types are used to describe static tables used to list the functions exported by a module or the data attributes of a new object type, and another is used to describe the value of a complex number. These will be discussed together with the functions that use them.
1.3 Exceptions

The Python programmer only needs to deal with exceptions if specific error handling is required; unhandled exceptions are automatically propagated to the caller, then to the caller's caller, and so on, until they reach the top-level interpreter, where they are reported to the user accompanied by a stack traceback.

For C programmers, however, error checking always has to be explicit. All functions in the Python/C API can raise exceptions, unless an explicit claim is made otherwise in a function's documentation. In general, when a function encounters an error, it sets an exception, discards any object references that it owns, and returns an error indicator -- usually NULL or -1. A few functions return a Boolean true/false result, with false indicating an error. Very few functions return no explicit error indicator or have an ambiguous return value, and require explicit testing for errors with PyErr_Occurred().

Exception state is maintained in per-thread storage (this is equivalent to using global storage in an unthreaded application). A thread can be in one of two states: an exception has occurred, or not. The function PyErr_Occurred() can be used to check for this: it returns a borrowed reference to the exception type object when an exception has occurred, and NULL otherwise. There are a number of functions to set the exception state: PyErr_SetString() is the most common (though not the most general) function to set the exception state, and PyErr_Clear() clears the exception state.

The full exception state consists of three objects (all of which can be NULL): the exception type, the corresponding exception value, and the traceback. These have the same meanings as the Python objects sys.exc_type, sys.exc_value, and sys.exc_traceback; however, they are not the same: the Python objects represent the last exception being handled by a Python try ... except statement, while the C level exception state only exists while an exception is being passed on between C functions until it reaches the Python bytecode interpreter's main loop, which takes care of transferring it to sys.exc_type and friends.

Note that starting with Python 1.5, the preferred, thread-safe way to access the
exception state from Python code is to call the function `sys.exc_info()`, which returns the per-thread exception state for Python code. Also, the semantics of both ways to access the exception state have changed so that a function which catches an exception will save and restore its thread's exception state so as to preserve the exception state of its caller. This prevents common bugs in exception handling code caused by an innocent-looking function overwriting the exception being handled; it also reduces the often unwanted lifetime extension for objects that are referenced by the stack frames in the traceback.

As a general principle, a function that calls another function to perform some task should check whether the called function raised an exception, and if so, pass the exception state on to its caller. It should discard any object references that it owns, and return an error indicator, but it should not set another exception -- that would overwrite the exception that was just raised, and lose important information about the exact cause of the error.

A simple example of detecting exceptions and passing them on is shown in the `sum_sequence()` example above. It so happens that that example doesn't need to clean up any owned references when it detects an error. The following example function shows some error cleanup. First, to remind you why you like Python, we show the equivalent Python code:

```python
def incr_item(dict, key):
    try:
        item = dict[key]
    except KeyError:
        item = 0
    dict[key] = item + 1
```

Here is the corresponding C code, in all its glory:

```c
int
incr_item(PyObject *dict, PyObject *key)
{
    /* Objects all initialized to NULL for Py_XDECREF */
    PyObject *item = NULL, *const_one = NULL, *incremented_item = NULL;
    int rv = -1; /* Return value initialized to -1 (failure) */

    item = PyObject_GetItem(dict, key);
    if (item == NULL) {
        /* Handle KeyError only: */
        if (!PyErr_ExceptionMatches(PyExc_KeyError))
            goto error;
```
/* Clear the error and use zero: */
PyErr_Clear();
item = PyInt_FromLong(0L);
if (item == NULL)
goto error;
}
const_one = PyInt_FromLong(1L);
if (const_one == NULL)
goto error;

incremented_item = PyNumber_Add(item, const_one);
if (incremented_item == NULL)
goto error;

if (PyObject_SetItem(dict, key, incremented_item) < 0)
goto error;
rv = 0; /* Success */
/* Continue with cleanup code */

error:
/* Cleanup code, shared by success and failure path */

/* Use Py_XDecref() to ignore NULL references */
Py_XDecref(item);
Py_XDecref(const_one);
Py_XDecref(incremented_item);

return rv; /* -1 for error, 0 for success */
}

This example represents an endorsed use of the goto statement in C! It illustrates the use of PyErr_ExceptionMatches() and PyErr_Clear() to handle specific exceptions, and the use of Py_XDecref() to dispose of owned references that may be NULL (note the "X" in the name; Py_DECREF() would crash when confronted with a NULL reference). It is important that the variables used to hold owned references are initialized to NULL for this to work; likewise, the proposed return value is initialized to -1 (failure) and only set to success after the final call made is successful.
1.4 Embedding Python

The one important task that only embedders (as opposed to extension writers) of the Python interpreter have to worry about is the initialization, and possibly the finalization, of the Python interpreter. Most functionality of the interpreter can only be used after the interpreter has been initialized.

The basic initialization function is `Py_Initialize()`. This initializes the table of loaded modules, and creates the fundamental modules `__builtin__`, `__main__`, `sys`, and `exceptions`. It also initializes the module search path (`sys.path`).

`Py_Initialize()` does not set the "script argument list" (`sys.argv`). If this variable is needed by Python code that will be executed later, it must be set explicitly with a call to `PySys_SetArgv(argc, argv)` subsequent to the call to `Py_Initialize()`.

On most systems (in particular, on UNIX and Windows, although the details are slightly different), `Py_Initialize()` calculates the module search path based upon its best guess for the location of the standard Python interpreter executable, assuming that the Python library is found in a fixed location relative to the Python interpreter executable. In particular, it looks for a directory named `lib/python2.5` relative to the parent directory where the executable named `python` is found on the shell command search path (the environment variable `PATH`).

For instance, if the Python executable is found in `/usr/local/bin/python`, it will assume that the libraries are in `/usr/local/lib/python2.5`. (In fact, this particular path is also the "fallback" location, used when no executable file named `python` is found along `PATH`.) The user can override this behavior by setting the environment variable `PYTHONHOME`, or insert additional directories in front of the standard path by setting `PYTHONPATH`.

The embedding application can steer the search by calling `Py_SetProgramName(file) before calling Py_Initialize()`. Note that `PYTHONHOME` still overrides this and `PYTHONPATH` is still inserted in front of the standard path. An application that requires total control has to provide its

Sometimes, it is desirable to ``uninitialize'' Python. For instance, the application may want to start over (make another call to `Py_Initialize()`) or the application is simply done with its use of Python and wants to free memory allocated by Python. This can be accomplished by calling `Py_Finalize()`. The function `Py_IsInitialized()` returns true if Python is currently in the initialized state. More information about these functions is given in a later chapter. Notice that `Py_Finalize` does not free all memory allocated by the Python interpreter, e.g. memory allocated by extension modules currently cannot be released.
1.5 Debugging Builds

Python can be built with several macros to enable extra checks of the interpreter and extension modules. These checks tend to add a large amount of overhead to the runtime so they are not enabled by default.

A full list of the various types of debugging builds is in the file Misc/SpecialBuilds.txt in the Python source distribution. Builds are available that support tracing of reference counts, debugging the memory allocator, or low-level profiling of the main interpreter loop. Only the most frequently-used builds will be described in the remainder of this section.

Compiling the interpreter with the Py_DEBUG macro defined produces what is generally meant by "a debug build" of Python. Py_DEBUG is enabled in the UNIX build by adding --with-pydebug to the configure command. It is also implied by the presence of the not-Python-specific _DEBUG macro. When Py_DEBUG is enabled in the UNIX build, compiler optimization is disabled.

In addition to the reference count debugging described below, the following extra checks are performed:

- Extra checks are added to the object allocator.
- Extra checks are added to the parser and compiler.
- Downcasts from wide types to narrow types are checked for loss of information.
- A number of assertions are added to the dictionary and set implementations. In addition, the set object acquires a test_c_api method.
- Sanity checks of the input arguments are added to frame creation.
- The storage for long ints is initialized with a known invalid pattern to catch reference to uninitialized digits.
- Low-level tracing and extra exception checking are added to the runtime virtual machine.
- Extra checks are added to the memory arena implementation.
- Extra debugging is added to the thread module.

There may be additional checks not mentioned here.
Defining Py_TRACE_REFS enables reference tracing. When defined, a circular doubly linked list of active objects is maintained by adding two extra fields to every PyObject. Total allocations are tracked as well. Upon exit, all existing references are printed. (In interactive mode this happens after every statement run by the interpreter.) Implied by Py_DEBUG.

Please refer to Misc/SpecialBuilds.txt in the Python source distribution for more detailed information.
2. The Very High Level Layer

The functions in this chapter will let you execute Python source code given in a file or a buffer, but they will not let you interact in a more detailed way with the interpreter.

Several of these functions accept a start symbol from the grammar as a parameter. The available start symbols are `Py_eval_input`, `Py_file_input`, and `Py_single_input`. These are described following the functions which accept them as parameters.

Note also that several of these functions take `FILE*` parameters. On particular issue which needs to be handled carefully is that the `FILE` structure for different C libraries can be different and incompatible. Under Windows (at least), it is possible for dynamically linked extensions to actually use different libraries, so care should be taken that `FILE*` parameters are only passed to these functions if it is certain that they were created by the same library that the Python runtime is using.

```c
int Py_Main( int argc, char **argv)
```

The main program for the standard interpreter. This is made available for programs which embed Python. The `argc` and `argv` parameters should be prepared exactly as those which are passed to a C program's `main()` function. It is important to note that the argument list may be modified (but the contents of the strings pointed to by the argument list are not). The return value will be the integer passed to the `sys.exit()` function, 1 if the interpreter exits due to an exception, or 2 if the parameter list does not represent a valid Python command line.

```c
int PyRun_AnyFile( FILE *fp, const char *filename)
```

This is a simplified interface to `PyRun_AnyFileExFlags()` below, leaving `closeit` set to 0 and `flags` set to NULL.

```c
int PyRun_AnyFileFlags(FILE *fp, const char *filename, PyCompilerFlags *flags)
```

This is a simplified interface to `PyRun_AnyFileExFlags()` below,
leaving the `closeit` argument set to 0.

```c
int PyRun<AnyFileEx>( FILE *fp, const char *filename, int closeit)
This is a simplified interface to `PyRun<AnyFileExFlags>()` below,
leaving the `flags` argument set to NULL.

int PyRun<AnyFileExFlags>( FILE *fp, const char *filename, int closeit,
PyCompilerFlags *flags)
If `fp` refers to a file associated with an interactive device (console or
terminal input or Unix pseudo-terminal), return the value of
`PyRun_InteractiveLoop()`, otherwise return the result of
`PyRun_SimpleFile()`. If `filename` is NULL, this function uses "???

int PyRun_SimpleString( const char *command)
This is a simplified interface to `PyRun_SimpleStringFlags()`
below, leaving the `PyCompilerFlags*` argument set to NULL.

int PyRun_SimpleStringFlags( const char *command, PyCompilerFlags
*flags)
Executes the Python source code from `command` in the __main__ module
according to the `flags` argument. If __main__ does not already exist, it is
created. Returns 0 on success or -1 if an exception was raised. If there was
an error, there is no way to get the exception information. For the meaning
of `flags`, see below.

int PyRun_SimpleFile( FILE *fp, const char *filename)
This is a simplified interface to `PyRun_SimpleFileExFlags()`
below, leaving `closeit` set to 0 and `flags` set to NULL.

int PyRun_SimpleFileFlags( FILE *fp, const char *filename,
PyCompilerFlags *flags)
This is a simplified interface to `PyRun_SimpleFileExFlags()`
below, leaving `closeit` set to 0.

int PyRun_SimpleFileEx( FILE *fp, const char *filename, int closeit)
This is a simplified interface to `PyRun_SimpleFileExFlags()`
below, leaving flags set to NULL.

int PyRun_SimpleFileExFlags(FILE *fp, const char *filename, int closeit, PyCompilerFlags *flags)

Similar to PyRun_SimpleStringFlags(), but the Python source code is read from fp instead of an in-memory string. filename should be the name of the file. If closeit is true, the file is closed before PyRun_SimpleFileExFlags returns.

int PyRun_InteractiveOne(FILE *fp, const char *filename)

This is a simplified interface to PyRun_InteractiveOneFlags() below, leaving flags set to NULL.

int PyRun_InteractiveOneFlags(FILE *fp, const char *filename, PyCompilerFlags *flags)

Read and execute a single statement from a file associated with an interactive device according to the flags argument. If filename is NULL, "???" is used instead. The user will be prompted using sys.ps1 and sys.ps2. Returns 0 when the input was executed successfully, -1 if there was an exception, or an error code from the errcode.h include file distributed as part of Python if there was a parse error. (Note that errcode.h is not included by Python.h, so must be included specifically if needed.)

int PyRun_InteractiveLoop(FILE *fp, const char *filename)

This is a simplified interface to PyRun_InteractiveLoopFlags() below, leaving flags set to NULL.

int PyRun_InteractiveLoopFlags(FILE *fp, const char *filename, PyCompilerFlags *flags)

Read and execute statements from a file associated with an interactive device until EOF is reached. If filename is NULL, "???" is used instead. The user will be prompted using sys.ps1 and sys.ps2. Returns 0 at EOF.

struct _node* PyParser_SimpleParseString(const char *str, int start)

This is a simplified interface to PyParser_SimpleParseStringFlagsFilename() below,
leaving `filename` set to NULL and `flags` set to 0.

```
struct _node* PyParser_SimpleParseStringFlags(const char* str, int start, int flags)
```

This is a simplified interface to `PyParser_SimpleParseStringFlagsFilename()` below, leaving `filename` set to NULL.

```
struct _node* PyParser_SimpleParseStringFlagsFilename(char *filename, int start, int flags)
```

Parse Python source code from `str` using the start token `start` according to the `flags` argument. The result can be used to create a code object which can be evaluated efficiently. This is useful if a code fragment must be evaluated many times.

```
struct _node* PyParser_SimpleParseFile(FILE *fp, const char *filename, int start)
```

This is a simplified interface to `PyParser_SimpleParseFileFlags()` below, leaving `flags` set to 0.

```
struct _node* PyParser_SimpleParseFileFlags(FILE *fp, const char *filename, int start, int flags)
```

Similar to `PyParser_SimpleParseStringFlagsFilename()`, but the Python source code is read from `fp` instead of an in-memory string.

```
PyObject* PyRun_String(const char* str, int start, PyObject* globals, PyObject* locals)
```

This is a simplified interface to `PyRun_StringFlags()` below, leaving `flags` set to NULL.

```
PyObject* PyRun_StringFlags(*globals, PyObject* locals,
```

const char *str, int start, PyObject

PyObject* PyRun_StringFlags(*globals, PyObject *locals,
PyCompilerFlags *flags)

Execute Python source code from str in the context specified by the
dictionaries globals and locals with the compiler flags specified by flags.
The parameter start specifies the start token that should be used to parse the
source code.

Returns the result of executing the code as a Python object, or NULL if an
exception was raised.

PyObject* PyRun_File(FILE *fp, const char *filename, int start, PyObject
*globals, PyObject *locals)

This is a simplified interface to PyRun_FileExFlags() below, leaving
closeit set to 0 and flags set to NULL.

PyObject* PyRun_FileEx(FILE *fp, const char *filename, int start,
PyObject *globals, PyObject *locals, int closeit)

This is a simplified interface to PyRun_FileExFlags() below, leaving
flags set to NULL.

PyObject* PyRun_FileFlags(FILE *fp, const char *filename, int start,
PyObject *globals, PyObject *locals, PyCompilerFlags *flags)

This is a simplified interface to PyRun_FileExFlags() below, leaving
closeit set to 0.

PyObject* PyRun_FileExFlags(FILE *fp, const char *filename, int start,
PyObject *globals, PyObject *locals, int closeit, PyCompilerFlags *flags)

Similar to PyRun_StringFlags(), but the Python source code is read
from fp instead of an in-memory string. filename should be the name of the
file. If closeit is true, the file is closed before PyRun_FileExFlags() returns.
PyObject* `Py_CompileString` (const char * `str`, const char * `filename`, int start)

*Return value: New reference.*
This is a simplified interface to `Py_CompileStringFlags()` below, leaving `flags` set to NULL.

PyObject* `Py_CompileStringFlags` (const char * `str`, const char * `filename`, int start, PyCompilerFlags * `flags`)

*Return value: New reference.*
Parse and compile the Python source code in `str`, returning the resulting code object. The start token is given by `start`; this can be used to constrain the code which can be compiled and should be `Py_eval_input`, `Py_file_input`, or `Py_single_input`. The filename specified by `filename` is used to construct the code object and may appear in traceback or `SyntaxError` exception messages. This returns NULL if the code cannot be parsed or compiled.

`int Py_eval_input`
The start symbol from the Python grammar for isolated expressions; for use with `Py_CompileString()`.

`int Py_file_input`
The start symbol from the Python grammar for sequences of statements as read from a file or other source; for use with `Py_CompileString()`. This is the symbol to use when compiling arbitrarily long Python source code.

`int Py_single_input`
The start symbol from the Python grammar for a single statement; for use with `Py_CompileString()`. This is the symbol used for the interactive interpreter loop.

`struct PyCompilerFlags`
This is the structure used to hold compiler flags. In cases where code is only being compiled, it is passed as `int flags`, and in cases where code is being executed, it is passed as `PyCompilerFlags *flags`. In this case, `from __future__ import` can modify `flags`. 
Whenever `PyCompilerFlags *flags` is `NULL`, `cf_flags` is treated as equal to 0, and any modification due to `from __future__ import` is discarded.

```c
struct PyCompilerFlags {
    int cf_flags;
}
```

### int `CO_FUTURE_DIVISION`

This bit can be set in `flags` to cause division operator `/` to be interpreted as ``true division`` according to PEP 238.
3. Reference Counting

The macros in this section are used for managing reference counts of Python objects.

void Py_INCREF( PyObject *o)
Increment the reference count for object o. The object must not be NULL; if you aren't sure that it isn't NULL, use Py_XINCREF().

void Py_XINCREF( PyObject *o)
Increment the reference count for object o. The object may be NULL, in which case the macro has no effect.

void Py_DECREF( PyObject *o)
Decrement the reference count for object o. The object must not be NULL; if you aren't sure that it isn't NULL, use Py_XDECREF(). If the reference count reaches zero, the object's type's deallocation function (which must not be NULL) is invoked.

**Warning:** The deallocation function can cause arbitrary Python code to be invoked (e.g. when a class instance with a __del__() method is deallocated). While exceptions in such code are not propagated, the executed code has free access to all Python global variables. This means that any object that is reachable from a global variable should be in a consistent state before Py_DECREF() is invoked. For example, code to delete an object from a list should copy a reference to the deleted object in a temporary variable, update the list data structure, and then call Py_DECREF() for the temporary variable.

void Py_XDECREF( PyObject *o)
Decrement the reference count for object o. The object may be NULL, in which case the macro has no effect; otherwise the effect is the same as for Py_DECREF(), and the same warning applies.

void Py_CLEAR( PyObject *o)
Decrement the reference count for object o. The object may be NULL, in which case the macro has no effect; otherwise the effect is the same as for Py_DECREF(), except that the argument is also set to NULL. The warning for Py_DECREF() does not apply with respect to the object passed because the macro carefully uses a temporary variable and sets the argument to NULL before decrementing its reference count.

It is a good idea to use this macro whenever decrementing the value of a variable that might be traversed during garbage collection.

New in version 2.4.

The following functions are for runtime dynamic embedding of Python: Py_IncRef(PyObject *o), Py_DecRef(PyObject *o). They are simply exported function versions of Py_XINCREF() and Py_XDECREF(), respectively.

The following functions or macros are only for use within the interpreter core: _Py_Dealloc(), _Py_ForgetReference(), _Py_NewReference(), as well as the global variable _Py_RefTotal.
4. Exception Handling

The functions described in this chapter will let you handle and raise Python exceptions. It is important to understand some of the basics of Python exception handling. It works somewhat like the UNIX \texttt{errno} variable: there is a global indicator (per thread) of the last error that occurred. Most functions don't clear this on success, but will set it to indicate the cause of the error on failure. Most functions also return an error indicator, usually \texttt{NULL} if they are supposed to return a pointer, or \texttt{-1} if they return an integer (exception: the \texttt{PyArg_*()} functions return \texttt{1} for success and \texttt{0} for failure).

When a function must fail because some function it called failed, it generally doesn't set the error indicator; the function it called already set it. It is responsible for either handling the error and clearing the exception or returning after cleaning up any resources it holds (such as object references or memory allocations); it should \textit{not} continue normally if it is not prepared to handle the error. If returning due to an error, it is important to indicate to the caller that an error has been set. If the error is not handled or carefully propagated, additional calls into the Python/C API may not behave as intended and may fail in mysterious ways.

The error indicator consists of three Python objects corresponding to the Python variables \texttt{sys.exc_type}, \texttt{sys.exc_value} and \texttt{sys.exc_traceback}. API functions exist to interact with the error indicator in various ways. There is a separate error indicator for each thread.

\textbf{void} \texttt{PyErr_Print()} \\
Print a standard traceback to \texttt{sys.stderr} and clear the error indicator. Call this function only when the error indicator is set. (Otherwise it will cause a fatal error!)

\textbf{PyObject*} \texttt{PyErr_Occurred()} \\
\textit{Return value: Borrowed reference.} Test whether the error indicator is set. If set, return the exception \texttt{type} (the first argument to the last call to one of the \texttt{PyErr_Set*()} functions or to \texttt{PyErr_Restore()}). If not set, return \texttt{NULL}. You do not own a reference
to the return value, so you do not need to \texttt{Py\_DECREF()} it. \textbf{Note:} Do not compare the return value to a specific exception; use \texttt{PyErr\_ExceptionMatches()} instead, shown below. (The comparison could easily fail since the exception may be an instance instead of a class, in the case of a class exception, or it may the a subclass of the expected exception.)

\begin{verbatim}
int PyErr\_ExceptionMatches( PyObject *exc)
  Equivalent to
  "PyErr\_GivenExceptionMatches(PyErr\_Occurred(),
  exc)". This should only be called when an exception is actually set; a
memory access violation will occur if no exception has been raised.
\end{verbatim}

\begin{verbatim}
int PyErr\_GivenExceptionMatches( PyObject *given, PyObject *exc)
  Return true if the \textit{given} exception matches the exception in \textit{exc}. If \textit{exc} is a
class object, this also returns true when \textit{given} is an instance of a subclass. If
\textit{exc} is a tuple, all exceptions in the tuple (and recursively in subtuples) are
searched for a match. If \textit{given} is NULL, a memory access violation will occur.
\end{verbatim}

\begin{verbatim}
void PyErr\_NormalizeException( PyObject**exc, PyObject**val,
                                PyObject**tb)
  Under certain circumstances, the values returned by \texttt{PyErr\_Fetch()}
below can be ``unnormalized'', meaning that *\textit{exc} is a class object but *\textit{val}
is not an instance of the same class. This function can be used to instantiate
the class in that case. If the values are already normalized, nothing happens.
The delayed normalization is implemented to improve performance.
\end{verbatim}

\begin{verbatim}
void PyErr\_Clear()
  Clear the error indicator. If the error indicator is not set, there is no effect.
\end{verbatim}

\begin{verbatim}
void PyErr\_Fetch( PyObject **ptype, PyObject **pvalue,
                  PyObject **ptraceback)
  Retrieve the error indicator into three variables whose addresses are passed.
If the error indicator is not set, set all three variables to NULL. If it is set, it
will be cleared and you own a reference to each object retrieved. The value
and traceback object may be NULL even when the type object is not. \textbf{Note:}
\end{verbatim}
This function is normally only used by code that needs to handle exceptions or by code that needs to save and restore the error indicator temporarily.

```c
void PyErr_Restore(PyObject *type, PyObject *value, PyObject *traceback)
```

Set the error indicator from the three objects. If the error indicator is already set, it is cleared first. If the objects are NULL, the error indicator is cleared. Do not pass a NULL type and non-NULL value or traceback. The exception type should be a class. Do not pass an invalid exception type or value. (Violating these rules will cause subtle problems later.) This call takes away a reference to each object: you must own a reference to each object before the call and after the call you no longer own these references. (If you don't understand this, don't use this function. I warned you.) **Note:** This function is normally only used by code that needs to save and restore the error indicator temporarily; use PyErr_Fetch() to save the current exception state.

```c
void PyErr_SetString(PyObject *type, const char *message)
```

This is the most common way to set the error indicator. The first argument specifies the exception type; it is normally one of the standard exceptions, e.g. PyExc_RuntimeError. You need not increment its reference count. The second argument is an error message; it is converted to a string object.

```c
void PyErr_SetObject(PyObject *type, PyObject *value)
```

This function is similar to PyErr_SetString() but lets you specify an arbitrary Python object for the ``value'' of the exception.

```c
PyObject* PyErr_Format(PyObject *exception, const char *format, ...)
```

**Return value:** *Always NULL.*

This function sets the error indicator and returns NULL. exception should be a Python exception (class, not an instance). format should be a string, containing format codes, similar to printf(). The width.precision before a format code is parsed, but the width part is ignored.

</tbody>
</table>

An unrecognized format character causes all the rest of the format string to be copied as-is to the result string, and any extra arguments discarded.

```c
void PyErr_SetNone( PyObject *type)
{
    This is a shorthand for "PyErr_SetObject(type, Py_None)".
}
```

```c
int PyErr_BadArgument()
{
    This is a shorthand for "PyErr_SetString(PyExc_TypeError, message)"", where message indicates that a built-in operation was invoked with an illegal argument. It is mostly for internal use.
}
```

```c
PyObject* PyErr_NoMemory( )
{
    Return value: Always NULL.
    This is a shorthand for "PyErr_SetNone(PyExc_MemoryError)"; it returns NULL so an object allocation function can write "return PyErr_NoMemory();" when it runs out of memory.
}
```

```c
PyObject* PyErr_SetFromErrno( PyObject *type)
```
Return value: Always NULL.
This is a convenience function to raise an exception when a C library function has returned an error and set the C variable errno. It constructs a tuple object whose first item is the integer errno value and whose second item is the corresponding error message (gotten from strerror()), and then calls "PyErr_SetObject(type, object)". On UNIX, when the errno value is EINTR, indicating an interrupted system call, this calls PyErr_CheckSignals(), and if that set the error indicator, leaves it set to that. The function always returns NULL, so a wrapper function around a system call can write "return PyErr_SetFromErrno(type);" when the system call returns an error.

PyObject* PyErr_SetFromErrnoWithFilename(PyObject *type, const char *filename)
Return value: Always NULL.
Similar to PyErr_SetFromErrno(), with the additional behavior that if filename is not NULL, it is passed to the constructor of type as a third parameter. In the case of exceptions such as IOError and OSError, this is used to define the filename attribute of the exception instance.

PyObject* PyErr_SetFromWindowsErr(int ierr)
Return value: Always NULL.
This is a convenience function to raise WindowsError. If called with ierr of 0, the error code returned by a call to GetLastError() is used instead. It calls the Win32 function FormatMessage() to retrieve the Windows description of error code given by ierr or GetLastError(), then it constructs a tuple object whose first item is the ierr value and whose second item is the corresponding error message (gotten from FormatMessage()), and then calls "PyErr_SetObject(PyExc_WindowsError, object)". This function always returns NULL. Availability: Windows.

PyObject* PyErr_SetExcFromWindowsErr(PyObject *type, int ierr)
Return value: Always NULL.
Similar to PyErr_SetFromWindowsErr(), with an additional parameter specifying the exception type to be raised. Availability: Windows. New in version 2.3.
PyObject* `PyErr_SetFromWindowsErrWithFilename`( int `ierr`, const char* `filename`)  

Return value: *Always NULL.*
Similar to `PyErr_SetFromWindowsErr()` , with the additional behavior that if `filename` is not NULL, it is passed to the constructor of `WindowsError` as a third parameter. Availability: Windows.

PyObject* `PyErr_SetExcFromWindowsErrWithFilename`( PyObject* `type`, int `ierr`, char* `filename`)  

Return value: *Always NULL.*
Similar to `PyErr_SetFromWindowsErrWithFilename()` , with an additional parameter specifying the exception type to be raised. Availability: Windows. New in version 2.3.

void `PyErr_BadInternalCall`()  
This is a shorthand for "`PyErr_SetString(PyExc_TypeError, message)`", where `message` indicates that an internal operation (e.g. a Python/C API function) was invoked with an illegal argument. It is mostly for internal use.

int `PyErr_WarnEx`( PyObject* `category`, char* `message`, int `stacklevel`)  
Issue a warning message. The `category` argument is a warning category (see below) or NULL; the `message` argument is a message string. `stacklevel` is a positive number giving a number of stack frames; the warning will be issued from the currently executing line of code in that stack frame. A `stacklevel` of 1 is the function calling `PyErr_WarnEx()` , 2 is the function above that, and so forth.

This function normally prints a warning message to `sys.stderr`; however, it is also possible that the user has specified that warnings are to be turned into errors, and in that case this will raise an exception. It is also possible that the function raises an exception because of a problem with the warning machinery (the implementation imports the `warnings` module to do the heavy lifting). The return value is 0 if no exception is raised, or -1 if an exception is raised. (It is not possible to determine whether a warning
message is actually printed, nor what the reason is for the exception; this is intentional.) If an exception is raised, the caller should do its normal exception handling (for example, `Py_DECREF()` owned references and return an error value).

Warning categories must be subclasses of `Warning`; the default warning category is `RuntimeWarning`. The standard Python warning categories are available as global variables whose names are "PyExc_" followed by the Python exception name. These have the type `PyObject*`; they are all class objects. Their names are `PyExc.Warning`, `PyExc.UserWarning`, `PyExc.UnicodeWarning`, `PyExc.DeprecationWarning`, `PyExc_SyntaxWarning`, `PyExc_RuntimeWarning`, and `PyExc.FutureWarning`. `PyExc.Warning` is a subclass of `PyExc_Exception`; the other warning categories are subclasses of `PyExc.Warning`.

For information about warning control, see the documentation for the `warnings` module and the `-W` option in the command line documentation. There is no C API for warning control.

```c
int PyErr_Warn( PyObject *category, char *message )
```

Issue a warning message. The `category` argument is a warning category (see below) or `NULL`; the `message` argument is a message string. The warning will appear to be issued from the function calling `PyErr_Warn()`, equivalent to calling `PyErr_WarnEx()` with a `stacklevel` of 1.

Deprecated; use `PyErr_WarnEx()` instead.

```c
int PyErr_WarnExplicit( char *filename, int lineno, const char *module, PyObject *registry)
```

Issue a warning message with explicit control over all warning attributes. This is a straightforward wrapper around the Python function `warnings.warn_explicit()`, see there for more information. The `module` and `registry` arguments may be set to `NULL` to get the default effect described there.

```c
int PyErr_CheckSignals()
```
This function interacts with Python's signal handling. It checks whether a signal has been sent to the processes and if so, invokes the corresponding signal handler. If the signal module is supported, this can invoke a signal handler written in Python. In all cases, the default effect for SIGINT is to raise the KeyboardInterrupt exception. If an exception is raised the error indicator is set and the function returns 1; otherwise the function returns 0. The error indicator may or may not be cleared if it was previously set.

void **PyErr_SetInterrupt**()

This function simulates the effect of a SIGINT signal arriving -- the next time **PyErr_CheckSignals**() is called, KeyboardInterrupt will be raised. It may be called without holding the interpreter lock.

PyObject* **PyErr_NewException**( char *name, PyObject *base, PyObject *dict)

*Return value: New reference.*

This utility function creates and returns a new exception object. The *name* argument must be the name of the new exception, a C string of the form module.class. The *base* and *dict* arguments are normally NULL. This creates a class object derived from Exception (accessible in C as PyExc_Exception).

The __module__ attribute of the new class is set to the first part (up to the last dot) of the *name* argument, and the class name is set to the last part (after the last dot). The *base* argument can be used to specify alternate base classes; it can either be only one class or a tuple of classes. The *dict* argument can be used to specify a dictionary of class variables and methods.

void **PyErr_WriteUnraisable**( PyObject *obj)

This utility function prints a warning message to sys.stderr when an exception has been set but it is impossible for the interpreter to actually raise the exception. It is used, for example, when an exception occurs in an __del__() method.

The function is called with a single argument *obj* that identifies the context in which the unraisable exception occurred. The repr of *obj* will be printed
in the warning message.

Subsections

- 4.1 Standard Exceptions
- 4.2 Deprecation of String Exceptions

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
4.1 Standard Exceptions

All standard Python exceptions are available as global variables whose names are "PyExc_" followed by the Python exception name. These have the type `PyObject*`; they are all class objects. For completeness, here are all the variables:

<table>
<thead>
<tr>
<th>C Name</th>
<th>Python Name</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>PyExc_BaseException</td>
<td>BaseException</td>
<td>(1),(4)</td>
</tr>

</tr>
<tr>
<td>PyExc_WindowsError</td>
<td>WindowsError</td>
<td></td>
</tr>
<tr>
<td>PyExc_ZeroDivisionError</td>
<td>ZeroDivisionError</td>
<td></td>
</tr>
</tbody>
</table>

Notes:

(1) This is a base class for other standard exceptions.

(2) This is the same as `weakref.ReferenceError`.

(3) Only defined on Windows; protect code that uses this by testing that the preprocessor macro `MS_WINDOWS` is defined.

(4) New in version 2.5.
4.2 Deprecation of String Exceptions

All exceptions built into Python or provided in the standard library are derived from `BaseException`.

String exceptions are still supported in the interpreter to allow existing code to run unmodified, but this will also change in a future release.
5. Utilities

The functions in this chapter perform various utility tasks, ranging from helping C code be more portable across platforms, using Python modules from C, and parsing function arguments and constructing Python values from C values.

Subsections

- 5.1 Operating System Utilities
- 5.2 Process Control
- 5.3 Importing Modules
- 5.4 Data marshalling support
- 5.5 Parsing arguments and building values
5.1 Operating System Utilities

```c
int Py_FdIsInteractive( FILE *fp, const char *filename )
    Return true (nonzero) if the standard I/O file fp with name filename is
deemed interactive. This is the case for files for which
"isatty(fileno(fp))" is true. If the global flag
Py_InteractiveFlag is true, this function also returns true if the
filename pointer is NULL or if the name is equal to one of the strings
'(<stdin>)' or '??'.
```

```c
long PyOS_GetLastModificationTime( char *filename )
    Return the time of last modification of the file filename. The result is
encoded in the same way as the timestamp returned by the standard C
library function time().
```

```c
void PyOS_AfterFork( )
    Function to update some internal state after a process fork; this should be
called in the new process if the Python interpreter will continue to be used.
If a new executable is loaded into the new process, this function does not
need to be called.
```

```c
int PyOS_CheckStack( )
    Return true when the interpreter runs out of stack space. This is a reliable
check, but is only available when USE_STACKCHECK is defined (currently
on Windows using the Microsoft Visual C++ compiler).
USE_STACKCHECK will be defined automatically; you should never
change the definition in your own code.
```

```c
PyOS_sighandler_t PyOS_getsig( int i )
    Return the current signal handler for signal i. This is a thin wrapper around
either sigaction() or signal(). Do not call those functions directly!
PyOS_sighandler_t is a typedef alias for void (*)(int).
```

```c
PyOS_sighandler_t PyOS_setsig( int i, PyOS_sighandler_t h )
    Set the signal handler for signal i to be h; return the old signal handler. This
```
is a thin wrapper around either `sigaction()` or `signal()`. Do not call those functions directly! `PyOS_sighandler_t` is a typedef alias for `void (*)(int)`.
5.2 Process Control

void Py_FatalError( const char *message)
    Print a fatal error message and kill the process. No cleanup is performed. This function should only be invoked when a condition is detected that would make it dangerous to continue using the Python interpreter; e.g., when the object administration appears to be corrupted. On UNIX, the standard C library function abort() is called which will attempt to produce a core file.

void Py_Exit( int status)
    Exit the current process. This calls Py_Finalize() and then calls the standard C library function exit(status).

int Py_AtExit( void (*func) ()
    Register a cleanup function to be called by Py_Finalize(). The cleanup function will be called with no arguments and should return no value. At most 32 cleanup functions can be registered. When the registration is successful, Py_AtExit() returns 0; on failure, it returns -1. The cleanup function registered last is called first. Each cleanup function will be called at most once. Since Python's internal finalization will have completed before the cleanup function, no Python APIs should be called by func.
5.3 Importing Modules

PyObject* `PyImport_ImportModule`( const char *name)

*Return value:* *New reference.*

This is a simplified interface to `PyImport_ImportModuleEx()` below, leaving the `globals` and `locals` arguments set to NULL. When the `name` argument contains a dot (when it specifies a submodule of a package), the `fromlist` argument is set to the list ['*'] so that the return value is the named module rather than the top-level package containing it as would otherwise be the case. (Unfortunately, this has an additional side effect when `name` in fact specifies a subpackage instead of a submodule: the submodules specified in the package's `__all__` variable are loaded.)

Return a new reference to the imported module, or NULL with an exception set on failure. Before Python 2.4, the module may still be created in the failure case -- examine `sys.modules` to find out. Starting with Python 2.4, a failing import of a module no longer leaves the module in `sys.modules`. Changed in version 2.4: failing imports remove incomplete module objects.

PyObject* `PyImport_ImportModuleEx`( PyObject *globals, PyObject *locals, PyObject *fromlist)

*Return value:* *New reference.*

Import a module. This is best described by referring to the built-in Python function `__import__()`, as the standard `__import__()` function calls this function directly.

The return value is a new reference to the imported module or top-level package, or NULL with an exception set on failure (before Python 2.4, the module may still be created in this case). Like for `__import__()`, the return value when a submodule of a package was requested is normally the top-level package, unless a non-empty `fromlist` was given. Changed in version 2.4: failing imports remove incomplete module objects.

PyObject* `PyImport_Import`( PyObject *name)

*Return value:* *New reference.*
This is a higher-level interface that calls the current "import hook function". It invokes the \_\_import\_\_() function from the \_\_builtins\_\_ of the current globals. This means that the import is done using whatever import hooks are installed in the current environment, e.g. by reexec or ihooks.

PyObject* **PyImport\_ReloadModule** (PyObject *m)

*Return value: New reference.*

Reload a module. This is best described by referring to the built-in Python function reload(), as the standard reload() function calls this function directly. Return a new reference to the reloaded module, or NULL with an exception set on failure (the module still exists in this case).

PyObject* **PyImport\_AddModule** (const char *name)

*Return value: Borrowed reference.*

Return the module object corresponding to a module name. The name argument may be of the form package.module. First check the modules dictionary if there’s one there, and if not, create a new one and insert it in the modules dictionary. Return NULL with an exception set on failure.  
**Note:** This function does not load or import the module; if the module wasn’t already loaded, you will get an empty module object. Use **PyImport\_ImportModule**() or one of its variants to import a module. Package structures implied by a dotted name for name are not created if not already present.

PyObject* **PyImport\_ExecCodeModule** (char *name, PyObject *co)

*Return value: New reference.*

Given a module name (possibly of the form package.module) and a code object read from a Python bytecode file or obtained from the built-in function compile(), load the module. Return a new reference to the module object, or NULL with an exception set if an error occurred. Before Python 2.4, the module could still be created in error cases. Starting with Python 2.4, name is removed from sys.modules in error cases, and even if name was already in sys.modules on entry to **PyImport\_ExecCodeModule**(). Leaving incompletely initialized modules in sys.modules is dangerous, as imports of such modules have no way to know that the module object is an unknown (and probably
damaged with respect to the module author's intents) state.

This function will reload the module if it was already imported. See `PyImport_ReloadModule()` for the intended way to reload a module.

If `name` points to a dotted name of the form `package.module`, any package structures not already created will still not be created.

Changed in version 2.4: `name` is removed from `sys.modules` in error cases.

```
long PyImport_GetMagicNumber()
Return the magic number for Python bytecode files (a.k.a. .pyc and .pyo files). The magic number should be present in the first four bytes of the bytecode file, in little-endian byte order.
```

```
PyObject* PyImport_GetModuleDict()
Return value: Borrowed reference.
Return the dictionary used for the module administration (a.k.a. `sys.modules`). Note that this is a per-interpreter variable.
```

```
void _PyImport_Init()
Initialize the import mechanism. For internal use only.
```

```
void PyImport_Cleanup()
Empty the module table. For internal use only.
```

```
void _PyImport_Fini()
Finalize the import mechanism. For internal use only.
```

```
PyObject* _PyImport_FindExtension( char *, char *)
Return value: Borrowed reference.
For internal use only.
```

```
PyObject* _PyImport_FixupExtension( char *, char *)
For internal use only.
```

```
int PyImport_ImportFrozenModule( char *name)
```
Load a frozen module named *name*. Return 1 for success, 0 if the module is not found, and -1 with an exception set if the initialization failed. To access the imported module on a successful load, use \texttt{PyImport_ImportModule()}. (Note the misnomer -- this function would reload the module if it was already imported.)

\textbf{struct } _\texttt{frozen}

This is the structure type definition for frozen module descriptors, as generated by the freeze utility (see Tools/freeze/ in the Python source distribution). Its definition, found in \texttt{Include/import.h}, is:

\begin{verbatim}
struct _frozen {
    char *name;
    unsigned char *code;
    int size;
};
\end{verbatim}

\texttt{struct } _\texttt{frozen}* \texttt{PyImport_FrozenModules}

This pointer is initialized to point to an array of \texttt{struct } _\texttt{frozen} records, terminated by one whose members are all NULL or zero. When a frozen module is imported, it is searched in this table. Third-party code could play tricks with this to provide a dynamically created collection of frozen modules.

\texttt{int } \texttt{PyImport_AppendInittab}( char *\texttt{name}, void (*\texttt{initfunc})(void))

Add a single module to the existing table of built-in modules. This is a convenience wrapper around \texttt{PyImport_ExtendInittab()}, returning -1 if the table could not be extended. The new module can be imported by the name \texttt{name}, and uses the function \texttt{initfunc} as the initialization function called on the first attempted import. This should be called before \texttt{Py_Initialize()}.

\textbf{struct } _\texttt{inittab}

Structure describing a single entry in the list of built-in modules. Each of these structures gives the name and initialization function for a module built into the interpreter. Programs which embed Python may use an array of these structures in conjunction with \texttt{PyImport_ExtendInittab()} to provide additional built-in modules. The structure is defined in \texttt{Include/import.h} as:
struct _inittab {
    char *name;
    void (*initfunc)(void);
};

int PyImport_ExtendInittab( struct _inittab *newtab )

    Add a collection of modules to the table of built-in modules. The newtab
    array must end with a sentinel entry which contains NULL for the name
    field; failure to provide the sentinel value can result in a memory fault.
    Returns 0 on success or -1 if insufficient memory could be allocated to
    extend the internal table. In the event of failure, no modules are added to
    the internal table. This should be called before Py_Initialize().
5.4 Data marshalling support

These routines allow C code to work with serialized objects using the same data format as the `marshal` module. There are functions to write data into the serialization format, and additional functions that can be used to read the data back. Files used to store marshalled data must be opened in binary mode.

Numeric values are stored with the least significant byte first.

The module supports two versions of the data format: version 0 is the historical version, version 1 (new in Python 2.4) shares interned strings in the file, and upon unmarshalling, `Py_MARSHAL_VERSION` indicates the current file format (currently 1).

```c
void PyMarshal_WriteLongToFile( long value, FILE *file, int version)
    Marshal a `long` integer, `value`, to `file`. This will only write the least-significant 32 bits of `value`; regardless of the size of the native `long` type.

    Changed in version 2.4: `version` indicates the file format.

void PyMarshal_WriteObjectToFile( PyObject *value, FILE *file, int version)
    Marshal a Python object, `value`, to `file`.

    Changed in version 2.4: `version` indicates the file format.

PyObject* PyMarshal_WriteObjectToString( PyObject *value, int version)
    Return a string object containing the marshalled representation of `value`.

    Changed in version 2.4: `version` indicates the file format.
```

The following functions allow marshalled values to be read back in.

XXX What about error detection? It appears that reading past the end of the file will always result in a negative numeric value (where that's relevant), but it's not
clear that negative values won't be handled properly when there's no error. What's the right way to tell? Should only non-negative values be written using these routines?

long **PyMarshal_ReadLongFromFile**( FILE *file)

    Return a C long from the data stream in a FILE* opened for reading. Only a 32-bit value can be read in using this function, regardless of the native size of long.

int **PyMarshal_ReadShortFromFile**( FILE *file)

    Return a C short from the data stream in a FILE* opened for reading. Only a 16-bit value can be read in using this function, regardless of the native size of short.

**PyObject**\* **PyMarshal_ReadObjectFromFile**( FILE *file)

    Return a Python object from the data stream in a FILE* opened for reading. On error, sets the appropriate exception (EOFError or TypeError) and returns NULL.

**PyObject**\* **PyMarshal_ReadLastObjectFromFile**( FILE *file)

    Return a Python object from the data stream in a FILE* opened for reading. Unlike PyMarshal_ReadObjectFromFile(), this function assumes that no further objects will be read from the file, allowing it to aggressively load file data into memory so that the de-serialization can operate from data in memory rather than reading a byte at a time from the file. Only use these variant if you are certain that you won't be reading anything else from the file. On error, sets the appropriate exception (EOFError or TypeError) and returns NULL.

**PyObject**\* **PyMarshal_ReadObjectFromString**( char *string,

Py_ssize_t len)

    Return a Python object from the data stream in a character buffer containing len bytes pointed to by string. On error, sets the appropriate exception (EOFError or TypeError) and returns NULL.
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
5.5 Parsing arguments and building values

These functions are useful when creating your own extensions functions and methods. Additional information and examples are available in *Extending and Embedding the Python Interpreter*.

The first three of these functions described, `PyArg_ParseTuple()`, `PyArg_ParseTupleAndKeywords()`, and `PyArg_Parse()`, all use *format strings* which are used to tell the function about the expected arguments. The format strings use the same syntax for each of these functions.

A format string consists of zero or more ``format units.`` A format unit describes one Python object; it is usually a single character or a parenthesized sequence of format units. With a few exceptions, a format unit that is not a parenthesized sequence normally corresponds to a single address argument to these functions. In the following description, the quoted form is the format unit; the entry in (round) parentheses is the Python object type that matches the format unit; and the entry in [square] brackets is the type of the C variable(s) whose address should be passed.

"s" (string or Unicode object) [const char *]

Convert a Python string or Unicode object to a C pointer to a character string. You must not provide storage for the string itself; a pointer to an existing string is stored into the character pointer variable whose address you pass. The C string is NUL-terminated. The Python string must not contain embedded NUL bytes; if it does, a *TypeError* exception is raised. Unicode objects are converted to C strings using the default encoding. If this conversion fails, a *UnicodeError* is raised.

"s#" (string, Unicode or any read buffer compatible object) [const char *, int]

This variant on "s" stores into two C variables, the first one a pointer to a character string, the second one its length. In this case the Python string may contain embedded null bytes. Unicode objects pass back a pointer to the default encoded string version of the object if such a conversion is
possible. All other read-buffer compatible objects pass back a reference to the raw internal data representation.

"z" (string or None) [const char *]
Like "s", but the Python object may also be None, in which case the C pointer is set to NULL.

"z#" (string or None or any read buffer compatible object) [const char *, int]
This is to "s#" as "z" is to "s".

"u" (Unicode object) [Py_UNICODE *]
Convert a Python Unicode object to a C pointer to a NUL-terminated buffer of 16-bit Unicode (UTF-16) data. As with "s", there is no need to provide storage for the Unicode data buffer; a pointer to the existing Unicode data is stored into the Py_UNICODE pointer variable whose address you pass.

"u#" (Unicode object) [Py_UNICODE *, int]
This variant on "u" stores into two C variables, the first one a pointer to a Unicode data buffer, the second one its length. Non-Unicode objects are handled by interpreting their read-buffer pointer as pointer to a Py_UNICODE array.

"es" (string, Unicode object or character buffer compatible object) [const char *encoding, char **buffer]
This variant on "s" is used for encoding Unicode and objects convertible to Unicode into a character buffer. It only works for encoded data without embedded NUL bytes.

This format requires two arguments. The first is only used as input, and must be a const char* which points to the name of an encoding as a NUL-terminated string, or NULL, in which case the default encoding is used. An exception is raised if the named encoding is not known to Python. The second argument must be a char**; the value of the pointer it references will be set to a buffer with the contents of the argument text. The text will be encoded in the encoding specified by the first argument.

PyArg_ParseTuple() will allocate a buffer of the needed size, copy the encoded data into this buffer and adjust *buffer to reference the newly
allocated storage. The caller is responsible for calling `PyMem_Free()` to free the allocated buffer after use.

"et" (string, Unicode object or character buffer compatible object) [const char *encoding, char **buffer]
Same as "es" except that 8-bit string objects are passed through without recoding them. Instead, the implementation assumes that the string object uses the encoding passed in as parameter.

"es#" (string, Unicode object or character buffer compatible object) [const char *encoding, char **buffer, int *buffer_length]
This variant on "s#" is used for encoding Unicode and objects convertible to Unicode into a character buffer. Unlike the "es" format, this variant allows input data which contains NUL characters.

It requires three arguments. The first is only used as input, and must be a const char* which points to the name of an encoding as a NUL-terminated string, or NULL, in which case the default encoding is used. An exception is raised if the named encoding is not known to Python. The second argument must be a char**; the value of the pointer it references will be set to a buffer with the contents of the argument text. The text will be encoded in the encoding specified by the first argument. The third argument must be a pointer to an integer; the referenced integer will be set to the number of bytes in the output buffer.

There are two modes of operation:

If *buffer points a NULL pointer, the function will allocate a buffer of the needed size, copy the encoded data into this buffer and set *buffer to reference the newly allocated storage. The caller is responsible for calling `PyMem_Free()` to free the allocated buffer after usage.

If *buffer points to a non-NULL pointer (an already allocated buffer), `PyArg_ParseTuple()` will use this location as the buffer and interpret the initial value of *buffer_length as the buffer size. It will then copy the encoded data into the buffer and NUL-terminate it. If the buffer is not large enough, a `ValueError` will be set.

In both cases, *buffer_length is set to the length of the encoded data without
the trailing NUL byte.

"et#" (string, Unicode object or character buffer compatible object) [const char *encoding, char **buffer]
Same as "es#" except that string objects are passed through without recoding them. Instead, the implementation assumes that the string object uses the encoding passed in as parameter.

"b" (integer) [char]
Convert a Python integer to a tiny int, stored in a C char.

"B" (integer) [unsigned char]
Convert a Python integer to a tiny int without overflow checking, stored in a C unsigned char. New in version 2.3.

"h" (integer) [short int]
Convert a Python integer to a C short int.

"H" (integer) [unsigned short int]
Convert a Python integer to a C unsigned short int, without overflow checking. New in version 2.3.

"i" (integer) [int]
Convert a Python integer to a plain C int.

"I" (integer) [unsigned int]
Convert a Python integer to a C unsigned int, without overflow checking. New in version 2.3.

"l" (integer) [long int]
Convert a Python integer to a C long int.

"k" (integer) [unsigned long]
Convert a Python integer or long integer to a C unsigned long without overflow checking. New in version 2.3.

"L" (integer) [PY_LONG_LONG]
Convert a Python integer to a C long long. This format is only available on platforms that support long long (or _int64 on Windows).
"K" (integer) [unsigned PY_LONG_LONG]
Convert a Python integer or long integer to a C unsigned long long without overflow checking. This format is only available on platforms that support unsigned long long (or unsigned _int64 on Windows). New in version 2.3.

"n" (integer) [Py_ssize_t]
Convert a Python integer or long integer to a C Py_ssize_t. New in version 2.5.

"c" (string of length 1) [char]
Convert a Python character, represented as a string of length 1, to a C char.

"f" (float) [float]
Convert a Python floating point number to a C float.

"d" (float) [double]
Convert a Python floating point number to a C double.

"D" (complex) [Py_complex]
Convert a Python complex number to a C Py_complex structure.

"O" (object) [PyObject *]
Store a Python object (without any conversion) in a C object pointer. The C program thus receives the actual object that was passed. The object's reference count is not increased. The pointer stored is not NULL.

"O!" (object) [typeobject, PyObject *]
Store a Python object in a C object pointer. This is similar to "O", but takes two C arguments: the first is the address of a Python type object, the second is the address of the C variable (of type PyObject*) into which the object pointer is stored. If the Python object does not have the required type, TypeError is raised.

"O&" (object) [converter, anything]
Convert a Python object to a C variable through a converter function. This takes two arguments: the first is a function, the second is the address of a C variable (of arbitrary type), converted to void *. The converter function
in turn is called as follows:

\[\text{status} = \text{converter(object, address)};\]

where \textit{object} is the Python object to be converted and \textit{address} is the \texttt{void*} argument that was passed to the \texttt{PyArg_Parse*()} function. The returned \textit{status} should be 1 for a successful conversion and 0 if the conversion has failed. When the conversion fails, the \textit{converter} function should raise an exception.

"S" (string) [PyStringObject *]
Like "O" but requires that the Python object is a string object. Raises \texttt{TypeError} if the object is not a string object. The C variable may also be declared as \texttt{PyObject*}.

"U" (Unicode string) [PyUnicodeObject *]
Like "O" but requires that the Python object is a Unicode object. Raises \texttt{TypeError} if the object is not a Unicode object. The C variable may also be declared as \texttt{PyObject*}.

"t#" (read-only character buffer) [char *, int]
Like "s#", but accepts any object which implements the read-only buffer interface. The \texttt{char *} variable is set to point to the first byte of the buffer, and the \texttt{int} is set to the length of the buffer. Only single-segment buffer objects are accepted; \texttt{TypeError} is raised for all others.

"w" (read-write character buffer) [char *]
Similar to "s", but accepts any object which implements the read-write buffer interface. The caller must determine the length of the buffer by other means, or use "w#" instead. Only single-segment buffer objects are accepted; \texttt{TypeError} is raised for all others.

"w#" (read-write character buffer) [char *, int]
Like "s#", but accepts any object which implements the read-write buffer interface. The \texttt{char *} variable is set to point to the first byte of the buffer, and the \texttt{int} is set to the length of the buffer. Only single-segment buffer objects are accepted; \texttt{TypeError} is raised for all others.

"(items)" (tuple) [matching-items]
The object must be a Python sequence whose length is the number of format units in \textit{items}. The C arguments must correspond to the individual format units in \textit{items}. Format units for sequences may be nested.

\textbf{Note:} Prior to Python version 1.5.2, this format specifier only accepted a tuple containing the individual parameters, not an arbitrary sequence. Code which previously caused \texttt{TypeError} to be raised here may now proceed without an exception. This is not expected to be a problem for existing code.

It is possible to pass Python long integers where integers are requested; however no proper range checking is done -- the most significant bits are silently truncated when the receiving field is too small to receive the value (actually, the semantics are inherited from downcasts in C -- your mileage may vary).

A few other characters have a meaning in a format string. These may not occur inside nested parentheses. They are:

\texttt{"|"}

Indicates that the remaining arguments in the Python argument list are optional. The C variables corresponding to optional arguments should be initialized to their default value -- when an optional argument is not specified, \texttt{PyArg_ParseTuple()} does not touch the contents of the corresponding C variable(s).

\texttt{";"}

The list of format units ends here; the string after the colon is used as the function name in error messages (the ``associated value'' of the exception that \texttt{PyArg_ParseTuple()} raises).

\texttt{";\;"}

The list of format units ends here; the string after the semicolon is used as the error message \textit{instead} of the default error message. Clearly, ";" and ";\;" mutually exclude each other.

Note that any Python object references which are provided to the caller are \textit{borrowed} references; do not decrement their reference count!

Additional arguments passed to these functions must be addresses of variables
whose type is determined by the format string; these are used to store values from the input tuple. There are a few cases, as described in the list of format units above, where these parameters are used as input values; they should match what is specified for the corresponding format unit in that case.

For the conversion to succeed, the arg object must match the format and the format must be exhausted. On success, the PyArg_Parse*() functions return true, otherwise they return false and raise an appropriate exception.

```c
int PyArg_ParseTuple(PyObject *args, const char *format, ...) 
Parse the parameters of a function that takes only positional parameters into local variables. Returns true on success; on failure, it returns false and raises the appropriate exception.

int PyArg_VaParse(PyObject *args, const char *format, va_list vargs) 
Identical to PyArg_ParseTuple(), except that it accepts a va_list rather than a variable number of arguments.
```

```c
int PyArg_ParseTupleAndKeywords(PyObject *args, PyObject *kw, const char *format, char *keywords[], ...) 
Parse the parameters of a function that takes both positional and keyword parameters into local variables. Returns true on success; on failure, it returns false and raises the appropriate exception.

int PyArg_VaParseTupleAndKeywords(PyObject *args, PyObject *kw, const char *format, char *keywords[], va_list vargs) 
Identical to PyArg_ParseTupleAndKeywords(), except that it accepts a va_list rather than a variable number of arguments.
```

```c
int PyArg_Parse(PyObject *args, const char *format, ...) 
Function used to deconstruct the argument lists of "old-style" functions -- these are functions which use the METH_OLDARGS parameter parsing method. This is not recommended for use in parameter parsing in new code, and most code in the standard interpreter has been modified to no longer use this for that purpose. It does remain a convenient way to decompose other tuples, however, and may continue to be used for that purpose.
```
int PyArg_UnpackTuple(PyObject *args, const char *name, Py_ssize_t min, Py_ssize_t max, ...)

A simpler form of parameter retrieval which does not use a format string to specify the types of the arguments. Functions which use this method to retrieve their parameters should be declared as METH_VARARGS in function or method tables. The tuple containing the actual parameters should be passed as args; it must actually be a tuple. The length of the tuple must be at least min and no more than max; min and max may be equal. Additional arguments must be passed to the function, each of which should be a pointer to a PyObject* variable; these will be filled in with the values from args; they will contain borrowed references. The variables which correspond to optional parameters not given by args will not be filled in; these should be initialized by the caller. This function returns true on success and false if args is not a tuple or contains the wrong number of elements; an exception will be set if there was a failure.

This is an example of the use of this function, taken from the sources for the _weakref helper module for weak references:

```c
static PyObject *
weakref_ref(PyObject *self, PyObject *args)
{
    PyObject *object;
    PyObject *callback = NULL;
    PyObject *result = NULL;

    if (PyArg_UnpackTuple(args, "ref", 1, 2, &object, &callback))
    {
        result = PyWeakref_NewRef(object, callback);
    }
    return result;
}
```

The call to PyArg_UnpackTuple() in this example is entirely equivalent to this call to PyArg_ParseTuple():

```c
PyArg_ParseTuple(args, "O|O:ref", &object, &callback)
```

New in version 2.2.

PyObject* Py_BuildValue( const char *format, ...)  

_Return value:_ **New reference.**  
Create a new value based on a format string similar to those accepted by the
PyArg_Parse*() family of functions and a sequence of values. Returns the value or NULL in the case of an error; an exception will be raised if NULL is returned.

Py_BuildValue() does not always build a tuple. It builds a tuple only if its format string contains two or more format units. If the format string is empty, it returns None; if it contains exactly one format unit, it returns whatever object is described by that format unit. To force it to return a tuple of size 0 or one, parenthesize the format string.

When memory buffers are passed as parameters to supply data to build objects, as for the "s" and "s#" formats, the required data is copied. Buffers provided by the caller are never referenced by the objects created by Py_BuildValue(). In other words, if your code invokes malloc() and passes the allocated memory to Py_BuildValue(), your code is responsible for calling free() for that memory once Py_BuildValue() returns.

In the following description, the quoted form is the format unit; the entry in (round) parentheses is the Python object type that the format unit will return; and the entry in [square] brackets is the type of the C value(s) to be passed.

The characters space, tab, colon and comma are ignored in format strings (but not within format units such as "s#"). This can be used to make long format strings a tad more readable.

"s" (string) [char *]
Convert a null-terminated C string to a Python object. If the C string pointer is NULL, None is used.

"s#" (string) [char *, int]
Convert a C string and its length to a Python object. If the C string pointer is NULL, the length is ignored and None is returned.

"z" (string or None) [char *]
Same as "s".

"z#" (string or None) [char *, int]
Same as "s#".

"u" (Unicode string) [Py_UNICODE *]
Convert a null-terminated buffer of Unicode (UCS-2 or UCS-4) data to a Python Unicode object. If the Unicode buffer pointer is NULL, None is returned.

"u#" (Unicode string) [Py_UNICODE *, int]
Convert a Unicode (UCS-2 or UCS-4) data buffer and its length to a Python Unicode object. If the Unicode buffer pointer is NULL, the length is ignored and None is returned.

"i" (integer) [int]
Convert a plain C int to a Python integer object.

"b" (integer) [char]
Convert a plain C char to a Python integer object.

"h" (integer) [short int]
Convert a plain C short int to a Python integer object.

"l" (integer) [long int]
Convert a C long int to a Python integer object.

"B" (integer) [unsigned char]
Convert a C unsigned char to a Python integer object.

"H" (integer) [unsigned short int]
Convert a C unsigned short int to a Python integer object.

"I" (integer/long) [unsigned int]
Convert a C unsigned int to a Python integer object or a Python long integer object, if it is larger than sys.maxint.

"k" (integer/long) [unsigned long]
Convert a C unsigned long to a Python integer object or a Python long integer object, if it is larger than sys.maxint.

"L" (long) [PY_LONG_LONG]
Convert a C `long long` to a Python long integer object. Only available on platforms that support `long long`.

"K" (long) [unsigned PY_LONG_LONG]
Convert a C unsigned `long long` to a Python long integer object. Only available on platforms that support unsigned `long long`.

"n" (int) [Py_ssize_t]
Convert a C `Py_ssize_t` to a Python integer or long integer. New in version 2.5.

"c" (string of length 1) [char]
Convert a C `int` representing a character to a Python string of length 1.

"d" (float) [double]
Convert a C `double` to a Python floating point number.

"f" (float) [float]
Same as "d".

"D" (complex) [Py_complex *]
Convert a C `Py_complex` structure to a Python complex number.

"O" (object) [PyObject *]
Pass a Python object untouched (except for its reference count, which is incremented by one). If the object passed in is a NULL pointer, it is assumed that this was caused because the call producing the argument found an error and set an exception. Therefore, `Py_BuildValue()` will return NULL but won't raise an exception. If no exception has been raised yet, `SystemError` is set.

"S" (object) [PyObject *]
Same as "O".

"N" (object) [PyObject *]
Same as "O", except it doesn't increment the reference count on the object. Useful when the object is created by a call to an object
constructor in the argument list.

"O" (object) [converter, anything]
Convert anything to a Python object through a converter function. The function is called with anything (which should be compatible with void *) as its argument and should return a "new" Python object, or NULL if an error occurred.

"(items)" (tuple) [matching-items]
Convert a sequence of C values to a Python tuple with the same number of items.

"[items]" (list) [matching-items]
Convert a sequence of C values to a Python list with the same number of items.

"{items}" (dictionary) [matching-items]
Convert a sequence of C values to a Python dictionary. Each pair of consecutive C values adds one item to the dictionary, serving as key and value, respectively.

If there is an error in the format string, the SystemError exception is set and NULL returned.
6. Abstract Objects Layer

The functions in this chapter interact with Python objects regardless of their type, or with wide classes of object types (e.g. all numerical types, or all sequence types). When used on object types for which they do not apply, they will raise a Python exception.

It is not possible to use these functions on objects that are not properly initialized, such as a list object that has been created by PyList_New(), but whose items have not been set to some non-NULL value yet.

Subsections

- 6.1 Object Protocol
- 6.2 Number Protocol
- 6.3 Sequence Protocol
- 6.4 Mapping Protocol
- 6.5 Iterator Protocol
- 6.6 Buffer Protocol

Release 2.5, documentation updated on 19th September, 2006. See About this document... for information on suggesting changes.
6.1 Object Protocol

int **PyObject_Print**( PyObject *o, FILE *fp, int flags)
Print an object o, on file fp. Returns -1 on error. The flags argument is used
to enable certain printing options. The only option currently supported is
Py_PRINT_RAW; if given, the str() of the object is written instead of
the repr().

int **PyObject_HasAttrString**( PyObject *o, const char *attr_name)
Returns 1 if o has the attribute attr_name, and 0 otherwise. This is
equivalent to the Python expression "hasattr(o, attr_name)". This
function always succeeds.

PyObject* **PyObject_GetAttrString**( PyObject *o, const char
*attr_name)
Return value: **New reference.**
Retrieve an attribute named attr_name from object o. Returns the attribute
value on success, or NULL on failure. This is the equivalent of the Python
expression "o.attr_name".

int **PyObject_HasAttr**( PyObject *o, PyObject *attr_name)
Returns 1 if o has the attribute attr_name, and 0 otherwise. This is
equivalent to the Python expression "hasattr(o, attr_name)". This
function always succeeds.

PyObject* **PyObject_GetAttr**( PyObject *o, PyObject *attr_name)
Return value: **New reference.**
Retrieve an attribute named attr_name from object o. Returns the attribute
value on success, or NULL on failure. This is the equivalent of the Python
expression "o.attr_name".

int **PyObject_SetAttrString**( PyObject *o, const char *attr_name,
PyObject *v)
Set the value of the attribute named attr_name, for object o, to the value v.
Returns -1 on failure. This is the equivalent of the Python statement
"o.attr_name = v".

int PyObject_SetAttr( PyObject *o, PyObject *attr_name, PyObject *v)
    Set the value of the attribute named attr_name, for object o, to the value v. Returns -1 on failure. This is the equivalent of the Python statement "o.attr_name = v".

int PyObject_DelAttrString( PyObject *o, const char *attr_name)
    Delete attribute named attr_name, for object o. Returns -1 on failure. This is the equivalent of the Python statement: "del o.attr_name".

int PyObject_DelAttr( PyObject *o, PyObject *attr_name)
    Delete attribute named attr_name, for object o. Returns -1 on failure. This is the equivalent of the Python statement "del o.attr_name".

PyObject* PyObject_RichCompare( PyObject *o1, PyObject *o2, int opid)
Compare the values of o1 and o2 using the operation specified by opid, which must be one of Py_LT, Py_LE, Py_EQ, Py_NE, Py_GT, or Py_GE, corresponding to <, <=, ==, !=, >, or >= respectively. This is the equivalent of the Python expression "o1 op o2", where op is the operator corresponding to opid. Returns the value of the comparison on success, or NULL on failure.

int PyObject_RichCompareBool( PyObject *o1, PyObject *o2, int opid)
Compare the values of o1 and o2 using the operation specified by opid, which must be one of Py_LT, Py_LE, Py_EQ, Py_NE, Py_GT, or Py_GE, corresponding to <, <=, ==, !=, >, or >= respectively. Returns -1 on error, 0 if the result is false, 1 otherwise. This is the equivalent of the Python expression "o1 op o2", where op is the operator corresponding to opid.

int PyObject_Cmp( PyObject *o1, PyObject *o2, int *result)
Compare the values of o1 and o2 using a routine provided by o1, if one exists, otherwise with a routine provided by o2. The result of the comparison is returned in result. Returns -1 on failure. This is the
equivalent of the Python statement "result = cmp(o1, o2)".

int **PyObject_Compare**( PyObject *o1, PyObject *o2)

Compare the values of o1 and o2 using a routine provided by o1, if one exists, otherwise with a routine provided by o2. Returns the result of the comparison on success. On error, the value returned is undefined; use PyErr_Occurred() to detect an error. This is equivalent to the Python expression "cmp(o1, o2)".

PyObject* **PyObject_Repr**( PyObject *o)

*Return value: New reference.*

Compute a string representation of object o. Returns the string representation on success, NULL on failure. This is the equivalent of the Python expression "repr(o)". Called by the repr() built-in function and by reverse quotes.

PyObject* **PyObject_Str**( PyObject *o)

*Return value: New reference.*

Compute a string representation of object o. Returns the string representation on success, NULL on failure. This is the equivalent of the Python expression "str(o)". Called by the str() built-in function and by the print statement.

PyObject* **PyObject_Unicode**( PyObject *o)

*Return value: New reference.*

Compute a Unicode string representation of object o. Returns the Unicode string representation on success, NULL on failure. This is the equivalent of the Python expression "unicode(o)". Called by the unicode() built-in function.

int **PyObject_IsInstance**( PyObject *inst, PyObject *cls)

Returns 1 if inst is an instance of the class cls or a subclass of cls, or 0 if not. On error, returns -1 and sets an exception. If cls is a type object rather than a class object, PyObject_IsInstance() returns 1 if inst is of type cls. If cls is a tuple, the check will be done against every entry in cls. The result will be 1 when at least one of the checks returns 1, otherwise it will be 0. If inst is not a class instance and cls is neither a type object, nor a
class object, nor a tuple, *inst* must have a __class__ attribute -- the class relationship of the value of that attribute with *cls* will be used to determine the result of this function. New in version 2.1. Changed in version 2.2: Support for a tuple as the second argument added.

Subclass determination is done in a fairly straightforward way, but includes a wrinkle that implementors of extensions to the class system may want to be aware of. If *A* and *B* are class objects, *B* is a subclass of *A* if it inherits from *A* either directly or indirectly. If either is not a class object, a more general mechanism is used to determine the class relationship of the two objects. When testing if *B* is a subclass of *A*, if *A* is *B*, *PyObject_IsSubclass()* returns true. If *A* and *B* are different objects, *B*’s __bases__ attribute is searched in a depth-first fashion for *A* -- the presence of the __bases__ attribute is considered sufficient for this determination.

```c
int PyObject_IsSubclass(PyObject *derived, PyObject *cls)
```

Returns 1 if the class *derived* is identical to or derived from the class *cls*, otherwise returns 0. In case of an error, returns -1. If *cls* is a tuple, the check will be done against every entry in *cls*. The result will be 1 when at least one of the checks returns 1, otherwise it will be 0. If either *derived* or *cls* is not an actual class object (or tuple), this function uses the generic algorithm described above. New in version 2.1. Changed in version 2.3: Older versions of Python did not support a tuple as the second argument.

```c
int PyCallable_Check(PyObject *o)
```

Determine if the object *o* is callable. Return 1 if the object is callable and 0 otherwise. This function always succeeds.

```c
PyObject* PyObject_Call(PyObject *callable_object, PyObject *args, PyObject *kw)
```

*Return value: New reference.*

Call a callable Python object *callable_object*, with arguments given by the tuple *args*, and named arguments given by the dictionary *kw*. If no named arguments are needed, *kw* may be NULL. *args* must not be NULL, use an empty tuple if no arguments are needed. Returns the result of the call on success, or NULL on failure. This is the equivalent of the Python expression "apply(*callable_object*, *args, **kw)" or "*callable_object*(*args, **kw)". New in version 2.2.
PyObject* **PyObject_CallObject**( PyObject *callable_object, PyObject *args)

*Return value: New reference.*
Call a callable Python object `callable_object`, with arguments given by the tuple `args`. If no arguments are needed, then `args` may be NULL. Returns the result of the call on success, or NULL on failure. This is the equivalent of the Python expression "apply(`callable_object`, `args`)" or "`callable_object(*args)`".

PyObject* **PyObject_CallFunction**( PyObject *callable, char *format, ...)

*Return value: New reference.*
Call a callable Python object `callable`, with a variable number of C arguments. The C arguments are described using a `Py_BuildValue()` style format string. The format may be NULL, indicating that no arguments are provided. Returns the result of the call on success, or NULL on failure. This is the equivalent of the Python expression "apply(`callable`, `args`)" or "`callable(*args)`". Note that if you only pass `PyObject * args`, `PyObject_CallFunctionObjArgs` is a faster alternative.

PyObject* **PyObject_CallMethod**( PyObject *o, char *method, char *format, ...)

*Return value: New reference.*
Call the method named `method` of object `o` with a variable number of C arguments. The C arguments are described by a `Py_BuildValue()` format string that should produce a tuple. The format may be NULL, indicating that no arguments are provided. Returns the result of the call on success, or NULL on failure. This is the equivalent of the Python expression "o.method(`args`)". Note that if you only pass `PyObject * args`, `PyObject_CallMethodObjArgs` is a faster alternative.

PyObject* **PyObject_CallFunctionObjArgs**( PyObject *callable, ..., NULL)

*Return value: New reference.*
Call a callable Python object `callable`, with a variable number of `PyObject*` arguments. The arguments are provided as a variable number of parameters followed by NULL. Returns the result of the call on success,
or NULL on failure. New in version 2.2.

PyObject* **PyObject_CallMethodObjArgs**( PyObject *o, PyObject *name, ..., NULL)

*Return value: New reference.*
Calls a method of the object o, where the name of the method is given as a Python string object in name. It is called with a variable number of PyObject* arguments. The arguments are provided as a variable number of parameters followed by NULL. Returns the result of the call on success, or NULL on failure. New in version 2.2.

long **PyObject_Hash**( PyObject *o)
Compute and return the hash value of an object o. On failure, return -1. This is the equivalent of the Python expression "hash(o)".

int **PyObject_IsTrue**( PyObject *o)
Returns 1 if the object o is considered to be true, and 0 otherwise. This is equivalent to the Python expression "not not o". On failure, return -1.

int **PyObject_Not**( PyObject *o)
Returns 0 if the object o is considered to be true, and 1 otherwise. This is equivalent to the Python expression "not o". On failure, return -1.

PyObject* **PyObject_Type**( PyObject *o)
*Return value: New reference.*
When o is non-NULL, returns a type object corresponding to the object type of object o. On failure, raises SystemError and returns NULL. This is equivalent to the Python expression type(o). This function increments the reference count of the return value. There's really no reason to use this function instead of the common expression o->ob_type, which returns a pointer of type PyTypeObject*, except when the incremented reference count is needed.

int **PyObject_TypeCheck**( PyObject *o, PyTypeObject *type)
Return true if the object o is of type type or a subtype of type. Both parameters must be non-NULL. New in version 2.2.
Py_ssize_t PyObject_Length( PyObject *o)

Py_ssize_t PyObject_Size( PyObject *o)

Return the length of object o. If the object o provides either the sequence and mapping protocols, the sequence length is returned. On error, -1 is returned. This is the equivalent to the Python expression "len(o)".

PyObject* PyObject_GetItem( PyObject *o, PyObject *key)

Return element of o corresponding to the object key or NULL on failure. This is the equivalent of the Python expression "o[key]".

int PyObject_SetItem( PyObject *o, PyObject *key, PyObject *v)

Map the object key to the value v. Returns -1 on failure. This is the equivalent of the Python statement "o[key] = v".

int PyObject_DelItem( PyObject *o, PyObject *key)

Delete the mapping for key from o. Returns -1 on failure. This is the equivalent of the Python statement "del o[key]".

int PyObject_AsFileDescriptor( PyObject *o)

Derives a file-descriptor from a Python object. If the object is an integer or long integer, its value is returned. If not, the object's fileno() method is called if it exists; the method must return an integer or long integer, which is returned as the file descriptor value. Returns -1 on failure.

PyObject* PyObject_Dir( PyObject *o)

This is equivalent to the Python expression "dir(o)" , returning a (possibly empty) list of strings appropriate for the object argument, or NULL if there was an error. If the argument is NULL, this is like the Python "dir()", returning the names of the current locals; in this case, if no execution frame is active then NULL is returned but PyErr_Occurred() will return false.

PyObject* PyObject_GetIter( PyObject *o)

This is equivalent to the Python expression \texttt{"iter(o)"}. It returns a new
iterator for the object argument, or the object itself if the object is already
an iterator. Raises \texttt{TypeError} and returns NULL if the object cannot be
iterated.
6.2 Number Protocol

int PyNumber_Check(PyObject *o)
    Returns 1 if the object o provides numeric protocols, and false otherwise. This function always succeeds.

PyObject* PyNumber_Add(PyObject *o1, PyObject *o2)
    Returns the result of adding o1 and o2, or NULL on failure. This is the equivalent of the Python expression "o1 + o2".

PyObject* PyNumber_Subtract(PyObject *o1, PyObject *o2)
    Returns the result of subtracting o2 from o1, or NULL on failure. This is the equivalent of the Python expression "o1 - o2".

PyObject* PyNumber_Multiply(PyObject *o1, PyObject *o2)
    Returns the result of multiplying o1 and o2, or NULL on failure. This is the equivalent of the Python expression "o1 * o2".

PyObject* PyNumber_Divide(PyObject *o1, PyObject *o2)
    Returns the result of dividing o1 by o2, or NULL on failure. This is the equivalent of the Python expression "o1 / o2".

PyObject* PyNumber_FloorDivide(PyObject *o1, PyObject *o2)
    Return the floor of o1 divided by o2, or NULL on failure. This is equivalent to the "classic" division of integers. New in version 2.2.

PyObject* PyNumber_TrueDivide(PyObject *o1, PyObject *o2)
    Return a reasonable approximation for the mathematical value of o1 divided by o2, or NULL on failure. The return value is "approximate"
because binary floating point numbers are approximate; it is not possible to represent all real numbers in base two. This function can return a floating point value when passed two integers. New in version 2.2.

PyObject* **PyNumber_Remainder**( PyObject *o1, PyObject *o2)

*Return value: New reference.*

Returns the remainder of dividing o1 by o2, or NULL on failure. This is the equivalent of the Python expression "o1 % o2".

PyObject* **PyNumber_Divmod**( PyObject *o1, PyObject *o2)

*Return value: New reference.*

See the built-in function `divmod()` function. Returns NULL on failure. This is the equivalent of the Python expression "divmod(o1, o2)".

PyObject* **PyNumber_Power**( PyObject *o1, PyObject *o2, PyObject *o3)

*Return value: New reference.*

See the built-in function `pow()` function. Returns NULL on failure. This is the equivalent of the Python expression "pow(o1, o2, o3)", where o3 is optional. If o3 is to be ignored, pass `Py_None` in its place (passing NULL for o3 would cause an illegal memory access).

PyObject* **PyNumber_Negative**( PyObject *o)

*Return value: New reference.*

Returns the negation of o on success, or NULL on failure. This is the equivalent of the Python expression "-o".

PyObject* **PyNumber_Positive**( PyObject *o)

*Return value: New reference.*

Returns o on success, or NULL on failure. This is the equivalent of the Python expression "+o".

PyObject* **PyNumber.Absolute**( PyObject *o)

*Return value: New reference.*

Returns the absolute value of o, or NULL on failure. This is the equivalent of the Python expression "abs(o)".

PyObject* **PyNumber_Invert**( PyObject *o)
Returns the bitwise negation of o on success, or NULL on failure. This is the equivalent of the Python expression "~o".

PyObject* PyNumber_Lshift( PyObject *o1, PyObject *o2)
Returns the result of left shifting o1 by o2 on success, or NULL on failure. This is the equivalent of the Python expression "o1 << o2".

PyObject* PyNumber_Rshift( PyObject *o1, PyObject *o2)
Returns the result of right shifting o1 by o2 on success, or NULL on failure. This is the equivalent of the Python expression "o1 >> o2".

PyObject* PyNumber_And( PyObject *o1, PyObject *o2)
Returns the "bitwise and" of o1 and o2 on success and NULL on failure. This is the equivalent of the Python expression "o1 & o2".

PyObject* PyNumber_Xor( PyObject *o1, PyObject *o2)
Returns the "bitwise exclusive or" of o1 by o2 on success, or NULL on failure. This is the equivalent of the Python expression "o1 ^ o2".

PyObject* PyNumber_Or( PyObject *o1, PyObject *o2)
Returns the "bitwise or" of o1 and o2 on success, or NULL on failure. This is the equivalent of the Python expression "o1 | o2".

PyObject* PyNumber_InPlaceAdd( PyObject *o1, PyObject *o2)
Returns the result of adding o1 and o2, or NULL on failure. The operation is done in-place when o1 supports it. This is the equivalent of the Python statement "o1 += o2".

PyObject* PyNumber_InPlaceSubtract( PyObject *o1, PyObject *o2)
Returns the result of subtracting o2 from o1, or NULL on failure. The operation is done *in-place* when o1 supports it. This is the equivalent of the Python statement "o1 -= o2".

PyObject* **PyNumber_InPlaceMultiply**( PyObject *o1, PyObject *o2)  
*Return value: New reference.*  
Returns the result of multiplying o1 and o2, or NULL on failure. The operation is done *in-place* when o1 supports it. This is the equivalent of the Python statement "o1 *= o2".

PyObject* **PyNumber_InPlaceDivide**( PyObject *o1, PyObject *o2)  
*Return value: New reference.*  
Returns the result of dividing o1 by o2, or NULL on failure. The operation is done *in-place* when o1 supports it. This is the equivalent of the Python statement "o1 /= o2".

PyObject* **PyNumber_InPlaceFloorDivide**( PyObject *o1, PyObject *o2)  
*Return value: New reference.*  
Returns the mathematical floor of dividing o1 by o2, or NULL on failure. The operation is done *in-place* when o1 supports it. This is the equivalent of the Python statement "o1 //= o2". New in version 2.2.

PyObject* **PyNumber_InPlaceTrueDivide**( PyObject *o1, PyObject *o2)  
*Return value: New reference.*  
Return a reasonable approximation for the mathematical value of o1 divided by o2, or NULL on failure. The return value is "approximate" because binary floating point numbers are approximate; it is not possible to represent all real numbers in base two. This function can return a floating point value when passed two integers. The operation is done *in-place* when o1 supports it. New in version 2.2.

PyObject* **PyNumber_InPlaceRemainder**( PyObject *o1, PyObject *o2)  
*Return value: New reference.*  
Returns the remainder of dividing o1 by o2, or NULL on failure. The operation is done *in-place* when o1 supports it. This is the equivalent of the
Python statement "o1 %= o2".

PyObject* **PyNumber_InPlacePower**( PyObject *o1, PyObject *o2, PyObject *o3)

*Return value: New reference.*
See the built-in function pow(). Returns NULL on failure. The operation is done in-place when o1 supports it. This is the equivalent of the Python statement "o1 **= o2" when o3 is Py_None, or an in-place variant of "pow(o1, o2, o3)" otherwise. If o3 is to be ignored, pass Py_None in its place (passing NULL for o3 would cause an illegal memory access).

PyObject* **PyNumber_InPlaceLshift**( PyObject *o1, PyObject *o2)

*Return value: New reference.*
Returns the result of left shifting o1 by o2 on success, or NULL on failure. The operation is done in-place when o1 supports it. This is the equivalent of the Python statement "o1 <<= o2".

PyObject* **PyNumber_InPlaceRshift**( PyObject *o1, PyObject *o2)

*Return value: New reference.*
Returns the result of right shifting o1 by o2 on success, or NULL on failure. The operation is done in-place when o1 supports it. This is the equivalent of the Python statement "o1 >>= o2".

PyObject* **PyNumber_InPlaceAnd**( PyObject *o1, PyObject *o2)

*Return value: New reference.*
Returns the "bitwise and" of o1 and o2 on success and NULL on failure. The operation is done in-place when o1 supports it. This is the equivalent of the Python statement "o1 &= o2".

PyObject* **PyNumber_InPlaceXor**( PyObject *o1, PyObject *o2)

*Return value: New reference.*
Returns the "bitwise exclusive or" of o1 by o2 on success, or NULL on failure. The operation is done in-place when o1 supports it. This is the equivalent of the Python statement "o1 ^= o2".

PyObject* **PyNumber_InPlaceOr**( PyObject *o1, PyObject *o2)

*Return value: New reference.*
Returns the "bitwise or" of o1 and o2 on success, or NULL on failure. The operation is done in-place when o1 supports it. This is the equivalent of the Python statement "o1 | = o2".

```c
int PyNumber_Coerce( PyObject **p1, PyObject **p2)
```
This function takes the addresses of two variables of type PyObject*. If the objects pointed to by *p1 and *p2 have the same type, increment their reference count and return 0 (success). If the objects can be converted to a common numeric type, replace *p1 and *p2 by their converted value (with 'new' reference counts), and return 0. If no conversion is possible, or if some other error occurs, return -1 (failure) and don't increment the reference counts. The call PyNumber_Coerce(&o1, &o2) is equivalent to the Python statement "o1, o2 = coerce(o1, o2)".

```c
PyObject* PyNumber_Int( PyObject *o)
```
*Return value: New reference.*
Returns the o converted to an integer object on success, or NULL on failure. If the argument is outside the integer range a long object will be returned instead. This is the equivalent of the Python expression "int(o)".

```c
PyObject* PyNumber_Long( PyObject *o)
```
*Return value: New reference.*
Returns the o converted to a long integer object on success, or NULL on failure. This is the equivalent of the Python expression "long(o)".

```c
PyObject* PyNumber_Float( PyObject *o)
```
*Return value: New reference.*
Returns the o converted to a float object on success, or NULL on failure. This is the equivalent of the Python expression "float(o)".

```c
PyObject* PyNumber_Index( PyObject *o)
```
Returns the o converted to a Python int or long on success or NULL with a TypeError exception raised on failure. New in version 2.5.

```c
Py_ssize_t PyNumber_AsSsize_t( PyObject *o, PyObject *exc)
```
Returns o converted to a Py_ssize_t value if o can be interpreted as an integer. If o can be converted to a Python int or long but the attempt to
convert to a `Py_ssize_t` value would raise an `OverflowError`, then the `exc` argument is the type of exception that will be raised (usually `IndexError` or `OverflowError`). If `exc` is `NULL`, then the exception is cleared and the value is clipped to `PY_SSIZE_T_MIN` for a negative integer or `PY_SSIZE_T_MAX` for a positive integer. New in version 2.5.

```c
int PyIndex_Check( PyObject *o )
```

Returns True if `o` is an index integer (has the `nb_index` slot of the `tp_as_number` structure filled in). New in version 2.5.
6.3 Sequence Protocol

int **PySequence_Check**( PyObject *o)

Return 1 if the object provides sequence protocol, and 0 otherwise. This function always succeeds.

**Py_ssize_t PySequence_Size**( PyObject *o)

Returns the number of objects in sequence \( o \) on success, and -1 on failure. For objects that do not provide sequence protocol, this is equivalent to the Python expression "\( \text{len}(o) \)".

**Py_ssize_t PySequence_Length**( PyObject *o)

Alternate name for **PySequence_Size()**.

**PyObject* PySequence_Concat**( PyObject *o1, PyObject *o2)

*Return value: New reference.*

Return the concatenation of \( o1 \) and \( o2 \) on success, and NULL on failure. This is the equivalent of the Python expression "\( o1 + o2 \)".

**PyObject* PySequence_Repeat**( PyObject *o, Py_ssize_t count)

*Return value: New reference.*

Return the result of repeating sequence object \( o \) \( \text{count} \) times, or NULL on failure. This is the equivalent of the Python expression "\( o \* \text{count} \)".

**PyObject* PySequence_InPlaceConcat**( PyObject *o1, PyObject *o2)

*Return value: New reference.*

Return the concatenation of \( o1 \) and \( o2 \) on success, and NULL on failure. The operation is done in-place when \( o1 \) supports it. This is the equivalent of the Python expression "\( o1 += o2 \)".

**PyObject* PySequence_InPlaceRepeat**( PyObject *o, Py_ssize_t count)

*Return value: New reference.*

Return the result of repeating sequence object \( o \) \( \text{count} \) times, or NULL on failure. The operation is done in-place when \( o \) supports it. This is the equivalent of the Python expression "\( o *= \text{count} \)".
PyObject* **PySequence_GetItem**( PyObject *o, Py_ssize_t i)

*Return value: New reference.*

Return the i\textsuperscript{th} element of o, or NULL on failure. This is the equivalent of the Python expression "o[i]".

PyObject* **PySequence_GetSlice**( PyObject *o, Py_ssize_t i1, Py_ssize_t i2)

*Return value: New reference.*

Return the slice of sequence object o between i1 and i2, or NULL on failure. This is the equivalent of the Python expression "o[i1:i2]".

int **PySequence_SetItem**( PyObject *o, Py_ssize_t i, PyObject *v)

Assign object v to the i\textsuperscript{th} element of o. Returns -1 on failure. This is the equivalent of the Python statement "o[i] = v". This function does not steal a reference to v.

int **PySequence_DelItem**( PyObject *o, Py_ssize_t i)

Delete the i\textsuperscript{th} element of object o. Returns -1 on failure. This is the equivalent of the Python statement "del o[i]".

int **PySequence_SetSlice**( PyObject *o, Py_ssize_t i1, Py_ssize_t i2, PyObject *v)

Assign the sequence object v to the slice in sequence object o from i1 to i2. This is the equivalent of the Python statement "o[i1:i2] = v".

int **PySequence_DelSlice**( PyObject *o, Py_ssize_t i1, Py_ssize_t i2)

Delete the slice in sequence object o from i1 to i2. Returns -1 on failure. This is the equivalent of the Python statement "del o[i1:i2]".

int **PySequence_Count**( PyObject *o, PyObject *value)

Return the number of occurrences of value in o, that is, return the number of keys for which o[key] == value. On failure, return -1. This is equivalent to the Python expression "o.count(value)".

int **PySequence_Contains**( PyObject *o, PyObject *value)

Determine if o contains value. If an item in o is equal to value, return 1, otherwise return 0. On error, return -1. This is equivalent to the Python
expression "value in o".

int PySequence_Index( PyObject *o, PyObject *value)
    Return the first index $i$ for which $o[i] == value$. On error, return -1. This is equivalent to the Python expression "o.index(value)".

PyObject* PySequence_List( PyObject *o)
    Return a list object with the same contents as the arbitrary sequence o. The returned list is guaranteed to be new.

PyObject* PySequence_Tuple( PyObject *o)
    Return a tuple object with the same contents as the arbitrary sequence o or NULL on failure. If o is a tuple, a new reference will be returned, otherwise a tuple will be constructed with the appropriate contents. This is equivalent to the Python expression "tuple(o)".

PyObject* PySequence_Fast( PyObject *o, const char *m)
    Returns the sequence o as a tuple, unless it is already a tuple or list, in which case o is returned. Use PySequence_Fast_GET_ITEM() to access the members of the result. Returns NULL on failure. If the object is not a sequence, raises TypeError with m as the message text.

PyObject* PySequence_Fast_GET_ITEM( PyObject *o, Py_ssize_t i)
    Return value: Borrowed reference.
    Return the $i$th element of o, assuming that o was returned by PySequence_Fast(), o is not NULL, and that $i$ is within bounds.

PyObject** PySequence_Fast_ITEMS( PyObject *o)
    Return the underlying array of PyObject pointers. Assumes that o was returned by PySequence_Fast() and o is not NULL. New in version 2.4.

PyObject* PySequence_ITEM( PyObject *o, Py_ssize_t i)
Return the $i$th element of $o$ or NULL on failure. Macro form of PySequence_GetItem() but without checking that PySequence_Check($o$) is true and without adjustment for negative indices. New in version 2.3.

int **PySequence_Fast_GET_SIZE**( PyObject *$o$)

Returns the length of $o$, assuming that $o$ was returned by PySequence_Fast() and that $o$ is not NULL. The size can also be gotten by calling PySequence_Size() on $o$, but PySequence_Fast_GET_SIZE() is faster because it can assume $o$ is a list or tuple.
6.4 Mapping Protocol

int **PyMapping_Check**( PyObject *\( o \))
Return 1 if the object provides mapping protocol, and 0 otherwise. This function always succeeds.

Py_ssize_t **PyMapping_Length**( PyObject *\( o \))
Returns the number of keys in object \( o \) on success, and -1 on failure. For objects that do not provide mapping protocol, this is equivalent to the Python expression "\len(o)\".

int **PyMapping_DelItemString**( PyObject *\( o \), char *\( key \))
Remove the mapping for object \( key \) from the object \( o \). Return -1 on failure. This is equivalent to the Python statement "\del o[\key]\".

int **PyMapping_DelItem**( PyObject *\( o \), PyObject *\( key \))
Remove the mapping for object \( key \) from the object \( o \). Return -1 on failure. This is equivalent to the Python statement "\del o[\key]\".

int **PyMapping_HasKeyString**( PyObject *\( o \), char *\( key \))
On success, return 1 if the mapping object has the key \( key \) and 0 otherwise. This is equivalent to the Python expression "\o .\has_key(\key)\". This function always succeeds.

int **PyMapping_HasKey**( PyObject *\( o \), PyObject *\( key \))
Return 1 if the mapping object has the key \( key \) and 0 otherwise. This is equivalent to the Python expression "\o .\has_key(\key)\". This function always succeeds.

PyObject* **PyMapping_Keys**( PyObject *\( o \))
Return value: **New reference**.
On success, return a list of the keys in object \( o \). On failure, return NULL. This is equivalent to the Python expression "\o .\keys()\".

PyObject* **PyMapping_Values**( PyObject *\( o \))
Return value: **New reference.**
On success, return a list of the values in object o. On failure, return NULL. This is equivalent to the Python expression "o.values()".

PyObject* **PyMapping_Items** (PyObject *o)

*Return value: New reference.*
On success, return a list of the items in object o, where each item is a tuple containing a key-value pair. On failure, return NULL. This is equivalent to the Python expression "o.items()".

PyObject* **PyMapping_GetItemString** (PyObject *o, char *key)

*Return value: New reference.*
Return element of o corresponding to the object key or NULL on failure. This is the equivalent of the Python expression "o[key]".

int **PyMapping_SetItemString** (PyObject *o, char *key, PyObject *v)

Map the object key to the value v in object o. Returns -1 on failure. This is the equivalent of the Python statement "o[key] = v".
6.5 Iterator Protocol

New in version 2.2.

There are only a couple of functions specifically for working with iterators.

```c
int PyIter_Check( PyObject *o)
   Return true if the object o supports the iterator protocol.

PyObject* PyIter_Next( PyObject *o)
   Return the next value from the iteration o. If the object is an iterator, this
   retrieves the next value from the iteration, and returns NULL with no
   exception set if there are no remaining items. If the object is not an iterator,
   TypeError is raised, or if there is an error in retrieving the item, returns
   NULL and passes along the exception.
```

To write a loop which iterates over an iterator, the C code should look something
like this:

```c
PyObject *iterator = PyObject_GetIter(obj);
PyObject *item;

if (iterator == NULL) {
   /* propagate error */
}

while (item = PyIter_Next(iterator)) {
   /* do something with item */
   ...
   /* release reference when done */
   Py_DECREF(item);
}

Py_DECREF(iterator);

if (PyErr_Occurred()) {
   /* propagate error */
}
else {
   /* continue doing useful work */
}
```
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
6.6 Buffer Protocol

int **buffer**

int `PyObject_AsCharBuffer`( PyObject *obj, const char **buffer, Py_ssize_t *buffer_len)

Returns a pointer to a read-only memory location useable as character-based input. The `obj` argument must support the single-segment character buffer interface. On success, returns 0, sets `buffer` to the memory location and `buffer_len` to the buffer length. Returns -1 and sets a `TypeError` on error. New in version 1.6.

int `PyObject_AsReadBuffer`( PyObject *obj, const void **buffer, Py_ssize_t *buffer_len)

Returns a pointer to a read-only memory location containing arbitrary data. The `obj` argument must support the single-segment readable buffer interface. On success, returns 0, sets `buffer` to the memory location and `buffer_len` to the buffer length. Returns -1 and sets a `TypeError` on error. New in version 1.6.

int `PyObject_CheckReadBuffer`( PyObject *o)

Returns 1 if `o` supports the single-segment readable buffer interface. Otherwise returns 0. New in version 2.2.

int `PyObject_AsWriteBuffer`( PyObject *obj, void **buffer, Py_ssize_t *buffer_len)

Returns a pointer to a writeable memory location. The `obj` argument must support the single-segment, character buffer interface. On success, returns 0, sets `buffer` to the memory location and `buffer_len` to the buffer length. Returns -1 and sets a `TypeError` on error. New in version 1.6.
7. Concrete Objects Layer

The functions in this chapter are specific to certain Python object types. Passing them an object of the wrong type is not a good idea; if you receive an object from a Python program and you are not sure that it has the right type, you must perform a type check first; for example, to check that an object is a dictionary, use `PyDict_Check()`. The chapter is structured like the "family tree" of Python object types.

**Warning:** While the functions described in this chapter carefully check the type of the objects which are passed in, many of them do not check for NULL being passed instead of a valid object. Allowing NULL to be passed in can cause memory access violations and immediate termination of the interpreter.

7.1 Fundamental Objects

This section describes Python type objects and the singleton object None.

Subsections

- 7.1.1 Type Objects
- 7.1.2 The None Object

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
The None Object
7.1.1 Type Objects

PyTypeObject
The C structure of the objects used to describe built-in types.

PyObject* PyType_Type
This is the type object for type objects; it is the same object as type and types.TypeType in the Python layer.

int PyType_Check( PyObject *o)
Return true if the object o is a type object, including instances of types derived from the standard type object. Return false in all other cases.

int PyType_CheckExact( PyObject *o)
Return true if the object o is a type object, but not a subtype of the standard type object. Return false in all other cases. New in version 2.2.

int PyType_HasFeature( PyObject *o, int feature)
Return true if the type object o sets the feature feature. Type features are denoted by single bit flags.

int PyType_IS_GC( PyObject *o)
Return true if the type object includes support for the cycle detector; this tests the type flag Py_TPFLAGS_HAVE_GC. New in version 2.0.

int PyType_IsSubtype( PyTypeObject *a, PyTypeObject *b)
Return true if a is a subtype of b. New in version 2.2.

PyObject* PyType_GenericAlloc( PyTypeObject *type, Py_ssize_t nitems)
New in version 2.2.

PyObject* PyType_GenericNew( PyTypeObject *type, PyObject *args, PyObject *kwds)
New in version 2.2.

```c
int PyType_Ready(PyTypeObject *type)
```

Finalize a type object. This should be called on all type objects to finish their initialization. This function is responsible for adding inherited slots from a type's base class. Return 0 on success, or return -1 and sets an exception on error. New in version 2.2.
7.1.2 The None Object

Note that the PyTypeObject for None is not directly exposed in the Python/C API. Since None is a singleton, testing for object identity (using "==" in C) is sufficient. There is no PyNone_Check() function for the same reason.

PyObject* Py_None

The Python None object, denoting lack of value. This object has no methods. It needs to be treated just like any other object with respect to reference counts.

Py_RETURN_NONE

Properly handle returning Py_None from within a C function.
7.2 Numeric Objects

Subsections

- 7.2.1 Plain Integer Objects
- 7.2.2 Boolean Objects
- 7.2.3 Long Integer Objects
- 7.2.4 Floating Point Objects
- 7.2.5 Complex Number Objects
  - 7.2.5.1 Complex Numbers as C Structures
  - 7.2.5.2 Complex Numbers as Python Objects

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
7.2.1 Plain Integer Objects

**PyIntObject**
This subtype of PyObject represents a Python integer object.

PyTypeObject **PyInt_Type**
This instance of PyTypeObject represents the Python plain integer type. This is the same object as int and types.IntType.

```c
int PyInt_Check( PyObject *o )
Return true if o is of type PyInt_Type or a subtype of PyInt_Type.
Changed in version 2.2: Allowed subtypes to be accepted.
```

```c
int PyInt_CheckExact( PyObject *o )
Return true if o is of type PyInt_Type, but not a subtype of PyInt_Type. New in version 2.2.
```

```c
PyObject* PyInt_FromString( char *str, char **pend, int base )
*Return value: New reference.*
Return a new PyIntObject or PyLongObject based on the string value in str, which is interpreted according to the radix in base. If pend is non-NULL, *pend will point to the first character in str which follows the representation of the number. If base is 0, the radix will be determined based on the leading characters of str: if str starts with '0x' or '0X', radix 16 will be used; if str starts with '0', radix 8 will be used; otherwise radix 10 will be used. If base is not 0, it must be between 2 and 36, inclusive. Leading spaces are ignored. If there are no digits, ValueError will be raised. If the string represents a number too large to be contained within the machine's long int type and overflow warnings are being suppressed, a PyLongObject will be returned. If overflow warnings are not being suppressed, NULL will be returned in this case.
```

```c
PyObject* PyInt_FromLong( long ival )
*Return value: New reference.*
Create a new integer object with a value of ival.
The current implementation keeps an array of integer objects for all integers between -5 and 256, when you create an int in that range you actually just get back a reference to the existing object. So it should be possible to change the value of 1. I suspect the behaviour of Python in this case is undefined. :-) 

PyObject* PyInt_FromSsize_t( Py_ssize_t ival)
Create a new integer object with a value of ival. If the value exceeds LONG_MAX, a long integer object is returned.

New in version 2.5.

long PyInt_AsLong( PyObject *io)
Will first attempt to cast the object to a PyIntObject, if it is not already one, and then return its value. If there is an error, -1 is returned, and the caller should check PyErr_Occurred() to find out whether there was an error, or whether the value just happened to be -1.

long PyInt_AS_LONG( PyObject *io)
Return the value of the object io. No error checking is performed.

unsigned long PyInt_AsUnsignedLongMask( PyObject *io)
Will first attempt to cast the object to a PyIntObject or PyLongObject, if it is not already one, and then return its value as unsigned long. This function does not check for overflow. New in version 2.3.

unsigned PY_LONG_LONG PyInt_AsUnsignedLongLongMask( PyObject *io)
Will first attempt to cast the object to a PyIntObject or PyLongObject, if it is not already one, and then return its value as unsigned long long, without checking for overflow. New in version 2.3.

Py_ssize_t PyInt_AsSsize_t( PyObject *io)
Will first attempt to cast the object to a PyIntObject or PyLongObject, if it is not already one, and then return its value as
Py_ssize_t. New in version 2.5.

long **PyInt_GetMax**()

Return the system's idea of the largest integer it can handle (LONG_MAX, as defined in the system header files).
7.2.2 Boolean Objects

Booleans in Python are implemented as a subclass of integers. There are only two booleans, Py_False and Py_True. As such, the normal creation and deletion functions don't apply to booleans. The following macros are available, however.

```c
int PyBool_Check( PyObject *o)
    Return true if o is of type PyBool_Type. New in version 2.3.
```

```c
PyObject* Py_False
    The Python False object. This object has no methods. It needs to be treated just like any other object with respect to reference counts.
```

```c
PyObject* Py_True
    The Python True object. This object has no methods. It needs to be treated just like any other object with respect to reference counts.
```

```c
Py_RETURN_FALSE
    Return Py_False from a function, properly incrementing its reference count. New in version 2.4.
```

```c
Py_RETURN_TRUE
    Return Py_True from a function, properly incrementing its reference count. New in version 2.4.
```

```c
PyObject* PyBool_FromLong( long v)
    Return a new reference to Py_True or Py_False depending on the truth value of v. New in version 2.3.
```
See About this document... for information on suggesting changes.
7.2.3 Long Integer Objects

**PyLongObject**
This subtype of PyObject represents a Python long integer object.

**PyTypeObject PyLong_Type**
This instance of PyTypeObject represents the Python long integer type. This is the same object as long and types.LongType.

```c
int PyLong_Check( PyObject *p)
```
Return true if its argument is a PyLongObject or a subtype of PyLongObject. Changed in version 2.2: Allowed subtypes to be accepted.

```c
int PyLong_CheckExact( PyObject *p)
```
Return true if its argument is a PyLongObject, but not a subtype of PyLongObject. New in version 2.2.

```c
PyObject* PyLong_FromLong( long v)
```
Return value: *New reference.*
Return a new PyLongObject object from v, or NULL on failure.

```c
PyObject* PyLong_FromUnsignedLong( unsigned long v)
```
Return value: *New reference.*
Return a new PyLongObject object from a C unsigned long, or NULL on failure.

```c
PyObject* PyLong_FromLongLong( PY_LONG_LONG v)
```
Return value: *New reference.*
Return a new PyLongObject object from a C long long, or NULL on failure.

```c
PyObject* PyLong_FromUnsignedLongLong( unsigned PY_LONG_LONG v)
```
Return value: *New reference.*
Return a new PyLongObject object from a C unsigned long long.
long, or NULL on failure.

PyObject* PyLong_FromDouble( double v)

Return a new PyLongObject object from the integer part of v, or NULL
on failure.

PyObject* PyLong_FromString( char *str, char **pend, int base)

Return a new PyLongObject based on the string value in str, which is
interpreted according to the radix in base. If pend is non-NULL, *pend will
point to the first character in str which follows the representation of the
number. If base is 0, the radix will be determined based on the leading
characters of str: if str starts with '0x' or '0X', radix 16 will be used; if
str starts with '0', radix 8 will be used; otherwise radix 10 will be used. If
base is not 0, it must be between 2 and 36, inclusive. Leading spaces are
ignored. If there are no digits, ValueError will be raised.

PyObject* PyLong_FromUnicode(Py_UNICODE *u, Py_ssize_t length, int base)

Convert a sequence of Unicode digits to a Python long integer value. The
first parameter, u, points to the first character of the Unicode string, length
gives the number of characters, and base is the radix for the conversion.
The radix must be in the range [2, 36]; if it is out of range, ValueError
will be raised. New in version 1.6.

PyObject* PyLong_FromVoidPtr( void *p)

Create a Python integer or long integer from the pointer p. The pointer
value can be retrieved from the resulting value using
PyLong_AsVoidPtr(). New in version 1.5.2. Changed in version 2.5:
If the integer is larger than LONG_MAX, a positive long integer is
returned.

long PyLong_AsLong( PyObject *pylong)

Return a C long representation of the contents of pylong. If pylong is
greater than LONG_MAX, an OverflowError is raised.

unsigned long **PyLong_AsUnsignedLong** (PyObject *pylong)
Return a C unsigned long representation of the contents of pylong. If pylong is greater than ULONG_MAX, an OverflowError is raised.

**PY_LONG_LONG PyLong_AsLongLong** (PyObject *pylong)
Return a C long long from a Python long integer. If pylong cannot be represented as a long long, an OverflowError will be raised. New in version 2.2.

unsigned PY_LONG_LONG **PyLong_AsUnsignedLongLong** (PyObject *pylong)
Return a C unsigned long long from a Python long integer. If pylong cannot be represented as an unsigned long long, an OverflowError will be raised if the value is positive, or a TypeError will be raised if the value is negative. New in version 2.2.

unsigned long **PyLong_AsUnsignedLongMask** (PyObject *io)
Return a C unsigned long long from a Python long integer, without checking for overflow. New in version 2.3.

unsigned PY_LONG_LONG **PyLong_AsUnsignedLongLongMask** (PyObject *io)
Return a C unsigned long long from a Python long integer, without checking for overflow. New in version 2.3.

double **PyLong_AsDouble** (PyObject *pylong)
Return a C double representation of the contents of pylong. If pylong cannot be approximately represented as a double, an OverflowError exception is raised and -1.0 will be returned.

void* **PyLong_AsVoidPtr** (PyObject *pylong)
Convert a Python integer or long integer pylong to a C void pointer. If pylong cannot be converted, an OverflowError will be raised. This is only assured to produce a usable void pointer for values created with PyLong_FromVoidPtr(). New in version 1.5.2. Changed in version
2.5: For values outside 0..LONG_MAX, both signed and unsigned integers are accepted.
7.2.4 Floating Point Objects

**PyFloatObject**
This subtype of PyObject represents a Python floating point object.

PyTypeObject **PyFloat_Type**
This instance of PyTypeObject represents the Python floating point type. This is the same object as float and types.FloatType.

int **PyFloat_Check**( PyObject *p)
Return true if its argument is a PyFloatObject or a subtype of PyFloatObject. Changed in version 2.2: Allowed subtypes to be accepted.

int **PyFloat_CheckExact**( PyObject *p)
Return true if its argument is a PyFloatObject, but not a subtype of PyFloatObject. New in version 2.2.

PyObject* **PyFloat_FromString**( PyObject *str, char **pend)
Return value: *New reference.*
Create a PyFloatObject object based on the string value in str, or NULL on failure. The pend argument is ignored. It remains only for backward compatibility.

PyObject* **PyFloat_FromDouble**( double v)
Return value: *New reference.*
Create a PyFloatObject object from v, or NULL on failure.

double **PyFloat_AsDouble**( PyObject *pyfloat)
Return a C double representation of the contents of pyfloat.

double **PyFloat_AS_DOUBLE**( PyObject *pyfloat)
Return a C double representation of the contents of pyfloat, but without error checking.
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
7.2.5 Complex Number Objects

Python's complex number objects are implemented as two distinct types when viewed from the C API: one is the Python object exposed to Python programs, and the other is a C structure which represents the actual complex number value. The API provides functions for working with both.

Subsections

- 7.2.5.1 Complex Numbers as C Structures
- 7.2.5.2 Complex Numbers as Python Objects

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
7.3 Sequence Objects

Generic operations on sequence objects were discussed in the previous chapter; this section deals with the specific kinds of sequence objects that are intrinsic to the Python language.

Subsections

- 7.3.1 String Objects
- 7.3.2 Unicode Objects
  - 7.3.2.1 Built-in Codecs
  - 7.3.2.2 Methods and Slot Functions
- 7.3.3 Buffer Objects
- 7.3.4 Tuple Objects
- 7.3.5 List Objects
7.3.1 String Objects

These functions raise `TypeError` when expecting a string parameter and are called with a non-string parameter.

**PyStringObject**
This subtype of `PyObject` represents a Python string object.

**PyTypeError**
This instance of `PyTypeObject` represents the Python string type; it is the same object as `str` and `types.StringType` in the Python layer.

```c
int PyString_Check( PyObject *o )
Return true if the object o is a string object or an instance of a subtype of the string type. Changed in version 2.2: Allowed subtypes to be accepted.
```

```c
int PyString_CheckExact( PyObject *o )
Return true if the object o is a string object, but not an instance of a subtype of the string type. New in version 2.2.
```

```c
PyObject* PyString_FromString( const char *v )
Return a new string object with the value v on success, and NULL on failure. The parameter v must not be NULL; it will not be checked.
```

```c
PyObject* PyString_FromStringAndSize( const char *v, Py_ssize_t len )
Return a new string object with the value v and length len on success, and NULL on failure. If v is NULL, the contents of the string are uninitialized.
```

```c
PyObject* PyString_FromFormat( const char *format, ... )
Take a C printf()-style format string and a variable number of arguments, calculate the size of the resulting Python string and return a string with the values formatted into it. The variable arguments must be C
types and must correspond exactly to the format characters in the *format* string. The following format characters are allowed:

<table>
<thead>
<tr>
<th>Format Characters</th>
<th>Type</th>
<th>Comment</th>
</tr>
</thead>
<tbody>
<tr>
<td>%</td>
<td>n/a</td>
<td>The literal % character.</td>
</tr>
<tr>
<td>%c</td>
<td>int</td>
<td>A single character, represented as an C int.</td>
</tr>
<tr>
<td>%d</td>
<td>int</td>
<td>Exactly equivalent to <code>printf(&quot;%d&quot;)</code>.</td>
</tr>
<tr>
<td>%u</td>
<td>unsigned int</td>
<td>Exactly equivalent to <code>printf(&quot;%u&quot;)</code>.</td>
</tr>
<tr>
<td>%ld</td>
<td>long</td>
<td>Exactly equivalent to <code>printf(&quot;%ld&quot;)</code>.</td>
</tr>
<tr>
<td>%lu</td>
<td>unsigned long</td>
<td>Exactly equivalent to <code>printf(&quot;%lu&quot;)</code>.</td>
</tr>
<tr>
<td>%zd</td>
<td>Py_ssize_t</td>
<td>Exactly equivalent to <code>printf(&quot;%zd&quot;)</code>.</td>
</tr>
<tr>
<td>%zu</td>
<td>size_t</td>
<td>Exactly equivalent to <code>printf(&quot;%zu&quot;)</code>.</td>
</tr>
<tr>
<td>%i</td>
<td>int</td>
<td>Exactly equivalent to <code>printf(&quot;%i&quot;)</code>.</td>
</tr>
<tr>
<td>%x</td>
<td>int</td>
<td>Exactly equivalent to <code>printf(&quot;%x&quot;)</code>.</td>
</tr>
<tr>
<td>%s</td>
<td>char*</td>
<td>A null-terminated C character array.</td>
</tr>
<tr>
<td>%p</td>
<td>void*</td>
<td>The hex representation of a C pointer. Mostly equivalent to <code>printf(&quot;%p&quot;)</code> except that it is guaranteed to start with the literal 0x regardless of what the platform's <code>printf</code> yields.</td>
</tr>
</tbody>
</table>

An unrecognized format character causes all the rest of the format string to be copied as-is to the result string, and any extra arguments discarded.

**PyObject** _**PyString_FromFormatV**( const char *format, va_list args)  
*Return value: New reference.*  
Identical to _PyString_FromFormat()_ except that it takes exactly two arguments.

**Py_ssize_t** _PyString_Size_( PyObject *string)  
Return the length of the string in string object *string*.

**Py_ssize_t** _PyString_GET_SIZE_( PyObject *string)
Macro form of `PyString_Size()` but without error checking.

```c
char* PyString_AsString( PyObject *string )
```

Return a NUL-terminated representation of the contents of `string`. The pointer refers to the internal buffer of `string`, not a copy. The data must not be modified in any way, unless the string was just created using `PyString_FromStringAndSize(NULL, size)`. It must not be deallocated. If `string` is a Unicode object, this function computes the default encoding of `string` and operates on that. If `string` is not a string object at all, `PyString_AsString()` returns NULL and raises `TypeError`.

```c
char* PyString_AS_STRING( PyObject *string )
```

Macro form of `PyString_AsString()` but without error checking. Only string objects are supported; no Unicode objects should be passed.

```c
int PyString_AsStringAndSize( PyObject *obj, char **buffer, Py_ssize_t *length )
```

Return a NUL-terminated representation of the contents of the object `obj` through the output variables `buffer` and `length`.

The function accepts both string and Unicode objects as input. For Unicode objects it returns the default encoded version of the object. If `length` is NULL, the resulting buffer may not contain NUL characters; if it does, the function returns -1 and a `TypeError` is raised.

The buffer refers to an internal string buffer of `obj`, not a copy. The data must not be modified in any way, unless the string was just created using `PyString_FromStringAndSize(NULL, size)`. It must not be deallocated. If `string` is a Unicode object, this function computes the default encoding of `string` and operates on that. If `string` is not a string object at all, `PyString_AsStringAndSize()` returns -1 and raises `TypeError`.

```c
void PyString_Concat( PyObject **string, PyObject *newpart )
```

Create a new string object in `*string` containing the contents of `newpart` appended to `string`; the caller will own the new reference. The reference to the old value of `string` will be stolen. If the new string cannot be created, the old reference to `string` will still be discarded and the value of `*string` will be set to NULL; the appropriate exception will be set.
void **PyString_ConcatAndDel( PyObject **string, PyObject *newpart)
    Create a new string object in *string containing the contents of newpart appended to string. This version decrements the reference count of newpart.

int _PyString_Resize( PyObject **string, Py_ssize_t newsize)
    A way to resize a string object even though it is ``immutable''. Only use this to build up a brand new string object; don't use this if the string may already be known in other parts of the code. It is an error to call this function if the refcount on the input string object is not one. Pass the address of an existing string object as an lvalue (it may be written into), and the new size desired. On success, *string holds the resized string object and 0 is returned; the address in *string may differ from its input value. If the reallocation fails, the original string object at *string is deallocated, *string is set to NULL, a memory exception is set, and -1 is returned.

PyObject* PyString_Format( PyObject *format, PyObject *args)
    Return a new string object from format and args. Analogous to format % args. The args argument must be a tuple.

void PyString_InternInPlace( PyObject **string)
    Intern the argument *string in place. The argument must be the address of a pointer variable pointing to a Python string object. If there is an existing interned string that is the same as *string, it sets *string to it (decrementing the reference count of the old string object and incrementing the reference count of the interned string object), otherwise it leaves *string alone and interns it (incrementing its reference count). (Clarification: even though there is a lot of talk about reference counts, think of this function as reference-count-neutral; you own the object after the call if and only if you owned it before the call.)

PyObject* PyString_InternFromString( const char *v)
    A combination of PyString_FromString() and PyString_InternInPlace(), returning either a new string object that has been interned, or a new (``owned'') reference to an earlier interned string object with the same value.
PyObject* **PyString.Decode** (const char *s, Py_ssize_t size, const char *encoding, const char *errors)

*Return value: New reference.*
Create an object by decoding size bytes of the encoded buffer s using the codec registered for encoding. encoding and errors have the same meaning as the parameters of the same name in the `unicode()` built-in function. The codec to be used is looked up using the Python codec registry. Return NULL if an exception was raised by the codec.

PyObject* **PyString.AsDecodedObject** (PyObject *str, const char *encoding, const char *errors)

*Return value: New reference.*
Decode a string object by passing it to the codec registered for encoding and return the result as Python object. encoding and errors have the same meaning as the parameters of the same name in the `encode()` method. The codec to be used is looked up using the Python codec registry. Return NULL if an exception was raised by the codec.

PyObject* **PyString.Encode** (const char *s, Py_ssize_t size, const char *encoding, const char *errors)

*Return value: New reference.*
Encode the char buffer of the given size by passing it to the codec registered for encoding and return a Python object. encoding and errors have the same meaning as the parameters of the same name in the `encode()` method. The codec to be used is looked up using the Python codec registry. Return NULL if an exception was raised by the codec.

PyObject* **PyString.AsEncodedObject** (PyObject *str, const char *encoding, const char *errors)

*Return value: New reference.*
Encode a string object using the codec registered for encoding and return the result as Python object. encoding and errors have the same meaning as the parameters of the same name in the `encode()` method. The codec to be used is looked up using the Python codec registry. Return NULL if an exception was raised by the codec.
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
7.3.2 Unicode Objects

These are the basic Unicode object types used for the Unicode implementation in Python:

**Py_UNICODE**

This type represents the storage type which is used by Python internally as basis for holding Unicode ordinals. Python's default builds use a 16-bit type for Py_UNICODE and store Unicode values internally as UCS2. It is also possible to build a UCS4 version of Python (most recent Linux distributions come with UCS4 builds of Python). These builds then use a 32-bit type for Py_UNICODE and store Unicode data internally as UCS4. On platforms where wchar_t is available and compatible with the chosen Python Unicode build variant, Py_UNICODE is a typedef alias for wchar_t to enhance native platform compatibility. On all other platforms, Py_UNICODE is a typedef alias for either unsigned short (UCS2) or unsigned long (UCS4).

Note that UCS2 and UCS4 Python builds are not binary compatible. Please keep this in mind when writing extensions or interfaces.

**PyUnicodeObject**

This subtype of PyObject represents a Python Unicode object.

**PyTypeObject PyUnicode_Type**

This instance of PyTypeObject represents the Python Unicode type. It is exposed to Python code as unicode and types.UnicodeType.

The following APIs are really C macros and can be used to do fast checks and to access internal read-only data of Unicode objects:

```c
int PyUnicode_Check( PyObject *o)

Return true if the object o is a Unicode object or an instance of a Unicode subtype. Changed in version 2.2: Allowed subtypes to be accepted.
```

```c
int PyUnicode_CheckExact( PyObject *o)

Return true if the object o is a Unicode object, but not an instance of a
```
Unicode provides many different character properties. The most often needed ones are available through these macros which are mapped to C functions depending on the Python configuration.

int `Py_UNICODE_ISSPACE`( Py_UNICODE ch)
    Return 1 or 0 depending on whether `ch` is a whitespace character.

int `Py_UNICODE_ISLOWER`( Py_UNICODE ch)
    Return 1 or 0 depending on whether `ch` is a lowercase character.

int `Py_UNICODE_ISUPPER`( Py_UNICODE ch)
    Return 1 or 0 depending on whether `ch` is an uppercase character.

int `Py_UNICODE_ISTITLE`( Py_UNICODE ch)
    Return 1 or 0 depending on whether `ch` is a titlecase character.

int `Py_UNICODE_ISLINEBREAK`( Py_UNICODE ch)
    Return 1 or 0 depending on whether `ch` is a linebreak character.
int Py_UNICODE_ISDECIMAL(Py_UNICODE ch)
    Return 1 or 0 depending on whether ch is a decimal character.

int Py_UNICODE_ISDIGIT(Py_UNICODE ch)
    Return 1 or 0 depending on whether ch is a digit character.

int Py_UNICODE_ISNUMERIC(Py_UNICODE ch)
    Return 1 or 0 depending on whether ch is a numeric character.

int Py_UNICODE_ISALPHA(Py_UNICODE ch)
    Return 1 or 0 depending on whether ch is an alphabetic character.

int Py_UNICODE_ISALNUM(Py_UNICODE ch)
    Return 1 or 0 depending on whether ch is an alphanumeric character.

These APIs can be used for fast direct character conversions:

Py_UNICODE Py_UNICODE_TOLOWER(Py_UNICODE ch)
    Return the character ch converted to lower case.

Py_UNICODE Py_UNICODE_TOUPPER(Py_UNICODE ch)
    Return the character ch converted to upper case.

Py_UNICODE Py_UNICODE_TOTITLE(Py_UNICODE ch)
    Return the character ch converted to title case.

int Py_UNICODE_TODECIMAL(Py_UNICODE ch)
    Return the character ch converted to a decimal positive integer. Return -1 if this is not possible. This macro does not raise exceptions.

int Py_UNICODE_TODIGIT(Py_UNICODE ch)
    Return the character ch converted to a single digit integer. Return -1 if this is not possible. This macro does not raise exceptions.

double Py_UNICODE_TONUMERIC(Py_UNICODE ch)
    Return the character ch converted to a double. Return -1.0 if this is not possible. This macro does not raise exceptions.
To create Unicode objects and access their basic sequence properties, use these APIs:

PyObject* `PyUnicode_FromUnicode` (const Py_UNICODE *u, Py_ssize_t size)

*Return value: *New reference.*
Create a Unicode Object from the Py_UNICODE buffer u of the given size. u may be NULL which causes the contents to be undefined. It is the user's responsibility to fill in the needed data. The buffer is copied into the new object. If the buffer is not NULL, the return value might be a shared object. Therefore, modification of the resulting Unicode object is only allowed when u is NULL.

Py_UNICODE* `PyUnicode_AsUnicode` (PyObject *unicode)
Return a read-only pointer to the Unicode object's internal Py_UNICODE buffer, NULL if unicode is not a Unicode object.

Py_ssize_t `PyUnicode_GetSize` (PyObject *unicode)
Return the length of the Unicode object.

PyObject* `PyUnicode_FromEncodedObject` (PyObject *obj, const char *encoding, const char *errors)

*Return value: *New reference.*
Coerce an encoded object obj to an Unicode object and return a reference with incremented refcount.

String and other char buffer compatible objects are decoded according to the given encoding and using the error handling defined by errors. Both can be NULL to have the interface use the default values (see the next section for details).

All other objects, including Unicode objects, cause a TypeError to be set.

The API returns NULL if there was an error. The caller is responsible for decref'ing the returned objects.
PyObject* \textbf{PyUnicode\_FromObject}( PyObject *obj)

\textit{Return value: \textit{New reference.}}

Shortcut for \texttt{PyUnicode\_FromEncodedObject(obj, NULL, "strict")} which is used throughout the interpreter whenever coercion to Unicode is needed.

If the platform supports \texttt{wchar\_t} and provides a header file \texttt{wchar.h}, Python can interface directly to this type using the following functions. Support is optimized if Python's own \texttt{Py\_UNICODE} type is identical to the system's \texttt{wchar\_t}.

PyObject* \textbf{PyUnicode\_FromWideChar}( const wchar\_t *w, Py\_ssize\_t size)

\textit{Return value: \textit{New reference.}}

Create a Unicode object from the \texttt{wchar\_t} buffer \texttt{w} of the given size. Return NULL on failure.

Py\_ssize\_t \textbf{PyUnicode\_AsWideChar}( PyUnicodeObject *unicode, wchar\_t *w, Py\_ssize\_t size)

Copy the Unicode object contents into the \texttt{wchar\_t} buffer \texttt{w}. At most \textit{size} \texttt{wchar\_t} characters are copied (excluding a possibly trailing 0-termination character). Return the number of \texttt{wchar\_t} characters copied or -1 in case of an error. Note that the resulting \texttt{wchar\_t} string may or may not be 0-terminated. It is the responsibility of the caller to make sure that the \texttt{wchar\_t} string is 0-terminated in case this is required by the application.

\section*{Subsections}

- \textbf{7.3.2.1} Built-in Codecs
- \textbf{7.3.2.2} Methods and Slot Functions
7.3.3 Buffer Objects

Python objects implemented in C can export a group of functions called the `buffer interface.` These functions can be used by an object to expose its data in a raw, byte-oriented format. Clients of the object can use the buffer interface to access the object data directly, without needing to copy it first.

Two examples of objects that support the buffer interface are strings and arrays. The string object exposes the character contents in the buffer interface's byte-oriented form. An array can also expose its contents, but it should be noted that array elements may be multi-byte values.

An example user of the buffer interface is the file object's `write()` method. Any object that can export a series of bytes through the buffer interface can be written to a file. There are a number of format codes to `PyArg_ParseTuple()` that operate against an object's buffer interface, returning data from the target object.

More information on the buffer interface is provided in the section `Buffer Object Structures" (section 10.7), under the description for `PyBufferProcs`.

A `buffer object" is defined in the `bufferobject.h` header (included by `Python.h`). These objects look very similar to string objects at the Python programming level: they support slicing, indexing, concatenation, and some other standard string operations. However, their data can come from one of two sources: from a block of memory, or from another object which exports the buffer interface.

Buffer objects are useful as a way to expose the data from another object's buffer interface to the Python programmer. They can also be used as a zero-copy slicing mechanism. Using their ability to reference a block of memory, it is possible to expose any data to the Python programmer quite easily. The memory could be a large, constant array in a C extension, it could be a raw block of memory for manipulation before passing to an operating system library, or it could be used to pass around structured data in its native, in-memory format.

**PyBufferObject**

This subtype of `PyObject` represents a buffer object.
PyTypeObject PyBuffer_Type
The instance of PyTypeObject which represents the Python buffer type; it is the same object as buffer and types.BufferType in the Python layer.

int Py_END_OF_BUFFER
This constant may be passed as the size parameter to PyBuffer_FromObject() or PyBuffer_FromReadWriteObject(). It indicates that the new PyBufferObject should refer to base object from the specified offset to the end of its exported buffer. Using this enables the caller to avoid querying the base object for its length.

int PyBuffer_Check( PyObject *p)
Return true if the argument has type PyBuffer_Type.

PyObject* PyBuffer_FromObject( PyObject *base, Py_ssize_t offset,
Py_ssize_t size)

Return a new read-only buffer object. This raises TypeError if base doesn't support the read-only buffer protocol or doesn't provide exactly one buffer segment, or it raises ValueError if offset is less than zero. The buffer will hold a reference to the base object, and the buffer's contents will refer to the base object's buffer interface, starting as position offset and extending for size bytes. If size is Py_END_OF_BUFFER, then the new buffer's contents extend to the length of the base object's exported buffer data.

PyObject* PyBuffer_FromReadWriteObject( Py_ssize_t offset,
Py_ssize_t size)

Return a new writable buffer object. Parameters and exceptions are similar to those for PyBuffer_FromObject(). If the base object does not export the writable buffer protocol, then TypeError is raised.

PyObject* PyBuffer_FromMemory( void *ptr, Py_ssize_t size)
Return a new read-only buffer object that reads from a specified location in memory, with a specified size. The caller is responsible for ensuring that the memory buffer, passed in as \textit{ptr}, is not deallocated while the returned buffer object exists. Raises \texttt{ValueError} if \textit{size} is less than zero. Note that \texttt{Py\_END\_OF\_BUFFER} may \textit{not} be passed for the \textit{size} parameter; \texttt{ValueError} will be raised in that case.

\begin{verbatim}
PyObject* PyBuffer_FromReadWriteMemory( void *ptr, Py_ssize_t size)

Return value: \textit{New reference.}
Similar to \texttt{PyBuffer\_FromMemory()}, but the returned buffer is writable.
\end{verbatim}

\begin{verbatim}
PyObject* PyBuffer\_New( Py_ssize_t size)

Return value: \textit{New reference.}
Return a new writable buffer object that maintains its own memory buffer of \textit{size} bytes. \texttt{ValueError} is returned if \textit{size} is not zero or positive. Note that the memory buffer (as returned by \texttt{PyObject\_AsWriteBuffer()}) is not specifically aligned.
\end{verbatim}
7.3.4 Tuple Objects

**PyTupleObject**
This subtype of PyObject represents a Python tuple object.

PyTypeObject **PyTuple_Type**
This instance of PyTypeObject represents the Python tuple type; it is the same object as `tuple` and `types.TupleType` in the Python layer.

```c
int PyTuple_Check( PyObject *p)
Return true if p is a tuple object or an instance of a subtype of the tuple type. Changed in version 2.2: Allowed subtypes to be accepted.
```

```c
int PyTuple_CheckExact( PyObject *p)
Return true if p is a tuple object, but not an instance of a subtype of the tuple type. New in version 2.2.
```

**PyObject** * PyTuple_New( Py_ssize_t len)
*Return value: New reference.*
Return a new tuple object of size `len`, or NULL on failure.

```c
PyObject* PyTuple_Pack( Py_ssize_t n, ...)
Return a new tuple object of size `n`, or NULL on failure. The tuple values are initialized to the subsequent `n` C arguments pointing to Python objects. "PyTuple_Pack(2, a, b)" is equivalent to "Py_BuildValue(" (00)", a, b)". New in version 2.4.
```

```c
int PyTuple_Size( PyObject *p)
Take a pointer to a tuple object, and return the size of that tuple.
```

```c
int PyTuple_GET_SIZE( PyObject *p)
Return the size of the tuple `p`, which must be non-NULL and point to a tuple; no error checking is performed.
```

**PyObject** * PyTuple_GetItem( PyObject *p, Py_ssize_t pos)
Return value: **Borrowed reference.**
Return the object at position *pos* in the tuple pointed to by *p*. If *pos* is out of bounds, return NULL and sets an *IndexError* exception.

PyObject* **PyTuple_GET_ITEM**( PyObject * *p*, Py_ssize_t *pos*)

Return value: **Borrowed reference.**
Like *PyTuple_GetItem()* , but does no checking of its arguments.

PyObject* **PyTuple_GetSlice**( PyObject * *p*, Py_ssize_t *low*, Py_ssize_t *high*)

Return value: **New reference.**
Take a slice of the tuple pointed to by *p* from *low* to *high* and return it as a new tuple.

int **PyTuple_SetItem**( PyObject * *p*, Py_ssize_t *pos*, PyObject * *o*)

Insert a reference to object *o* at position *pos* of the tuple pointed to by *p*. Return 0 on success. **Note:** This function \``steals\'' a reference to *o*.

void **PyTuple_SET_ITEM**( PyObject * *p*, Py_ssize_t *pos*, PyObject * *o*)

Like *PyTuple_SetItem()* , but does no error checking, and should only be used to fill in brand new tuples. **Note:** This function \``steals\'' a reference to *o*.

int **_PyTuple_Resize**( PyObject ***p*, Py_ssize_t *newsize*)

Can be used to resize a tuple. *newsize* will be the new length of the tuple. Because tuples are *supposed* to be immutable, this should only be used if there is only one reference to the object. Do *not* use this if the tuple may already be known to some other part of the code. The tuple will always grow or shrink at the end. Think of this as destroying the old tuple and creating a new one, only more efficiently. Returns 0 on success. Client code should never assume that the resulting value of *p* will be the same as before calling this function. If the object referenced by *p* is replaced, the original *p* is destroyed. On failure, returns -1 and sets *p* to NULL, and raises *MemoryError* or *SystemError*. Changed in version 2.2: Removed unused third parameter, *last_is_sticky*. 
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
7.3.5 List Objects

**PyListObject**
This subtype of *PyObject* represents a Python list object.

**PyTypeObject PyList_Type**
This instance of *PyTypeObject* represents the Python list type. This is the same object as *list* and *types.ListType* in the Python layer.

```c
int PyList_Check( PyObject *p)
```
Return true if *p* is a list object or an instance of a subtype of the list type. Changed in version 2.2: Allowed subtypes to be accepted.

```c
int PyList_CheckExact( PyObject *p)
```
Return true if *p* is a list object, but not an instance of a subtype of the list type. New in version 2.2.

```c
PyObject* PyList_New( Py_ssize_t len)
```
*Return value: New reference.*
Return a new list of length *len* on success, or NULL on failure. **Note:** If *length* is greater than zero, the returned list object's items are set to NULL. Thus you cannot use abstract API functions such as *PySequence_SetItem()* or expose the object to Python code before setting all items to a real object with *PyList_SetItem()*.

```c
Py_ssize_t PyList_Size( PyObject *list)
```
Return the length of the list object in *list*; this is equivalent to "\len(list)\" on a list object.

```c
Py_ssize_t PyList_GET_SIZE( PyObject *list)
```
Macro form of *PyList_Size()* without error checking.

```c
PyObject* PyList_GetItem( PyObject *list, Py_ssize_t index)
```
*Return value: Borrowed reference.*
Return the object at position *pos* in the list pointed to by *p*. The position must be positive, indexing from the end of the list is not supported. If *pos* is
out of bounds, return NULL and set an IndexError exception.

PyObject* **PyList_GET_ITEM** (PyObject *list, Py_ssize_t i)

*Return value: Borrowed reference.*
Macro form of PyList_GetItem() without error checking.

int **PyList_SetItem** (PyObject *list, Py_ssize_t index, PyObject *item)

Set the item at index index in list to item. Return 0 on success or -1 on failure. **Note:** This function `"steals"` a reference to item and discards a reference to an item already in the list at the affected position.

void **PyList_SET_ITEM** (PyObject *list, Py_ssize_t i, PyObject *o)

Macro form of PyList_SetItem() without error checking. This is normally only used to fill in new lists where there is no previous content. **Note:** This function `"steals"` a reference to item, and, unlike PyList_SetItem(), does not discard a reference to any item that it being replaced; any reference in list at position i will be leaked.

int **PyList_Insert** (PyObject *list, Py_ssize_t index, PyObject *item)

Insert the item item into list list in front of index index. Return 0 if successful; return -1 and set an exception if unsuccessful. Analogous to list.insert(index, item).

int **PyList_Append** (PyObject *list, PyObject *item)

Append the object item at the end of list list. Return 0 if successful; return -1 and set an exception if unsuccessful. Analogous to list.append(item).

PyObject* **PyList_GetSlice** (PyObject *list, Py_ssize_t low, Py_ssize_t high)

*Return value: New reference.*
Return a list of the objects in list containing the objects between low and high. Return NULL and set an exception if unsuccessful. Analogous to list[low:high].

int **PyList_SetSlice** (PyObject *list, Py_ssize_t low, Py_ssize_t high, PyObject *itemlist)
Set the slice of list between low and high to the contents of itemlist. Analogous to list[low:high] = itemlist. The itemlist may be NULL, indicating the assignment of an empty list (slice deletion). Return 0 on success, -1 on failure.

int PyList_Sort( PyObject *list)
Sort the items of list in place. Return 0 on success, -1 on failure. This is equivalent to "list.sort()".

int PyList_Reverse( PyObject *list)
Reverse the items of list in place. Return 0 on success, -1 on failure. This is the equivalent of "list.reverse()".

PyObject* PyList_AsTuple( PyObject *list)
Return a new tuple object containing the contents of list; equivalent to "tuple(list)".
7.4 Mapping Objects

Subsections

- 7.4.1 Dictionary Objects

Release 2.5, documentation updated on 19th September, 2006. See About this document... for information on suggesting changes.
# 7.4.1 Dictionary Objects

**PyDictObject**
This subtype of PyObject represents a Python dictionary object.

**PyTypeObject PyDict_Type**
This instance of PyTypeObject represents the Python dictionary type. This is exposed to Python programs as dict and types.DictType.

```c
int PyDict_Check( PyObject *p )
    Return true if p is a dict object or an instance of a subtype of the dict type. Changed in version 2.2: Allowed subtypes to be accepted.
```

```c
int PyDict_CheckExact( PyObject *p )
    Return true if p is a dict object, but not an instance of a subtype of the dict type. New in version 2.4.
```

```c
PyObject* PyDict_New()
    Return a new empty dictionary, or NULL on failure.
```

```c
PyObject* PyDictProxy_New( PyObject *dict )
    Return a proxy object for a mapping which enforces read-only behavior. This is normally used to create a proxy to prevent modification of the dictionary for non-dynamic class types. New in version 2.2.
```

```c
void PyDict_Clear( PyObject *p )
    Empty an existing dictionary of all key-value pairs.
```

```c
int PyDict_Contains( PyObject *p, PyObject *key )
    Determine if dictionary p contains key. If an item in p is matches key, return 1, otherwise return 0. On error, return -1. This is equivalent to the Python expression "key in p". New in version 2.4.
```

```c
PyObject* PyDict_Copy( PyObject *p )
```
Return value: *New reference.*
Return a new dictionary that contains the same key-value pairs as \( p \). New in version 1.6.

```c
int PyDict_SetItem( PyObject *p, PyObject *key, PyObject *val )
```

Insert value into the dictionary \( p \) with a key of \( key \). \( key \) must be hashable; if it isn't, TypeError will be raised. Return 0 on success or -1 on failure.

```c
int PyDict_SetItemString( PyObject *p, const char *key, PyObject *val )
```

Insert value into the dictionary \( p \) using \( key \) as a key. \( key \) should be a char*. The key object is created using `PyString_FromString(key)`. Return 0 on success or -1 on failure.

```c
int PyDict_DelItem( PyObject *p, PyObject *key )
```

Remove the entry in dictionary \( p \) with key \( key \). \( key \) must be hashable; if it isn't, TypeError is raised. Return 0 on success or -1 on failure.

```c
int PyDict_DelItemString( PyObject *p, char *key )
```

Remove the entry in dictionary \( p \) which has a key specified by the string \( key \). Return 0 on success or -1 on failure.

```c
PyObject* PyDict_GetItem( PyObject *p, PyObject *key )
```

*Return value: *Borrowed reference.*
Return the object from dictionary \( p \) which has a key \( key \). Return NULL if the key \( key \) is not present, but without setting an exception.

```c
PyObject* PyDict_GetItemString( PyObject *p, const char *key )
```

*Return value: *Borrowed reference.*
This is the same as `PyDict_GetItem()`, but \( key \) is specified as a char*, rather than a PyObject*.

```c
PyObject* PyDict_Items( PyObject *p )
```

*Return value: *New reference.*
Return a PyListObject containing all the items from the dictionary, as in the dictionary method `items()` (see the [Python Library Reference](https://docs.python.org/)).

```c
PyObject* PyDict_Keys( PyObject *p )
```
Return value: **New reference.**
Return a **PyListObject** containing all the keys from the dictionary, as in the dictionary method `keys()` (see the [Python Library Reference](#)).

**PyObject* PyDict_Values**( PyObject *p)

*Return value: New reference.*
Return a **PyListObject** containing all the values from the dictionary `p`, as in the dictionary method `values()` (see the [Python Library Reference](#)).

**Py_ssize_t PyDict_Size**( PyObject *p)

Return the number of items in the dictionary. This is equivalent to "len(p)" on a dictionary.

**int PyDict_Next**( PyObject *p, Py_ssize_t *ppos, PyObject **pkey, PyObject **pvalue)

Iterate over all key-value pairs in the dictionary `p`. The **int** referred to by `ppos` must be initialized to 0 prior to the first call to this function to start the iteration; the function returns true for each pair in the dictionary, and false once all pairs have been reported. The parameters `pkey` and `pvalue` should either point to **PyObject*** variables that will be filled in with each key and value, respectively, or may be NULL. Any references returned through them are borrowed. `ppos` should not be altered during iteration. Its value represents offsets within the internal dictionary structure, and since the structure is sparse, the offsets are not consecutive.

For example:

```c
PyObject *key, *value;
int pos = 0;

while (PyDict_Next(self->dict, &pos, &key, &value)) {
    /* do something interesting with the values... */
    ...
}
```

The dictionary `p` should not be mutated during iteration. It is safe (since Python 2.1) to modify the values of the keys as you iterate over the dictionary, but only so long as the set of keys does not change. For example:
PyObject *key, *value;
int pos = 0;

while (PyDict_Next(self->dict, &pos, &key, &value)) {
    int i = PyInt_AS_LONG(value) + 1;
    PyObject *o = PyInt_FromLong(i);
    if (o == NULL)
        return -1;
    if (PyDict_SetItem(self->dict, key, o) < 0) {
        Py_DECREF(o);
        return -1;
    }
    Py_DECREF(o);
}

int PyDict_Merge( PyObject *a, PyObject *b, int override)
    Iterate over mapping object b adding key-value pairs to dictionary a. b may
    be a dictionary, or any object supporting PyMapping_Keys() and
    PyObject_GetItem(). If override is true, existing pairs in a will be
    replaced if a matching key is found in b, otherwise pairs will only be added
    if there is not a matching key in a. Return 0 on success or -1 if an
    exception was raised. New in version 2.2.

int PyDict_Update( PyObject *a, PyObject *b)
    This is the same as PyDict_Merge(a, b, 1) in C, or a.update(b)
    in Python. Return 0 on success or -1 if an exception was raised. New in
    version 2.2.

int PyDict_MergeFromSeq2( PyObject *a, PyObject *seq2, int override)
    Update or merge into dictionary a, from the key-value pairs in seq2. seq2
    must be an iterable object producing iterable objects of length 2, viewed as
    key-value pairs. In case of duplicate keys, the last wins if override is true,
    else the first wins. Return 0 on success or -1 if an exception was raised.
    Equivalent Python (except for the return value):

    def PyDict_MergeFromSeq2(a, seq2, override):
        for key, value in seq2:
            if override or key not in a:
                a[key] = value

    New in version 2.2.
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
7.5 Other Objects

- 7.5.14 Set Objects

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
7.5.1 File Objects

Python's built-in file objects are implemented entirely on the FILE* support from the C standard library. This is an implementation detail and may change in future releases of Python.

**PyFileObject**
This subtype of PyObject represents a Python file object.

**PyTypeObject PyFile_Type**
This instance of PyTypeObject represents the Python file type. This is exposed to Python programs as file and types.FileType.

```c
int PyFile_Check(PyObject *p)

Return true if its argument is a PyFileObject or a subtype of PyFileObject. Changed in version 2.2: Allowed subtypes to be accepted.
```

```c
int PyFile_CheckExact(PyObject *p)

Return true if its argument is a PyFileObject, but not a subtype of PyFileObject. New in version 2.2.
```

```c
PyObject* PyFile_FromString(char *filename, char *mode)

On success, return a new file object that is opened on the file given by filename, with a file mode given by mode, where mode has the same semantics as the standard C routine fopen(). On failure, return NULL.
```

```c
PyObject* PyFile_FromFile(FILE *fp, char *name, char *mode, int (*close)(FILE*))

Create a new PyFileObject from the already-open standard C file pointer, fp. The function close will be called when the file should be closed. Return NULL on failure.
```

```c
FILE* PyFile_AsFile(PyObject *p)
```
Return the file object associated with \( p \) as a `FILE*`.

**PyObject**\* `PyFile_GetLine`( PyObject \*\( p \), int \( n \))

*Return value: New reference.*

Equivalent to \( p.\text{readline}([n]) \), this function reads one line from the object \( p \). \( p \) may be a file object or any object with a `readline()` method. If \( n \) is \( 0 \), exactly one line is read, regardless of the length of the line. If \( n \) is greater than \( 0 \), no more than \( n \) bytes will be read from the file; a partial line can be returned. In both cases, an empty string is returned if the end of the file is reached immediately. If \( n \) is less than \( 0 \), however, one line is read regardless of length, but `EOFError` is raised if the end of the file is reached immediately.

**PyObject**\* `PyFile_Name`( PyObject \*\( p \))

*Return value: Borrowed reference.*

Return the name of the file specified by \( p \) as a string object.

**void** `PyFile_SetBufSize`( PyFileObject \*\( p \), int \( n \))

Available on systems with `setvbuf()` only. This should only be called immediately after file object creation.

**int** `PyFile_Encoding`( PyFileObject \*\( p \), char \*\( enc \))

Set the file's encoding for Unicode output to \( enc \). Return 1 on success and 0 on failure. New in version 2.3.

**int** `PyFile_SoftSpace`( PyObject \*\( p \), int \( newflag \))

This function exists for internal use by the interpreter. Set the `softspace` attribute of \( p \) to \( newflag \) and return the previous value. \( p \) does not have to be a file object for this function to work properly; any object is supported (thought its only interesting if the `softspace` attribute can be set). This function clears any errors, and will return \( 0 \) as the previous value if the attribute either does not exist or if there were errors in retrieving it. There is no way to detect errors from this function, but doing so should not be needed.

**int** `PyFile_WriteObject`( PyObject \*\( obj \), PyObject \*\( p \), int \( flags \))

Write object \( obj \) to file object \( p \). The only supported flag for \( flags \) is
Py_PRINT_RAW; if given, the str() of the object is written instead of the repr(). Return 0 on success or -1 on failure; the appropriate exception will be set.

int PyFile_WriteString( const char *s, PyObject *p)
Write string s to file object p. Return 0 on success or -1 on failure; the appropriate exception will be set.
7.5.2 Instance Objects

There are very few functions specific to instance objects.

PyTypeObject **PyInstance_Type**
Type object for class instances.

int **PyInstance_Check**( PyObject *obj)
Return true if obj is an instance.

PyObject* **PyInstance_New**( PyObject *class, PyObject *arg, PyObject *
*kw)
*Return value: New reference.*
Create a new instance of a specific class. The parameters arg and kw are used as the positional and keyword parameters to the object's constructor.

PyObject* **PyInstance_NewRaw**( PyObject *class, PyObject *
dict)
*Return value: New reference.*
Create a new instance of a specific class without calling its constructor. class is the class of new object. The dict parameter will be used as the object's __dict__; if NULL, a new dictionary will be created for the instance.
7.5.3 Function Objects

There are a few functions specific to Python functions.

**PyFunctionObject**
The C structure used for functions.

PyTypeObject **PyFunction_Type**
This is an instance of PyTypeObject and represents the Python function type. It is exposed to Python programmers as `types.FunctionType`.

```c
int PyFunction_Check( PyObject *o)
Return true if `o` is a function object (has type `PyFunction_Type`). The parameter must not be NULL.
```

```c
PyObject* PyFunction_New( PyObject *code, PyObject *globals)
Return a new function object associated with the code object `code`. `globals` must be a dictionary with the global variables accessible to the function.

The function's docstring, name and `__module__` are retrieved from the code object, the argument defaults and closure are set to NULL.
```

```c
PyObject* PyFunction_GetCode( PyObject *op)
Return value: Borrowed reference.
Return the code object associated with the function object `op`.
```

```c
PyObject* PyFunction_GetGlobals( PyObject *op)
Return value: Borrowed reference.
Return the globals dictionary associated with the function object `op`.
```

```c
PyObject* PyFunction_GetModule( PyObject *op)
Return value: Borrowed reference.
Return the `__module__` attribute of the function object `op`. This is normally a string containing the module name, but can be set to any other object by Python code.
PyObject* **PyFunction_GetDefaults**( PyObject *op)

*Return value: Borrowed reference.*

Return the argument default values of the function object *op*. This can be a tuple of arguments or NULL.

int **PyFunction_SetDefaults**( PyObject *op, PyObject *defaults)

Set the argument default values for the function object *op*. *defaults* must be *Py_None* or a tuple.

Raises SystemError and returns -1 on failure.

PyObject* **PyFunction_GetClosure**( PyObject *op)

*Return value: Borrowed reference.*

Return the closure associated with the function object *op*. This can be NULL or a tuple of cell objects.

int **PyFunction_SetClosure**( PyObject *op, PyObject *closure)

Set the closure associated with the function object *op*. *closure* must be *Py_None* or a tuple of cell objects.

Raises SystemError and returns -1 on failure.
7.5.4 Method Objects

There are some useful functions that are useful for working with method objects.

PyTypeObject **PyMethod_Type**

This instance of PyTypeObject represents the Python method type. This is exposed to Python programs as *types.MethodType*.

`int PyMethod_Check( PyObject *o)`

Return true if o is a method object (has type PyMethod_Type). The parameter must not be NULL.

`PyObject* PyMethod_New( PyObject *func, PyObject *self, PyObject *class)`

*Return value: New reference.*

Return a new method object, with *func* being any callable object; this is the function that will be called when the method is called. If this method should be bound to an instance, *self* should be the instance and *class* should be the class of *self*, otherwise *self* should be NULL and *class* should be the class which provides the unbound method..

`PyObject* PyMethod_Class( PyObject *meth)`

*Return value: Borrowed reference.*

Return the class object from which the method *meth* was created; if this was created from an instance, it will be the class of the instance.

`PyObject* PyMethod_GET_CLASS( PyObject *meth)`

*Return value: Borrowed reference.*

Macro version of PyMethod_Class() which avoids error checking.

`PyObject* PyMethod_Function( PyObject *meth)`

*Return value: Borrowed reference.*

Return the function object associated with the method *meth*.

`PyObject* PyMethod_GET_FUNCTION( PyObject *meth)`

*Return value: Borrowed reference.*

Macro version of PyMethod_Function() which avoids error checking.
(PyObject* PyMethod_Self( PyObject *meth))

Return value: Borrowed reference.
Return the instance associated with the method meth if it is bound, otherwise return NULL.

(PyObject* PyMethod_GET_SELF( PyObject *meth))

Return value: Borrowed reference.
Macro version of PyMethod_Self() which avoids error checking.
7.5.5 Module Objects

There are only a few functions special to module objects.

PyTypeObject PyModule_Type
   This instance of PyTypeObject represents the Python module type. This is exposed to Python programs as types.ModuleType.

int PyModule_Check( PyObject *p)
   Return true if p is a module object, or a subtype of a module object. Changed in version 2.2: Allowed subtypes to be accepted.

int PyModule_CheckExact( PyObject *p)
   Return true if p is a module object, but not a subtype of PyModule_Type. New in version 2.2.

PyObject* PyModule_New( const char *name)
   Return a new module object with the __name__ attribute set to name. Only the module's __doc__ and __name__ attributes are filled in; the caller is responsible for providing a __file__ attribute.

PyObject* PyModule_GetDict( PyObject *module)
   Return value: Borrowed reference.
   Return the dictionary object that implements module's namespace; this object is the same as the __dict__ attribute of the module object. This function never fails. It is recommended extensions use other PyModule_*() and PyObject_*() functions rather than directly manipulate a module's __dict__.

char* PyModule_GetName( PyObject *module)
   Return module's __name__ value. If the module does not provide one, or if it is not a string, SystemError is raised and NULL is returned.

char* PyModule_GetFilename( PyObject *module)
   Return the name of the file from which module was loaded using module's
__file__ attribute. If this is not defined, or if it is not a string, raise SystemError and return NULL.

int PyModule_AddObject(PyObject *module, const char *name, PyObject *value)

Add an object to module as name. This is a convenience function which can be used from the module's initialization function. This steals a reference to value. Return -1 on error, 0 on success. New in version 2.0.

int PyModule_AddIntConstant(PyObject *module, const char *name, long value)

Add an integer constant to module as name. This convenience function can be used from the module's initialization function. Return -1 on error, 0 on success. New in version 2.0.

int PyModule_AddStringConstant(PyObject *module, const char *name, const char *value)

Add a string constant to module as name. This convenience function can be used from the module's initialization function. The string value must be null-terminated. Return -1 on error, 0 on success. New in version 2.0.
7.5.6 Iterator Objects

Python provides two general-purpose iterator objects. The first, a sequence iterator, works with an arbitrary sequence supporting the `__getitem__()` method. The second works with a callable object and a sentinel value, calling the callable for each item in the sequence, and ending the iteration when the sentinel value is returned.

PyTypeObject **PySeqIter_Type**

Type object for iterator objects returned by `PySeqIter_New()` and the one-argument form of the `iter()` built-in function for built-in sequence types. New in version 2.2.

```
int PySeqIter_Check( op)
Return true if the type of op is PySeqIter_Type. New in version 2.2.
```

```
PyObject* PySeqIter_New( PyObject *seq)
Return an iterator that works with a general sequence object, seq. The iteration ends when the sequence raises IndexError for the subscripting operation. New in version 2.2.
```

PyTypeObject **PyCallIter_Type**

Type object for iterator objects returned by `PyCallIter_New()` and the two-argument form of the `iter()` built-in function. New in version 2.2.

```
int PyCallIter_Check( op)
Return true if the type of op is PyCallIter_Type. New in version 2.2.
```

```
PyObject* PyCallIter_New( PyObject *callable, PyObject *sentinel)
Return a new iterator. The first parameter, callable, can be any Python callable object that can be called with no parameters; each call to it should return the next item in the iteration. When callable returns a value equal to sentinel, the iteration will be terminated. New in version 2.2.
```
7.5.7 Descriptor Objects

`Descriptors" are objects that describe some attribute of an object. They are found in the dictionary of type objects.

PyTypeObject **PyProperty>Type**
The type object for the built-in descriptor types. New in version 2.2.

PyObject* **PyDescr_NewGetSet**(PyTypeObject *type, struct PyGetSetDef *getset)

*Return value: New reference.*
New in version 2.2.

PyObject* **PyDescr_NewMember**(PyTypeObject *type, struct PyMemberDef *meth)

*Return value: New reference.*
New in version 2.2.

PyObject* **PyDescr_NewMethod**(PyTypeObject *type, struct PyMethodDef *meth)

*Return value: New reference.*
New in version 2.2.

PyObject* **PyDescr_NewWrapper**(PyTypeObject *type, struct wrapperbase *wrapper, void *wrapped)

*Return value: New reference.*
New in version 2.2.

PyObject* **PyDescr_NewClassMethod**(PyTypeObject *type, PyMethodDef *method)

*Return value: New reference.*
New in version 2.3.

int **PyDescr_IsData**(PyObject *descr)

Return true if the descriptor objects *descr* describes a data attribute, or false if it describes a method. *descr* must be a descriptor object; there is no error
checking. New in version 2.2.

PyObject* PyWrapper_New( PyObject *, PyObject *)

New in version 2.2.
7.5.8 Slice Objects

PyTypeObject **PySlice_Type**
The type object for slice objects. This is the same as `slice` and `types.SliceType`.

int **PySlice_Check**( PyObject *ob)
Return true if `ob` is a slice object; `ob` must not be NULL.

PyObject* **PySlice_New**( PyObject *start, PyObject *stop, PyObject *step)

*Return value: New reference.*

Return a new slice object with the given values. The `start`, `stop`, and `step` parameters are used as the values of the slice object attributes of the same names. Any of the values may be NULL, in which case the `None` will be used for the corresponding attribute. Return NULL if the new object could not be allocated.

PySliceObject *slice, Py_ssize_t length,
int **PySlice_GetIndices**( Py_ssize_t *start, Py_ssize_t *stop, Py_ssize_t *step)

Retrieve the start, stop and step indices from the slice object `slice`, assuming a sequence of length `length`. Treats indices greater than `length` as errors.

Returns 0 on success and -1 on error with no exception set (unless one of the indices was not `None` and failed to be converted to an integer, in which case -1 is returned with an exception set).

You probably do not want to use this function. If you want to use slice objects in versions of Python prior to 2.3, you would probably do well to incorporate the source of `PySlice_GetIndicesEx`, suitably renamed, in the source of your extension.

PySliceObject *slice, Py_ssize_t length,
int **PySlice_GetIndicesEx**( Py_ssize_t *start, Py_ssize_t *stop,
    Py_ssize_t *step, Py_ssize_t *slicelength)

Usable replacement for `PySlice_GetIndices`. Retrieve the start, stop,
and step indices from the slice object \textit{slice} assuming a sequence of length \textit{length}, and store the length of the slice in \textit{slicelength}. Out of bounds indices are clipped in a manner consistent with the handling of normal slices.

Returns 0 on success and -1 on error with exception set.

New in version 2.3.
7.5.9 Weak Reference Objects

Python supports weak references as first-class objects. There are two specific object types which directly implement weak references. The first is a simple reference object, and the second acts as a proxy for the original object as much as it can.

```c
int PyWeakref_Check( ob)
    Return true if ob is either a reference or proxy object. New in version 2.2.

int PyWeakref_CheckRef( ob)
    Return true if ob is a reference object. New in version 2.2.

int PyWeakref_CheckProxy( ob)
    Return true if ob is a proxy object. New in version 2.2.
```

```c
PyObject* PyWeakref_NewRef( PyObject *ob, PyObject *callback)
    Return a weak reference object for the object ob. This will always return a new reference, but is not guaranteed to create a new object; an existing reference object may be returned. The second parameter, callback, can be a callable object that receives notification when ob is garbage collected; it should accept a single parameter, which will be the weak reference object itself. callback may also be None or NULL. If ob is not a weakly-referencable object, or if callback is not callable, None, or NULL, this will return NULL and raise TypeError. New in version 2.2.
```

```c
PyObject* PyWeakref_NewProxy( PyObject *ob, PyObject *callback)
    Return a weak reference proxy object for the object ob. This will always return a new reference, but is not guaranteed to create a new object; an existing proxy object may be returned. The second parameter, callback, can be a callable object that receives notification when ob is garbage collected; it should accept a single parameter, which will be the weak reference object itself. callback may also be None or NULL. If ob is not a weakly-referencable object, or if callback is not callable, None, or NULL, this will
return NULL and raise TypeError. New in version 2.2.

PyObject* **PyWeakref_GetObject** (PyObject *ref)

*Return value: Borrowed reference.*

Return the referenced object from a weak reference, *ref*. If the referent is no longer live, returns None. New in version 2.2.

PyObject* **PyWeakref_GET_OBJECT** (PyObject *ref)

*Return value: Borrowed reference.*

Similar to PyWeakref_GetObject(), but implemented as a macro that does no error checking. New in version 2.2.
7.5.10 CObjects

Refer to *Extending and Embedding the Python Interpreter*, section 1.12, "Providing a C API for an Extension Module," for more information on using these objects.

**PyCObject**

This subtype of PyObject represents an opaque value, useful for C extension modules who need to pass an opaque value (as a void* pointer) through Python code to other C code. It is often used to make a C function pointer defined in one module available to other modules, so the regular import mechanism can be used to access C APIs defined in dynamically loaded modules.

int `PyCObject_Check`( PyObject *p)

Return true if its argument is a PyCObject.

PyObject* `PyCObject_FromVoidPtr`( void* obj, void (*destr)(void *))

*Return value: New reference.*

Create a PyCObject from the void *obj. The destr function will be called when the object is reclaimed, unless it is NULL.

PyObject* `PyCObject_FromVoidPtrAndDesc`( void *obj, void* desc, void (*destr)(void *, void *))

*Return value: New reference.*

Create a PyCObject from the void *obj. The destr function will be called when the object is reclaimed. The desc argument can be used to pass extra callback data for the destructor function.

void* `PyCObject_AsVoidPtr`( PyObject* self)

Return the object void * that the PyCObject self was created with.

void* `PyCObject_GetDesc`( PyObject* self)

Return the description void * that the PyCObject self was created with.
int PyCObject_SetVoidPtr(PyObject* self, void* cobj)

Set the void pointer inside *self* to *cobj*. The PyCObject must not have an
associated destructor. Return true on success, false on failure.
7.5.11 Cell Objects

``Cell'' objects are used to implement variables referenced by multiple scopes. For each such variable, a cell object is created to store the value; the local variables of each stack frame that references the value contains a reference to the cells from outer scopes which also use that variable. When the value is accessed, the value contained in the cell is used instead of the cell object itself. This de-referencing of the cell object requires support from the generated byte-code; these are not automatically de-referenced when accessed. Cell objects are not likely to be useful elsewhere.

**PyCellObject**
The C structure used for cell objects.

PyTypeObject **PyCell_Type**
The type object corresponding to cell objects.

```c
int PyCell_Check( PyObject *ob )
    Return true if ob is a cell object; ob must not be NULL.
```

```c
PyObject* PyCell_New( PyObject *ob )
    Create and return a new cell object containing the value ob. The parameter may be NULL.
```

```c
PyObject* PyCell_Get( PyObject *cell )
    Return the contents of the cell cell.
```

```c
PyObject* PyCell_GET( PyObject *cell )
    Return value: Borrowed reference.
    Return the contents of the cell cell, but without checking that cell is non-NULL and a cell object.
```

```c
int PyCell_Set( PyObject *cell, PyObject *value )
    Set the contents of the cell object cell to value. This releases the reference
to any current content of the cell. value may be NULL. cell must be non-NULL; if it is not a cell object, -1 will be returned. On success, 0 will be returned.

void **PyCell_SET**( PyObject *cell, PyObject *value)
Sets the value of the cell object cell to value. No reference counts are adjusted, and no checks are made for safety; cell must be non-NULL and must be a cell object.
7.5.12 Generator Objects

Generator objects are what Python uses to implement generator iterators. They are normally created by iterating over a function that yields values, rather than explicitly calling PyGen_New.

**PyGenObject**

The C structure used for generator objects.

**PyTypeObject PyGen_Type**

The type object corresponding to generator objects

```c
int PyGen_Check( ob)
    Return true if ob is a generator object; ob must not be NULL.
```

```c
int PyGen_CheckExact( ob)
    Return true if ob's type is PyGen_Type is a generator object; ob must not be NULL.
```

```c
PyObject* PyGen_New( PyFrameObject *frame)
    Create and return a new generator object based on the frame object. A reference to frame is stolen by this function. The parameter must not be NULL.
```
7.5.13 DateTime Objects

Various date and time objects are supplied by the datetime module. Before using any of these functions, the header file datetime.h must be included in your source (note that this is not include by Python.h), and macro PyDateTime_IMPORT() must be invoked. The macro arranges to put a pointer to a C structure in a static variable PyDateTimeAPI, which is used by the following macros.

Type-check macros:

int PyDate_Check( PyObject *ob)
    Return true if ob is of type PyDateTime_DateType or a subtype of PyDateTime_DateType. ob must not be NULL. New in version 2.4.

int PyDate_CheckExact( PyObject *ob)
    Return true if ob is of type PyDateTime_DateType. ob must not be NULL. New in version 2.4.

int PyDateTime_Check( PyObject *ob)
    Return true if ob is of type PyDateTime_DateTimeType or a subtype of PyDateTime_DateTimeType. ob must not be NULL. New in version 2.4.

int PyDateTime_CheckExact( PyObject *ob)
    Return true if ob is of type PyDateTime_DateTimeType. ob must not be NULL. New in version 2.4.

int PyTime_Check( PyObject *ob)
    Return true if ob is of type PyDateTime_TimeType or a subtype of PyDateTime_TimeType. ob must not be NULL. New in version 2.4.

int PyTime_CheckExact( PyObject *ob)
    Return true if ob is of type PyDateTime_TimeType. ob must not be NULL. New in version 2.4.
int **PyDelta**.Check( PyObject *ob)
Return true if ob is of type **PyDateTime**.DeltaType or a subtype of
**PyDateTime**.DeltaType. ob must not be NULL. New in version 2.4.

int **PyDelta**.CheckExact( PyObject *ob)
Return true if ob is of type **PyDateTime**.DeltaType. ob must not be
NULL. New in version 2.4.

int **PyTZInfo**.Check( PyObject *ob)
Return true if ob is of type **PyDateTime**.TZInfoType or a subtype of
**PyDateTime**.TZInfoType. ob must not be NULL. New in version 2.4.

int **PyTZInfo**.CheckExact( PyObject *ob)
Return true if ob is of type **PyDateTime**.TZInfoType. ob must not be
NULL. New in version 2.4.

Macros to create objects:

PyObject* **PyDate**.FromDate( int year, int month, int day)
Return a datetime.date object with the specified year, month and day.
New in version 2.4.

PyObject* **PyDateTime**.FromDateAndTime( int hour, int minute, int
second, int usecond)
Return a datetime.datetime object with the specified year, month,
day, hour, minute, second and microsecond. New in version 2.4.

PyObject* **PyTime**.FromTime( int hour, int minute, int second, int usecond)
Return a datetime.time object with the specified hour, minute, second
and microsecond. New in version 2.4.

PyObject* **PyDelta**.FromDSU( int days, int seconds, int useconds)
Return a `datetime.timedelta` object representing the given number of days, seconds and microseconds. Normalization is performed so that the resulting number of microseconds and seconds lie in the ranges documented for `datetime.timedelta` objects. New in version 2.4.

Macros to extract fields from date objects. The argument must be an instance of `PyDateTime_Date`, including subclasses (such as `PyDateTime_DateTime`). The argument must not be `NULL`, and the type is not checked:

```c
int PyDateTime_GET_YEAR( PyDateTime_Date *o)
    return the year, as a positive int. New in version 2.4.
```

```c
int PyDateTime_GET_MONTH( PyDateTime_Date *o)
    return the month, as an int from 1 through 12. New in version 2.4.
```

```c
int PyDateTime_GET_DAY( PyDateTime_Date *o)
    return the day, as an int from 1 through 31. New in version 2.4.
```

Macros to extract fields from datetime objects. The argument must be an instance of `PyDateTime_DateTime`, including subclasses. The argument must not be `NULL`, and the type is not checked:

```c
int PyDateTime_DATE_GET_HOUR( PyDateTime_DateTime *o)
    return the hour, as an int from 0 through 23. New in version 2.4.
```

```c
int PyDateTime_DATE_GET_MINUTE( PyDateTime_DateTime *o)
    return the minute, as an int from 0 through 59. New in version 2.4.
```

```c
int PyDateTime_DATE_GET_SECOND( PyDateTime_DateTime *o)
    return the second, as an int from 0 through 59. New in version 2.4.
```

```c
int PyDateTime_DATE_GET_MICROSECOND( PyDateTime_DateTime *o)
    return the microsecond, as an int from 0 through 999999. New in version 2.4.
```

Macros to extract fields from time objects. The argument must be an instance of `PyDateTime_Time`, including subclasses. The argument must not be `NULL`,
and the type is not checked:

```c
int PyDateTime_TIME_GET_HOUR( PyDateTime_Time *o)
    Return the hour, as an int from 0 through 23. New in version 2.4.
```

```c
int PyDateTime_TIME_GET_MINUTE( PyDateTime_Time *o)
    Return the minute, as an int from 0 through 59. New in version 2.4.
```

```c
int PyDateTime_TIME_GET_SECOND( PyDateTime_Time *o)
    Return the second, as an int from 0 through 59. New in version 2.4.
```

```c
int PyDateTime_TIME_GET_MICROSECOND( PyDateTime_Time *o)
    Return the microsecond, as an int from 0 through 999999. New in version 2.4.
```

Macros for the convenience of modules implementing the DB API:

```c
PyObject* PyDateTime_FromTimestamp( PyObject *args)
    Create and return a new datetime.datetime object given an argument tuple suitable for passing to
datetime.datetime.fromtimestamp(). New in version 2.4.
```

```c
PyObject* PyDate_FromTimestamp( PyObject *args)
    Create and return a new datetime.date object given an argument tuple suitable for passing to
datetime.date.fromtimestamp(). New in version 2.4.
```
7.5.14 Set Objects

New in version 2.5.

This section details the public API for set and frozenset objects. Any functionality not listed below is best accessed using the either the abstract object protocol (including PyObject_CallMethod(), PyObject_RichCompareBool(), PyObject_Repr(), PyObject_IsTrue(), PyObject_Print(), and PyObject_GetIter()) or the abstract number protocol (including PyNumber_Add(), PyNumber_Subtract(), PyNumber_Or(), PyNumber_Xor(), PyNumber_InPlaceAdd(), PyNumber_InPlaceSubtract(), PyNumber_InPlaceOr(), and PyNumber_InPlaceXor()).

**PySetObject**
This subtype of PyObject is used to hold the internal data for both set and frozenset objects. It is like a PyDictObject in that it is a fixed size for small sets (much like tuple storage) and will point to a separate, variable sized block of memory for medium and large sized sets (much like list storage). None of the fields of this structure should be considered public and are subject to change. All access should be done through the documented API rather than by manipulating the values in the structure.

PyTypeObject **PySet_Type**
This is an instance of PyTypeObject representing the Python set type.

PyTypeObject **PyFrozenSet_Type**
This is an instance of PyTypeObject representing the Python frozenset type.

The following type check macros work on pointers to any Python object. Likewise, the constructor functions work with any iterable Python object.

```
int PyAnySet_Check( PyObject *p)
Return true if p is a set object, a frozenset object, or an instance of a subtype.
```

int PyAnySet_CheckExact( PyObject *p)
    Return true if p is a set object or a frozenset object but not an instance of a subtype.

int PyFrozenSet_CheckExact( PyObject *p)
    Return true if p is a frozenset object but not an instance of a subtype.

PyObject* PySet_New( PyObject *iterable)
    Return a new set containing objects returned by the iterable. The iterable may be NULL to create a new empty set. Return the new set on success or NULL on failure. Raise TypeError if iterable is not actually iterable. The constructor is also useful for copying a set (c=set(s)).

PyObject* PyFrozenSet_New( PyObject *iterable)
    Return a new frozenset containing objects returned by the iterable. The iterable may be NULL to create a new empty frozenset. Return the new set on success or NULL on failure. Raise TypeError if iterable is not actually iterable.

The following functions and macros are available for instances of set or frozenset or instances of their subtypes.

int PySet_Size( PyObject *anyset)
    Return the length of a set or frozenset object. Equivalent to "len(anyset)". Raises a PyExc_SystemError if anyset is not a set, frozenset, or an instance of a subtype.

int PySet_GET_SIZE( PyObject *anyset)
    Macro form of PySet_Size() without error checking.

int PySet_Contains( PyObject *anyset, PyObject *key)
    Return 1 if found, 0 if not found, and -1 if an error is encountered. Unlike the Python __contains__() method, this function does not automatically convert unhashable sets into temporary frozensets. Raise a TypeError if the key is unhashable. Raise PyExc_SystemError if
anynet is not a set, frozenset, or an instance of a subtype.

The following functions are available for instances of set or its subtypes but not for instances of frozenset or its subtypes.

int PySet_Add( PyObject *set, PyObject *key)

Add key to a set instance. Does not apply to frozenset instances. Return 0 on success or -1 on failure. Raise a TypeError if the key is unhashable. Raise a MemoryError if there is no room to grow. Raise a SystemError if set is an not an instance of set or its subtype.

int PySet_Discard( PyObject *set, PyObject *key)

Return 1 if found and removed, 0 if not found (no action taken), and -1 if an error is encountered. Does not raise KeyError for missing keys. Raise a TypeError if the key is unhashable. Unlike the Python discard() method, this function does not automatically convert unhashable sets into temporary frozensets. Raise PyExc_SystemError if set is an not an instance of set or its subtype.

PyObject* PySet_Pop( PyObject *set)

Return a new reference to an arbitrary object in the set, and removes the object from the set. Return NULL on failure. Raise KeyError if the set is empty. Raise a SystemError if set is an not an instance of set or its subtype.

int PySet_Clear( PyObject *set)

Empty an existing set of all elements.
8. Initialization, Finalization, and Threads

void **Py_Initialize**()

Initialize the Python interpreter. In an application embedding Python, this should be called before using any other Python/C API functions; with the exception of `Py_SetProgramName()`, `PyEval_InitThreads()`, `PyEval_ReleaseLock()`, and `PyEval_AcquireLock()`. This initializes the table of loaded modules (`sys.modules`), and creates the fundamental modules `__builtin__`, `__main__` and `sys`. It also initializes the module search path (`sys.path`). It does not set `sys.argv`; use `PySys_SetArgv()` for that. This is a no-op when called for a second time (without calling `Py_Finalize()` first). There is no return value; it is a fatal error if the initialization fails.

void **Py_InitializeEx**( int initsigs)

This function works like `Py_Initialize()` if `initsigs` is 1. If `initsigs` is 0, it skips initialization registration of signal handlers, which might be useful when Python is embedded. New in version 2.4.

int **Py_IsInitialized**()

Return true (nonzero) when the Python interpreter has been initialized, false (zero) if not. After `Py_Finalize()` is called, this returns false until `Py_Initialize()` is called again.

void **Py_Finalize**()

Undo all initializations made by `Py_Initialize()` and subsequent use of Python/C API functions, and destroy all sub-interpreters (see `Py_NewInterpreter()` below) that were created and not yet destroyed since the last call to `Py_Initialize()`. Ideally, this frees all memory allocated by the Python interpreter. This is a no-op when called for a second time (without calling `Py_Initialize()` again first). There is no return value; errors during finalization are ignored.
This function is provided for a number of reasons. An embedding application might want to restart Python without having to restart the application itself. An application that has loaded the Python interpreter from a dynamically loadable library (or DLL) might want to free all memory allocated by Python before unloading the DLL. During a hunt for memory leaks in an application a developer might want to free all memory allocated by Python before exiting from the application.

**Bugs and caveats:** The destruction of modules and objects in modules is done in random order; this may cause destructors (__del__ methods) to fail when they depend on other objects (even functions) or modules. Dynamically loaded extension modules loaded by Python are not unloaded. Small amounts of memory allocated by the Python interpreter may not be freed (if you find a leak, please report it). Memory tied up in circular references between objects is not freed. Some memory allocated by extension modules may not be freed. Some extensions may not work properly if their initialization routine is called more than once; this can happen if an application calls Py_Initialize() and Py_Finalize() more than once.

**PyThreadState** *Py_NewInterpreter()**

Create a new sub-interpreter. This is an (almost) totally separate environment for the execution of Python code. In particular, the new interpreter has separate, independent versions of all imported modules, including the fundamental modules __builtin__, __main__ and sys. The table of loaded modules (sys.modules) and the module search path (sys.path) are also separate. The new environment has no sys.argv variable. It has new standard I/O stream file objects sys.stdin, sys.stdout and sys.stderr (however these refer to the same underlying FILE structures in the C library).

The return value points to the first thread state created in the new sub-interpreter. This thread state is made in the current thread state. Note that no actual thread is created; see the discussion of thread states below. If creation of the new interpreter is unsuccessful, NULL is returned; no exception is set since the exception state is stored in the current thread state and there may not be a current thread state. (Like all other Python/C API functions, the global interpreter lock must be held before calling this function and is still
Extension modules are shared between (sub-)interpreters as follows: the first time a particular extension is imported, it is initialized normally, and a (shallow) copy of its module's dictionary is squirreled away. When the same extension is imported by another (sub-)interpreter, a new module is initialized and filled with the contents of this copy; the extension's \texttt{init} function is not called. Note that this is different from what happens when an extension is imported after the interpreter has been completely re-initialized by calling \texttt{Py_Finalize()} and \texttt{Py_Initialize()}; in that case, the extension's \texttt{initmodule} function is called again.

\textbf{Bugs and caveats:} Because sub-interpreters (and the main interpreter) are part of the same process, the insulation between them isn't perfect -- for example, using low-level file operations like \texttt{os.close()} they can (accidentally or maliciously) affect each other's open files. Because of the way extensions are shared between (sub-)interpreters, some extensions may not work properly; this is especially likely when the extension makes use of (static) global variables, or when the extension manipulates its module's dictionary after its initialization. It is possible to insert objects created in one sub-interpreter into a namespace of another sub-interpreter; this should be done with great care to avoid sharing user-defined functions, methods, instances or classes between sub-interpreters, since import operations executed by such objects may affect the wrong (sub-)interpreter's dictionary of loaded modules. (XXX This is a hard-to-fix bug that will be addressed in a future release.)

Also note that the use of this functionality is incompatible with extension modules such as PyObjC and ctypes that use the \texttt{PyGILState_*} APIs (and this is inherent in the way the \texttt{PyGILState_*} functions work). Simple things may work, but confusing behavior will always be near.

void \texttt{Py_EndInterpreter( PyThreadState *tstate)}

Destroy the (sub-)interpreter represented by the given thread state. The given thread state must be the current thread state. See the discussion of thread states below. When the call returns, the current thread state is \texttt{NULL}. All thread states associated with this interpreter are destroyed. (The global interpreter lock must be held before calling this function and is still held
when it returns.) \texttt{Py_Finalize()} will destroy all sub-interpreters that haven't been explicitly destroyed at that point.

\textbf{void \texttt{Py_SetProgramName}( char *name)}

This function should be called before \texttt{Py_Initialize()} is called for the first time, if it is called at all. It tells the interpreter the value of the \texttt{argv[0]} argument to the \texttt{main()} function of the program. This is used by \texttt{Py_GetPath()} and some other functions below to find the Python run-time libraries relative to the interpreter executable. The default value is 'python'. The argument should point to a zero-terminated character string in static storage whose contents will not change for the duration of the program's execution. No code in the Python interpreter will change the contents of this storage.

\textbf{char* \texttt{Py_GetProgramName}()}

Return the program name set with \texttt{Py_SetProgramName()}, or the default. The returned string points into static storage; the caller should not modify its value.

\textbf{char* \texttt{Py_GetPrefix}()}

Return the \textit{prefix} for installed platform-independent files. This is derived through a number of complicated rules from the program name set with \texttt{Py_SetProgramName()} and some environment variables; for example, if the program name is '/usr/local/bin/python', the prefix is '/usr/local'. The returned string points into static storage; the caller should not modify its value. This corresponds to the prefix variable in the top-level Makefile and the --prefix argument to the configure script at build time. The value is available to Python code as \texttt{sys.prefix}. It is only useful on UNIX. See also the next function.

\textbf{char* \texttt{Py_GetExecPrefix}()}

Return the \textit{exec-prefix} for installed platform-dependent files. This is derived through a number of complicated rules from the program name set with \texttt{Py_SetProgramName()} and some environment variables; for example, if the program name is '/usr/local/bin/python', the exec-prefix is '/usr/local'. The returned string points into static storage; the caller should not modify its value. This corresponds to the exec_prefix variable in
the top-level Makefile and the --exec-prefix argument to the configure script at build time. The value is available to Python code as sys.exec_prefix. It is only useful on Unix.

Background: The exec-prefix differs from the prefix when platform dependent files (such as executables and shared libraries) are installed in a different directory tree. In a typical installation, platform dependent files may be installed in the /usr/local/plat subtree while platform independent may be installed in /usr/local.

Generally speaking, a platform is a combination of hardware and software families, e.g. Sparc machines running the Solaris 2.x operating system are considered the same platform, but Intel machines running Solaris 2.x are another platform, and Intel machines running Linux are yet another platform. Different major revisions of the same operating system generally also form different platforms. Non-Unix operating systems are a different story; the installation strategies on those systems are so different that the prefix and exec-prefix are meaningless, and set to the empty string. Note that compiled Python bytecode files are platform independent (but not independent from the Python version by which they were compiled!).

System administrators will know how to configure the mount or automount programs to share /usr/local between platforms while having /usr/local/plat be a different filesystem for each platform.

char* Py_GetProgramFullPath()

Return the full program name of the Python executable; this is computed as a side-effect of deriving the default module search path from the program name (set by Py_SetProgramName() above). The returned string points into static storage; the caller should not modify its value. The value is available to Python code as sys.executable.

char* Py_GetPath()

Return the default module search path; this is computed from the program name (set by Py_SetProgramName() above) and some environment variables. The returned string consists of a series of directory names separated by a platform dependent delimiter character. The delimiter character is "::" on Unix and Mac OS X, ";" on Windows. The returned
string points into static storage; the caller should not modify its value. The value is available to Python code as the list `sys.path`, which may be modified to change the future search path for loaded modules.

```c
const char* Py_GetVersion()
```

Return the version of this Python interpreter. This is a string that looks something like

```
"1.5 (#67, Dec 31 1997, 22:34:28) [GCC 2.7.2.2]"
```

The first word (up to the first space character) is the current Python version; the first three characters are the major and minor version separated by a period. The returned string points into static storage; the caller should not modify its value. The value is available to Python code as `sys.version`.

```c
const char* Py_GetBuildNumber()
```

Return a string representing the Subversion revision that this Python executable was built from. This number is a string because it may contain a trailing 'M' if Python was built from a mixed revision source tree. New in version 2.5.

```c
const char* Py_GetPlatform()
```

Return the platform identifier for the current platform. On UNIX, this is formed from the ``official'' name of the operating system, converted to lower case, followed by the major revision number; e.g., for Solaris 2.x, which is also known as SunOS 5.x, the value is 'sunos5'. On Mac OS X, it is 'darwin'. On Windows, it is 'win'. The returned string points into static storage; the caller should not modify its value. The value is available to Python code as `sys.platform`.

```c
const char* Py_GetCopyright()
```

Return the official copyright string for the current Python version, for example

```
'Copyright 1991-1995 Stichting Mathematisch Centrum, Amsterdam'
```

The returned string points into static storage; the caller should not modify
its value. The value is available to Python code as `sys.copyright`.

```
const char* Py_GetCompiler()
```

Return an indication of the compiler used to build the current Python version, in square brackets, for example:

```
"[GCC 2.7.2.2]"
```

The returned string points into static storage; the caller should not modify its value. The value is available to Python code as part of the variable `sys.version`.

```
const char* Py_GetBuildInfo()
```

Return information about the sequence number and build date and time of the current Python interpreter instance, for example

```
"#67, Aug  1 1997, 22:34:28"
```

The returned string points into static storage; the caller should not modify its value. The value is available to Python code as part of the variable `sys.version`.

```
void PySys_SetArgv( int argc, char **argv)
```

Set `sys.argv` based on `argc` and `argv`. These parameters are similar to those passed to the program's `main()` function with the difference that the first entry should refer to the script file to be executed rather than the executable hosting the Python interpreter. If there isn't a script that will be run, the first entry in `argv` can be an empty string. If this function fails to initialize `sys.argv`, a fatal condition is signalled using `Py_FatalError()`.

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
8.1 Thread State and the Global Interpreter Lock

The Python interpreter is not fully thread safe. In order to support multi-threaded Python programs, there’s a global lock that must be held by the current thread before it can safely access Python objects. Without the lock, even the simplest operations could cause problems in a multi-threaded program: for example, when two threads simultaneously increment the reference count of the same object, the reference count could end up being incremented only once instead of twice.

Therefore, the rule exists that only the thread that has acquired the global interpreter lock may operate on Python objects or call Python/C API functions. In order to support multi-threaded Python programs, the interpreter regularly releases and reacquires the lock -- by default, every 100 bytecode instructions (this can be changed with `sys.setcheckinterval()`). The lock is also released and reacquired around potentially blocking I/O operations like reading or writing a file, so that other threads can run while the thread that requests the I/O is waiting for the I/O operation to complete.

The Python interpreter needs to keep some bookkeeping information separate per thread -- for this it uses a data structure called `PyThreadState`. There's one global variable, however: the pointer to the current `PyThreadState` structure. While most thread packages have a way to store "per-thread global data," Python's internal platform independent thread abstraction doesn't support this yet. Therefore, the current thread state must be manipulated explicitly.

This is easy enough in most cases. Most code manipulating the global interpreter lock has the following simple structure:

```
Save the thread state in a local variable.
Release the interpreter lock.
...Do some blocking I/O operation...
Reacquire the interpreter lock.
Restore the thread state from the local variable.
```

This is so common that a pair of macros exists to simplify it:
The `Py_BEGIN_ALLOW_THREADS` macro opens a new block and declares a hidden local variable; the `Py_END_ALLOW_THREADS` macro closes the block. Another advantage of using these two macros is that when Python is compiled without thread support, they are defined empty, thus saving the thread state and lock manipulations.

When thread support is enabled, the block above expands to the following code:

```c
PyThreadState *_save;
_save = PyEval_SaveThread();
...Do some blocking I/O operation...
PyEval_RestoreThread(_save);
```

Using even lower level primitives, we can get roughly the same effect as follows:

```c
PyThreadState * _save;
_save = PyThreadState_Swap(NULL);
PyEval_ReleaseLock();
...Do some blocking I/O operation...
PyEval_AcquireLock();
PyThreadState_Swap(_save);
```

There are some subtle differences; in particular, `PyEval_RestoreThread()` saves and restores the value of the global variable `errno`, since the lock manipulation does not guarantee that `errno` is left alone. Also, when thread support is disabled, `PyEval_SaveThread()` and `PyEval_RestoreThread()` don't manipulate the lock; in this case, `PyEval_ReleaseLock()` and `PyEval_AcquireLock()` are not available. This is done so that dynamically loaded extensions compiled with thread support enabled can be loaded by an interpreter that was compiled with disabled thread support.

The global interpreter lock is used to protect the pointer to the current thread state. When releasing the lock and saving the thread state, the current thread state pointer must be retrieved before the lock is released (since another thread could immediately acquire the lock and store its own thread state in the global
variable). Conversely, when acquiring the lock and restoring the thread state, the lock must be acquired before storing the thread state pointer.

Why am I going on with so much detail about this? Because when threads are created from C, they don’t have the global interpreter lock, nor is there a thread state data structure for them. Such threads must bootstrap themselves into existence, by first creating a thread state data structure, then acquiring the lock, and finally storing their thread state pointer, before they can start using the Python/C API. When they are done, they should reset the thread state pointer, release the lock, and finally free their thread state data structure.

Beginning with version 2.3, threads can now take advantage of the PyGILState_*() functions to do all of the above automatically. The typical idiom for calling into Python from a C thread is now:

```c
PyGILState_STATE gstate;
gstate = PyGILState_Ensure();

/* Perform Python actions here. */
result = CallSomeFunction();
/* evaluate result */

/* Release the thread. No Python API allowed beyond this point. */
PyGILState_Release(gstate);
```

Note that the PyGILState_*() functions assume there is only one global interpreter (created automatically by Py_Initialize()). Python still supports the creation of additional interpreters (using Py_NewInterpreter()), but mixing multiple interpreters and the PyGILState_*() API is unsupported.

**PyInterpreterState**

This data structure represents the state shared by a number of cooperating threads. Threads belonging to the same interpreter share their module administration and a few other internal items. There are no public members in this structure.

Threads belonging to different interpreters initially share nothing, except process state like available memory, open file descriptors and such. The global interpreter lock is also shared by all threads, regardless of to which interpreter they belong.
**PyThreadState**

This data structure represents the state of a single thread. The only public data member is `PyInterpreterState * interp`, which points to this thread's interpreter state.

```c
void PyEval_InitThreads()
```

Initialize and acquire the global interpreter lock. It should be called in the main thread before creating a second thread or engaging in any other thread operations such as `PyEval_ReleaseLock()` or `PyEval_ReleaseThread(tstate)`. It is not needed before calling `PyEval_SaveThread()` or `PyEval_RestoreThread()`.

This is a no-op when called for a second time. It is safe to call this function before calling `Py_Initialize()`.

When only the main thread exists, no lock operations are needed. This is a common situation (most Python programs do not use threads), and the lock operations slow the interpreter down a bit. Therefore, the lock is not created initially. This situation is equivalent to having acquired the lock: when there is only a single thread, all object accesses are safe. Therefore, when this function initializes the lock, it also acquires it. Before the Python thread module creates a new thread, knowing that either it has the lock or the lock hasn't been created yet, it calls `PyEval_InitThreads()`. When this call returns, it is guaranteed that the lock has been created and that the calling thread has acquired it.

It is **not** safe to call this function when it is unknown which thread (if any) currently has the global interpreter lock.

This function is not available when thread support is disabled at compile time.

```c
int PyEval_ThreadsInitialized()
```

Returns a non-zero value if `PyEval_InitThreads()` has been called. This function can be called without holding the lock, and therefore can be used to avoid calls to the locking API when running single-threaded. This function is not available when thread support is disabled at compile time. New in version 2.4.
void PyEval_AcquireLock()

Acquire the global interpreter lock. The lock must have been created earlier. If this thread already has the lock, a deadlock ensues. This function is not available when thread support is disabled at compile time.

void PyEval_ReleaseLock()

Release the global interpreter lock. The lock must have been created earlier. This function is not available when thread support is disabled at compile time.

void PyEval_AcquireThread( PyThreadState *tstate)

Acquire the global interpreter lock and set the current thread state to tstate, which should not be NULL. The lock must have been created earlier. If this thread already has the lock, deadlock ensues. This function is not available when thread support is disabled at compile time.

void PyEval_ReleaseThread( PyThreadState *tstate)

Reset the current thread state to NULL and release the global interpreter lock. The lock must have been created earlier and must be held by the current thread. The tstate argument, which must not be NULL, is only used to check that it represents the current thread state -- if it isn't, a fatal error is reported. This function is not available when thread support is disabled at compile time.

PyThreadState* PyEval_SaveThread()

Release the interpreter lock (if it has been created and thread support is enabled) and reset the thread state to NULL, returning the previous thread state (which is not NULL). If the lock has been created, the current thread must have acquired it. (This function is available even when thread support is disabled at compile time.)

void PyEval_RestoreThread( PyThreadState *tstate)

Acquire the interpreter lock (if it has been created and thread support is enabled) and set the thread state to tstate, which must not be NULL. If the lock has been created, the current thread must not have acquired it, otherwise deadlock ensues. (This function is available even when thread support is disabled at compile time.)
The following macros are normally used without a trailing semicolon; look for example usage in the Python source distribution.

**Py_BEGIN_ALLOW_THREADS**
This macro expands to "\{ PyThreadState * _save; _save = PyEval_SaveThread(); \}". Note that it contains an opening brace; it must be matched with a following Py_END_ALLOW_THREADS macro. See above for further discussion of this macro. It is a no-op when thread support is disabled at compile time.

**Py_END_ALLOW_THREADS**
This macro expands to "PyEval_RestoreThread(_save); \}". Note that it contains a closing brace; it must be matched with an earlier Py_BEGIN_ALLOW_THREADS macro. See above for further discussion of this macro. It is a no-op when thread support is disabled at compile time.

**Py_BLOCK_THREADS**
This macro expands to "PyEval_RestoreThread(_save); ": it is equivalent to Py_END_ALLOW_THREADS without the closing brace. It is a no-op when thread support is disabled at compile time.

**Py_UNBLOCK_THREADS**
This macro expands to "_save = PyEval_SaveThread(); ": it is equivalent to Py_BEGIN_ALLOW_THREADS without the opening brace and variable declaration. It is a no-op when thread support is disabled at compile time.

All of the following functions are only available when thread support is enabled at compile time, and must be called only when the interpreter lock has been created.

PyInterpreterState* **PyInterpreterState_New( )**
Create a new interpreter state object. The interpreter lock need not be held, but may be held if it is necessary to serialize calls to this function.

void **PyInterpreterState_Clear( PyInterpreterState *interp)**
Reset all information in an interpreter state object. The interpreter lock must be held.
void **PyInterpreterState_Delete** (PyInterpreterState *interp)

Destroy an interpreter state object. The interpreter lock need not be held. The interpreter state must have been reset with a previous call to **PyInterpreterState_Clear()**.

PyThreadState* **PyThreadState_New** (PyInterpreterState *interp)

Create a new thread state object belonging to the given interpreter object. The interpreter lock need not be held, but may be held if it is necessary to serialize calls to this function.

void **PyThreadState_Clear** (PyThreadState *tstate)

Reset all information in a thread state object. The interpreter lock must be held.

void **PyThreadState_Delete** (PyThreadState *tstate)

Destroy a thread state object. The interpreter lock need not be held. The thread state must have been reset with a previous call to **PyThreadState_Clear()**.

PyThreadState* **PyThreadState_Get** ()

Return the current thread state. The interpreter lock must be held. When the current thread state is NULL, this issues a fatal error (so that the caller needn't check for NULL).

PyThreadState* **PyThreadState_Swap** (PyThreadState *tstate)

Swap the current thread state with the thread state given by the argument tstate, which may be NULL. The interpreter lock must be held.

PyObject* **PyThreadState_GetDict** ()

*Return value: Borrowed reference.*

Return a dictionary in which extensions can store thread-specific state information. Each extension should use a unique key to use to store state in the dictionary. It is okay to call this function when no current thread state is available. If this function returns NULL, no exception has been raised and the caller should assume no current thread state is available. Changed in version 2.3: Previously this could only be called when a current thread is active, and NULL meant that an exception was raised.
int PyThreadState_SetAsyncExc( long id, PyObject *exc)

Asynchronously raise an exception in a thread. The "id" argument is the thread id of the target thread; "exc" is the exception object to be raised. This function does not steal any references to "exc". To prevent naive misuse, you must write your own C extension to call this. Must be called with the GIL held. Returns the number of thread states modified; this is normally one, but will be zero if the thread id isn't found. If "exc" is NULL, the pending exception (if any) for the thread is cleared. This raises no exceptions. New in version 2.3.

PyGILState_STATE PyGILState_Ensure()

Ensure that the current thread is ready to call the Python C API regardless of the current state of Python, or of its thread lock. This may be called as many times as desired by a thread as long as each call is matched with a call to PyGILState_Release(). In general, other thread-related APIs may be used between PyGILState_Ensure() and PyGILState_Release() calls as long as the thread state is restored to its previous state before the Release(). For example, normal usage of the Py_BEGIN_ALLOW_THREADS and Py_END_ALLOW_THREADS macros is acceptable.

The return value is an opaque "handle" to the thread state when PyGILState_Acquire() was called, and must be passed to PyGILState_Release() to ensure Python is left in the same state. Even though recursive calls are allowed, these handles cannot be shared - each unique call to PyGILState_Ensure must save the handle for its call to PyGILState_Release.

When the function returns, the current thread will hold the GIL. Failure is a fatal error. New in version 2.3.

void PyGILState_Release( PyGILState_STATE)

Release any resources previously acquired. After this call, Python's state will be the same as it was prior to the corresponding PyGILState_Ensure call (but generally this state will be unknown to the caller, hence the use of the GILState API.)

Every call to PyGILState_Ensure() must be matched by a call to
PyGILState_Release() on the same thread. New in version 2.3.
8.2 Profiling and Tracing

The Python interpreter provides some low-level support for attaching profiling and execution tracing facilities. These are used for profiling, debugging, and coverage analysis tools.

Starting with Python 2.2, the implementation of this facility was substantially revised, and an interface from C was added. This C interface allows the profiling or tracing code to avoid the overhead of calling through Python-level callable objects, making a direct C function call instead. The essential attributes of the facility have not changed; the interface allows trace functions to be installed per-thread, and the basic events reported to the trace function are the same as had been reported to the Python-level trace functions in previous versions.

```c
int (*Py_tracefunc)(PyObject *obj, PyFrameObject *frame, int what, PyObject *arg)
```

The type of the trace function registered using `PyEval_SetProfile()` and `PyEval_SetTrace()`. The first parameter is the object passed to the registration function as `obj`, `frame` is the frame object to which the event pertains, `what` is one of the constants `PyTrace_CALL`, `PyTrace_EXCEPTION`, `PyTrace_LINE`, `PyTrace_RETURN`, `PyTrace_C_CALL`, `PyTrace_C_EXCEPTION`, or `PyTrace_C_RETURN`, and `arg` depends on the value of `what`:

<table>
<thead>
<tr>
<th>Value of <code>what</code></th>
<th>Meaning of <code>arg</code></th>
</tr>
</thead>
<tbody>
<tr>
<td>PyTrace_CALL</td>
<td>Always NULL</td>
</tr>
<tr>
<td>PyTrace_EXCEPTION</td>
<td>Exception information as returned by <code>sys.exc_info()</code></td>
</tr>
<tr>
<td>PyTrace_LINE</td>
<td>Always NULL</td>
</tr>
<tr>
<td>PyTrace_RETURN</td>
<td>Value being returned to the caller</td>
</tr>
<tr>
<td>PyTrace_C_CALL</td>
<td>Name of function being called</td>
</tr>
<tr>
<td>PyTrace_C_EXCEPTION</td>
<td>Always NULL</td>
</tr>
<tr>
<td>PyTrace_C_RETURN</td>
<td>Always NULL</td>
</tr>
</tbody>
</table>

```c
int PyTrace_CALL
```
The value of the *what* parameter to a `Py_tracefunc` function when a new call to a function or method is being reported, or a new entry into a generator. Note that the creation of the iterator for a generator function is not reported as there is no control transfer to the Python bytecode in the corresponding frame.

`int PyTrace_EXCEPTION`
The value of the *what* parameter to a `Py_tracefunc` function when an exception has been raised. The callback function is called with this value for *what* when after any bytecode is processed after which the exception becomes set within the frame being executed. The effect of this is that as exception propagation causes the Python stack to unwind, the callback is called upon return to each frame as the exception propagates. Only trace functions receives these events; they are not needed by the profiler.

`int PyTrace_LINE`
The value passed as the *what* parameter to a trace function (but not a profiling function) when a line-number event is being reported.

`int PyTrace_RETURN`
The value for the *what* parameter to `Py_tracefunc` functions when a call is returning without propagating an exception.

`int PyTrace_C_CALL`
The value for the *what* parameter to `Py_tracefunc` functions when a C function is about to be called.

`int PyTrace_C_EXCEPTION`
The value for the *what* parameter to `Py_tracefunc` functions when a C function has thrown an exception.

`int PyTrace_C_RETURN`
The value for the *what* parameter to `Py_tracefunc` functions when a C function has returned.

`void PyEval_SetProfile( Py_tracefunc func, PyObject *obj)`
Set the profiler function to *func*. The *obj* parameter is passed to the function as its first parameter, and may be any Python object, or NULL. If the profile function needs to maintain state, using a different value for *obj* for each
thread provides a convenient and thread-safe place to store it. The profile function is called for all monitored events except the line-number events.

void **PyEval_SetTrace**( Py_tracefunc *func, PyObject *obj)
Set the tracing function to *func*. This is similar to PyEval_SetProfile(), except the tracing function does receive line-number events.

---

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
8.3 Advanced Debugger Support

These functions are only intended to be used by advanced debugging tools.

PyInterpreterState* PyInterpreterState_Head()
    Return the interpreter state object at the head of the list of all such objects. New in version 2.2.

PyInterpreterState* PyInterpreterState_Next(PyInterpreterState *interp)
    Return the next interpreter state object after interp from the list of all such objects. New in version 2.2.

PyThreadState * PyInterpreterState_ThreadHead(PyInterpreterState *interp)
    Return the a pointer to the first PyThreadState object in the list of threads associated with the interpreter interp. New in version 2.2.

PyThreadState* PyThreadState_Next(PyThreadState *tstate)
    Return the next thread state object after tstate from the list of all such objects belonging to the same PyInterpreterState object. New in version 2.2.
9. Memory Management

Subsections

- 9.1 Overview
- 9.2 Memory Interface
- 9.3 Examples

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
9.1 Overview

Memory management in Python involves a private heap containing all Python objects and data structures. The management of this private heap is ensured internally by the *Python memory manager*. The Python memory manager has different components which deal with various dynamic storage management aspects, like sharing, segmentation, preallocation or caching.

At the lowest level, a raw memory allocator ensures that there is enough room in the private heap for storing all Python-related data by interacting with the memory manager of the operating system. On top of the raw memory allocator, several object-specific allocators operate on the same heap and implement distinct memory management policies adapted to the peculiarities of every object type. For example, integer objects are managed differently within the heap than strings, tuples or dictionaries because integers imply different storage requirements and speed/space tradeoffs. The Python memory manager thus delegates some of the work to the object-specific allocators, but ensures that the latter operate within the bounds of the private heap.

It is important to understand that the management of the Python heap is performed by the interpreter itself and that the user has no control over it, even if she regularly manipulates object pointers to memory blocks inside that heap. The allocation of heap space for Python objects and other internal buffers is performed on demand by the Python memory manager through the Python/C API functions listed in this document.

To avoid memory corruption, extension writers should never try to operate on Python objects with the functions exported by the C library: `malloc()`, `calloc()`, `realloc()` and `free()`. This will result in mixed calls between the C allocator and the Python memory manager with fatal consequences, because they implement different algorithms and operate on different heaps. However, one may safely allocate and release memory blocks with the C library allocator for individual purposes, as shown in the following example:

```c
PyObject *res;
char *buf = (char *) malloc(BUFSIZ); /* for I/O */
if (buf == NULL)
```

```c
```
In this example, the memory request for the I/O buffer is handled by the C library allocator. The Python memory manager is involved only in the allocation of the string object returned as a result.

In most situations, however, it is recommended to allocate memory from the Python heap specifically because the latter is under control of the Python memory manager. For example, this is required when the interpreter is extended with new object types written in C. Another reason for using the Python heap is the desire to inform the Python memory manager about the memory needs of the extension module. Even when the requested memory is used exclusively for internal, highly-specific purposes, delegating all memory requests to the Python memory manager causes the interpreter to have a more accurate image of its memory footprint as a whole. Consequently, under certain circumstances, the Python memory manager may or may not trigger appropriate actions, like garbage collection, memory compaction or other preventive procedures. Note that by using the C library allocator as shown in the previous example, the allocated memory for the I/O buffer escapes completely the Python memory manager.
9.2 Memory Interface

The following function sets, modeled after the ANSI C standard, but specifying behavior when requesting zero bytes, are available for allocating and releasing memory from the Python heap:

```c
void* PyMemMalloc(size_t n)
Allocates n bytes and returns a pointer of type void* to the allocated memory, or NULL if the request fails. Requesting zero bytes returns a distinct non-NULL pointer if possible, as if PyMemMalloc(1) had been called instead. The memory will not have been initialized in any way.

void* PyMemRealloc(void* p, size_t n)
Resizes the memory block pointed to by p to n bytes. The contents will be unchanged to the minimum of the old and the new sizes. If p is NULL, the call is equivalent to PyMemMalloc(n); else if n is equal to zero, the memory block is resized but is not freed, and the returned pointer is non-NULL. Unless p is NULL, it must have been returned by a previous call to PyMemMalloc() or PyMemRealloc().

void PyMemFree(void* p)
Frees the memory block pointed to by p, which must have been returned by a previous call to PyMemMalloc() or PyMemRealloc(). Otherwise, or if PyMemFree(p) has been called before, undefined behavior occurs. If p is NULL, no operation is performed.
```

The following type-oriented macros are provided for convenience. Note that TYPE refers to any C type.

```c
TYPE* PyMemNew(TYPE, size_t n)
Same as PyMemMalloc(), but allocates (n * sizeof(TYPE)) bytes of memory. Returns a pointer cast to TYPE*. The memory will not have been initialized in any way.

TYPE* PyMemResize(void* p, TYPE, size_t n)
```
Same as `PyMem_Realloc()`, but the memory block is resized to \((n \times \text{sizeof}(\text{TYPE}))\) bytes. Returns a pointer cast to `TYPE*`.

```c
void PyMem_Del(void *p)
```

Same as `PyMem_Free()`.

In addition, the following macro sets are provided for calling the Python memory allocator directly, without involving the C API functions listed above. However, note that their use does not preserve binary compatibility across Python versions and is therefore deprecated in extension modules.

`PyMem_MALLOC()`, `PyMem_REALLOC()`, `PyMem_FREE()`.

`PyMem_NEW()`, `PyMem_RESIZE()`, `PyMem_DEL()`.
9.3 Examples

Here is the example from section 9.1, rewritten so that the I/O buffer is allocated from the Python heap by using the first function set:

```c
PyObject *res;
char *buf = (char *) PyMem_Malloc(BUFSIZ); /* for I/O */

if (buf == NULL)
    return PyErr_NoMemory();
/* ...Do some I/O operation involving buf... */
res = PyString_FromString(buf);
PyMem_Free(buf); /* allocated with PyMem_Malloc */
return res;
```

The same code using the type-oriented function set:

```c
PyObject *res;
char *buf = PyMem_New(char, BUFSIZ); /* for I/O */

if (buf == NULL)
    return PyErr_NoMemory();
/* ...Do some I/O operation involving buf... */
res = PyString_FromString(buf);
PyMem_Del(buf); /* allocated with PyMem_New */
return res;
```

Note that in the two examples above, the buffer is always manipulated via functions belonging to the same set. Indeed, it is required to use the same memory API family for a given memory block, so that the risk of mixing different allocators is reduced to a minimum. The following code sequence contains two errors, one of which is labeled as fatal because it mixes two different allocators operating on different heaps.

```c
char *buf1 = PyMem_New(char, BUFSIZ);
char *buf2 = (char *) malloc(BUFSIZ);
char *buf3 = (char *) PyMem_Malloc(BUFSIZ);
...
PyMem_Del(buf3); /* Wrong -- should be PyMem_Free() */
free(buf2);      /* Right -- allocated via malloc() */
free(buf1);      /* Fatal -- should be PyMem_Del() */
```

In addition to the functions aimed at handling raw memory blocks from the Python heap, objects in Python are allocated and released with
PyObject_New(), PyObject_NewVar() and PyObject_Del().

These will be explained in the next chapter on defining and implementing new object types in C.
10. Object Implementation Support

This chapter describes the functions, types, and macros used when defining new object types.

Subsections

- 10.1 Allocating Objects on the Heap
- 10.2 Common Object Structures
- 10.3 Type Objects
- 10.4 Mapping Object Structures
- 10.5 Number Object Structures
- 10.6 Sequence Object Structures
- 10.7 Buffer Object Structures
- 10.8 Supporting the Iterator Protocol
- 10.9 Supporting Cyclic Garbage Collection

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
10.1 Allocating Objects on the Heap

PyObject* _PyObject_New( PyTypeObject *type)

PyVarObject* _PyObject_NewVar( PyTypeObject *type, Py_ssize_t size)

void _PyObject_Del( PyObject *op)

PyObject* PyObject_Init( PyObject *op, PyTypeObject *type)
Return value: Borrowed reference.
Initialize a newly-allocated object op with its type and initial reference.
Returns the initialized object. If type indicates that the object participates in
the cyclic garbage detector, it is added to the detector's set of observed
objects. Other fields of the object are not affected.

PyVarObject* PyObject_InitVar( PyVarObject *op, PyTypeObject *type,
Py_ssize_t size)
This does everything PyObject_Init() does, and also initializes the
length information for a variable-size object.

TYPE* PyObject_New( TYPE, PyTypeObject *type)
Allocate a new Python object using the C structure type TYPE and the
Python type object type. Fields not defined by the Python object header are
not initialized; the object's reference count will be one. The size of the
memory allocation is determined from the tp_basicsize field of the
type object.

TYPE* PyObject_NewVar( TYPE, PyTypeObject *type, Py_ssize_t size)
Allocate a new Python object using the C structure type TYPE and the
Python type object type. Fields not defined by the Python object header are
not initialized. The allocated memory allows for the TYPE structure plus
size fields of the size given by the tp_itemsize field of type. This is useful for implementing objects like tuples, which are able to determine their size at construction time. Embedding the array of fields into the same allocation decreases the number of allocations, improving the memory management efficiency.

void **PyObject** _**Del***( PyObject *op)
Releases memory allocated to an object using **PyObject** _**New***( ) or **PyObject** _**NewVar***( ). This is normally called from the tp_dealloc handler specified in the object's type. The fields of the object should not be accessed after this call as the memory is no longer a valid Python object.

PyObject* **Py_InitModule** *( char *name, PyMethodDef *methods)
*Return value: Borrowed reference.*
Create a new module object based on a name and table of functions, returning the new module object.

Changed in version 2.3: Older versions of Python did not support NULL as the value for the methods argument.

PyObject* **Py_InitModule3** *( char *name, PyMethodDef *methods, char *doc)
*Return value: Borrowed reference.*
Create a new module object based on a name and table of functions, returning the new module object. If doc is non-NULL, it will be used to define the docstring for the module.

Changed in version 2.3: Older versions of Python did not support NULL as the value for the methods argument.

PyObject* **Py_InitModule4** *( char *name, PyMethodDef *methods, char *doc, PyObject *self, int apiver)
*Return value: Borrowed reference.*
Create a new module object based on a name and table of functions, returning the new module object. If doc is non-NULL, it will be used to define the docstring for the module. If self is non-NULL, it will passed to the functions of the module as their (otherwise NULL) first parameter. (This was added as an experimental feature, and there are no known uses in the
current version of Python.) For \textit{apiver}, the only value which should be passed is defined by the constant \texttt{PYTHON\_API\_VERSION}.

\textbf{Note:} Most uses of this function should probably be using the \texttt{Py\_InitModule3()} instead; only use this if you are sure you need it.

Changed in version 2.3: Older versions of Python did not support NULL as the value for the \textit{methods} argument.

\texttt{DL\_IMPORT}

\texttt{PyObject \_Py\_NoneStruct}

Object which is visible in Python as \texttt{None}. This should only be accessed using the \texttt{Py\_None} macro, which evaluates to a pointer to this object.
10.2 Common Object Structures

There are a large number of structures which are used in the definition of object types for Python. This section describes these structures and how they are used.

All Python objects ultimately share a small number of fields at the beginning of the object's representation in memory. These are represented by the PyObject and PyVarObject types, which are defined, in turn, by the expansions of some macros also used, whether directly or indirectly, in the definition of all other Python objects.

PyObject

All object types are extensions of this type. This is a type which contains the information Python needs to treat a pointer to an object as an object. In a normal "release" build, it contains only the objects reference count and a pointer to the corresponding type object. It corresponds to the fields defined by the expansion of the PyObject_HEAD macro.

PyVarObject

This is an extension of PyObject that adds the ob_size field. This is only used for objects that have some notion of length. This type does not often appear in the Python/C API. It corresponds to the fields defined by the expansion of the PyObject_VAR_HEAD macro.

These macros are used in the definition of PyObject and PyVarObject:

PyObject_HEAD

This is a macro which expands to the declarations of the fields of the PyObject type; it is used when declaring new types which represent objects without a varying length. The specific fields it expands to depend on the definition of Py_TRACE_REFS. By default, that macro is not defined, and PyObject_HEAD expands to:

```c
Py_ssize_t ob_refcnt;
PyTypeObject *ob_type;
```

When Py_TRACE_REFS is defined, it expands to:

```c
PyObject *__ob_next, *__ob_prev;
```
Py_ssize_t ob_refcnt;
PyTypeObject *ob_type;

PyObject_VAR_HEAD

This is a macro which expands to the declarations of the fields of the PyVarObject type; it is used when declaring new types which represent objects with a length that varies from instance to instance. This macro always expands to:

PyObject_HEAD
Py_ssize_t ob_size;

Note that PyObject_HEAD is part of the expansion, and that its own expansion varies depending on the definition of Py_TRACE_REFS.

PyObject_HEAD_INIT

PyCFunction

Type of the functions used to implement most Python callables in C. Functions of this type take two PyObject* parameters and return one such value. If the return value is NULL, an exception shall have been set. If not NULL, the return value is interpreted as the return value of the function as exposed in Python. The function must return a new reference.

PyMethodDef

Structure used to describe a method of an extension type. This structure has four fields:

<table>
<thead>
<tr>
<th>Field</th>
<th>C Type</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>ml_name</td>
<td>char *</td>
<td>name of the method</td>
</tr>
<tr>
<td>ml_meth</td>
<td>PyCFunction</td>
<td>pointer to the C implementation</td>
</tr>
<tr>
<td>ml_flags</td>
<td>int</td>
<td>flag bits indicating how the call should be constructed</td>
</tr>
<tr>
<td>ml_doc</td>
<td>char *</td>
<td>points to the contents of the docstring</td>
</tr>
</tbody>
</table>

The ml_meth is a C function pointer. The functions may be of different types, but they always return PyObject*. If the function is not of the PyCFunction, the compiler will require a cast in the method table. Even though PyCFunction defines the first parameter as PyObject*, it is common that the method implementation uses a the specific C type of the self
The `ml_flags` field is a bitfield which can include the following flags. The individual flags indicate either a calling convention or a binding convention. Of the calling convention flags, only `METH_VARARGS` and `METH_KEYWORDS` can be combined (but note that `METH_KEYWORDS` alone is equivalent to `METH_VARARGS | METH_KEYWORDS`). Any of the calling convention flags can be combined with a binding flag.

**METH_VARARGS**
This is the typical calling convention, where the methods have the type `PyCFunction`. The function expects two `PyObject*` values. The first one is the `self` object for methods; for module functions, it has the value given to `Py_InitModule4()` (or NULL if `Py_InitModule()` was used). The second parameter (often called `args`) is a tuple object representing all arguments. This parameter is typically processed using `PyArg_ParseTuple()` or `PyArg_UnpackTuple()`.

**METH_KEYWORDS**
Methods with these flags must be of type `PyCFunctionWithKeywords`. The function expects three parameters: `self`, `args`, and a dictionary of all the keyword arguments. The flag is typically combined with `METH_VARARGS`, and the parameters are typically processed using `PyArg_ParseTupleAndKeywords()`.

**METH_NOARGS**
Methods without parameters don't need to check whether arguments are given if they are listed with the `METH_NOARGS` flag. They need to be of type `PyCFunction`. When used with object methods, the first parameter is typically named `self` and will hold a reference to the object instance. In all cases the second parameter will be NULL.

**METH_O**
Methods with a single object argument can be listed with the `METH_O` flag, instead of invoking `PyArg_ParseTuple()` with a "O" argument. They have the type `PyCFunction`, with the `self` parameter, and a `PyObject*` parameter representing the single argument.

**METH_OLDARGS**
This calling convention is deprecated. The method must be of type `PyCFunction`. The second argument is `NULL` if no arguments are given, a single object if exactly one argument is given, and a tuple of objects if more than one argument is given. There is no way for a function using this convention to distinguish between a call with multiple arguments and a call with a tuple as the only argument.

These two constants are not used to indicate the calling convention but the binding when use with methods of classes. These may not be used for functions defined for modules. At most one of these flags may be set for any given method.

**METH_CLASS**

The method will be passed the type object as the first parameter rather than an instance of the type. This is used to create class methods, similar to what is created when using the `classmethod()` built-in function. New in version 2.3.

**METH_STATIC**

The method will be passed `NULL` as the first parameter rather than an instance of the type. This is used to create static methods, similar to what is created when using the `staticmethod()` built-in function. New in version 2.3.

One other constant controls whether a method is loaded in place of another definition with the same method name.

**METH_COEXIST**

The method will be loaded in place of existing definitions. Without `METH_COEXIST`, the default is to skip repeated definitions. Since slot wrappers are loaded before the method table, the existence of a `sq_contains` slot, for example, would generate a wrapped method named `__contains__()` and preclude the loading of a corresponding `PyCFunction` with the same name. With the flag defined, the `PyCFunction` will be loaded in place of the wrapper object and will co-exist with the slot. This is helpful because calls to `PyCFunctions` are optimized more than wrapper object calls. New in version 2.4.

```c
PyMethodDef table[], PyObject *ob, char
```
PyObject* **Py_FindMethod**( *name*)

*Return value: New reference.*

Return a bound method object for an extension type implemented in C. This can be useful in the implementation of a `tp_getattro` or `tp_getattr` handler that does not use the `PyObject_GenericGetAttr()` function.
### 10.3 Type Objects

Perhaps one of the most important structures of the Python object system is the structure that defines a new type: the `PyTypeObject` structure. Type objects can be handled using any of the `PyObject_*()` or `PyType_*()` functions, but do not offer much that's interesting to most Python applications. These objects are fundamental to how objects behave, so they are very important to the interpreter itself and to any extension module that implements new types.

Type objects are fairly large compared to most of the standard types. The reason for the size is that each type object stores a large number of values, mostly C function pointers, each of which implements a small part of the type's functionality. The fields of the type object are examined in detail in this section. The fields will be described in the order in which they occur in the structure.

Typedefs: unaryfunc, binaryfunc, ternaryfunc, inquiry, coercion, intargfunc, intintargfunc, intobjargproc, intintobjargproc, objobjargproc, destructor, freefunc, printfunc, setattrfunc, getattrofunc, setattrofunc, cmpfunc, reprfunc, hashfunc

The structure definition for `PyTypeObject` can be found in `Include/object.h`. For convenience of reference, this repeats the definition found there:

```c
typedef struct _typeobject {
    PyObject_VAR_HEAD
    char *tp_name; /* For printing, in format "<module>.<name>" */
    int tp_basicsize, tp_itemsize; /* For allocation */

    /* Methods to implement standard operations */

destructor tp_dealloc;
printfunc tp_print;
getattrfunc tp_getattr;
setattrfunc tp_setattr;
cmpfunc tp_compare;
reprfunc tp_repr;

    /* Method suites for standard classes */

PyNumberMethods *tp_as_number;
PySequenceMethods *tp_as_sequence;
PyMappingMethods *tp_as_mapping;
```
/* More standard operations (here for binary compatibility) */

hashfunc tp_hash;
ternaryfunc tp_call;
reprfunc tp_str;
getattrofunc tp_getattro;
setattrofunc tp_setattro;

/* Functions to access object as input/output buffer */
PyBufferProcs *tp_as_buffer;

/* Flags to define presence of optional/expanded features */
long tp_flags;

char *tp_doc; /* Documentation string */

/* Assigned meaning in release 2.0 */
/* call function for all accessible objects */
traverseproc tp_traverse;

/* delete references to contained objects */
inquiry tp_clear;

/* Assigned meaning in release 2.1 */
/* rich comparisons */
richcmpfunc tp_richcompare;

/* weak reference enabler */
long tp_weaklistoffset;

/* Added in release 2.2 */
/* Iterators */
getiterfunc tp_iter;
iternextfunc tp_iternext;

/* Attribute descriptor and subclassing stuff */
struct PyMethodDef *tp_methods;
struct PyMemberDef *tp_members;
struct PyGetSetDef *tp_getset;
struct _typeobject *tp_base;
PyObject *tp_dict;
descrgetfunc tp_descr_get;
desrcsetfunc tp_descr_set;
long tp_dictoffset;
initproc tp_init;
allocfunc tp_alloc;
newfunc tp_new; /* Low-level free-memory routine */
inquiry tp_is_gc; /* For PyObject_IS_GC */
PyObject *tp_bases;
PyObject *tp_mro; /* method resolution order */
The type object structure extends the `PyVarObject` structure. The `ob_size` field is used for dynamic types (created by `type_new()`, usually called from a class statement). Note that `PyType_Type` (the metatype) initializes `tp_itemsize`, which means that its instances (i.e. type objects) must have the `ob_size` field.

**PyObject* _ob_next**

**PyObject* _ob_prev**

These fields are only present when the macro `Py_TRACE_REFS` is defined. Their initialization to NULL is taken care of by the `PyObject_HEAD_INIT` macro. For statically allocated objects, these fields always remain NULL. For dynamically allocated objects, these two fields are used to link the object into a doubly-linked list of all live objects on the heap. This could be used for various debugging purposes; currently the only use is to print the objects that are still alive at the end of a run when the environment variable `PYTHONDUMPREFS` is set.

These fields are not inherited by subtypes.

**Py_ssize_t ob_refcnt**

This is the type object's reference count, initialized to 1 by the `PyObject_HEAD_INIT` macro. Note that for statically allocated type objects, the type's instances (objects whose `ob_type` points back to the type) do not count as references. But for dynamically allocated type objects, the instances do count as references.

This field is not inherited by subtypes.

**PyTypeObject* ob_type**

This is the type's type, in other words its metatype. It is initialized by the argument to the `PyObject_HEAD_INIT` macro, and its value should normally be `&PyType_Type`. However, for dynamically loadable
extension modules that must be usable on Windows (at least), the compiler
complains that this is not a valid initializer. Therefore, the convention is to
pass NULL to the PyObject_HEAD_INIT macro and to initialize this
field explicitly at the start of the module's initialization function, before
doing anything else. This is typically done like this:

    Foo_Type.ob_type = &PyType_Type;

This should be done before any instances of the type are created.
PyType_Ready() checks if ob_type is NULL, and if so, initializes it:
in Python 2.2, it is set to &PyType_Type; in Python 2.2.1 and later it is
initialized to the ob_type field of the base class. PyType_Ready() will
not change this field if it is non-zero.

In Python 2.2, this field is not inherited by subtypes. In 2.2.1, and in 2.3
and beyond, it is inherited by subtypes.

Py_ssize_t ob_size
    For statically allocated type objects, this should be initialized to zero. For
dynamically allocated type objects, this field has a special internal meaning.

    This field is not inherited by subtypes.

char* tp_name
    Pointer to a NUL-terminated string containing the name of the type. For
types that are accessible as module globals, the string should be the full
module name, followed by a dot, followed by the type name; for built-in
types, it should be just the type name. If the module is a submodule of a
package, the full package name is part of the full module name. For
example, a type named T defined in module M in subpackage Q in package
P should have the tp_name initializer "P.Q.M.T".

    For dynamically allocated type objects, this should just be the type name,
    and the module name explicitly stored in the type dict as the value for key
    '__module__'.

    For statically allocated type objects, the tp_name field should contain a dot.
    Everything before the last dot is made accessible as the __module__
    attribute, and everything after the last dot is made accessible as the
__name__ attribute.

If no dot is present, the entire tp_name field is made accessible as the __name__ attribute, and the __module__ attribute is undefined (unless explicitly set in the dictionary, as explained above). This means your type will be impossible to pickle.

This field is not inherited by subtypes.

Py_ssize_t tp_basicsize
Py_ssize_t tp_itemsize

These fields allow calculating the size in bytes of instances of the type.

There are two kinds of types: types with fixed-length instances have a zero tp_itemsize field, types with variable-length instances have a non-zero tp_itemsize field. For a type with fixed-length instances, all instances have the same size, given in tp_basicsize.

For a type with variable-length instances, the instances must have an ob_size field, and the instance size is tp_basicsize plus N times tp_itemsize, where N is the "length" of the object. The value of N is typically stored in the instance's ob_size field. There are exceptions: for example, long ints use a negative ob_size to indicate a negative number, and N is abs(ob_size) there. Also, the presence of an ob_size field in the instance layout doesn't mean that the instance structure is variable-length (for example, the structure for the list type has fixed-length instances, yet those instances have a meaningful ob_size field).

The basic size includes the fields in the instance declared by the macro PyObject_HEAD or PyObject_VAR_HEAD (whichever is used to declare the instance struct) and this in turn includes the _ob_prev and _ob_next fields if they are present. This means that the only correct way to get an initializer for the tp_basicsize is to use the sizeof operator on the struct used to declare the instance layout. The basic size does not include the GC header size (this is new in Python 2.2; in 2.1 and 2.0, the GC header size was included in tp_basicsize).

These fields are inherited separately by subtypes. If the base type has a non-zero tp_itemsize, it is generally not safe to set tp_itemsize to a
different non-zero value in a subtype (though this depends on the implementation of the base type).

A note about alignment: if the variable items require a particular alignment, this should be taken care of by the value of \texttt{tp\_basicsize}. Example: suppose a type implements an array of \texttt{double}. \texttt{tp\_itemsize} is \texttt{sizeof(double)}. It is the programmer's responsibility that \texttt{tp\_basicsize} is a multiple of \texttt{sizeof(double)} (assuming this is the alignment requirement for \texttt{double}).

destructor \texttt{tp\_dealloc}

A pointer to the instance destructor function. This function must be defined unless the type guarantees that its instances will never be deallocated (as is the case for the singletons \texttt{None} and \texttt{Ellipsis}).

The destructor function is called by the \texttt{Py\_DECREF()} and \texttt{Py\_XDECREF()} macros when the new reference count is zero. At this point, the instance is still in existence, but there are no references to it. The destructor function should free all references which the instance owns, free all memory buffers owned by the instance (using the freeing function corresponding to the allocation function used to allocate the buffer), and finally (as its last action) call the type's \texttt{tp\_free} function. If the type is not subtypable (doesn't have the \texttt{Py\_TPFLAGS\_BASETYPE} flag bit set), it is permissible to call the object deallocator directly instead of via \texttt{tp\_free}. The object deallocator should be the one used to allocate the instance; this is normally \texttt{PyObject\_Del()} if the instance was allocated using \texttt{PyObject\_New()} or \texttt{PyObject\_VarNew()}, or \texttt{PyObject\_GC\_Del()} if the instance was allocated using \texttt{PyObject\_GC\_New()} or \texttt{PyObject\_GC\_VarNew()}.

This field is inherited by subtypes.

printfunc \texttt{tp\_print}

An optional pointer to the instance print function.

The print function is only called when the instance is printed to a \textit{real} file; when it is printed to a pseudo-file (like a \texttt{StringIO} instance), the instance's \texttt{tp\_repr} or \texttt{tp\_str} function is called to convert it to a string. These are also called when the type's \texttt{tp\_print} field is \texttt{NULL}. A type
should never implement `tp_print` in a way that produces different output than `tp_repr` or `tp_str` would.

The print function is called with the same signature as `PyObject_Print()`. The `self` argument is the instance to be printed. The `file` argument is the stdio file to which it is to be printed. The `flags` argument is composed of flag bits. The only flag bit currently defined is `Py_PRINT_RAW`. When the `Py_PRINT_RAW` flag bit is set, the instance should be printed the same way as `tp_str` would format it; when the `Py_PRINT_RAW` flag bit is clear, the instance should be printed the same was as `tp_repr` would format it. It should return `-1` and set an exception condition when an error occurred during the comparison.

It is possible that the `tp_print` field will be deprecated. In any case, it is recommended not to define `tp_print`, but instead to rely on `tp_repr` and `tp_str` for printing.

This field is inherited by subtypes.

**getattribfunc** `tp_getattr`

An optional pointer to the get-attribute-string function.

This field is deprecated. When it is defined, it should point to a function that acts the same as the `tp_getattro` function, but taking a C string instead of a Python string object to give the attribute name. The signature is the same as for `PyObject_GetAttrString()`.

This field is inherited by subtypes together with `tp_getattro`: a subtype inherits both `tp_getattr` and `tp_getattro` from its base type when the subtype's `tp_getattr` and `tp_getattro` are both NULL.

**setattribfunc** `tp_setattr`

An optional pointer to the set-attribute-string function.

This field is deprecated. When it is defined, it should point to a function that acts the same as the `tp_setattro` function, but taking a C string instead of a Python string object to give the attribute name. The signature is the same as for `PyObject_SetAttrString()`.
This field is inherited by subtypes together with \texttt{tp\_setattro}: a subtype inherits both \texttt{tp\_setattr} and \texttt{tp\_setattro} from its base type when the subtype's \texttt{tp\_setattr} and \texttt{tp\_setattro} are both \texttt{NULL}.

\textbf{cmpfunc} \texttt{tp\_compare}

An optional pointer to the three-way comparison function.

The signature is the same as for \texttt{PyObject\_Compare()}. The function should return \texttt{1} if \texttt{self} greater than \texttt{other}, \texttt{0} if \texttt{self} is equal to \texttt{other}, and \texttt{-1} if \texttt{self} less than \texttt{other}. It should return \texttt{-1} and set an exception condition when an error occurred during the comparison.

This field is inherited by subtypes together with \texttt{tp\_richcompare} and \texttt{tp\_hash}: a subtypes inherits all three of \texttt{tp\_compare}, \texttt{tp\_richcompare}, and \texttt{tp\_hash} when the subtype's \texttt{tp\_compare}, \texttt{tp\_richcompare}, and \texttt{tp\_hash} are all \texttt{NULL}.

\textbf{reprfunc} \texttt{tp\_repr}

An optional pointer to a function that implements the built-in function \texttt{repr()}. The signature is the same as for \texttt{PyObject\_Repr()}; it must return a string or a Unicode object. Ideally, this function should return a string that, when passed to \texttt{eval()}, given a suitable environment, returns an object with the same value. If this is not feasible, it should return a string starting with "<" and ending with ">", from which both the type and the value of the object can be deduced.

When this field is not set, a string of the form "<\texttt{%s object at %p}>" is returned, where \texttt{%s} is replaced by the type name, and \texttt{%p} by the object's memory address.

This field is inherited by subtypes.

\texttt{PyNumberMethods *}\texttt{tp\_as\_number};

\texttt{XXX}

\texttt{PySequenceMethods *}\texttt{tp\_as\_sequence};
PyMappingMethods *tp_as_mapping;

hashfunc tp_hash
An optional pointer to a function that implements the built-in function hash().

The signature is the same as for PyObject_Hash(); it must return a C long. The value -1 should not be returned as a normal return value; when an error occurs during the computation of the hash value, the function should set an exception and return -1.

When this field is not set, two possibilities exist: if the tp_compare and tp_richcompare fields are both NULL, a default hash value based on the object's address is returned; otherwise, a TypeError is raised.

This field is inherited by subtypes together with tp_richcompare and tp_compare: a subtypes inherits all three of tp_compare, tp_richcompare, and tp_hash, when the subtype's tp_compare, tp_richcompare and tp_hash are all NULL.

ternaryfunc tp_call
An optional pointer to a function that implements calling the object. This should be NULL if the object is not callable. The signature is the same as for PyObject_Call().

This field is inherited by subtypes.

reprfunc tp_str
An optional pointer to a function that implements the built-in operation str(). (Note that str is a type now, and str() calls the constructor for that type. This constructor calls PyObject_Str() to do the actual work, and PyObject_Str() will call this handler.)

The signature is the same as for PyObject_Str(); it must return a string or a Unicode object. This function should return a ``friendly'' string
representation of the object, as this is the representation that will be used by the print statement.

When this field is not set, \code{PyObject_Repr()} is called to return a string representation.

This field is inherited by subtypes.

\textbf{getattrofunc \code{tp_getattro}}

An optional pointer to the get-attribute function.

The signature is the same as for \code{PyObject_GetAttr()}. It is usually convenient to set this field to \code{PyObject_GenericGetAttr()}, which implements the normal way of looking for object attributes.

This field is inherited by subtypes together with \code{tp_getattr}: a subtype inherits both \code{tp_getattr} and \code{tp_getattro} from its base type when the subtype's \code{tp_getattr} and \code{tp_getattro} are both NULL.

\textbf{setattrofunc \code{tp_setattro}}

An optional pointer to the set-attribute function.

The signature is the same as for \code{PyObject_SetAttr()}. It is usually convenient to set this field to \code{PyObject_GenericSetAttr()}, which implements the normal way of setting object attributes.

This field is inherited by subtypes together with \code{tp_setattr}: a subtype inherits both \code{tp_setattr} and \code{tp_setattro} from its base type when the subtype's \code{tp_setattr} and \code{tp_setattro} are both NULL.

\textbf{PyBufferProcs* \code{tp_as_buffer}}

Pointer to an additional structure that contains fields relevant only to objects which implement the buffer interface. These fields are documented in "Buffer Object Structures" (section 10.7).

The \code{tp_as_buffer} field is not inherited, but the contained fields are inherited individually.

\textbf{long \code{tp_flags}}
This field is a bit mask of various flags. Some flags indicate variant semantics for certain situations; others are used to indicate that certain fields in the type object (or in the extension structures referenced via \texttt{tp\_as\_number}, \texttt{tp\_as\_sequence}, \texttt{tp\_as\_mapping}, and \texttt{tp\_as\_buffer}) that were historically not always present are valid; if such a flag bit is clear, the type fields it guards must not be accessed and must be considered to have a zero or NULL value instead.

Inheritance of this field is complicated. Most flag bits are inherited individually, i.e. if the base type has a flag bit set, the subtype inherits this flag bit. The flag bits that pertain to extension structures are strictly inherited if the extension structure is inherited, i.e. the base type’s value of the flag bit is copied into the subtype together with a pointer to the extension structure. The \texttt{Py\_TPFLAGS\_HAVE\_GC} flag bit is inherited together with the \texttt{tp\_traverse} and \texttt{tp\_clear} fields, i.e. if the \texttt{Py\_TPFLAGS\_HAVE\_GC} flag bit is clear in the subtype and the \texttt{tp\_traverse} and \texttt{tp\_clear} fields in the subtype exist (as indicated by the \texttt{Py\_TPFLAGS\_HAVE\_RICHCOMPARE} flag bit) and have NULL values.

The following bit masks are currently defined; these can be or-ed together using the \texttt{|} operator to form the value of the \texttt{tp\_flags} field. The macro \texttt{PyType\_HasFeature()} takes a type and a flags value, \texttt{tp} and \texttt{f}, and checks whether \texttt{tp\->tp\_flags \& f} is non-zero.

\textbf{Py\_TPFLAGS\_HAVE\_GETCHARBUFFER}

If this bit is set, the \texttt{PyBufferProcs} struct referenced by \texttt{tp\_as\_buffer} has the \texttt{bf\_getcharbuffer} field.

\textbf{Py\_TPFLAGS\_HAVE\_SEQUENCE\_IN}

If this bit is set, the \texttt{PySequenceMethods} struct referenced by \texttt{tp\_as\_sequence} has the \texttt{sq\_contains} field.

\textbf{Py\_TPFLAGS\_GC}

This bit is obsolete. The bit it used to name is no longer in use. The symbol is now defined as zero.

\textbf{Py\_TPFLAGS\_HAVE\_INPLACEOPS}

If this bit is set, the \texttt{PySequenceMethods} struct referenced by
tp_as_sequence and the PyNumberMethods structure referenced by tp_as_number contain the fields for in-place operators. In particular, this means that the PyNumberMethods structure has the fields nb_inplace_add, nb_inplace_subtract, nb_inplace_multiply, nb_inplace_divide, nb_inplace_remainder, nb_inplace_power, nb_inplace_lshift, nb_inplace_rshift, nb_inplace_and, nb_inplace_xor, and nb_inplace_or; and the PySequenceMethods struct has the fields sq_inplace_concat and sq_inplace_repeat.

**Py_TPFLAGS_CHECKTYPES**
If this bit is set, the binary and ternary operations in the PyNumberMethods structure referenced by tp_as_number accept arguments of arbitrary object types, and do their own type conversions if needed. If this bit is clear, those operations require that all arguments have the current type as their type, and the caller is supposed to perform a coercion operation first. This applies to nb_add, nb_subtract, nb_multiply, nb_divide, nb_remainder, nb_divmod, nb_power, nb_lshift, nb_rshift, nb_and, nb_xor, and nb_or.

**Py_TPFLAGS_HAVE_RICHCOMPARE**
If this bit is set, the type object has the tp_richcompare field, as well as the tp_traverse and the tp_clear fields.

**Py_TPFLAGS_HAVE_WEAKREFS**
If this bit is set, the tp_weaklistoffset field is defined. Instances of a type are weakly referenceable if the type's tp_weaklistoffset field has a value greater than zero.

**Py_TPFLAGS_HAVE_ITER**
If this bit is set, the type object has the tp_iter and tp_iternext fields.

**Py_TPFLAGS_HAVE_CLASS**
If this bit is set, the type object has several new fields defined starting in Python 2.2: tp_methods, tp_members, tp_getset,
tp_base, tp_dict, tp_descr_get, tp_descr_set, 
tp_dictoffset, tp_init, tp_alloc, tp_new, tp_free, 
.tp_is_gc, tp_bases, tp_mro, tp_cache, tp_subclasses, 
and tp_weaklist.

**Py_TPFLAGS_HEAPTYPE**
This bit is set when the type object itself is allocated on the heap. In
this case, the ob_type field of its instances is considered a reference
to the type, and the type object is INCREF’ed when a new instance is
created, andDECREF’ed when an instance is destroyed (this does not
apply to instances of subtypes; only the type referenced by the
instance's ob_type gets INCREF’ed orDECREF’ed).

**Py_TPFLAGS_BASETYPE**
This bit is set when the type can be used as the base type of another
type. If this bit is clear, the type cannot be subtyped (similar to a
"final" class in Java).

**Py_TPFLAGS_READY**
This bit is set when the type object has been fully initialized by
PyType_Ready().

**Py_TPFLAGS_READYING**
This bit is set while PyType_Ready() is in the process of
initializing the type object.

**Py_TPFLAGS_HAVE_GC**
This bit is set when the object supports garbage collection. If this bit is
set, instances must be created using PyObject_GC_New() and
destroyed using PyObject_GC_Del(). More information in section
XXX about garbage collection. This bit also implies that the GC-
related fields tp_traverse and tp_clear are present in the type
object; but those fields also exist when Py_TPFLAGS_HAVE_GC is
clear but Py_TPFLAGS_HAVE_RICHCOMPARE is set.

**Py_TPFLAGS_DEFAULT**
This is a bitmask of all the bits that pertain to the existence of certain
fields in the type object and its extension structures. Currently, it
includes the following bits:
```c
static int
local_traverse(localobject *self, visitproc visit, void *arg)
{
    Py_VISIT(self->args);
    Py_VISIT(self->kw);
    Py_VISIT(self->dict);
    return 0;
}
```

Note that `Py_VISIT()` is called only on those members that can participate in reference cycles. Although there is also a "self->key" member, it can only be `NULL` or a Python string and therefore cannot be part of a reference cycle.
On the other hand, even if you know a member can never be part of a cycle, as a debugging aid you may want to visit it anyway just so the gc module's get_referents() function will include it.

Note that Py_VISIT() requires the visit and arg parameters to local_traverse to have these specific names; don't name them just anything.

This field is inherited by subtypes together with tp_clear and the Py_TPFLAGS_HAVE_GC flag bit: the flag bit, tp_traverse, and tp_clear are all inherited from the base type if they are all zero in the subtype and the subtype has the Py_TPFLAGS_HAVE_RICHCOMPARE flag bit set.

inquiry **tp_clear**
An optional pointer to a clear function for the garbage collector. This is only used if the Py_TPFLAGS_HAVE_GC flag bit is set.

The tp_clear member function is used to break reference cycles in cyclic garbage detected by the garbage collector. Taken together, all tp_clear functions in the system must combine to break all reference cycles. This is subtle, and if in any doubt supply a tp_clear function. For example, the tuple type does not implement a tp_clear function, because it's possible to prove that no reference cycle can be composed entirely of tuples. Therefore the tp_clear functions of other types must be sufficient to break any cycle containing a tuple. This isn't immediately obvious, and there's rarely a good reason to avoid implementing tp_clear.

Implementations of tp_clear should drop the instance's references to those of its members that may be Python objects, and set its pointers to those members to NULL, as in the following example:

```c
static int
local_clear(localobject *self)
{
    Py_CLEAR(self->key);
    Py_CLEAR(self->args);
    Py_CLEAR(self->kw);
    Py_CLEAR(self->dict);
    return 0;
}
```
The Py_CLEAR() macro should be used, because clearing references is delicate: the reference to the contained object must not be decremented until after the pointer to the contained object is set to NULL. This is because decrementing the reference count may cause the contained object to become trash, triggering a chain of reclamation activity that may include invoking arbitrary Python code (due to finalizers, or weakref callbacks, associated with the contained object). If it's possible for such code to reference self again, it's important that the pointer to the contained object be NULL at that time, so that self knows the contained object can no longer be used. The Py_CLEAR() macro performs the operations in a safe order.

Because the goal of tp_clear functions is to break reference cycles, it's not necessary to clear contained objects like Python strings or Python integers, which can't participate in reference cycles. On the other hand, it may be convenient to clear all contained Python objects, and write the type's tp_dealloc function to invoke tp_clear.

More information about Python's garbage collection scheme can be found in section 10.9.

This field is inherited by subtypes together with tp_traverse and the Py_TPFLAGS_HAVE_GC flag bit: the flag bit, tp_traverse, and tp_clear are all inherited from the base type if they are all zero in the subtype and the subtype has the Py_TPFLAGS_HAVE_RICHCOMPARE flag bit set.

richcmpfunc tp_richcompare
An optional pointer to the rich comparison function.

The signature is the same as for PyObject_RichCompare(). The function should return the result of the comparison (usually Py_True or Py_False). If the comparison is undefined, it must return Py_NotImplemented, if another error occurred it must return NULL and set an exception condition.

This field is inherited by subtypes together with tp_compare and tp_hash: a subtype inherits all three of tp_compare,
tp_richcompare, and tp_hash, when the subtype's tp_compare, tp_richcompare, and tp_hash are all NULL.

The following constants are defined to be used as the third argument for tp_richcompare and for PyObject_RichCompare():

<table>
<thead>
<tr>
<th>Constant</th>
<th>Comparison</th>
</tr>
</thead>
<tbody>
<tr>
<td>Py_LT</td>
<td>&lt;</td>
</tr>
<tr>
<td>Py_LE</td>
<td>&lt;=</td>
</tr>
<tr>
<td>Py_EQ</td>
<td>==</td>
</tr>
<tr>
<td>Py_NE</td>
<td>!=</td>
</tr>
<tr>
<td>Py_GT</td>
<td>&gt;</td>
</tr>
<tr>
<td>Py_GE</td>
<td>&gt;=</td>
</tr>
</tbody>
</table>

The next field only exists if the Py_TPFLAGS_HAVE_WEAKREFS flag bit is set.

long **tp_weaklistoffset**

If the instances of this type are weakly referenceable, this field is greater than zero and contains the offset in the instance structure of the weak reference list head (ignoring the GC header, if present); this offset is used by PyObject_ClearWeakRefs() and the PyWeakref_*() functions. The instance structure needs to include a field of type PyObject* which is initialized to NULL.

Do not confuse this field with tp_weaklist; that is the list head for weak references to the type object itself.

This field is inherited by subtypes, but see the rules listed below. A subtype may override this offset; this means that the subtype uses a different weak reference list head than the base type. Since the list head is always found via tp_weaklistoffset, this should not be a problem.

When a type defined by a class statement has no **slots** declaration, and none of its base types are weakly referenceable, the type is made weakly referenceable by adding a weak reference list head slot to the instance layout and setting the tp_weaklistoffset of that slot's offset.
When a type's __slots__ declaration contains a slot named __weakref__, that slot becomes the weak reference list head for instances of the type, and the slot's offset is stored in the type's tp_weaklistoffset.

When a type's __slots__ declaration does not contain a slot named __weakref__, the type inherits its tp_weaklistoffset from its base type.

The next two fields only exist if the Py_TPFLAGS_HAVE_CLASS flag bit is set.

getiterfunc tp_iter
An optional pointer to a function that returns an iterator for the object. Its presence normally signals that the instances of this type are iterable (although sequences may be iterable without this function, and classic instances always have this function, even if they don't define an __iter__() method).

This function has the same signature as PyObject_GetIter().

This field is inherited by subtypes.

iternextfunc tp_iternext
An optional pointer to a function that returns the next item in an iterator, or raises StopIteration when the iterator is exhausted. Its presence normally signals that the instances of this type are iterators (although classic instances always have this function, even if they don't define a next() method).

Iterator types should also define the tp_iter function, and that function should return the iterator instance itself (not a new iterator instance).

This function has the same signature as PyIter_Next().

This field is inherited by subtypes.

The next fields, up to and including tp_weaklist, only exist if the Py_TPFLAGS_HAVE_CLASS flag bit is set.
struct PyMethodDef* **tp_methods**
An optional pointer to a static NULL-terminated array of PyMethodDef structures, declaring regular methods of this type.

For each entry in the array, an entry is added to the type's dictionary (see **tp_dict** below) containing a method descriptor.

This field is not inherited by subtypes (methods are inherited through a different mechanism).

struct PyMemberDef* **tp_members**
An optional pointer to a static NULL-terminated array of PyMemberDef structures, declaring regular data members (fields or slots) of instances of this type.

For each entry in the array, an entry is added to the type's dictionary (see **tp_dict** below) containing a member descriptor.

This field is not inherited by subtypes (members are inherited through a different mechanism).

struct PyGetSetDef* **tp_getset**
An optional pointer to a static NULL-terminated array of PyGetSetDef structures, declaring computed attributes of instances of this type.

For each entry in the array, an entry is added to the type's dictionary (see **tp_dict** below) containing a getset descriptor.

This field is not inherited by subtypes (computed attributes are inherited through a different mechanism).

Docs for PyGetSetDef (XXX belong elsewhere):

```c
typedef PyObject *(*getter)(PyObject *, void *);
typedef int (*setter)(PyObject *, PyObject *, void *);

typedef struct PyGetSetDef {
    char *name;     /* attribute name */
    getter get;     /* C function to get the attribute */
    setter set;     /* C function to set the attribute */
    char *doc;      /* optional doc string */
    void *closure;  /* optional additional data for getter and setter */
} PyGetSetDef;
```
An optional pointer to a base type from which type properties are inherited. At this level, only single inheritance is supported; multiple inheritance require dynamically creating a type object by calling the metatype.

This field is not inherited by subtypes (obviously), but it defaults to &PyBaseObject_Type (which to Python programmers is known as the type object).

The type's dictionary is stored here by PyType_Ready().

This field should normally be initialized to NULL before PyType_Ready is called; it may also be initialized to a dictionary containing initial attributes for the type. Once PyType_Ready() has initialized the type, extra attributes for the type may be added to this dictionary only if they don't correspond to overloaded operations (like __add__( )).

This field is not inherited by subtypes (though the attributes defined in here are inherited through a different mechanism).

descrgetfunc tp_descr_get
An optional pointer to a "descriptor get" function.

The function signature is

    PyObject * tp_descr_get(PyObject *self, PyObject *obj, PyObject

    XXX blah, blah.

This field is inherited by subtypes.

descrsetfunc tp_descr_set
An optional pointer to a "descriptor set" function.

The function signature is

    int tp_descr_set(PyObject *self, PyObject *obj, PyObject *value);
This field is inherited by subtypes.

XXX blah, blah.

**long tp_dictoffset**

If the instances of this type have a dictionary containing instance variables, this field is non-zero and contains the offset in the instances of the type of the instance variable dictionary; this offset is used by PyObject_GenericGetAttr().

Do not confuse this field with tp_dict; that is the dictionary for attributes of the type object itself.

If the value of this field is greater than zero, it specifies the offset from the start of the instance structure. If the value is less than zero, it specifies the offset from the end of the instance structure. A negative offset is more expensive to use, and should only be used when the instance structure contains a variable-length part. This is used for example to add an instance variable dictionary to subtypes of str or tuple. Note that the tp_basicsize field should account for the dictionary added to the end in that case, even though the dictionary is not included in the basic object layout. On a system with a pointer size of 4 bytes, tp_dictoffset should be set to -4 to indicate that the dictionary is at the very end of the structure.

The real dictionary offset in an instance can be computed from a negative tp_dictoffset as follows:

\[
\text{dictoffset} = \text{tp_basicsize} + \text{abs}(\text{ob_size}) \times \text{tp_itemsize} + \text{tp_dictoffset}
\]

if dictoffset is not aligned on sizeof(void*):
    round up to sizeof(void*)

where tp_basicsize, tp_itemsize and tp_dictoffset are taken from the type object, and ob_size is taken from the instance. The absolute value is taken because long ints use the sign of ob_size to store the sign of the number. (There's never a need to do this calculation yourself; it is done for you by _PyObject_GetDictPtr().)

This field is inherited by subtypes, but see the rules listed below. A subtype may override this offset; this means that the subtype instances store the
dictionary at a difference offset than the base type. Since the dictionary is always found via `tp_dictoffset`, this should not be a problem.

When a type defined by a class statement has no `__slots__` declaration, and none of its base types has an instance variable dictionary, a dictionary slot is added to the instance layout and the `tp_dictoffset` is set to that slot's offset.

When a type defined by a class statement has a `__slots__` declaration, the type inherits its `tp_dictoffset` from its base type.

(Adding a slot named `__dict__` to the `__slots__` declaration does not have the expected effect, it just causes confusion. Maybe this should be added as a feature just like `__weakref__` though.)

**initproc tp_init**  
An optional pointer to an instance initialization function.

This function corresponds to the `__init__() method of classes. Like `__init__()`, it is possible to create an instance without calling `__init__()`, and it is possible to reinitialize an instance by calling its `__init__()` method again.

The function signature is

```
    int tp_init(PyObject *self, PyObject *args, PyObject *kwds)
```

The self argument is the instance to be initialized; the `args` and `kwds` arguments represent positional and keyword arguments of the call to `__init__()`. The `tp_init` function, if not NULL, is called when an instance is created normally by calling its type, after the type's `tp_new` function has returned an instance of the type. If the `tp_new` function returns an instance of some other type that is not a subtype of the original type, no `tp_init` function is called; if `tp_new` returns an instance of a subtype of the original type, the subtype's `tp_init` is called. (VERSION NOTE: described here is what is implemented in Python 2.2.1 and later. In Python 2.2, the `tp_init` of the type of the object returned by `tp_new` was always called, if not
This field is inherited by subtypes.

.allocfunc **tp_alloc**
An optional pointer to an instance allocation function.

The function signature is

```
PyObject *tp_alloc(PyTypeObject *self, Py_ssize_t nitems)
```

The purpose of this function is to separate memory allocation from memory initialization. It should return a pointer to a block of memory of adequate length for the instance, suitably aligned, and initialized to zeros, but with **ob_refcnt** set to 1 and **ob_type** set to the type argument. If the type's **tp_itemsize** is non-zero, the object's **ob_size** field should be initialized to **nitems** and the length of the allocated memory block should be **tp_basicsize** + **nitems*** **tp_itemsize**, rounded up to a multiple of **sizeof(void*)**; otherwise, **nitems** is not used and the length of the block should be **tp_basicsize**.

Do not use this function to do any other instance initialization, not even to allocate additional memory; that should be done by **tp_new**.

This field is inherited by static subtypes, but not by dynamic subtypes (subtypes created by a class statement); in the latter, this field is always set to **PyType_GenericAlloc()**, to force a standard heap allocation strategy. That is also the recommended value for statically defined types.

.newfunc **tp_new**
An optional pointer to an instance creation function.

If this function is **NULL** for a particular type, that type cannot be called to create new instances; presumably there is some other way to create instances, like a factory function.

The function signature is

```
PyObject *tp_new(PyTypeObject *subtype, PyObject *args, PyObject *kwds)
```
The subtype argument is the type of the object being created; the args and kwds arguments represent positional and keyword arguments of the call to the type. Note that subtype doesn't have to equal the type whose tp_new function is called; it may be a subtype of that type (but not an unrelated type).

The tp_new function should call subtype->tp_alloc(subtype, nitems) to allocate space for the object, and then do only as much further initialization as is absolutely necessary. Initialization that can safely be ignored or repeated should be placed in the tp_init handler. A good rule of thumb is that for immutable types, all initialization should take place in tp_new, while for mutable types, most initialization should be deferred to tp_init.

This field is inherited by subtypes, except it is not inherited by static types whose tp_base is NULL or &PyBaseObject_Type. The latter exception is a precaution so that old extension types don't become callable simply by being linked with Python 2.2.

destructor tp_free
An optional pointer to an instance deallocation function.

The signature of this function has changed slightly: in Python 2.2 and 2.2.1, its signature is destructor:

    void tp_free(PyObject *)

In Python 2.3 and beyond, its signature is freecfunc:

    void tp_free(void *)

The only initializer that is compatible with both versions is _PyObject_Del, whose definition has suitably adapted in Python 2.3.

This field is inherited by static subtypes, but not by dynamic subtypes (subtypes created by a class statement); in the latter, this field is set to a deallocator suitable to match PyType_GenericAlloc() and the value of the Py_TPFLAGS_HAVE_GC flag bit.

inquiry tp_is_gc
An optional pointer to a function called by the garbage collector.

The garbage collector needs to know whether a particular object is collectible or not. Normally, it is sufficient to look at the object's type's `tp_flags` field, and check the `Py_TPFLAGS_HAVE_GC` flag bit. But some types have a mixture of statically and dynamically allocated instances, and the statically allocated instances are not collectible. Such types should define this function; it should return 1 for a collectible instance, and 0 for a non-collectible instance. The signature is

```
int tp_is_gc(PyObject *self)
```

(The only example of this are types themselves. The metatype, `PyType_Type`, defines this function to distinguish between statically and dynamically allocated types.)

This field is inherited by subtypes. (VERSION NOTE: in Python 2.2, it was not inherited. It is inherited in 2.2.1 and later versions.)

**PyObject**

### `tp_flags`

Tuple of base types.

This is set for types created by a class statement. It should be NULL for statically defined types.

This field is not inherited.

**PyObject**

### `tp_mro`

Tuple containing the expanded set of base types, starting with the type itself and ending with `object`, in Method Resolution Order.

This field is not inherited; it is calculated fresh by `PyType_Ready()`.

**PyObject**

### `tp_cache`

Unused. Not inherited. Internal use only.

**PyObject**

### `tp_subclasses`

List of weak references to subclasses. Not inherited. Internal use only.

**PyObject**

### `tp_weaklist`
Weak reference list head, for weak references to this type object. Not inherited. Internal use only.

The remaining fields are only defined if the feature test macro `COUNT_ALLOCS` is defined, and are for internal use only. They are documented here for completeness. None of these fields are inherited by subtypes.

`Py_ssize_t tp_allocs`
Number of allocations.

`Py_ssize_t tp_frees`
Number of frees.

`Py_ssize_t tp_maxalloc`
Maximum simultaneously allocated objects.

`PyTypeObject* tp_next`
Pointer to the next type object with a non-zero `tp_allocs` field.

Also, note that, in a garbage collected Python, `tp_dealloc` may be called from any Python thread, not just the thread which created the object (if the object becomes part of a refcount cycle, that cycle might be collected by a garbage collection on any thread). This is not a problem for Python API calls, since the thread on which `tp_dealloc` is called will own the Global Interpreter Lock (GIL). However, if the object being destroyed in turn destroys objects from some other C or C++ library, care should be taken to ensure that destroying those objects on the thread which called `tp_dealloc` will not violate any assumptions of the library.
10.4 Mapping Object Structures

PyMappingMethods
Structure used to hold pointers to the functions used to implement the mapping protocol for an extension type.
10.5 Number Object Structures

PyNumberMethods
Structure used to hold pointers to the functions an extension type uses to implement the number protocol.
10.6 Sequence Object Structures

**PySequenceMethods**

Structure used to hold pointers to the functions which an object uses to implement the sequence protocol.
10.7 Buffer Object Structures

The buffer interface exports a model where an object can expose its internal data as a set of chunks of data, where each chunk is specified as a pointer/length pair. These chunks are called segments and are presumed to be non-contiguous in memory.

If an object does not export the buffer interface, then its `tp_as_buffer` member in the `PyTypeObject` structure should be NULL. Otherwise, the `tp_as_buffer` will point to a `PyBufferProcs` structure.

**Note:** It is very important that your `PyTypeObject` structure uses `Py_TPFLAGS_DEFAULT` for the value of the `tp_flags` member rather than 0. This tells the Python runtime that your `PyBufferProcs` structure contains the `bf_getcharbuffer` slot. Older versions of Python did not have this member, so a new Python interpreter using an old extension needs to be able to test for its presence before using it.

**PyBufferProcs**

Structure used to hold the function pointers which define an implementation of the buffer protocol.

The first slot is `bf_getreadbuffer`, of type `getreadbufferproc`. If this slot is NULL, then the object does not support reading from the internal data. This is non-sensical, so implementors should fill this in, but callers should test that the slot contains a non-NULL value.

The next slot is `bf_getwritebuffer` having type `getwritebufferproc`. This slot may be NULL if the object does not allow writing into its returned buffers.

The third slot is `bf_getsegcount`, with type `getsegcountproc`. This slot must not be NULL and is used to inform the caller how many segments the object contains. Simple objects such as `PyString_Type` and `PyBuffer_Type` objects contain a single segment.

The last slot is `bf_getcharbuffer`, of type `getcharbufferproc`. 
This slot will only be present if the
Py_TPFLAGS_HAVE_GETCHARBUFFER flag is present in the
tp_flags field of the object's PyTypeObject. Before using this slot,
the caller should test whether it is present by using the
PyType_HasFeature() function. If the flag is present,
bf_getcharbuffer may be NULL, indicating that the object's contents
cannot be used as 8-bit characters. The slot function may also raise an error
if the object's contents cannot be interpreted as 8-bit characters. For
example, if the object is an array which is configured to hold floating point
values, an exception may be raised if a caller attempts to use
bf_getcharbuffer to fetch a sequence of 8-bit characters. This notion
of exporting the internal buffers as "text" is used to distinguish between
objects that are binary in nature, and those which have character-based
content.

Note: The current policy seems to state that these characters may be multi-
byte characters. This implies that a buffer size of $N$ does not mean there are
$N$ characters present.

**Py_TPFLAGS_HAVE_GETCHARBUFFER**
Flag bit set in the type structure to indicate that the bf_getcharbuffer
slot is known. This being set does not indicate that the object supports the
buffer interface or that the bf_getcharbuffer slot is non-NULL.

**Py_ssize_t (*readbufferproc) (PyObject *self,**
Py_ssize_t segment, void **ptrptr)**
Return a pointer to a readable segment of the buffer in *ptrptr. This
function is allowed to raise an exception, in which case it must return -1.
The segment which is specified must be zero or positive, and strictly less
than the number of segments returned by the bf_getsegcount slot
function. On success, it returns the length of the segment, and sets *ptrptr
to a pointer to that memory.

**Py_ssize_t (*writebufferproc) (PyObject *self,**
Py_ssize_t segment, void **ptrptr)**
Return a pointer to a writable memory buffer in *ptrptr, and the length of
that segment as the function return value. The memory buffer must
correspond to buffer segment segment. Must return -1 and set an exception
on error. TypeError should be raised if the object only supports read-
only buffers, and SystemError should be raised when `segment` specifies a segment that doesn't exist.

```python
Py_ssize_t (*segcountproc) (PyObject *self, Py_ssize_t *lenp)
    Return the number of memory segments which comprise the buffer. If `lenp` is not NULL, the implementation must report the sum of the sizes (in bytes) of all segments in `lenp`. The function cannot fail.
```

```python
Py_ssize_t (*charbufferproc) (PyObject *self, Py_ssize_t segment, const char **ptrptr)
    Return the size of the segment `segment` that `ptrptr` is set to. `*ptrptr` is set to the memory buffer. Returns -1 on error.
```
10.8 Supporting the Iterator Protocol
10.9 Supporting Cyclic Garbage Collection

Python's support for detecting and collecting garbage which involves circular references requires support from object types which are "containers" for other objects which may also be containers. Types which do not store references to other objects, or which only store references to atomic types (such as numbers or strings), do not need to provide any explicit support for garbage collection.

An example showing the use of these interfaces can be found in "Supporting the Cycle Collector" in *Extending and Embedding the Python Interpreter*.

To create a container type, the *tp_flags* field of the type object must include the *Py_TPFLAGS_HAVE_GC* and provide an implementation of the *tp_traverse* handler. If instances of the type are mutable, a *tp_clear* implementation must also be provided.

**Py_TPFLAGS_HAVE_GC**

Objects with a type with this flag set must conform with the rules documented here. For convenience these objects will be referred to as container objects.

Constructors for container types must conform to two rules:

1. The memory for the object must be allocated using
   `PyObject_GC_New()` or `PyObject_GC_VarNew()`.

2. Once all the fields which may contain references to other containers are initialized, it must call `PyObject_GC_Track()`.

```
TYPE* PyObject_GC_New( TYPE, PyTypeObject *type)
   Analogous to `PyObject_New()` but for container objects with the
   Py_TPFLAGS_HAVE_GC flag set.

TYPE* PyObject_GC_NewVar( TYPE, PyTypeObject *type, Py_ssize_t size)
```
Analogous to \texttt{PyObject\_NewVar()} but for container objects with the 
\texttt{Py\_TPFLAGS\_HAVE\_GC} flag set.

\begin{verbatim}
PyVarObject * \textbf{PyObject\_GC\_Resize}( PyVarObject *op, Py\_ssize_t)
   Resize an object allocated by \texttt{PyObject\_NewVar()}. Returns the resized
   object or NULL on failure.
\end{verbatim}

\begin{verbatim}
void \textbf{PyObject\_GC\_Track}( PyObject *op)
   Adds the object \texttt{op} to the set of container objects tracked by the collector.
   The collector can run at unexpected times so objects must be valid while
   being tracked. This should be called once all the fields followed by the
   \texttt{tp\_traverse} handler become valid, usually near the end of the
   constructor.
\end{verbatim}

\begin{verbatim}
void \_\textbf{PyObject\_GC\_TRACK}( PyObject *op)
   A macro version of \texttt{PyObject\_GC\_Track()}. It should not be used for
   extension modules.
\end{verbatim}

Similarly, the deallocator for the object must conform to a similar pair of rules:

1. Before fields which refer to other containers are invalidated, 
   \texttt{PyObject\_GC\_UnTrack()} must be called.

2. The object's memory must be deallocated using \texttt{PyObject\_GC\_Del()}. 

\begin{verbatim}
void \textbf{PyObject\_GC\_Del}( void *op)
   Releases memory allocated to an object using \texttt{PyObject\_GC\_New()} or 
   \texttt{PyObject\_GC\_NewVar()}. 
\end{verbatim}

\begin{verbatim}
void \textbf{PyObject\_GC\_UnTrack}( void *op)
   Remove the object \texttt{op} from the set of container objects tracked by the
   collector. Note that \texttt{PyObject\_GC\_Track()} can be called again on this 
   object to add it back to the set of tracked objects. The deallocator 
   (\texttt{tp\_dealloc} handler) should call this for the object before any of the
   fields used by the \texttt{tp\_traverse} handler become invalid.
\end{verbatim}

\begin{verbatim}
void \_\textbf{PyObject\_GC\_UNTRACK}( PyObject *op)
\end{verbatim}
A macro version of `PyObject_GC_UnTrack()`. It should not be used for extension modules.

The `tp_traverse` handler accepts a function parameter of this type:

```c
int (*visitproc)(PyObject *object, void *arg)
```

Type of the visitor function passed to the `tp_traverse` handler. The function should be called with an object to traverse as `object` and the third parameter to the `tp_traverse` handler as `arg`. The Python core uses several visitor functions to implement cyclic garbage detection; it's not expected that users will need to write their own visitor functions.

The `tp_traverse` handler must have the following type:

```c
int (*traverseproc)(PyObject *self, visitproc visit, void *arg)
```

Traversal function for a container object. Implementations must call the `visit` function for each object directly contained by `self`, with the parameters to `visit` being the contained object and the `arg` value passed to the handler. The `visit` function must not be called with a NULL object argument. If `visit` returns a non-zero value that value should be returned immediately.

To simplify writing `tp_traverse` handlers, a `Py_VISIT()` macro is provided. In order to use this macro, the `tp_traverse` implementation must name its arguments exactly `visit` and `arg`:

```c
void Py_VISIT( PyObject *o)
```

Call the `visit` callback, with arguments `o` and `arg`. If `visit` returns a non-zero value, then return it. Using this macro, `tp_traverse` handlers look like:

```c
static int
my_traverse(Noddy *self, visitproc visit, void *arg)
{
    Py_VISIT(self->foo);
    Py_VISIT(self->bar);
    return 0;
}
```

New in version 2.4.

The `tp_clear` handler must be of the `inquiry` type, or NULL if the object is
immutable.

int (*inquiry)(PyObject *self)

Drop references that may have created reference cycles. Immutable objects do not have to define this method since they can never directly create reference cycles. Note that the object must still be valid after calling this method (don't just call Py_INCREF( ) on a reference). The collector will call this method if it detects that this object is involved in a reference cycle.
A. Reporting Bugs

Python is a mature programming language which has established a reputation for stability. In order to maintain this reputation, the developers would like to know of any deficiencies you find in Python or its documentation.

Before submitting a report, you will be required to log into SourceForge; this will make it possible for the developers to contact you for additional information if needed. It is not possible to submit a bug report anonymously.

All bug reports should be submitted via the Python Bug Tracker on SourceForge (http://sourceforge.net/bugs/?group_id=5470). The bug tracker offers a Web form which allows pertinent information to be entered and submitted to the developers.

The first step in filing a report is to determine whether the problem has already been reported. The advantage in doing so, aside from saving the developers time, is that you learn what has been done to fix it; it may be that the problem has already been fixed for the next release, or additional information is needed (in which case you are welcome to provide it if you can!). To do this, search the bug database using the search box on the left side of the page.

If the problem you're reporting is not already in the bug tracker, go back to the Python Bug Tracker (http://sourceforge.net/bugs/?group_id=5470). Select the "Submit a Bug" link at the top of the page to open the bug reporting form.

The submission form has a number of fields. The only fields that are required are the "Summary" and "Details" fields. For the summary, enter a very short description of the problem; less than ten words is good. In the Details field, describe the problem in detail, including what you expected to happen and what did happen. Be sure to include the version of Python you used, whether any extension modules were involved, and what hardware and software platform you were using (including version information as appropriate).

The only other field that you may want to set is the "Category" field, which allows you to place the bug report into a broad category (such as "Documentation" or "Library").
Each bug report will be assigned to a developer who will determine what needs to be done to correct the problem. You will receive an update each time action is taken on the bug.

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
B.1 History of the software

Python was created in the early 1990s by Guido van Rossum at Stichting Mathematisch Centrum (CWI, see http://www.cwi.nl/) in the Netherlands as a successor of a language called ABC. Guido remains Python's principal author, although it includes many contributions from others.

In 1995, Guido continued his work on Python at the Corporation for National Research Initiatives (CNRI, see http://www.cnri.reston.va.us/) in Reston, Virginia where he released several versions of the software.

In May 2000, Guido and the Python core development team moved to BeOpen.com to form the BeOpen PythonLabs team. In October of the same year, the PythonLabs team moved to Digital Creations (now Zope Corporation; see http://www.zope.com/). In 2001, the Python Software Foundation (PSF, see http://www.python.org/psf/) was formed, a non-profit organization created specifically to own Python-related Intellectual Property. Zope Corporation is a sponsoring member of the PSF.

All Python releases are Open Source (see http://www.opensource.org/ for the Open Source Definition). Historically, most, but not all, Python releases have also been GPL-compatible; the table below summarizes the various releases.

**Note:** GPL-compatible doesn't mean that we're distributing Python under the GPL. All Python licenses, unlike the GPL, let you distribute a modified version without making your changes open source. The GPL-compatible licenses make it possible to combine Python with other software that is released under the GPL; the others don't.

Thanks to the many outside volunteers who have worked under Guido's direction to make these releases possible.
B.2 Terms and conditions for accessing or otherwise using Python

PSF LICENSE AGREEMENT FOR PYTHON 2.5

1. This LICENSE AGREEMENT is between the Python Software Foundation ("PSF"), and the Individual or Organization ("Licensee") accessing and otherwise using Python 2.5 software in source or binary form and its associated documentation.

2. Subject to the terms and conditions of this License Agreement, PSF hereby grants Licensee a nonexclusive, royalty-free, world-wide license to reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use Python 2.5 alone or in any derivative version, provided, however, that PSF's License Agreement and PSF's notice of copyright, i.e., "Copyright © 2001-2006 Python Software Foundation; All Rights Reserved" are retained in Python 2.5 alone or in any derivative version prepared by Licensee.

3. In the event Licensee prepares a derivative work that is based on or incorporates Python 2.5 or any part thereof, and wants to make the derivative work available to others as provided herein, then Licensee hereby agrees to include in any such work a brief summary of the changes made to Python 2.5.

4. PSF is making Python 2.5 available to Licensee on an "AS IS" basis. PSF MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT LIMITATION, PSF MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF PYTHON 2.5 WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.

5. PSF SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS
6. This License Agreement will automatically terminate upon a material breach of its terms and conditions.

7. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between PSF and Licensee. This License Agreement does not grant permission to use PSF trademarks or trade name in a trademark sense to endorse or promote products or services of Licensee, or any third party.

8. By copying, installing or otherwise using Python 2.5, Licensee agrees to be bound by the terms and conditions of this License Agreement.

BEOPEN.COM LICENSE AGREEMENT FOR PYTHON 2.0

BEOPEN PYTHON OPEN SOURCE LICENSE AGREEMENT VERSION 1

1. This LICENSE AGREEMENT is between BeOpen.com (``BeOpen''), having an office at 160 Saratoga Avenue, Santa Clara, CA 95051, and the Individual or Organization (``Licensee'') accessing and otherwise using this software in source or binary form and its associated documentation (``the Software'').

2. Subject to the terms and conditions of this BeOpen Python License Agreement, BeOpen hereby grants Licensee a non-exclusive, royalty-free, world-wide license to reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use the Software alone or in any derivative version, provided, however, that the BeOpen Python License is retained in the Software, alone or in any derivative version prepared by Licensee.

3. BeOpen is making the Software available to Licensee on an ``AS IS'' basis. BEOPEN MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT
LIMITATION, BEOPEN MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF THE SOFTWARE WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.

4. BEOPEN SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS OF THE SOFTWARE FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF USING, MODIFYING OR DISTRIBUTING THE SOFTWARE, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.

5. This License Agreement will automatically terminate upon a material breach of its terms and conditions.

6. This License Agreement shall be governed by and interpreted in all respects by the law of the State of California, excluding conflict of law provisions. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between BeOpen and Licensee. This License Agreement does not grant permission to use BeOpen trademarks or trade names in a trademark sense to endorse or promote products or services of Licensee, or any third party. As an exception, the ``BeOpen Python" logos available at http://www.pythonlabs.com/logos.html may be used according to the permissions granted on that web page.

7. By copying, installing or otherwise using the software, Licensee agrees to be bound by the terms and conditions of this License Agreement.

CNRI LICENSE AGREEMENT FOR PYTHON 1.6.1

1. This LICENSE AGREEMENT is between the Corporation for National Research Initiatives, having an office at 1895 Preston White Drive, Reston, VA 20191 (``CNRI"), and the Individual or Organization (``Licensee") accessing and otherwise using Python 1.6.1 software in source or binary form and its associated documentation.

2. Subject to the terms and conditions of this License Agreement, CNRI hereby grants Licensee a nonexclusive, royalty-free, world-wide license to
reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use Python 1.6.1 alone or in any derivative version, provided, however, that CNRI's License Agreement and CNRI's notice of copyright, i.e., ``Copyright © 1995-2001 Corporation for National Research Initiatives; All Rights Reserved'' are retained in Python 1.6.1 alone or in any derivative version prepared by Licensee. Alternately, in lieu of CNRI's License Agreement, Licensee may substitute the following text (omitting the quotes): ``Python 1.6.1 is made available subject to the terms and conditions in CNRI's License Agreement. This Agreement together with Python 1.6.1 may be located on the Internet using the following unique, persistent identifier (known as a handle): 1895.22/1013. This Agreement may also be obtained from a proxy server on the Internet using the following URL: http://hdl.handle.net/1895.22/1013."

3. In the event Licensee prepares a derivative work that is based on or incorporates Python 1.6.1 or any part thereof, and wants to make the derivative work available to others as provided herein, then Licensee hereby agrees to include in any such work a brief summary of the changes made to Python 1.6.1.

4. CNRI is making Python 1.6.1 available to Licensee on an ``AS IS'' basis. CNRI MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT LIMITATION, CNRI MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF PYTHON 1.6.1 WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.

5. CNRI SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS OF PYTHON 1.6.1 FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF MODIFYING, DISTRIBUTING, OR OTHERWISE USING PYTHON 1.6.1, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.

6. This License Agreement will automatically terminate upon a material breach of its terms and conditions.

7. This License Agreement shall be governed by the federal intellectual
property law of the United States, including without limitation the federal copyright law, and, to the extent such U.S. federal law does not apply, by the law of the Commonwealth of Virginia, excluding Virginia's conflict of law provisions. Notwithstanding the foregoing, with regard to derivative works based on Python 1.6.1 that incorporate non-separable material that was previously distributed under the GNU General Public License (GPL), the law of the Commonwealth of Virginia shall govern this License Agreement only as to issues arising under or with respect to Paragraphs 4, 5, and 7 of this License Agreement. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between CNRI and Licensee. This License Agreement does not grant permission to use CNRI trademarks or trade name in a trademark sense to endorse or promote products or services of Licensee, or any third party.

8. By clicking on the "ACCEPT" button where indicated, or by copying, installing or otherwise using Python 1.6.1, Licensee agrees to be bound by the terms and conditions of this License Agreement.

ACCEPT

CWI LICENSE AGREEMENT FOR PYTHON 0.9.0 THROUGH 1.2

Copyright © 1991 - 1995, Stichting Mathematisch Centrum Amsterdam, The Netherlands. All rights reserved.

Permission to use, copy, modify, and distribute this software and its documentation for any purpose and without fee is hereby granted, provided that the above copyright notice appear in all copies and that both that copyright notice and this permission notice appear in supporting documentation, and that the name of Stichting Mathematisch Centrum or CWI not be used in advertising or publicity pertaining to distribution of the software without specific, written prior permission.

B.3 Licenses and Acknowledgements for Incorporated Software

This section is an incomplete, but growing list of licenses and acknowledgements for third-party software incorporated in the Python distribution.

Subsections

- B.3.1 Mersenne Twister
- B.3.2 Sockets
- B.3.3 Floating point exception control
- B.3.4 MD5 message digest algorithm
- B.3.5 Asynchronous socket services
- B.3.6 Cookie management
- B.3.7 Profiling
- B.3.8 Execution tracing
- B.3.9 UUencode and UUdecode functions
- B.3.10 XML Remote Procedure Calls

Previous: B.2 Terms and conditions  Up: B. History and License  Next: B.3.1 Mersenne Twister

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
B.3.1 Mersenne Twister

The _random module includes code based on a download from [http://www.math.keio.ac.jp/~matumoto/MT2002/emt19937ar.html](http://www.math.keio.ac.jp/~matumoto/MT2002/emt19937ar.html). The following are the verbatim comments from the original code:

A C-program for MT19937, with initialization improved 2002/1/26. Coded by Takuji Nishimura and Makoto Matsumoto.

Before using, initialize the state by using init_genrand(seed) or init_by_array(init_key, key_length).

Copyright (C) 1997 - 2002, Makoto Matsumoto and Takuji Nishimura, All rights reserved.

Redistribution and use in source and binary forms, with or without modification, are permitted provided that the following conditions are met:

1. Redistributions of source code must retain the above copyright notice, this list of conditions and the following disclaimer.

2. Redistributions in binary form must reproduce the above copyright notice, this list of conditions and the following disclaimer in documentation and/or other materials provided with the distribution.

3. The names of its contributors may not be used to endorse or promote products derived from this software without specific prior written permission.

THIS SOFTWARE IS PROVIDED BY THE COPYRIGHT HOLDERS AND CONTRIBUTORS "AS IS" AND ANY EXPRESS OR IMPLIED WARRANTIES, INCLUDING, BUT NOT LIMITED TO, THE IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS FOR A PARTICULAR PURPOSE ARE DISCLAIMED. IN NO EVENT SHALL THE COPYRIGHT HOLDERS BE LIABLE FOR ANY DIRECT, INDIRECT, INCIDENTAL, SPECIAL, EXEMPLARY, OR CONSEQUENTIAL DAMAGES (INCLUDING, BUT NOT LIMITED TO, PROCUREMENT OF SUBSTITUTE GOODS OR SERVICES; LOSS OF USE, DATA, OR PROFITS; OR BUSINESS INTERRUPTION) HOWEVER CAUSED AND ON ANY THEORY OF LIABILITY, WHETHER IN CONTRACT, STRICT LIABILITY, OR TORT (INCLUDING NEGLIGENCE OR OTHERWISE) ARISING IN ANY WAY OUT OF THE USE OF THIS SOFTWARE, EVEN IF ADVISED OF THE POSSIBILITY OF SUCH DAMAGE.

Any feedback is very welcome.

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
B.3.4 MD5 message digest algorithm

The source code for the md5 module contains the following notice:

    Copyright (C) 1999, 2002 Aladdin Enterprises. All rights reserved

    This software is provided 'as-is', without any express or implied
    warranty. In no event will the authors be held liable for any dam
    arising from the use of this software.

    Permission is granted to anyone to use this software for any purpo
    including commercial applications, and to alter it and redistribut
    freely, subject to the following restrictions:

    1. The origin of this software must not be misrepresented; you mus
    claim that you wrote the original software. If you use this sof
    in a product, an acknowledgment in the product documentation wo
    appreciated but is not required.
    2. Altered source versions must be plainly marked as such, and mus
    misrepresented as being the original software.
    3. This notice may not be removed or altered from any source distr

    L. Peter Deutsch
    ghost@aladdin.com

    Independent implementation of MD5 (RFC 1321).

    This code implements the MD5 Algorithm defined in RFC 1321, whose
text is available at
        http://www.ietf.org/rfc/rfc1321.txt
    The code is derived from the text of the RFC, including the test s
    (section A.5) but excluding the rest of Appendix A. It does not i
    any code or documentation that is identified in the RFC as being
    copyrighted.

    The original and principal author of md5.h is L. Peter Deutsch
    <ghost@aladdin.com>. Other authors are noted in the change histor
    that follows (in reverse chronological order):

    2002-04-13 lpd Removed support for non-ANSI compilers; removed
    references to Ghostscript; clarified derivation from RFC 132
    now handles byte order either statically or dynamically.
    1999-11-04 lpd Edited comments slightly for automatic TOC extracti
    1999-10-18 lpd Fixed typo in header comment (ansi2knr rather than
    added conditionalization for C++ compilation from Martin
    Purschke <purschke@bnl.gov>.
    1999-05-03 lpd Original version.
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
B.3.5 Asynchronous socket services

The `asynchat` and `asyncore` modules contain the following notice:

Copyright 1996 by Sam Rushing

All Rights Reserved

Permission to use, copy, modify, and distribute this software and its documentation for any purpose and without fee is hereby granted, provided that the above copyright notice appear in all copies and that both that copyright notice and this permission notice appear in supporting documentation, and that the name of Sam Rushing not be used in advertising or publicity pertaining to distribution of the software without specific, written prior permission.

SAM RUSHING DISCLAIMS ALL WARRANTIES WITH REGARD TO THIS SOFTWARE, INCLUDING ALL IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS, IN NO EVENT SHALL SAM RUSHING BE LIABLE FOR ANY SPECIAL, INDIRECT OR CONSEQUENTIAL DAMAGES OR ANY DAMAGES WHATSOEVER RESULTING FROM LOSS OF USE, DATA OR PROFITS, WHETHER IN AN ACTION OF CONTRACT, NEGLIGENCE OR OTHER TORTIOUS ACTION, ARISING OUT OF OR IN CONNECTION WITH THE USE OR PERFORMANCE OF THIS SOFTWARE.
B.3.6 Cookie management

The Cookie module contains the following notice:

Copyright 2000 by Timothy O'Malley <timo@alum.mit.edu>

All Rights Reserved

Permission to use, copy, modify, and distribute this software and its documentation for any purpose and without fee is hereby granted, provided that the above copyright notice appear in all copies and that both that copyright notice and this permission notice appear in supporting documentation, and that the name of Timothy O'Malley not be used in advertising or publicity pertaining to distribution of the software without specific, written prior permission.

Timothy O'Malley DISCLAIMS ALL WARRANTIES WITH REGARD TO THIS SOFTWARE, INCLUDING ALL IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS, IN NO EVENT SHALL Timothy O'Malley BE LIABLE FOR ANY SPECIAL, INDIRECT OR CONSEQUENTIAL DAMAGES OR ANY DAMAGES WHATSOEVER RESULTING FROM LOSS OF USE, DATA OR PROFITS, WHETHER IN AN ACTION OF CONTRACT, NEGLIGENCE OR OTHER TORTIOUS ACTION, ARISING OUT OF OR IN CONNECTION WITH THE USE OR PERFORMANCE OF THIS SOFTWARE.
B.3.7 Profiling

The profile and pstats modules contain the following notice:

```
Copyright 1994, by InfoSeek Corporation, all rights reserved.
Written by James Roskind

Permission to use, copy, modify, and distribute this Python softwar
and its associated documentation for any purpose (subject to the
restriction in the following sentence) without fee is hereby grante
provided that the above copyright notice appears in all copies, and
that both that copyright notice and this permission notice appear i
supporting documentation, and that the name of InfoSeek not be used
advertising or publicity pertaining to distribution of the software
without specific, written prior permission. This permission is
explicitly restricted to the copying and modification of the softwa
to remain in Python, compiled Python, or other languages (such as C
wherein the modified or derived code is exclusively imported into a
Python module.

INFOSEEK CORPORATION DISCLAIMS ALL WARRANTIES WITH REGARD TO THIS
SOFTWARE, INCLUDING ALL IMPLIED WARRANTIES OF MERCHANTABILITY AND
FITNESS. IN NO EVENT SHALL INFOSEEK CORPORATION BE LIABLE FOR ANY
SPECIAL, INDIRECT OR CONSEQUENTIAL DAMAGES OR ANY DAMAGES WHATSOEVE
RESULTING FROM LOSS OF USE, DATA OR PROFITS, WHETHER IN AN ACTION O
CONTRACT, NEGLIGENCE OR OTHER TORTIOUS ACTION, ARISING OUT OF OR IN
CONNECTION WITH THE USE OR PERFORMANCE OF THIS SOFTWARE.
```
B.3.8 Execution tracing

The `trace` module contains the following notice:

```plaintext
portions copyright 2001, Autonomous Zones Industries, Inc., all rig
err... reserved and offered to the public under the terms of the
Python 2.2 license.

```

Permission to use, copy, modify, and distribute this Python softwar
its associated documentation for any purpose without fee is hereby
granted, provided that the above copyright notice appears in all co
and that both that copyright notice and this permission notice appe
supporting documentation, and that the name of neither Automatrix,
Bioreason or Mojam Media be used in advertising or publicity pertai
distribution of the software without specific, written prior permis
B.3.9 UUencode and UUdecode functions

The uu module contains the following notice:

Copyright 1994 by Lance Ellinghouse
Cathedral City, California Republic, United States of America.
All Rights Reserved
Permission to use, copy, modify, and distribute this software and its
documentation for any purpose and without fee is hereby granted,
provided that the above copyright notice appear in all copies and that
both that copyright notice and this permission notice appear in
supporting documentation, and that the name of Lance Ellinghouse
not be used in advertising or publicity pertaining to distribution
of the software without specific, written prior permission.
LANCE ELLINGHOUSE DISCLAIMS ALL WARRANTIES WITH REGARD TO
THIS SOFTWARE, INCLUDING ALL IMPLIED WARRANTIES OF MERCHANTABILITY
FITNESS, IN NO EVENT SHALL LANCE ELLINGHOUSE CENTRUM BE LIABLE
FOR ANY SPECIAL, INDIRECT OR CONSEQUENTIAL DAMAGES OR ANY DAMAGES
WHATSOEVER RESULTING FROM LOSS OF USE, DATA OR PROFITS, WHETHER IN
ACTION OF CONTRACT, NEGLIGENCE OR OTHER TORTIOUS ACTION, ARISING OU
OF OR IN CONNECTION WITH THE USE OR PERFORMANCE OF THIS SOFTWARE.

Modified by Jack Jansen, CWI, July 1995:
- Use binascii module to do the actual line-by-line conversion
  between ascii and binary. This results in a 1000-fold speedup. Th
  version is still 5 times faster, though.
- Arguments more compliant with python standard
B.3.10 XML Remote Procedure Calls

The xmlrpclib module contains the following notice:

The XML-RPC client interface is

Copyright (c) 1999-2002 by Secret Labs AB
Copyright (c) 1999-2002 by Fredrik Lundh

By obtaining, using, and/or copying this software and/or its associated documentation, you agree that you have read, understood, and will comply with the following terms and conditions:

Permission to use, copy, modify, and distribute this software and its associated documentation for any purpose and without fee is hereby granted, provided that the above copyright notice appears in all copies, and that both that copyright notice and this permission notice appear in supporting documentation, and that the name of Secret Labs AB or the author not be used in advertising or publicit pertaining to distribution of the software without specific, written prior permission.

SECRET LABS AB AND THE AUTHOR DISCLAIMS ALL WARRANTIES WITH REGARD TO THIS SOFTWARE, INCLUDING ALL IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS. IN NO EVENT SHALL SECRET LABS AB OR THE AUTHOR BE LIABLE FOR ANY SPECIAL, INDIRECT OR CONSEQUENTIAL DAMAGES OR ANY DAMAGES WHATSOEVER RESULTING FROM LOSS OF USE, DATA OR PROFITS, WHETHER IN AN ACTION OF CONTRACT, NEGLIGENCE OR OTHER TORTIOUS ACTION, ARISING OUT OF OR IN CONNECTION WITH THE USE OR PERFORMANCE OF THIS SOFTWARE.

Abstract:

The Python language has a substantial body of documentation, much of it contributed by various authors. The markup used for the Python documentation is based on LaTeX and requires a significant set of macros written specifically for documenting Python. This document describes the macros introduced to support Python documentation and how they should be used to support a wide range of output formats.

This document describes the document classes and special markup used in the Python documentation. Authors may use this guide, in conjunction with the template files provided with the distribution, to create or maintain whole documents or sections.

If you're interested in contributing to Python's documentation, there's no need to learn LaTeX if you're not so inclined; plain text contributions are more than welcome as well.
4.2 Hierarchical Structure
4.3 Common Environments

5 Document Classes

6 Special Markup Constructs
6.1 Markup for the Preamble
6.2 Meta-information Markup
6.3 Information Units
6.4 Showing Code Examples
6.5 Inline Markup
6.6 Miscellaneous Text Markup
6.7 Module-specific Markup
6.8 Library-level Markup
6.9 Table Markup
6.10 Reference List Markup
6.11 Index-generating Markup
6.12 Grammar Production Displays
6.13 Graphical Interface Components

7 Processing Tools
7.1 External Tools
7.2 Internal Tools
7.3 Working on Cygwin

9 Future Directions
9.1 Structured Documentation
9.2 Discussion Forums

About this document...
1 Introduction

Python's documentation has long been considered to be good for a free programming language. There are a number of reasons for this, the most important being the early commitment of Python's creator, Guido van Rossum, to providing documentation on the language and its libraries, and the continuing involvement of the user community in providing assistance for creating and maintaining documentation.

The involvement of the community takes many forms, from authoring to bug reports to just plain complaining when the documentation could be more complete or easier to use. All of these forms of input from the community have proved useful during the time I've been involved in maintaining the documentation.

This document is aimed at authors and potential authors of documentation for Python. More specifically, it is for people contributing to the standard documentation and developing additional documents using the same tools as the standard documents. This guide will be less useful for authors using the Python documentation tools for topics other than Python, and less useful still for authors not using the tools at all.

The material in this guide is intended to assist authors using the Python documentation tools. It includes information on the source distribution of the standard documentation, a discussion of the document types, reference material on the markup defined in the document classes, a list of the external tools needed for processing documents, and reference material on the tools provided with the documentation resources. At the end, there is also a section discussing future directions for the Python documentation and where to turn for more information.

If your interest is in contributing to the Python documentation, but you don't have the time or inclination to learn LaTeX and the markup structures documented here, there's a welcoming place for you among the Python contributors as well. Any time you feel that you can clarify existing documentation or provide documentation that's missing, the existing documentation team will gladly work with you to integrate your text, dealing with the markup for you. Please don't let the material in this document stand
between the documentation and your desire to help out!
2 Directory Structure

The source distribution for the standard Python documentation contains a large number of directories. While third-party documents do not need to be placed into this structure or need to be placed within a similar structure, it can be helpful to know where to look for examples and tools when developing new documents using the Python documentation tools. This section describes this directory structure.

The documentation sources are usually placed within the Python source distribution as the top-level directory Doc/, but are not dependent on the Python source distribution in any way.

The Doc/ directory contains a few files and several subdirectories. The files are mostly self-explanatory, including a README and a Makefile. The directories fall into three categories:

Document Sources
The LaTeX sources for each document are placed in a separate directory. These directories are given short names which vaguely indicate the document in each:

<table>
<thead>
<tr>
<th>Directory</th>
<th>Document Title</th>
</tr>
</thead>
<tbody>
<tr>
<td>api/</td>
<td>The Python/C API</td>
</tr>
<tr>
<td>dist/</td>
<td>Distributing Python Modules</td>
</tr>
<tr>
<td>doc/</td>
<td>Documenting Python</td>
</tr>
<tr>
<td>ext/</td>
<td>Extending and Embedding the Python Interpreter</td>
</tr>
<tr>
<td>inst/</td>
<td>Installing Python Modules</td>
</tr>
<tr>
<td>lib/</td>
<td>Python Library Reference</td>
</tr>
<tr>
<td>mac/</td>
<td>Macintosh Module Reference</td>
</tr>
<tr>
<td>ref/</td>
<td>Python Reference Manual</td>
</tr>
<tr>
<td>tut/</td>
<td>Python Tutorial</td>
</tr>
<tr>
<td>whatsnew/</td>
<td>What's New in Python 2.5</td>
</tr>
</tbody>
</table>

Format-Specific Output
Most output formats have a directory which contains a Makefile which
controls the generation of that format and provides storage for the formatted
documents. The only variations within this category are the Portable
Document Format (PDF) and PostScript versions are placed in the
directories paper-a4/ and paper-letter/ (this causes all the temporary files
created by LaTeX to be kept in the same place for each paper size, where
they can be more easily ignored).

<table>
<thead>
<tr>
<th>Directory</th>
<th>Output Formats</th>
</tr>
</thead>
<tbody>
<tr>
<td>html/</td>
<td>HTML output</td>
</tr>
<tr>
<td>info/</td>
<td>GNU info output</td>
</tr>
<tr>
<td>isilo/</td>
<td>iSilo documents (for Palm OS devices)</td>
</tr>
<tr>
<td>paper-a4/</td>
<td>PDF and PostScript, A4 paper</td>
</tr>
</tbody>
</table>

Supplemental Files

Some additional directories are used to store supplemental files used for the
various processes. Directories are included for the shared LaTeX document
classes, the LaTeX2HTML support, template files for various document
components, and the scripts used to perform various steps in the formatting
processes.

<table>
<thead>
<tr>
<th>Directory</th>
<th>Contents</th>
</tr>
</thead>
<tbody>
<tr>
<td>commontex/</td>
<td>Document content shared among documents</td>
</tr>
<tr>
<td>perl/</td>
<td>Support for LaTeX2HTML processing</td>
</tr>
<tr>
<td>templates/</td>
<td>Example files for source documents</td>
</tr>
<tr>
<td>texinputs/</td>
<td>Style implementation for LaTeX</td>
</tr>
<tr>
<td>tools/</td>
<td>Custom processing scripts</td>
</tr>
</tbody>
</table>
3 Style Guide

The Python documentation should follow the *Apple Publications Style Guide* wherever possible. This particular style guide was selected mostly because it seems reasonable and is easy to get online.

Topics which are not covered in the Apple's style guide will be discussed in this document if necessary.

Footnotes are generally discouraged due to the pain of using footnotes in the HTML conversion of documents. Footnotes may be used when they are the best way to present specific information. When a footnote reference is added at the end of the sentence, it should follow the sentence-ending punctuation. The LaTeX markup should appear something like this:

```
This sentence has a footnote reference.\
\footnote{This is the footnote text.}
```

Footnotes may appear in the middle of sentences where appropriate.

Many special names are used in the Python documentation, including the names of operating systems, programming languages, standards bodies, and the like. Many of these were assigned LaTeX macros at some point in the distant past, and these macros lived on long past their usefulness. In the current markup, most of these entities are not assigned any special markup, but the preferred spellings are given here to aid authors in maintaining the consistency of presentation in the Python documentation.

Other terms and words deserve special mention as well; these conventions should be used to ensure consistency throughout the documentation:

**CPU**

For ``central processing unit.'' Many style guides say this should be spelled out on the first use (and if you must use it, do so!). For the Python documentation, this abbreviation should be avoided since there's no reasonable way to predict which occurrence will be the first seen by the reader. It is better to use the word ``processor'' instead.
POSIX
The name assigned to a particular group of standards. This is always uppercase. Use the macro \POSIX to represent this name.

Python
The name of our favorite programming language is always capitalized.

Unicode
The name of a character set and matching encoding. This is always written capitalized.

UNIX
The name of the operating system developed at AT&T Bell Labs in the early 1970s. Use the macro \UNIX to use this name.

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
4 LaTeX Primer

This section is a brief introduction to LaTeX concepts and syntax, to provide authors enough information to author documents productively without having to become ``TeXnicians.'' This does not teach everything needed to know about writing LaTeX for Python documentation; many of the standard ``environments'' are not described here (though you will learn how to mark something as an environment).

Perhaps the most important concept to keep in mind while marking up Python documentation is that while TeX is unstructured, LaTeX was designed as a layer on top of TeX which specifically supports structured markup. The Python-specific markup is intended to extend the structure provided by standard LaTeX document classes to support additional information specific to Python.

LaTeX documents contain two parts: the preamble and the body. The preamble is used to specify certain metadata about the document itself, such as the title, the list of authors, the date, and the class the document belongs to. Additional information used to control index generation and the use of bibliographic databases can also be placed in the preamble. For most authors, the preamble can be most easily created by copying it from an existing document and modifying a few key pieces of information.

The class of a document is used to place a document within a broad category of documents and set some fundamental formatting properties. For Python documentation, two classes are used: the manual class and the howto class. These classes also define the additional markup used to document Python concepts and structures. Specific information about these classes is provided in section §5. ``Document Classes,'' below. The first thing in the preamble is the declaration of the document's class.

After the class declaration, a number of macros are used to provide further information about the document and setup any additional markup that is needed. No output is generated from the preamble; it is an error to include free text in the preamble because it would cause output.

The document body follows the preamble. This contains all the printed
components of the document marked up structurally. Generic LaTeX structures include hierarchical sections, numbered and bulleted lists, and special structures for the document abstract and indexes.

### Subsections

- [4.1 Syntax](#)
- [4.2 Hierarchical Structure](#)
- [4.3 Common Environments](#)
4.1 Syntax

There are some things that an author of Python documentation needs to know about LaTeX syntax.

A comment is started by the `\percent` character ("\%") and continues through the end of the line and all leading whitespace on the following line. This is a little different from any programming language I know of, so an example is in order:

```
This is text. \% comment
   This is more text.  \% another comment
Still more text.
```

The first non-comment character following the first comment is the letter "T" on the second line; the leading whitespace on that line is consumed as part of the first comment. This means that there is no space between the first and second sentences, so the period and letter "T" will be directly adjacent in the typeset document.

Note also that though the first non-comment character after the second comment is the letter "S", there is whitespace preceding the comment, so the two sentences are separated as expected.

A group is an enclosure for a collection of text and commands which encloses the formatting context and constrains the scope of any changes to that context made by commands within the group. Groups can be nested hierarchically. The formatting context includes the font and the definition of additional macros (or overrides of macros defined in outer groups). Syntactically, groups are enclosed in braces:

```
{text in a group}
```

An alternate syntax for a group using brackets, [ . . . ], is used by macros and environment constructors which take optional parameters; brackets do not normally hold syntactic significance. A degenerate group, containing only one atomic bit of content, does not need to have an explicit group, unless it is required to avoid ambiguity. Since Python tends toward the explicit, groups are also made explicit in the documentation markup.
Groups are used only sparingly in the Python documentation, except for their use in marking parameters to macros and environments.

A *macro* is usually a simple construct which is identified by name and can take some number of parameters. In normal LaTeX usage, one of these can be optional. The markup is introduced using the backslash character ("\"), and the name is given by alphabetic characters (no digits, hyphens, or underscores). Required parameters should be marked as a group, and optional parameters should be marked using the alternate syntax for a group.

For example, a macro which takes a single parameter would appear like this:

\name{parameter}

A macro which takes an optional parameter would be typed like this when the optional parameter is given:

\name[optional]

If both optional and required parameters are to be required, it looks like this:

\name[optional]{required}

A macro name may be followed by a space or newline; a space between the macro name and any parameters will be consumed, but this usage is not practiced in the Python documentation. Such a space is still consumed if there are no parameters to the macro, in which case inserting an empty group (\{\}) or explicit word space ("\ " ) immediately after the macro name helps to avoid running the expansion of the macro into the following text. Macros which take no parameters but which should not be followed by a word space do not need special treatment if the following character in the document source if not a name character (such as punctuation).

Each line of this example shows an appropriate way to write text which includes a macro which takes no parameters:

This \UNIX{} is followed by a space.
This \UNIX\ is also followed by a space.
\UNIX, followed by a comma, needs no additional markup.

An *environment* is a larger construct than a macro, and can be used for things with more content than would conveniently fit in a macro parameter. They are
primarily used when formatting parameters need to be changed before and after a large chunk of content, but the content itself needs to be highly flexible. Code samples are presented using an environment, and descriptions of functions, methods, and classes are also marked using environments.

Since the content of an environment is free-form and can consist of several paragraphs, they are actually marked using a pair of macros: \texttt{\texttt{\begin{abstract}} and \texttt{\end{abstract}}. These macros both take the name of the environment as a parameter. An example is the environment used to mark the abstract of a document:

\begin{abstract}
This is the text of the abstract. It concisely explains what information is found in the document.

It can consist of multiple paragraphs.
\end{abstract}

An environment can also have required and optional parameters of its own. These follow the parameter of the \texttt{\texttt{\begin{abstract}}} macro. This example shows an environment which takes a single required parameter:

\begin{datadesc}{controlnames}
A 33-element string array that contains the ASCII mnemonics for the thirty-two ASCII control characters from \texttt{0} (NUL) to \texttt{0x1f} (US), in order, plus the mnemonic \texttt{\texttt{\samp{SP}}} for the space character.
\end{datadesc}

There are a number of less-used marks in LaTeX which are used to enter characters which are not found in ASCII or which a considered special, or active in TeX or LaTeX. Given that these are often used adjacent to other characters, the markup required to produce the proper character may need to be followed by a space or an empty group, or the markup can be enclosed in a group. Some which are found in Python documentation are:

<table>
<thead>
<tr>
<th>Character</th>
<th>Markup</th>
</tr>
</thead>
<tbody>
<tr>
<td>^</td>
<td>\textasciicircum</td>
</tr>
<tr>
<td>~</td>
<td>\textasciitilde</td>
</tr>
<tr>
<td>&gt;</td>
<td>\textgreater</td>
</tr>
<tr>
<td>&lt;</td>
<td>\textless</td>
</tr>
<tr>
<td>ç</td>
<td>\texttt{\texttt{c c}}</td>
</tr>
</tbody>
</table>
| ö         | \textasciitilde
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
4.2 Hierarchical Structure

LaTeX expects documents to be arranged in a conventional, hierarchical way, with chapters, sections, sub-sections, appendixes, and the like. These are marked using macros rather than environments, probably because the end of a section can be safely inferred when a section of equal or higher level starts.

There are six "levels" of sectioning in the document classes used for Python documentation, and the deepest two levels\(^1\) are not used. The levels are:

<table>
<thead>
<tr>
<th>Level</th>
<th>Macro Name</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>\chapter</td>
<td>(1)</td>
</tr>
<tr>
<td>2</td>
<td>\section</td>
<td></td>
</tr>
<tr>
<td>3</td>
<td>\subsection</td>
<td></td>
</tr>
<tr>
<td>4</td>
<td>\subsubsection</td>
<td></td>
</tr>
<tr>
<td>5</td>
<td>\paragraph</td>
<td>(2)</td>
</tr>
<tr>
<td>6</td>
<td>\subparagraph</td>
<td></td>
</tr>
</tbody>
</table>

Notes:

(1) Only used for the manual documents, as described in section 5, "Document Classes."

(2) Not the same as a paragraph of text; nobody seems to use this.

Footnotes

... levels\(^1\)

The deepest levels have the highest numbers in the table.
4.3 Common Environments

LaTeX provides a variety of environments even without the additional markup provided by the Python-specific document classes introduced in the next section. The following environments are provided as part of standard LaTeX and are being used in the standard Python documentation; descriptions will be added here as time allows.

abstract
alltt
description
displaymath
document
enumerate
figure
flushleft
itemize
list
math
quotation
quote
sloppypar
verbatim
5 Document Classes

Two LaTeX document classes are defined specifically for use with the Python documentation. The \texttt{manual} class is for large documents which are sectioned into chapters, and the \texttt{howto} class is for smaller documents.

The \texttt{manual} documents are larger and are used for most of the standard documents. This document class is based on the standard LaTeX \texttt{report} class and is formatted very much like a long technical report. The \texttt{Python Reference Manual} is a good example of a \texttt{manual} document, and the \texttt{Python Library Reference} is a large example.

The \texttt{howto} documents are shorter, and don't have the large structure of the \texttt{manual} documents. This class is based on the standard LaTeX \texttt{article} class and is formatted somewhat like the Linux Documentation Project's ``HOWTO'' series as done originally using the LinuxDoc software. The original intent for the document class was that it serve a similar role as the LDP's HOWTO series, but the applicability of the class turns out to be somewhat broader. This class is used for ``how-to'' documents (this document is an example) and for shorter reference manuals for small, fairly cohesive module libraries. Examples of the later use include \texttt{Using Kerberos from Python}, which contains reference material for an extension package. These documents are roughly equivalent to a single chapter from a larger work.
6 Special Markup Constructs

The Python document classes define a lot of new environments and macros. This section contains the reference material for these facilities. Documentation for ``standard'' LaTeX constructs is not included here, though they are used in the Python documentation.

Subsections

- 6.1 Markup for the Preamble
- 6.2 Meta-information Markup
- 6.3 Information Units
- 6.4 Showing Code Examples
- 6.5 Inline Markup
- 6.6 Miscellaneous Text Markup
- 6.7 Module-specific Markup
- 6.8 Library-level Markup
- 6.9 Table Markup
- 6.10 Reference List Markup
- 6.11 Index-generating Markup
- 6.12 Grammar Production Displays
- 6.13 Graphical Interface Components

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
6.1 Markup for the Preamble

\release{ver}

Set the version number for the software described in the document.

\setshortversion{sver}

Specify the ``short'' version number of the documented software to be sver.
6.2 Meta-information Markup

\sectionauthor{author}{email}
Identifies the author of the current section. \textit{author} should be the author's name such that it can be used for presentation (though it isn't), and \textit{email} should be the author's email address. The domain name portion of the address should be lower case.

No presentation is generated from this markup, but it is used to help keep track of contributions.
6.3 Information Units

XXX Explain terminology, or come up with something more `lay.''

There are a number of environments used to describe specific features provided by modules. Each environment requires parameters needed to provide basic information about what is being described, and the environment content should be the description. Most of these environments make entries in the general index (if one is being produced for the document); if no index entry is desired, non-indexing variants are available for many of these environments. The environments have names of the form `featuredesc', and the non-indexing variants are named `featuredescni'. The available variants are explicitly included in the list below.

For each of these environments, the first parameter, name, provides the name by which the feature is accessed.

Environments which describe features of objects within a module, such as object methods or data attributes, allow an optional type name parameter. When the feature is an attribute of class instances, type name only needs to be given if the class was not the most recently described class in the module; the name value from the most recent `classdesc' is implied. For features of built-in or extension types, the type name value should always be provided. Another special case includes methods and members of general ``protocols," such as the formatter and writer protocols described for the formatter module: these may be documented without any specific implementation classes, and will always require the type name parameter to be provided.

\begin{cfuncdesc} \{type\}\{name\}\{args\} \\
\end{cfuncdesc}

Environment used to described a C function. The type should be specified as a typedef name, struct tag, or the name of a primitive type. If it is a pointer type, the trailing asterisk should not be preceded by a space. name should be the name of the function (or function-like pre-processor macro), and args should give the types and names of the parameters. The names need to be given so they may be used in the description.
\begin{cmemberdesc} \{container\}\{type\}\{name\} \\
\end{cmemberdesc}

Description for a structure member. \textit{container} should be the \texttt{typedef} name, if there is one, otherwise if should be \texttt{struct tag}'. The type of the member should given as \textit{type}, and the name should be given as \textit{name}. The text of the description should include the range of values allowed, how the value should be interpreted, and whether the value can be changed. References to structure members in text should use the \texttt{\member} macro.

\begin{csimplemacrodesc} \{name\} \\
\end{csimplemacrodesc}

Documentation for a ``simple'' macro. Simple macros are macros which are used for code expansion, but which do not take arguments so cannot be described as functions. This is not to be used for simple constant definitions. Examples of its use in the Python documentation include PyObject\_HEAD and Py\_BEGIN\_ALLOW\_THREADS.

\begin{ctypedesc} [\texttt{tag}]\{name\} \\
\end{ctypedesc}

Environment used to described a C type. The \textit{name} parameter should be the \texttt{typedef} name. If the type is defined as a \texttt{struct} without a \texttt{typedef}, \textit{name} should have the form \texttt{struct tag}. \textit{name} will be added to the index unless \texttt{tag} is provided, in which case \texttt{tag} will be used instead. \texttt{tag} should not be used for a \texttt{typedef} name.

\begin{cvardesc} \{type\}\{name\} \\
\end{cvardesc}

Description of a global C variable. \textit{type} should be the \texttt{typedef} name, \texttt{struct tag}, or the name of a primitive type. If variable has a pointer type, the trailing asterisk should not be preceded by a space.

\begin{datadesc} \{name\} \\
\end{datadesc}

This environment is used to document global data in a module, including both variables and values used as ``defined constants.'' Class and object attributes are not documented using this environment.

\begin{datadescni} \{name\} \\
\end{datadescni}
Like `{datadesc}`, but without creating any index entries.

\begin{excclassdesc} {name}{constructor parameters}\end{excclassdesc}
Describe an exception defined by a class. `constructor parameters` should not include the `self` parameter or the parentheses used in the call syntax. To describe an exception class without describing the parameters to its constructor, use the `{excdesc}` environment.

\begin{excdesc} {name}\end{excdesc}
Describe an exception. In the case of class exceptions, the constructor parameters are not described; use `{excclassdesc}` to describe an exception class and its constructor.

\begin{funcdesc} {name}{parameters}\end{funcdesc}
Describe a module-level function. `parameters` should not include the parentheses used in the call syntax. Object methods are not documented using this environment. Bound object methods placed in the module namespace as part of the public interface of the module are documented using this, as they are equivalent to normal functions for most purposes. The description should include information about the parameters required and how they are used (especially whether mutable objects passed as parameters are modified), side effects, and possible exceptions. A small example may be provided.

\begin{funcdescni} {name}{parameters}\end{funcdescni}
Like `{funcdesc}`, but without creating any index entries.

\begin{classdesc} {name}{constructor parameters}\end{classdesc}
Describe a class and its constructor. `constructor parameters` should not include the `self` parameter or the parentheses used in the call syntax.

\begin{classdesc*} {name}\end{classdesc*}
Describe a class without describing the constructor. This can be used to describe classes that are merely containers for attributes or which should never be instantiated or subclassed by user code.

\begin{memberdesc} [type name]{name}
\end{memberdesc}

Describe an object data attribute. The description should include information about the type of the data to be expected and whether it may be changed directly.

\begin{memberdescni} [type name]{name}
\end{memberdescni}

Like \memberdesc, but without creating any index entries.

\begin{methoddesc} [type name]{name}{parameters}
\end{methoddesc}

Describe an object method. \texttt{parameters} should not include the \texttt{self} parameter or the parentheses used in the call syntax. The description should include similar information to that described for \funcdesc.

\begin{methoddescni} [type name]{name}{parameters}
\end{methoddescni}

Like \methoddesc, but without creating any index entries.
6.4 Showing Code Examples

Examples of Python source code or interactive sessions are represented as `\verbatim` environments. This environment is a standard part of LaTeX. It is important to only use spaces for indentation in code examples since TeX drops tabs instead of converting them to spaces.

Representing an interactive session requires including the prompts and output along with the Python code. No special markup is required for interactive sessions. After the last line of input or output presented, there should not be an "unused" primary prompt; this is an example of what not to do:

```
>>> 1 + 1
2
>>> 
```

Within the `\verbatim` environment, characters special to LaTeX do not need to be specially marked in any way. The entire example will be presented in a monospaced font; no attempt at "pretty-printing" is made, as the environment must work for non-Python code and non-code displays. There should be no blank lines at the top or bottom of any `\verbatim` display.

Longer displays of verbatim text may be included by storing the example text in an external file containing only plain text. The file may be included using the standard `\verbatiminput` macro; this macro takes a single argument naming the file containing the text. For example, to include the Python source file `example.py`, use:

```
\verbatiminput{example.py}
```

Use of `\verbatiminput` allows easier use of special editing modes for the included file. The file should be placed in the same directory as the LaTeX files for the document.

The Python Documentation Special Interest Group has discussed a number of approaches to creating pretty-printed code displays and interactive sessions; see the Doc-SIG area on the Python Web site for more information on this topic.
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
6.5 Inline Markup

The macros described in this section are used to mark just about anything interesting in the document text. They may be used in headings (though anything involving hyperlinks should be avoided there) as well as in the body text.

\bfcode {text}
Like \code, but also makes the font bold-face.

\cdata \{name\}
The name of a C-language variable.

\cfunction \{name\}
The name of a C-language function. name should include the function name and the trailing parentheses.

\character \{char\}
A character when discussing the character rather than a one-byte string value. The character will be typeset as with \samp.

\citetitle \[url\]\{title\}
A title for a referenced publication. If url is specified, the title will be made into a hyperlink when formatted as HTML.

\class \{name\}
A class name; a dotted name may be used.

\code \{text\}
A short code fragment or literal constant value. Typically, it should not include any spaces since no quotation marks are added.

\constant \{name\}
The name of a ``defined'' constant. This may be a C-language \#define or a Python variable that is not intended to be changed.

\csimplemacro \{name\}
The name of a ``simple'' macro. Simple macros are macros which are used for code expansion, but which do not take arguments so cannot be described
as functions. This is not to be used for simple constant definitions. Examples of its use in the Python documentation include PyObject\_HEAD and Py\_BEGIN\_ALLOW\_THREADS.

\ctype \{name\}
The name of a C typedef or structure. For structures defined without a typedef, use \ctype{struct struct_tag} to make it clear that the struct is required.

\deprecated \{version\}\{what to do\}
Declare whatever is being described as being deprecated starting with release version. The text given as what to do should recommend something to use instead. It should be complete sentences. The entire deprecation notice will be presented as a separate paragraph; it should either precede or succeed the description of the deprecated feature.

\dfn \{term\}
Mark the defining instance of term in the text. (No index entries are generated.)

\e
Produces a backslash. This is convenient in \code, \file, and similar macros, and the \alltt environment, and is only defined there. To create a backslash in ordinary text (such as the contents of the \citetitle macro), use the standard \textbackslash macro.

\email \{address\}
An email address. Note that this is not hyperlinked in any of the possible output formats. The domain name portion of the address should be lower case.

\emph \{text\}
Emphasized text; this will be presented in an italic font.

\envvar \{name\}
An environment variable. Index entries are generated.

\exception \{name\}
The name of an exception. A dotted name may be used.
\file \{file or dir\}
The name of a file or directory. In the PDF and PostScript outputs, single quotes and a font change are used to indicate the file name, but no quotes are used in the HTML output. **Warning:** The \file macro cannot be used in the content of a section title due to processing limitations.

\filenq \{file or dir\}
Like \file, but single quotes are never used. This can be used in conjunction with tables if a column will only contain file or directory names. **Warning:** The \filenq macro cannot be used in the content of a section title due to processing limitations.

\function \{name\}
The name of a Python function; dotted names may be used.

\infinity
The symbol for mathematical infinity: \( \infty \). Some Web browsers are not able to render the HTML representation of this symbol properly, but support is growing.

\kbd \{key sequence\}
Mark a sequence of keystrokes. What form *key sequence* takes may depend on platform- or application-specific conventions. When there are no relevant conventions, the names of modifier keys should be spelled out, to improve accessibility for new users and non-native speakers. For example, an *xemacs* key sequence may be marked like \kbd{C-x C-f}, but without reference to a specific application or platform, the same sequence should be marked as \kbd{Control-x Control-f}.

\keyword \{name\}
The name of a keyword in a programming language.

\mailheader \{name\}
The name of an RFC 822-style mail header. This markup does not imply that the header is being used in an email message, but can be used to refer to any header of the same ```style.' This is also used for headers defined by the various MIME specifications. The header name should be entered in the same way it would normally be found in practice, with the camel-casing conventions being preferred where there is more than one common usage.
The colon which follows the name of the header should not be included.
For example: \mailheader{Content-Type}.

\makevar {name}
The name of a make variable.

\manpage {name} {section}
A reference to a UNIX manual page.

\member {name}
The name of a data attribute of an object.

\method {name}
The name of a method of an object. name should include the method name
and the trailing parentheses. A dotted name may be used.

\mimetype {name}
The name of a MIME type, or a component of a MIME type (the major or
minor portion, taken alone).

\module {name}
The name of a module; a dotted name may be used. This should also be
used for package names.

\newsgroup {name}
The name of a Usenet newsgroup.

\note {text}
An especially important bit of information about an API that a user should
be aware of when using whatever bit of API the note pertains to. This
should be the last thing in the paragraph as the end of the note is not
visually marked in any way. The content of text should be written in
complete sentences and include all appropriate punctuation.

\pep {number}
A reference to a Python Enhancement Proposal. This generates appropriate
index entries. The text "PEP number" is generated; in the HTML output,
this text is a hyperlink to an online copy of the specified PEP.
The symbol for indicating a value that may take a positive or negative value of a specified magnitude, typically represented by a plus sign placed over a minus sign. For example: \plusminus 3%.

\program {name}
The name of an executable program. This may differ from the file name for the executable for some platforms. In particular, the .exe (or other) extension should be omitted for Windows programs.

\programopt {option}
A command-line option to an executable program. Use this only for ``short'' options, and include the leading hyphen.

\longprogramopt {option}
A long command-line option to an executable program. This should only be used for long option names which will be prefixed by two hyphens; the hyphens should not be provided as part of option.

\refmodule [key]{name}
Like \module, but create a hyperlink to the documentation for the named module. Note that the corresponding \declaremodule must be in the same document. If the \declaremodule defines a module key different from the module name, it must also be provided as key to the \refmodule macro.

\regexp {string}
Mark a regular expression.

\rfc {number}
A reference to an Internet Request for Comments. This generates appropriate index entries. The text "RFC number" is generated; in the HTML output, this text is a hyperlink to an online copy of the specified RFC.

\samp {text}
A short code sample, but possibly longer than would be given using \code. Since quotation marks are added, spaces are acceptable.
\shortversion
The ``short'' version number of the documented software, as specified using the \setshortversion macro in the preamble. For Python, the short version number for a release is the first three characters of the sys\texttt{.version} value. For example, versions 2.0b1 and 2.0.1 both have a short version of 2.0. This may not apply for all packages; if \setshortversion is not used, this produces an empty expansion. See also the \version macro.

\strong{\textit{text}}
Strongly emphasized text; this will be presented using a bold font.

\ulink{\textit{\texttt{url}}}{\textit{\texttt{url}}}
A hypertext link with a target specified by a URL, but for which the link text should not be the title of the resource. For resources being referenced by name, use the \texttt{\citetitle} macro. Not all formatted versions support arbitrary hypertext links. Note that many characters are special to LaTeX and this macro does not always do the right thing. In particular, the tilde character ("~") is mis-handled; encoding it as a hex-sequence does work, use "%7e" in place of the tilde character.

\url{\texttt{url}}
A URL (or URN). The URL will be presented as text. In the HTML and PDF formatted versions, the URL will also be a hyperlink. This can be used when referring to external resources without specific titles; references to resources which have titles should be marked using the \texttt{\citetitle} macro. See the comments about special characters in the description of the \ulink macro for special considerations.

\var{name}
The name of a variable or formal parameter in running text.

\version
The version number of the described software, as specified using \texttt{\release} in the preamble. See also the \shortversion macro.

\warning{\textit{\texttt{text}}}
An important bit of information about an API that a user should be very aware of when using whatever bit of API the warning pertains to. This
should be the last thing in the paragraph as the end of the warning is not visually marked in any way. The content of text should be written in complete sentences and include all appropriate punctuation. This differs from note in that it is recommended over note for information regarding security.

The following two macros are used to describe information that's associated with changes from one release to another. For features which are described by a single paragraph, these are typically added as separate source lines at the end of the paragraph. When adding these to features described by multiple paragraphs, they are usually collected in a single separate paragraph after the description. When both versionadded and versionchanged are used, versionadded should come first; the versions should be listed in chronological order. Both of these should come before availability statements. The location should be selected so the explanation makes sense and may vary as needed.

\versionadded [explanation]{version}
The version of Python which added the described feature to the library or C API. explanation should be a brief explanation of the change consisting of a capitalized sentence fragment; a period will be appended by the formatting process. When this applies to an entire module, it should be placed at the top of the module section before any prose.

\versionchanged [explanation]{version}
The version of Python in which the named feature was changed in some way (new parameters, changed side effects, etc.). explanation should be a brief explanation of the change consisting of a capitalized sentence fragment; a period will be appended by the formatting process. This should not generally be applied to modules.
6.6 Miscellaneous Text Markup

In addition to the inline markup, some additional ``block'' markup is defined to make it easier to bring attention to various bits of text. The markup described here serves this purpose, and is intended to be used when marking one or more paragraphs or other block constructs (such as \verbatim environments).

\begin{notice} [type] \end{notice}

Label some paragraphs as being worthy of additional attention from the reader. What sort of attention is warranted can be indicated by specifying the type of the notice. The only values defined for type are note and warning; these are equivalent in intent to the inline markup of the same name. If type is omitted, note is used. Additional values may be defined in the future.
6.7 Module-specific Markup

The markup described in this section is used to provide information about a module being documented. Each module should be documented in its own \section. A typical use of this markup appears at the top of that section and might look like this:

\section{\module{spam} ---
    Access to the SPAM facility}
\declaremodule{extension}{spam}
\platform{Unix}
\modulesynopsis{Access to the SPAM facility of \UNIX.}
\moduleauthor{Jane Doe}{jane.doe@frobnitz.org}

Python packages -- collections of modules that can be described as a unit -- are documented using the same markup as modules. The name for a module in a package should be typed in ``fully qualified'' form (it should include the package name). For example, a module ``foo'' in package ``bar'' should be marked as \module{bar.foo}, and the beginning of the reference section would appear as:

\section{\module{bar.foo} ---
    Module from the \module{bar} package}
\declaremodule{extension}{bar.foo}
\modulesynopsis{Nifty module from the \module{bar} package.}
\moduleauthor{Jane Doe}{jane.doe@frobnitz.org}

Note that the name of a package is also marked using \module.

\declaremodule \key \type \name
Requires two parameters: module type ("standard", "builtin", "extension", or "))", and the module name. An optional parameter should be given as the basis for the module's \``key'' used for linking to or referencing the section. The \``key'' should only be given if the module's name contains any underscores, and should be the name with the underscores stripped. Note that the \type\ parameter must be one of the values listed above or an error will be printed. For modules which are contained in packages, the fully-qualified name should be given as \name parameter. This should be the first thing after the \section used to
introduce the module.

\platform {specifier}
Specifies the portability of the module. specifier is a comma-separated list of keys that specify what platforms the module is available on. The keys are short identifiers; examples that are in use include "IRIX", "Mac", "Windows", and "Unix". It is important to use a key which has already been used when applicable. This is used to provide annotations in the Module Index and the HTML and GNU info output.

\modulesynopsis {text}
The text is a short, "one line" description of the module that can be used as part of the chapter introduction. This is must be placed after \declaremodule. The synopsis is used in building the contents of the table inserted as the \localmoduletable. No text is produced at the point of the markup.

\moduleauthor {name} {email}
This macro is used to encode information about who authored a module. This is currently not used to generate output, but can be used to help determine the origin of the module.
6.8 Library-level Markup

This markup is used when describing a selection of modules. For example, the Macintosh Library Modules document uses this to help provide an overview of the modules in the collection, and many chapters in the Python Library Reference use it for the same purpose.

\localmoduletable

If a .syn file exists for the current chapter (or for the entire document in howto documents), a \synopsistable is created with the contents loaded from the .syn file.
6.9 Table Markup

There are three general-purpose table environments defined which should be used whenever possible. These environments are defined to provide tables of specific widths and some convenience for formatting. These environments are not meant to be general replacements for the standard LaTeX table environments, but can be used for an advantage when the documents are processed using the tools for Python documentation processing. In particular, the generated HTML looks good! There is also an advantage for the eventual conversion of the documentation to XML (see section 9, "Future Directions").

Each environment is named \texttt{tablecols}, where \texttt{cols} is the number of columns in the table specified in lower-case Roman numerals. Within each of these environments, an additional macro, \texttt{linecols}, is defined, where \texttt{cols} matches the \texttt{cols} value of the corresponding table environment. These are supported for \texttt{cols} values of \texttt{ii}, \texttt{iii}, and \texttt{iv}. These environments are all built on top of the \texttt{tabular} environment. Variants based on the \texttt{longtable} environment are also provided.

Note that all tables in the standard Python documentation use vertical lines between columns, and this must be specified in the markup for each table. A general border around the outside of the table is not used, but would be the responsibility of the processor; the document markup should not include an exterior border.

The \texttt{longtable}-based variants of the table environments are formatted with extra space before and after, so should only be used on tables which are long enough that splitting over multiple pages is reasonable; tables with fewer than twenty rows should never be marked using the long flavors of the table environments. The header row is repeated across the top of each part of the table.

\begin{tableii} \{colspec\}\{col1font\}\{heading1\}\{heading2\} \\end{tableii}

Create a two-column table using the LaTeX column specifier \texttt{colspec}. The column specifier should indicate vertical bars between columns as appropriate for the specific table, but should not specify vertical bars on the outside of the table (that is considered a stylesheet issue). The \texttt{col1font}
parameter is used as a stylicic treatment of the first column of the table: the first column is presented as $\textsc{col1font}\{\text{column1}\}$. To avoid treating the first column specially, $\textsc{col1font}$ may be "\textit{textrm}". The column headings are taken from the values $heading1$ and $heading2$.

\begin{longtable}{l}
... \end{longtable}

Like \texttt{\textbackslash tableii}, but produces a table which may be broken across page boundaries. The parameters are the same as for \texttt{\textbackslash tableii}.

\begin{lineii}{column1}{column2}
Create a single table row within a \texttt{\textbackslash tableii} or \texttt{\textbackslash longtableii} environment. The text for the first column will be generated by applying the macro named by the $\textsc{col1font}$ value when the \texttt{\textbackslash tableii} was opened.

\begin{tableiii}{c}{c}{c}{c}
\texttt{\textbackslash colspec}{\textsc{col1font}}\{\textit{heading1}\}\{\textit{heading2}\}
\texttt{\textbackslash heading3}
\end{tableiii}

Like the \texttt{\textbackslash tableii} environment, but with a third column. The heading for the third column is given by $heading3$.

\begin{longtableiii} ...
\end{longtableiii}

Like \texttt{\textbackslash tableiii}, but produces a table which may be broken across page boundaries. The parameters are the same as for \texttt{\textbackslash tableiii}.

\begin{lineiii}{column1}{column2}{column3}
Like the \texttt{\textbackslash lineii} macro, but with a third column. The text for the third column is given by $column3$.

\begin{tableiv}{c}{c}{c}{c}
\texttt{\textbackslash colspec}{\textsc{col1font}}\{\textit{heading1}\}\{\textit{heading2}\}
\texttt{\textbackslash heading3}{\textit{heading4}}
\end{tableiv}

Like the \texttt{\textbackslash tableiii} environment, but with a fourth column. The heading for the fourth column is given by $heading4$.

\begin{longtableiv} ...
\end{longtableiv}

Like \texttt{\textbackslash tableiv}, but produces a table which may be broken across page
boundaries. The parameters are the same as for \texttt{tableiv}.

\texttt{\lineiv column1}\{column2}\{column3}\{column4}
Like the \texttt{\lineiii} macro, but with a fourth column. The text for the fourth column is given by \texttt{column4}.

\texttt{\begin{tablev} colspec\{col1font\}heading1\{heading2\}heading3\{heading4\}heading5\end{tablev}}
Like the \texttt{\tableiv} environment, but with a fifth column. The heading for the fifth column is given by \texttt{heading5}.

\texttt{\begin{longtablev} ...
\end{longtablev}}
Like \texttt{\tablev}, but produces a table which may be broken across page boundaries. The parameters are the same as for \texttt{\tablev}.

\texttt{\linev column1}\{column2}\{column3}\{column4}\{column5}
Like the \texttt{\lineiv} macro, but with a fifth column. The text for the fifth column is given by \texttt{column5}.

An additional table-like environment is \texttt{synopsistable}. The table generated by this environment contains two columns, and each row is defined by an alternate definition of \texttt{modulesynopsis}. This environment is not normally used by authors, but is created by the \texttt{\localmoduletable} macro.

Here is a small example of a table given in the documentation for the \texttt{warnings} module; markup inside the table cells is minimal so the markup for the table itself is readily discernable. Here is the markup for the table:

\texttt{\begin{tableii}{l|l}{exception}{Class}{Description}
\lineii{Warning}
{This is the base class of all warning category classes. It is a subclass of \texttt{Exception}.}
\lineii{UserWarning}
{The default category for \texttt{warn}().}
\lineii{DeprecationWarning}
{Base category for warnings about deprecated features.}
\lineii{SyntaxWarning}
{Base category for warnings about dubious syntactic features.}
\lineii{RuntimeWarning}
\end{tableii}}
Here is the resulting table:

<table>
<thead>
<tr>
<th>Class</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Warning</td>
<td>This is the base class of all warning category classes. It is a subclass of Exception.</td>
</tr>
<tr>
<td>UserWarning</td>
<td>The default category for warn().</td>
</tr>
<tr>
<td>DeprecationWarning</td>
<td>Base category for warnings about deprecated features.</td>
</tr>
<tr>
<td>SyntaxWarning</td>
<td>Base category for warnings about dubious syntactic features.</td>
</tr>
<tr>
<td>RuntimeWarning</td>
<td>Base category for warnings about dubious runtime features.</td>
</tr>
</tbody>
</table>

Note that the class names are implicitly marked using the \texttt{exception} macro, since that is given as the \texttt{col1font} value for the \texttt{tableii} environment. To create a table using different markup for the first column, use \texttt{textrm} for the \texttt{col1font} value and mark each entry individually.

To add a horizontal line between vertical sections of a table, use the standard \texttt{hline} macro between the rows which should be separated:

\begin{tableii}{l|l}{constant}{Language}{Audience}
\texttt{APL}\{Masochists.\}
\texttt{BASIC}\{First-time programmers on PC hardware.\}
\texttt{C}\{\texttt{UNIX}\} \&\ \texttt{Linux kernel developers.}\n\texttt{Python}\{Everyone!\}
\end{tableii}

Note that not all presentation formats are capable of displaying a horizontal rule in this position. This is how the table looks in the format you're reading now:

<table>
<thead>
<tr>
<th>Language</th>
<th>Audience</th>
</tr>
</thead>
<tbody>
<tr>
<td>APL</td>
<td>Masochists.</td>
</tr>
<tr>
<td>C</td>
<td>\texttt{UNIX} &amp; Linux kernel developers.</td>
</tr>
</tbody>
</table>
6.10 Reference List Markup

Many sections include a list of references to module documentation or external documents. These lists are created using the `\seealso` or `\seealso*` environments. These environments define some additional macros to support creating reference entries in a reasonable manner.

The `\seealso` environment is typically placed in a section just before any sub-sections. This is done to ensure that reference links related to the section are not hidden in a subsection in the hypertext renditions of the documentation. For the HTML output, it is shown as a ``side bar," boxed off from the main flow of the text. The `\seealso*` environment is different in that it should be used when a list of references is being presented as part of the primary content; it is not specially set off from the text.

\begin{seealso} 
\end{seealso} 

This environment creates a ``See also:" heading and defines the markup used to describe individual references.

\begin{seealso*} 
\end{seealso*} 

This environment is used to create a list of references which form part of the main content. It is not given a special header and is not set off from the main flow of the text. It provides the same additional markup used to describe individual references.

For each of the following macros, `why` should be one or more complete sentences, starting with a capital letter (unless it starts with an identifier, which should not be modified), and ending with the appropriate punctuation.

These macros are only defined within the content of the `\seealso` and `\seealso*` environments.

\seelink \{url\}\{linktext\}\{why\} 
References to specific on-line resources should be given using the `\seelink` macro if they don't have a meaningful title but there is some short description of what's at the end of the link. Online documents which
have identifiable titles should be referenced using the `\seetitle` macro, using the optional parameter to that macro to provide the URL.

\seemodule [key]{name}{why}
Refers to another module. *why* should be a brief explanation of why the reference may be interesting. The module name is given in *name*, with the link key given in *key* if necessary. In the HTML and PDF conversions, the module name will be a hyperlink to the referred-to module. **Note:** The module must be documented in the same document (the corresponding `\declaremodule` is required).

\seepep {number}{title}{why}
Refer to a Python Enhancement Proposal (PEP). *number* should be the official number assigned by the PEP Editor, *title* should be the human-readable title of the PEP as found in the official copy of the document, and *why* should explain what's interesting about the PEP. This should be used to refer the reader to PEPs which specify interfaces or language features relevant to the material in the annotated section of the documentation.

\seerfc {number}{title}{why}
Refer to an IETF Request for Comments (RFC). Otherwise very similar to `\seepep`. This should be used to refer the reader to PEPs which specify protocols or data formats relevant to the material in the annotated section of the documentation.

\seetext {text}
Add arbitrary text *text* to the "See also:" list. This can be used to refer to off-line materials or on-line materials using the `\url` macro. This should consist of one or more complete sentences.

\seetitle [url]{title}{why}
Add a reference to an external document named *title*. If *url* is given, the title is made a hyperlink in the HTML version of the documentation, and displayed below the title in the typeset versions of the documentation.

\seeurl {url}{why}
References to specific on-line resources should be given using the `\seeurl` macro if they don't have a meaningful title. Online documents which have identifiable titles should be referenced using the `\seetitle`
macro, using the optional parameter to that macro to provide the URL.
6.11 Index-generating Markup

Effective index generation for technical documents can be very difficult, especially for someone familiar with the topic but not the creation of indexes. Much of the difficulty arises in the area of terminology: including the terms an expert would use for a concept is not sufficient. Coming up with the terms that a novice would look up is fairly difficult for an author who, typically, is an expert in the area she is writing on.

The truly difficult aspects of index generation are not areas with which the documentation tools can help. However, ease of producing the index once content decisions are made is within the scope of the tools. Markup is provided which the processing software is able to use to generate a variety of kinds of index entry with minimal effort. Additionally, many of the environments described in section 6.3, ``Information Units,'' will generate appropriate entries into the general and module indexes.

The following macro can be used to control the generation of index data, and should be used in the document preamble:

\makemodindex

This should be used in the document preamble if a ``Module Index'' is desired for a document containing reference material on many modules. This causes a data file libjobname.idx to be created from the \declaremodule macros. This file can be processed by the makeindex program to generate a file which can be \input into the document at the desired location of the module index.

There are a number of macros that are useful for adding index entries for particular concepts, many of which are specific to programming languages or even Python.

\bifuncindex {name}

Add an index entry referring to a built-in function named name; parentheses should not be included after name.

\exindex {exception}

Add a reference to an exception named exception. The exception should be
class-based.

\kwindex{keyword}
Add a reference to a language keyword (not a keyword parameter in a function or method call).

\obindex{object type}
Add an index entry for a built-in object type.

\opindex{operator}
Add a reference to an operator, such as "+".

\refmodindex{key}{module}
Add an index entry for module module; if module contains an underscore, the optional parameter key should be provided as the same string with underscores removed. An index entry `module (module)` will be generated. This is intended for use with non-standard modules implemented in Python.

\refexmodindex{key}{module}
As for \refmodindex, but the index entry will be `module (extension module)'. This is intended for use with non-standard modules not implemented in Python.

\refbimodindex{key}{module}
As for \refmodindex, but the index entry will be `module (built-in module)'. This is intended for use with standard modules not implemented in Python.

\refstmodindex{key}{module}
As for \refmodindex, but the index entry will be `module (standard module)'. This is intended for use with standard modules implemented in Python.

\stindex{statement}
Add an index entry for a statement type, such as print or try/finally.

XXX Need better examples of difference from \kwindex.
Additional macros are provided which are useful for conveniently creating general index entries which should appear at many places in the index by rotating a list of words. These are simple macros that simply use `\index` to build some number of index entries. Index entries build using these macros contain both primary and secondary text.

\texttt{\textbf{\indexii}} \{word1\}\{word2\}

Build two index entries. This is exactly equivalent to using `\index{word1!word2}` and `\index{word2!word1}`.

\texttt{\textbf{\indexiii}} \{word1\}\{word2\}\{word3\}

Build three index entries. This is exactly equivalent to using `\index{word1!word2 word3}`, `\index{word2!word3, word1}`, and `\index{word3!word1 word2}`.

\texttt{\textbf{\indexiv}} \{word1\}\{word2\}\{word3\}\{word4\}

Build four index entries. This is exactly equivalent to using `\index{word1!word2 word3 word4}`, `\index{word2!word3 word4, word1}`, `\index{word3!word4, word1 word2}`, and `\index{word4!word1 word2 word3}`.
6.12 Grammar Production Displays

Special markup is available for displaying the productions of a formal grammar. The markup is simple and does not attempt to model all aspects of BNF (or any derived forms), but provides enough to allow context-free grammars to be displayed in a way that causes uses of a symbol to be rendered as hyperlinks to the definition of the symbol. There is one environment and a pair of macros:

\begin{productionlist} [language]
\end{productionlist}

This environment is used to enclose a group of productions. The two macros are only defined within this environment. If a document describes more than one language, the optional parameter *language* should be used to distinguish productions between languages. The value of the parameter should be a short name that can be used as part of a filename; colons or other characters that can't be used in filename across platforms should be included.

\production {name} {definition}

A production rule in the grammar. The rule defines the symbol *name* to be *definition*. *name* should not contain any markup, and the use of hyphens in a document which supports more than one grammar is undefined. *definition* may contain \token macros and any additional content needed to describe the grammatical model of *symbol*. Only one \production may be used to define a symbol -- multiple definitions are not allowed.

\token {name}

The name of a symbol defined by a \production macro, used in the definition of a symbol. Where possible, this will be rendered as a hyperlink to the definition of the symbol *name*.

Note that the entire grammar does not need to be defined in a single \productionlist environment; any number of groupings may be used to describe the grammar. Every use of the \token must correspond to a \production.

The following is an example taken from the *Python Reference Manual*:
\begin{productionlist}
\production{identifier}
  {{\token{letter}"_"} {\token{letter} | \token{digit} |}
\production{letter}
  {\token{lowercase} | \token{uppercase}}
\production{lowercase}
  {"a"..."z"}
\production{uppercase}
  {"A"..."Z"}
\production{digit}
  {"0"..."9"}
\end{productionlist}
6.13 Graphical Interface Components

The components of graphical interfaces will be assigned markup, but most of the specifics have not been determined.

\guilabel \{label\}
Labels presented as part of an interactive user interface should be marked using \guilabel. This includes labels from text-based interfaces such as those created using \curses or other text-based libraries. Any label used in the interface should be marked with this macro, including button labels, window titles, field names, menu and menu selection names, and even values in selection lists.

\menuselection \{menupath\}
Menu selections should be marked using a combination of \menuselection and \sub. This macro is used to mark a complete sequence of menu selections, including selecting submenus and choosing a specific operation, or any subsequence of such a sequence. The names of individual selections should be separated by occurrences of \sub.

For example, to mark the selection ``Start > Programs'', use this markup:

\menuselection{Start \sub Programs}

When including a selection that includes some trailing indicator, such as the ellipsis some operating systems use to indicate that the command opens a dialog, the indicator should be omitted from the selection name.

Individual selection names within the \menuselection should not be marked using \guilabel since that's implied by using \menuselection.

\sub
Separator for menu selections that include multiple levels. This macro is only defined within the context of the \menuselection macro.
7 Processing Tools

Subsections

- 7.1 External Tools
- 7.2 Internal Tools
- 7.3 Working on Cygwin

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
7.1 External Tools

Many tools are needed to be able to process the Python documentation if all supported formats are required. This section lists the tools used and when each is required. Consult the Doc/README file to see if there are specific version requirements for any of these.

**dvips**
This program is a typical part of TeX installations. It is used to generate PostScript from the ``device independent`` .dvi files. It is needed for the conversion to PostScript.

**emacs**
Emacs is the kitchen sink of programmers' editors, and a damn fine kitchen sink it is. It also comes with some of the processing needed to support the proper menu structures for Texinfo documents when an info conversion is desired. This is needed for the info conversion. Using xemacs instead of FSF emacs may lead to instability in the conversion, but that's because nobody seems to maintain the Emacs Texinfo code in a portable manner.

**latex**
LaTeX is a large and extensible macro package by Leslie Lamport, based on TeX, a world-class typesetter by Donald Knuth. It is used for the conversion to PostScript, and is needed for the HTML conversion as well (LaTeX2HTML requires one of the intermediate files it creates).

**latex2html**
Probably the longest Perl script anyone ever attempted to maintain. This converts LaTeX documents to HTML documents, and does a pretty reasonable job. It is required for the conversions to HTML and GNU info.

**lynx**
This is a text-mode Web browser which includes an HTML-to-plain text conversion. This is used to convert howto documents to text.

**make**
Just about any version should work for the standard documents, but GNU make is required for the experimental processes in Doc/tools/sgmlconv/,
at least while they're experimental. This is not required for running the
**mkhowto** script.

**makeindex**
This is a standard program for converting LaTeX index data to a formatted
index; it should be included with all LaTeX installations. It is needed for the
PDF and PostScript conversions.

**makeinfo**
GNU **makeinfo** is used to convert Texinfo documents to GNU info files.
Since Texinfo is used as an intermediate format in the info conversion, this
program is needed in that conversion.

**pdflatex**
pdfTeX is a relatively new variant of TeX, and is used to generate the PDF
version of the manuals. It is typically installed as part of most of the large
TeX distributions. **pdflatex** is pdfTeX using the LaTeX format.

**perl**
Perl is required for LaTeX2HTML and one of the scripts used to post-
process LaTeX2HTML output, as well as the HTML-to-Texinfo conversion.
This is required for the HTML and GNU info conversions.

**python**
Python is used for many of the scripts in the Doc/tools/ directory; it is
required for all conversions. This shouldn't be a problem if you're interested
in writing documentation for Python!
7.2 Internal Tools

This section describes the various scripts that are used to implement various stages of document processing or to orchestrate entire build sequences. Most of these tools are only useful in the context of building the standard documentation, but some are more general.

**mkhowto**

This is the primary script used to format third-party documents. It contains all the logic needed to ``get it right.'' The proper way to use this script is to make a symbolic link to it or run it in place; the actual script file must be stored as part of the documentation source tree, though it may be used to format documents outside the tree. Use `mkhowto --help` for a list of command line options.

`mkhowto` can be used for both `howto` and `manual` class documents. It is usually a good idea to always use the latest version of this tool rather than a version from an older source release of Python. It can be used to generate DVI, HTML, PDF, PostScript, and plain text documents. The GNU info and iSilo formats will be supported by this script in some future version.

Use the `--help` option on this script's command line to get a summary of options for this script.

XXX Need more here.
7.3 Working on Cygwin

Installing the required tools under Cygwin under Cygwin can be a little tedious. Most of the required packages can be installed using Cygwin's graphical installer, while netpbm and LaTeX2HTML must be installed from source.

Start with a reasonably modern version of Cygwin. If you haven't upgraded for a few years, now would be a good time.

Using the Cygwin installer, make sure your Cygwin installation includes Perl, Python, and the TeX packages. Perl and Python are located under the Interpreters heading. The TeX packages are located under the Text heading, and are named tetex-* . To ensure that all required packages are available, install every tetex package, except tetex-x11. (There may be a more minimal set, but I've not spent time trying to minimize the installation.)

The netpbm package is used by LaTeX2HTML, and must be installed before LaTeX2HTML can be successfully installed, even though its features will not be used for most Python documentation. References to download locations are located in the netpbm README. Install from the latest stable source distribution according to the instructions. (Note that binary packages of netpbm are sometimes available, but these may not work correctly with LaTeX2HTML.)

LaTeX2HTML can be installed from the source archive, but only after munging one of the files in the distribution. Download the source archive from the LaTeX2HTML website http://www.latex2html.org/ (or one of the many alternate sites) and unpack it to a build directory. In the top level of this build directory there will be a file named L2hos.pm. Open L2hos.pm in an editor, and near the bottom of the file replace the text $^O with the text 'unix'. Proceed using this command to build and install the software:

% ./configure && make install

You should now be able to build at least the DVI, HTML, PDF, and PostScript versions of the formatted documentation.
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.

8 Including Graphics

The standard documentation included with Python makes no use of diagrams or images; this is intentional. The outside tools used to format the documentation have not always been suited to working with graphics. As the tools have evolved and been improved by their maintainers, support for graphics has improved.

The internal tools, starting with the mkhowto script, do not provide any direct support for graphics. However, mkhowto will not interfere with graphics support in the external tools.

Experience using graphics together with these tools and the howto and manual document classes is not extensive, but has been known to work. The basic approach is this:

1. Create the image or graphic using your favorite application.

2. Convert the image to a format supported by the conversion to your desired output format. If you want to generate HTML or PostScript, you can convert the image or graphic to encapsulated PostScript (a .eps file); LaTeX2HTML can convert that to a .gif file; it may be possible to provide a .gif file directly. If you want to generate PDF, you need to provide an `"encapsulated" PDF file. This can be generated from encapsulated PostScript using the epstopdf tool provided with the tEx distribution on Linux and UNIX.

3. In your document, add this line to `"import" the general graphics support package graphicx:

   \usepackage{graphicx}

4. Where you want to include your graphic or image, include markup similar to this:

   \begin{figure}
     \centering
     \includegraphics[width=5in]{myimage}
     \caption{Description of my image}
   \end{figure}
In particular, note for the `\includegraphics` macro that no file extension is provided. If you're only interested in one target format, you can include the extension of the appropriate input file, but to allow support for multiple formats, omitting the extension makes life easier.

5. Run `mkhowto` normally.

If you're working on systems which support some sort of `make` facility, you can use that to ensure the intermediate graphic formats are kept up to date. This example shows a Makefile used to format a document containing a diagram created using the `dia` application:

```
default: pdf
all: html pdf ps

html: mydoc/mydoc.html
pdf: mydoc.pdf
ps: mydoc.ps

mydoc/mydoc.html: mydoc.tex mygraphic.eps
         mkhowto --html $<

mydoc.pdf: mydoc.tex mygraphic.pdf
         mkhowto --pdf $<

mydoc.ps: mydoc.tex mygraphic.eps
         mkhowto --postscript $<

.SUFFIXES: .dia .eps .pdf
.dia.eps:
         dia --nosplash --export @$<

.eps.pdf:
         epstopdf $<
```
9 Future Directions

The history of the Python documentation is full of changes, most of which have been fairly small and evolutionary. There has been a great deal of discussion about making large changes in the markup languages and tools used to process the documentation. This section deals with the nature of the changes and what appears to be the most likely path of future development.

Subsections

- 9.1 Structured Documentation
- 9.2 Discussion Forums

Release 2.5, documentation updated on 19th September, 2006. See About this document... for information on suggesting changes.
9.1 Structured Documentation

Most of the small changes to the LaTeX markup have been made with an eye to divorcing the markup from the presentation, making both a bit more maintainable. Over the course of 1998, a large number of changes were made with exactly this in mind; previously, changes had been made but in a less systematic manner and with more concern for not needing to update the existing content. The result has been a highly structured and semantically loaded markup language implemented in LaTeX. With almost no basic TeX or LaTeX markup in use, however, the markup syntax is about the only evidence of LaTeX in the actual document sources.

One side effect of this is that while we've been able to use standard `\``engines" for manipulating the documents, such as LaTeX and LaTeX2HTML, most of the actual transformations have been created specifically for Python. The LaTeX document classes and LaTeX2HTML support are both complete implementations of the specific markup designed for these documents.

Combining highly customized markup with the somewhat esoteric systems used to process the documents leads us to ask some questions: Can we do this more easily? and, Can we do this better? After a great deal of discussion with the community, we have determined that actively pursuing modern structured documentation systems is worth some investment of time.

There appear to be two real contenders in this arena: the Standard General Markup Language (SGML), and the Extensible Markup Language (XML). Both of these standards have advantages and disadvantages, and many advantages are shared.

SGML offers advantages which may appeal most to authors, especially those using ordinary text editors. There are also additional abilities to define content models. A number of high-quality tools with demonstrated maturity are available, but most are not free; for those which are, portability issues remain a problem.

The advantages of XML include the availability of a large number of evolving tools. Unfortunately, many of the associated standards are still evolving, and the tools will have to follow along. This means that developing a robust tool set that
uses more than the basic XML 1.0 recommendation is not possible in the short term. The promised availability of a wide variety of high-quality tools which support some of the most important related standards is not immediate. Many tools are likely to be free, and the portability issues of those which are, are not expected to be significant.

It turns out that converting to an XML or SGML system holds promise for translators as well; how much can be done to ease the burden on translators remains to be seen, and may have some impact on the schema and specific technologies used.

XXX Eventual migration to XML.

The documentation will be moved to XML in the future, and tools are being written which will convert the documentation from the current format to something close to a finished version, to the extent that the desired information is already present in the documentation. Some XSLT stylesheets have been started for presenting a preliminary XML version as HTML, but the results are fairly rough.

The timeframe for the conversion is not clear since there doesn't seem to be much time available to work on this, but the apparent benefits are growing more substantial at a moderately rapid pace.
9.2 Discussion Forums

Discussion of the future of the Python documentation and related topics takes place in the Documentation Special Interest Group, or `Doc-SIG." Information on the group, including mailing list archives and subscription information, is available at [http://www.python.org/sigs/doc-sig/](http://www.python.org/sigs/doc-sig/). The SIG is open to all interested parties.

Comments and bug reports on the standard documents should be sent to docs@python.org. This may include comments about formatting, content, grammatical and spelling errors, or this document. You can also send comments on this document directly to the author at fdrake@acm.org.
Abstract:
This document describes the Python Distribution Utilities (``Distutils'') from the
end-user's point-of-view, describing how to extend the capabilities of a standard
Python installation by building and installing third-party Python modules and
extensions.
6 Building Extensions: Tips and Tricks
   6.1 Tweaking compiler/linker flags
   6.2 Using non-Microsoft compilers on Windows
      ■ 6.2.1 Borland C++
      ■ 6.2.2 GNU C / Cygwin / MinGW

About this document...
Subsections

- 1.1 Best case: trivial installation
- 1.2 The new standard: Distutils
1 Introduction

Although Python's extensive standard library covers many programming needs, there often comes a time when you need to add some new functionality to your Python installation in the form of third-party modules. This might be necessary to support your own programming, or to support an application that you want to use and that happens to be written in Python.

In the past, there has been little support for adding third-party modules to an existing Python installation. With the introduction of the Python Distribution Utilities (Distutils for short) in Python 2.0, this changed.

This document is aimed primarily at the people who need to install third-party Python modules: end-users and system administrators who just need to get some Python application running, and existing Python programmers who want to add some new goodies to their toolbox. You don't need to know Python to read this document; there will be some brief forays into using Python's interactive mode to explore your installation, but that's it. If you're looking for information on how to distribute your own Python modules so that others may use them, see the \textit{Distributing Python Modules} manual.
1.1 Best case: trivial installation

In the best case, someone will have prepared a special version of the module distribution you want to install that is targeted specifically at your platform and is installed just like any other software on your platform. For example, the module developer might make an executable installer available for Windows users, an RPM package for users of RPM-based Linux systems (Red Hat, SuSE, Mandrake, and many others), a Debian package for users of Debian-based Linux systems, and so forth.

In that case, you would download the installer appropriate to your platform and do the obvious thing with it: run it if it's an executable installer, `rpm --install` it if it's an RPM, etc. You don't need to run Python or a setup script, you don't need to compile anything--you might not even need to read any instructions (although it's always a good idea to do so anyways).

Of course, things will not always be that easy. You might be interested in a module distribution that doesn't have an easy-to-use installer for your platform. In that case, you'll have to start with the source distribution released by the module's author/maintainer. Installing from a source distribution is not too hard, as long as the modules are packaged in the standard way. The bulk of this document is about building and installing modules from standard source distributions.
1.2 The new standard: Distutils

If you download a module source distribution, you can tell pretty quickly if it was packaged and distributed in the standard way, i.e. using the Distutils. First, the distribution's name and version number will be featured prominently in the name of the downloaded archive, e.g. foo-1.0.tar.gz or widget-0.9.7.zip. Next, the archive will unpack into a similarly-named directory: foo-1.0 or widget-0.9.7. Additionally, the distribution will contain a setup script setup.py, and a file named README.txt or possibly just README, which should explain that building and installing the module distribution is a simple matter of running

    python setup.py install

If all these things are true, then you already know how to build and install the modules you've just downloaded: Run the command above. Unless you need to install things in a non-standard way or customize the build process, you don't really need this manual. Or rather, the above command is everything you need to get out of this manual.
Subsections

- 2.1 Platform variations
- 2.2 Splitting the job up
- 2.3 How building works
- 2.4 How installation works
2 Standard Build and Install

As described in section 1.2, building and installing a module distribution using the Distutils is usually one simple command:

```python
python setup.py install
```

On UNIX, you'd run this command from a shell prompt; on Windows, you have to open a command prompt window (``DOS box'') and do it there; on Mac OS X, you open a Terminal window to get a shell prompt.
2.1 Platform variations

You should always run the setup command from the distribution root directory, i.e. the top-level subdirectory that the module source distribution unpacks into. For example, if you've just downloaded a module source distribution foo-1.0.tar.gz onto a UNIX system, the normal thing to do is:

```
    gunzip -c foo-1.0.tar.gz | tar xf -     # unpacks into directory foo-
    cd foo-1.0
    python setup.py install
```

On Windows, you'd probably download foo-1.0.zip. If you downloaded the archive file to C:\Temp, then it would unpack into C:\Temp\foo-1.0; you can use either a archive manipulator with a graphical user interface (such as WinZip) or a command-line tool (such as `unzip` or `pkunzip`) to unpack the archive. Then, open a command prompt window (``DOS box''), and run:

```
    cd c:\Temp\foo-1.0
    python setup.py install
```
2.2 Splitting the job up

Running `setup.py install` builds and installs all modules in one run. If you prefer to work incrementally--especially useful if you want to customize the build process, or if things are going wrong--you can use the setup script to do one thing at a time. This is particularly helpful when the build and install will be done by different users--for example, you might want to build a module distribution and hand it off to a system administrator for installation (or do it yourself, with super-user privileges).

For example, you can build everything in one step, and then install everything in a second step, by invoking the setup script twice:

```bash
  python setup.py build
  python setup.py install
```

If you do this, you will notice that running the `install` command first runs the `build` command, which--in this case--quickly notices that it has nothing to do, since everything in the `build` directory is up-to-date.

You may not need this ability to break things down often if all you do is install modules downloaded off the 'net, but it's very handy for more advanced tasks. If you get into distributing your own Python modules and extensions, you'll run lots of individual Distutils commands on their own.
2.3 How building works

As implied above, the build command is responsible for putting the files to install into a build directory. By default, this is build under the distribution root; if you're excessively concerned with speed, or want to keep the source tree pristine, you can change the build directory with the --build-base option. For example:

```bash
    python setup.py build --build-base=/tmp/pybuild/foo-1.0
```

(Or you could do this permanently with a directive in your system or personal Distutils configuration file; see section 5.) Normally, this isn't necessary.

The default layout for the build tree is as follows:

```plaintext
    --- build/ --- lib/
    or
    --- build/ --- lib.<plat>/
        temp.<plat>/
```

where `<plat>` expands to a brief description of the current OS/hardware platform and Python version. The first form, with just a lib directory, is used for "pure module distributions"--that is, module distributions that include only pure Python modules. If a module distribution contains any extensions (modules written in C/C++), then the second form, with two `<plat>` directories, is used. In that case, the temp.<plat> directory holds temporary files generated by the compile/link process that don't actually get installed. In either case, the lib (or lib.<plat>) directory contains all Python modules (pure Python and extensions) that will be installed.

In the future, more directories will be added to handle Python scripts, documentation, binary executables, and whatever else is needed to handle the job of installing Python modules and applications.
2.4 How installation works

After the build command runs (whether you run it explicitly, or the install command does it for you), the work of the install command is relatively simple: all it has to do is copy everything under build/lib (or build/lib.plat) to your chosen installation directory.

If you don't choose an installation directory--i.e., if you just run setup.py install--then the install command installs to the standard location for third-party Python modules. This location varies by platform and by how you built/installed Python itself. On UNIX (and Mac OS X, which is also UNIX-based), it also depends on whether the module distribution being installed is pure Python or contains extensions (``non-pure'')):

<table>
<thead>
<tr>
<th>Platform</th>
<th>Standard installation location</th>
<th>Default value</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>UNIX (pure)</td>
<td>prefix/lib/python2.5/site-packages</td>
<td>/usr/local/lib/python2.5/site-packages</td>
<td>(1)</td>
</tr>
<tr>
<td>UNIX (non-pure)</td>
<td>exec-prefix/lib/python2.5/site-packages</td>
<td>/usr/local/lib/python2.5/site-packages</td>
<td>(1)</td>
</tr>
<tr>
<td>Windows</td>
<td>prefix</td>
<td>C:\Python</td>
<td>(2)</td>
</tr>
</tbody>
</table>

Notes:

(1) Most Linux distributions include Python as a standard part of the system, so prefix and exec-prefix are usually both /usr on Linux. If you build Python yourself on Linux (or any UNIX-like system), the default prefix and exec-prefix are /usr/local.

(2) The default installation directory on Windows was C:\Program Files\Python under Python 1.6a1, 1.5.2, and earlier.

prefix and exec-prefix stand for the directories that Python is installed to, and where it finds its libraries at run-time. They are always the same under Windows, and very often the same under UNIX and Mac OS X. You can find out
what your Python installation uses for *prefix* and *exec-prefix* by running Python in interactive mode and typing a few simple commands. Under *Unix*, just type `python` at the shell prompt. Under Windows, choose `Start > Programs > Python 2.5 > Python (command line)`. Once the interpreter is started, you type Python code at the prompt. For example, on my Linux system, I type the three Python statements shown below, and get the output as shown, to find out my *prefix* and *exec-prefix*:

```python
Python 2.4 (#26, Aug 7 2004, 17:19:02)
Type "help", "copyright", "credits" or "license" for more informatio
>>> import sys
>>> sys.prefix
'/usr'
>>> sys.exec_prefix
'/usr'
```

If you don't want to install modules to the standard location, or if you don't have permission to write there, then you need to read about alternate installations in section 3. If you want to customize your installation directories more heavily, see section 4 on custom installations.
Subsections

- 3.1 Alternate installation: the home scheme
- 3.2 Alternate installation: UNIX (the prefix scheme)
- 3.3 Alternate installation: Windows (the prefix scheme)
3 Alternate Installation

Often, it is necessary or desirable to install modules to a location other than the standard location for third-party Python modules. For example, on a UNIX system you might not have permission to write to the standard third-party module directory. Or you might wish to try out a module before making it a standard part of your local Python installation. This is especially true when upgrading a distribution already present: you want to make sure your existing base of scripts still works with the new version before actually upgrading.

The Distutils install command is designed to make installing module distributions to an alternate location simple and painless. The basic idea is that you supply a base directory for the installation, and the install command picks a set of directories (called an installation scheme) under this base directory in which to install files. The details differ across platforms, so read whichever of the following sections applies to you.
3.1 Alternate installation: the home scheme

The idea behind the ``home scheme'' is that you build and maintain a personal stash of Python modules. This scheme's name is derived from the idea of a ``home'' directory on UNIX, since it's not unusual for a UNIX user to make their home directory have a layout similar to /usr/ or /usr/local/. This scheme can be used by anyone, regardless of the operating system their installing for.

Installing a new module distribution is as simple as

```
python setup.py install --home=<dir>
```

where you can supply any directory you like for the --home option. On UNIX, lazy typists can just type a tilde (~); the install command will expand this to your home directory:

```
python setup.py install --home=~
```

The --home option defines the installation base directory. Files are installed to the following directories under the installation base as follows:

<table>
<thead>
<tr>
<th>Type of file</th>
<th>Installation Directory</th>
<th>Override option</th>
</tr>
</thead>
<tbody>
<tr>
<td>pure module distribution</td>
<td>home/lib/python</td>
<td>--install-purelib</td>
</tr>
<tr>
<td>non-pure module distribution</td>
<td>home/lib/python</td>
<td>--install-platlib</td>
</tr>
<tr>
<td>scripts</td>
<td>home/bin</td>
<td>--install-scripts</td>
</tr>
<tr>
<td>data</td>
<td>home/share</td>
<td>--install-data</td>
</tr>
</tbody>
</table>

Changed in version 2.4: The --home option used to be supported only on UNIX.
3.2 Alternate installation: UNIX (the prefix scheme)

The ``prefix scheme'' is useful when you wish to use one Python installation to perform the build/install (i.e., to run the setup script), but install modules into the third-party module directory of a different Python installation (or something that looks like a different Python installation). If this sounds a trifle unusual, it is—that's why the ``home scheme'' comes first. However, there are at least two known cases where the prefix scheme will be useful.

First, consider that many Linux distributions put Python in /usr, rather than the more traditional /usr/local. This is entirely appropriate, since in those cases Python is part of ``the system'' rather than a local add-on. However, if you are installing Python modules from source, you probably want them to go in /usr/local/lib/python2.X rather than /usr/lib/python2.X. This can be done with

```
/usr/bin/python setup.py install --prefix=/usr/local
```

Another possibility is a network filesystem where the name used to write to a remote directory is different from the name used to read it: for example, the Python interpreter accessed as /usr/local/bin/python might search for modules in /usr/local/lib/python2.X, but those modules would have to be installed to, say, /mnt/@server/export/lib/python2.X. This could be done with

```
/usr/local/bin/python setup.py install --prefix=/mnt/@server/export
```

In either case, the --prefix option defines the installation base, and the --exec-prefix option defines the platform-specific installation base, which is used for platform-specific files. (Currently, this just means non-pure module distributions, but could be expanded to C libraries, binary executables, etc.) If --exec-prefix is not supplied, it defaults to --prefix. Files are installed as follows:

<table>
<thead>
<tr>
<th>Type of file</th>
<th>Installation Directory</th>
<th>Override option</th>
</tr>
</thead>
<tbody>
<tr>
<td>pure module distribution</td>
<td>prefix/lib/python2.X/site-packages</td>
<td>--install-purelib</td>
</tr>
<tr>
<td>non-pure module distribution</td>
<td>exec-prefix/lib/python2.X/site-packages</td>
<td>--install-platlib</td>
</tr>
<tr>
<td>scripts</td>
<td>prefix/bin</td>
<td>--install-scripts</td>
</tr>
<tr>
<td>------------------</td>
<td>----------------</td>
<td>--------------------</td>
</tr>
<tr>
<td>data</td>
<td>prefix/share</td>
<td>--install-data</td>
</tr>
</tbody>
</table>

There is no requirement that `--prefix` or `--exec-prefix` actually point to an alternate Python installation; if the directories listed above do not already exist, they are created at installation time.

Incidentally, the real reason the prefix scheme is important is simply that a standard UNIX installation uses the prefix scheme, but with `--prefix` and `--exec-prefix` supplied by Python itself as `sys.prefix` and `sys.exec_prefix`. Thus, you might think you'll never use the prefix scheme, but every time you run `python setup.py install` without any other options, you're using it.

Note that installing extensions to an alternate Python installation has no effect on how those extensions are built: in particular, the Python header files (`Python.h` and friends) installed with the Python interpreter used to run the setup script will be used in compiling extensions. It is your responsibility to ensure that the interpreter used to run extensions installed in this way is compatible with the interpreter used to build them. The best way to do this is to ensure that the two interpreters are the same version of Python (possibly different builds, or possibly copies of the same build). (Of course, if your `--prefix` and `--exec-prefix` don't even point to an alternate Python installation, this is immaterial.)
3.3 Alternate installation: Windows (the prefix scheme)

Windows has no concept of a user's home directory, and since the standard Python installation under Windows is simpler than under UNIX, the `--prefix` option has traditionally been used to install additional packages in separate locations on Windows.

```
python setup.py install --prefix="\Temp\Python"
```

to install modules to the `\Temp\Python` directory on the current drive.

The installation base is defined by the `--prefix` option; the `--exec-prefix` option is not supported under Windows. Files are installed as follows:

<table>
<thead>
<tr>
<th>Type of file</th>
<th>Installation Directory</th>
<th>Override option</th>
</tr>
</thead>
<tbody>
<tr>
<td>pure module distribution</td>
<td><code>prefix</code></td>
<td><code>--install-purelib</code></td>
</tr>
<tr>
<td>non-pure module distribution</td>
<td><code>prefix</code></td>
<td><code>--install-platlib</code></td>
</tr>
<tr>
<td>scripts</td>
<td><code>prefix\Scripts</code></td>
<td><code>--install-scripts</code></td>
</tr>
<tr>
<td>data</td>
<td><code>prefix\Data</code></td>
<td><code>--install-data</code></td>
</tr>
</tbody>
</table>

- 4.1 Modifying Python's Search Path
4 Custom Installation

Sometimes, the alternate installation schemes described in section 3 just don't do what you want. You might want to tweak just one or two directories while keeping everything under the same base directory, or you might want to completely redefine the installation scheme. In either case, you're creating a custom installation scheme.

You probably noticed the column of "override options" in the tables describing the alternate installation schemes above. Those options are how you define a custom installation scheme. These override options can be relative, absolute, or explicitly defined in terms of one of the installation base directories. (There are two installation base directories, and they are normally the same--they only differ when you use the UNIX "prefix scheme" and supply different --prefix and --exec-prefix options.)

For example, say you're installing a module distribution to your home directory under UNIX--but you want scripts to go in ~/scripts rather than ~/bin. As you might expect, you can override this directory with the --install-scripts option; in this case, it makes most sense to supply a relative path, which will be interpreted relative to the installation base directory (your home directory, in this case):

```
python setup.py install --home=~ --install-scripts=scripts
```

Another UNIX example: suppose your Python installation was built and installed with a prefix of /usr/local/python, so under a standard installation scripts will wind up in /usr/local/python/bin. If you want them in /usr/local/bin instead, you would supply this absolute directory for the --install-scripts option:

```
python setup.py install --install-scripts=/usr/local/bin
```

(This performs an installation using the "prefix scheme," where the prefix is whatever your Python interpreter was installed with-- /usr/local/python in this case.)

If you maintain Python on Windows, you might want third-party modules to live in a subdirectory of prefix, rather than right in prefix itself. This is almost as easy as customizing the script installation directory--you just have to remember
that there are two types of modules to worry about, pure modules and non-pure modules (i.e., modules from a non-pure distribution). For example:

```
python setup.py install --install-purelib=Site --install-platlib=Site
```

The specified installation directories are relative to `prefix`. Of course, you also have to ensure that these directories are in Python's module search path, such as by putting a `.pth` file in `prefix`. See section 4.1 to find out how to modify Python's search path.

If you want to define an entire installation scheme, you just have to supply all of the installation directory options. The recommended way to do this is to supply relative paths; for example, if you want to maintain all Python module-related files under `python` in your home directory, and you want a separate directory for each platform that you use your home directory from, you might define the following installation scheme:

```
python setup.py install --home=~
   --install-purelib=python/lib 
   --install-platlib=python/lib.$PLAT 
   --install-scripts=python/scripts
   --install-data=python/data
```

or, equivalently,

```
python setup.py install --home=~/python
   --install-purelib=lib 
   --install-platlib='lib.$PLAT' 
   --install-scripts=scripts
   --install-data=data
```

$PLAT is not (necessarily) an environment variable--it will be expanded by the Distutils as it parses your command line options, just as it does when parsing your configuration file(s).

Obviously, specifying the entire installation scheme every time you install a new module distribution would be very tedious. Thus, you can put these options into your Distutils config file (see section 5):

```
[install]
install-base=$HOME
install-purelib=python/lib
install-platlib=python/lib.$PLAT
install-scripts=python/scripts
```
install-data=python/data

or, equivalently,

[install]
install-base=$HOME/python
install-purelib=lib
install-platlib=lib.$PLAT
install-scripts=scripts
install-data=data

Note that these two are not equivalent if you supply a different installation base directory when you run the setup script. For example,

python setup.py --install-base=/tmp

would install pure modules to /tmp/python/lib in the first case, and to /tmp/lib in the second case. (For the second case, you probably want to supply an installation base of /tmp/python.)

You probably noticed the use of $HOME and $PLAT in the sample configuration file input. These are Distutils configuration variables, which bear a strong resemblance to environment variables. In fact, you can use environment variables in config files on platforms that have such a notion but the Distutils additionally define a few extra variables that may not be in your environment, such as $PLAT. (And of course, on systems that don't have environment variables, such as Mac OS 9, the configuration variables supplied by the Distutils are the only ones you can use.) See section 5 for details.
4.1 Modifying Python's Search Path

When the Python interpreter executes an import statement, it searches for both Python code and extension modules along a search path. A default value for the path is configured into the Python binary when the interpreter is built. You can determine the path by importing the sys module and printing the value of sys.path.

```
$ python
[GCC 2.96 20000731 (Red Hat Linux 7.3 2.96-112)] on linux2
Type `''help'', `''copyright'', `''credits'' or `''license'' for more in
>>> import sys
>>> sys.path
['', '/usr/local/lib/python2.3', '/usr/local/lib/python2.3/plat-linux2'
'/usr/local/lib/python2.3/lib-tk', '/usr/local/lib/python2.3/lib-dynload'
'/usr/local/lib/python2.3/site-packages']
>>> 
```

The null string in sys.path represents the current working directory.

The expected convention for locally installed packages is to put them in the .../site-packages/ directory, but you may want to install Python modules into some arbitrary directory. For example, your site may have a convention of keeping all software related to the web server under /www. Add-on Python modules might then belong in /www/python, and in order to import them, this directory must be added to sys.path. There are several different ways to add the directory.

The most convenient way is to add a path configuration file to a directory that's already on Python's path, usually to the .../site-packages/ directory. Path configuration files have an extension of .pth, and each line must contain a single path that will be appended to sys.path. (Because the new paths are appended to sys.path, modules in the added directories will not override standard modules. This means you can't use this mechanism for installing fixed versions of standard modules.)

Paths can be absolute or relative, in which case they're relative to the directory containing the .pth file. Any directories added to the search path will be scanned in turn for .pth files. See site module documentation for more information.
A slightly less convenient way is to edit the site.py file in Python's standard library, and modify sys.path. site.py is automatically imported when the Python interpreter is executed, unless the -S switch is supplied to suppress this behaviour. So you could simply edit site.py and add two lines to it:

```python
import sys
sys.path.append('/www/python/)
```

However, if you reinstall the same major version of Python (perhaps when upgrading from 2.2 to 2.2.2, for example) site.py will be overwritten by the stock version. You'd have to remember that it was modified and save a copy before doing the installation.

There are two environment variables that can modify sys.path. PYTHONHOME sets an alternate value for the prefix of the Python installation. For example, if PYTHONHOME is set to "/www/python", the search path will be set to ['', '/www/python/lib/python2.5/', '/www/python/lib/python2.5/plat-linux2', ...].

The PYTHONPATH variable can be set to a list of paths that will be added to the beginning of sys.path. For example, if PYTHONPATH is set to "/www/python:/opt/py", the search path will begin with ['/www/python', '/opt/py']. (Note that directories must exist in order to be added to sys.path; the site module removes paths that don't exist.)

Finally, sys.path is just a regular Python list, so any Python application can modify it by adding or removing entries.
Subsections

- 5.1 Location and names of config files
- 5.2 Syntax of config files
As mentioned above, you can use Distutils configuration files to record personal or site preferences for any Distutils options. That is, any option to any command can be stored in one of two or three (depending on your platform) configuration files, which will be consulted before the command-line is parsed. This means that configuration files will override default values, and the command-line will in turn override configuration files. Furthermore, if multiple configuration files apply, values from ``earlier'' files are overridden by ``later'' files.
5.1 Location and names of config files

The names and locations of the configuration files vary slightly across platforms. On UNIX and Mac OS X, the three configuration files (in the order they are processed) are:

<table>
<thead>
<tr>
<th>Type of file</th>
<th>Location and filename</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>system</td>
<td>prefix/lib/pythonver/distutils/distutils.cfg</td>
<td>(1)</td>
</tr>
<tr>
<td>personal</td>
<td>$HOME/.pydistutils.cfg</td>
<td>(2)</td>
</tr>
<tr>
<td>local</td>
<td>setup.cfg</td>
<td>(3)</td>
</tr>
</tbody>
</table>

And on Windows, the configuration files are:

<table>
<thead>
<tr>
<th>Type of file</th>
<th>Location and filename</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>system</td>
<td>prefix\Lib\distutils\distutils.cfg</td>
<td>(4)</td>
</tr>
<tr>
<td>personal</td>
<td>%HOME%\pydistutils.cfg</td>
<td>(5)</td>
</tr>
<tr>
<td>local</td>
<td>setup.cfg</td>
<td>(3)</td>
</tr>
</tbody>
</table>

Notes:

(1) Strictly speaking, the system-wide configuration file lives in the directory where the Distutils are installed; under Python 1.6 and later on UNIX, this is as shown. For Python 1.5.2, the Distutils will normally be installed to prefix/lib/python1.5/site-packages/distutils, so the system configuration file should be put there under Python 1.5.2.

(2) On UNIX, if the HOME environment variable is not defined, the user's home directory will be determined with the getpwuid() function from the standard pwd module.

(3) I.e., in the current directory (usually the location of the setup script).

(4) (See also note (1).) Under Python 1.6 and later, Python's default "installation prefix" is C:\Python, so the system configuration file is normally C:\Python\Lib\distutils\distutils.cfg. Under Python 1.5.2, the
default prefix was *C:\Program Files\Python*, and the Distutils were not part of the standard library--so the system configuration file would be *C:\Program Files\Python\distutils\distutils.cfg* in a standard Python 1.5.2 installation under Windows.

(5) On Windows, if the HOME environment variable is not defined, no personal configuration file will be found or used. (In other words, the Distutils make no attempt to guess your home directory on Windows.)
5.2 Syntax of config files

The Distutils configuration files all have the same syntax. The config files are grouped into sections. There is one section for each Distutils command, plus a global section for global options that affect every command. Each section consists of one option per line, specified as option=value.

For example, the following is a complete config file that just forces all commands to run quietly by default:

```
[global]
verbose=0
```

If this is installed as the system config file, it will affect all processing of any Python module distribution by any user on the current system. If it is installed as your personal config file (on systems that support them), it will affect only module distributions processed by you. And if it is used as the setup.cfg for a particular module distribution, it affects only that distribution.

You could override the default `"build base" directory and make the `build* commands always forcibly rebuild all files with the following:

```
[build]
build-base=blib
force=1
```

which corresponds to the command-line arguments

```
python setup.py build --build-base=blib --force
```

except that including the build command on the command-line means that command will be run. Including a particular command in config files has no such implication; it only means that if the command is run, the options in the config file will apply. (Or if other commands that derive values from it are run, they will use the values in the config file.)

You can find out the complete list of options for any command using the --help option, e.g.:

```
python setup.py build --help
```
and you can find out the complete list of global options by using --help without a command:

    python setup.py --help

6 Building Extensions: Tips and Tricks

Whenever possible, the Distutils try to use the configuration information made available by the Python interpreter used to run the setup.py script. For example, the same compiler and linker flags used to compile Python will also be used for compiling extensions. Usually this will work well, but in complicated situations this might be inappropriate. This section discusses how to override the usual Distutils behaviour.
### 6.1 Tweaking compiler/linker flags

Compiling a Python extension written in C or C++ will sometimes require specifying custom flags for the compiler and linker in order to use a particular library or produce a special kind of object code. This is especially true if the extension hasn't been tested on your platform, or if you're trying to cross-compile Python.

In the most general case, the extension author might have foreseen that compiling the extensions would be complicated, and provided a `Setup` file for you to edit. This will likely only be done if the module distribution contains many separate extension modules, or if they often require elaborate sets of compiler flags in order to work.

A `Setup` file, if present, is parsed in order to get a list of extensions to build. Each line in a `Setup` describes a single module. Lines have the following structure:

```
module ... [sourcefile ...] [cpparg ...] [library ...]
```

Let's examine each of the fields in turn.

- **module** is the name of the extension module to be built, and should be a valid Python identifier. You can't just change this in order to rename a module (edits to the source code would also be needed), so this should be left alone.

- **sourcefile** is anything that's likely to be a source code file, at least judging by the filename. Filenames ending in `.c` are assumed to be written in C, filenames ending in `.C`, `.cc`, and `.c++` are assumed to be C++, and filenames ending in `.m` or `.mm` are assumed to be in Objective C.

- **cpparg** is an argument for the C preprocessor, and is anything starting with `-I`, `-D`, `-U` or `-C`.

- **library** is anything ending in `.a` or beginning with `-l` or `-L`. 

If a particular platform requires a special library on your platform, you can add it by editing the Setup file and running `python setup.py build`. For example, if the module defined by the line

```python
foo foomodule.c
```

must be linked with the math library `libm.a` on your platform, simply add `-lm` to the line:

```bash
foo foomodule.c -lm
```

Arbitrary switches intended for the compiler or the linker can be supplied with the `-Xcompiler arg` and `-Xlinker arg` options:

```bash
foo foomodule.c -Xcompiler -o32 -Xlinker -shared -lm
```

The next option after `-Xcompiler` and `-Xlinker` will be appended to the proper command line, so in the above example the compiler will be passed the `-o32` option, and the linker will be passed `-shared`. If a compiler option requires an argument, you'll have to supply multiple `-Xcompiler` options; for example, to pass `-x c++` the Setup file would have to contain `-Xcompiler -x - Xcompiler c++`.

Compiler flags can also be supplied through setting the `CFLAGS` environment variable. If set, the contents of `CFLAGS` will be added to the compiler flags specified in the Setup file.
6.2 Using non-Microsoft compilers on Windows

6.2.1 Borland C++

This subsection describes the necessary steps to use Distutils with the Borland C++ compiler version 5.5.

First you have to know that Borland's object file format (OMF) is different from the format used by the Python version you can download from the Python or ActiveState Web site. (Python is built with Microsoft Visual C++, which uses COFF as the object file format.) For this reason you have to convert Python's library python25.lib into the Borland format. You can do this as follows:

```
coff2omf python25.lib python25_bcpp.lib
```

The `coff2omf` program comes with the Borland compiler. The file `python25.lib` is in the `Libs` directory of your Python installation. If your extension uses other libraries (zlib,...) you have to convert them too.

The converted files have to reside in the same directories as the normal libraries.

How does Distutils manage to use these libraries with their changed names? If the extension needs a library (eg. foo) Distutils checks first if it finds a library with suffix _bcpp (eg. foo_bcpp.lib) and then uses this library. In the case it doesn't find such a special library it uses the default name (foo.lib.).

To let Distutils compile your extension with Borland C++ you now have to type:

```
python setup.py build --compiler=bcpp
```

If you want to use the Borland C++ compiler as the default, you could specify this in your personal or system-wide configuration file for Distutils (see section 5.)

See Also:

[C++Builder Compiler]
6.2.2 GNU C / Cygwin / MinGW

These instructions only apply if you're using a version of Python prior to 2.4.1 with a MinGW prior to 3.0.0 (with binutils-2.13.90-20030111-1).

This section describes the necessary steps to use Distutils with the GNU C/C++ compilers in their Cygwin and MinGW distributions. For a Python interpreter that was built with Cygwin, everything should work without any of these following steps.

These compilers require some special libraries. This task is more complex than for Borland's C++, because there is no program to convert the library.

First you have to create a list of symbols which the Python DLL exports. (You can find a good program for this task at http://starship.python.net/crew/kernr/mingw32/Notes.html, see at PExports 0.42h there.)

```
pexports python25.dll >python25.def
```

The location of an installed python25.dll will depend on the installation options and the version and language of Windows. In a ``just for me'' installation, it will appear in the root of the installation directory. In a shared installation, it will be located in the system directory.

Then you can create from these information an import library for gcc.

```
/cygwin/bin/dlltool --dllname python25.dll --def python25.def --outp
```

The resulting library has to be placed in the same directory as python25.lib. (Should be the libs directory under your Python installation directory.)
If your extension uses other libraries (zlib,...) you might have to convert them too. The converted files have to reside in the same directories as the normal libraries do.

To let Distutils compile your extension with Cygwin you now have to type

```
python setup.py build --compiler=cygwin
```

and for Cygwin in no-cygwin mode\(^3\) or for MinGW type:

```
python setup.py build --compiler=mingw32
```

If you want to use any of these options/compilers as default, you should consider to write it in your personal or system-wide configuration file for Distutils (see section \(^5\)).

... mode

Then you have no POSIX emulation available, but you also don't need cygwin1.dll.
About the Python Documentation

The Python documentation was originally written by Guido van Rossum, but has increasingly become a community effort over the past several years. This growing collection of documents is available in several formats, including typeset versions in PDF and PostScript for printing, from the Python Web site.

A list of contributors is available.
Comments and Questions

General comments and questions regarding this document should be sent by email to docs@python.org. If you find specific errors in this document, please report the bug at the Python Bug Tracker at SourceForge. If you are able to provide suggested text, either to replace existing incorrect or unclear material, or additional text to supplement what's already available, we'd appreciate the contribution. There's no need to worry about text markup; our documentation team will gladly take care of that.

Questions regarding how to use the information in this document should be sent to the Python news group, comp.lang.python, or the Python mailing list (which is gated to the newsgroup and carries the same content).

For any of these channels, please be sure not to send HTML email. Thanks.
Abstract:

This document describes the Python Distribution Utilities (``Distutils'') from the module developer's point of view, describing how to use the Distutils to make Python modules and extensions easily available to a wider audience with very little overhead for build/release/install mechanics.

**Distributing Python Modules**

Up: Python Documentation Index  Next: 1. An Introduction to

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
1. An Introduction to Distutils

This document covers using the Distutils to distribute your Python modules, concentrating on the role of developer/distributor: if you're looking for information on installing Python modules, you should refer to the Installing Python Modules manual.

Subsections

- 1.1 Concepts & Terminology
- 1.2 A Simple Example
- 1.3 General Python terminology
- 1.4 Distutils-specific terminology

Release 2.5, documentation updated on 19th September, 2006. See About this document... for information on suggesting changes.
1.1 Concepts & Terminology

Using the Distutils is quite simple, both for module developers and for users/administrators installing third-party modules. As a developer, your responsibilities (apart from writing solid, well-documented and well-tested code, of course!) are:

- write a setup script (setup.py by convention)
- (optional) write a setup configuration file
- create a source distribution
- (optional) create one or more built (binary) distributions

Each of these tasks is covered in this document.

Not all module developers have access to a multitude of platforms, so it's not always feasible to expect them to create a multitude of built distributions. It is hoped that a class of intermediaries, called *packagers*, will arise to address this need. Packagers will take source distributions released by module developers, build them on one or more platforms, and release the resulting built distributions. Thus, users on the most popular platforms will be able to install most popular Python module distributions in the most natural way for their platform, without having to run a single setup script or compile a line of code.
1.2 A Simple Example

The setup script is usually quite simple, although since it's written in Python, there are no arbitrary limits to what you can do with it, though you should be careful about putting arbitrarily expensive operations in your setup script. Unlike, say, Autoconf-style configure scripts, the setup script may be run multiple times in the course of building and installing your module distribution.

If all you want to do is distribute a module called `foo`, contained in a file `foo.py`, then your setup script can be as simple as this:

```python
from distutils.core import setup
setup(name='foo',
      version='1.0',
      py_modules=['foo'],
)
```

Some observations:

- most information that you supply to the Distutils is supplied as keyword arguments to the `setup()` function
- those keyword arguments fall into two categories: package metadata (name, version number) and information about what's in the package (a list of pure Python modules, in this case)
- modules are specified by module name, not filename (the same will hold true for packages and extensions)
- it's recommended that you supply a little more metadata, in particular your name, email address and a URL for the project (see section 2 for an example)

To create a source distribution for this module, you would create a setup script, `setup.py`, containing the above code, and run:

```bash
python setup.py sdist
```

which will create an archive file (e.g., tarball on UNIX, ZIP file on Windows) containing your setup script `setup.py`, and your module `foo.py`. The archive file will be named `foo-1.0.tar.gz` (or `.zip`), and will unpack into a directory `foo-1.0`. 
If an end-user wishes to install your foo module, all she has to do is download foo-1.0.tar.gz (or .zip), unpack it, and--from the foo-1.0 directory--run

```
python setup.py install
```

which will ultimately copy foo.py to the appropriate directory for third-party modules in their Python installation.

This simple example demonstrates some fundamental concepts of the Distutils. First, both developers and installers have the same basic user interface, i.e. the setup script. The difference is which Distutils commands they use: the sdist command is almost exclusively for module developers, while install is more often for installers (although most developers will want to install their own code occasionally).

If you want to make things really easy for your users, you can create one or more built distributions for them. For instance, if you are running on a Windows machine, and want to make things easy for other Windows users, you can create an executable installer (the most appropriate type of built distribution for this platform) with the bdist_wininst command. For example:

```
python setup.py bdist_wininst
```

will create an executable installer, foo-1.0.win32.exe, in the current directory.

Other useful built distribution formats are RPM, implemented by the bdist_rpm command, Solaris pkgtool (bdist_pkgtool), and HP-UX swinstall (bdist_sdux). For example, the following command will create an RPM file called foo-1.0.noarch.rpm:

```
python setup.py bdist_rpm
```

(The bdist_rpm command uses the rpm executable, therefore this has to be run on an RPM-based system such as Red Hat Linux, SuSE Linux, or Mandrake Linux.)

You can find out what distribution formats are available at any time by running

```
python setup.py bdist --help-formats
```
Distributing Python Modules

Previous: 1.1 Concepts & Terminology  Up: 1. An Introduction to  Next: 1.3
General Python terminology

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
1.3 General Python terminology

If you're reading this document, you probably have a good idea of what modules, extensions, and so forth are. Nevertheless, just to be sure that everyone is operating from a common starting point, we offer the following glossary of common Python terms:

**module**
the basic unit of code reusability in Python: a block of code imported by some other code. Three types of modules concern us here: pure Python modules, extension modules, and packages.

**pure Python module**
a module written in Python and contained in a single .py file (and possibly associated .pyc and/or .pyo files). Sometimes referred to as a ``pure module.''

**extension module**
a module written in the low-level language of the Python implementation: C/C++ for Python, Java for Jython. Typically contained in a single dynamically loadable pre-compiled file, e.g. a shared object (.so) file for Python extensions on UNIX, a DLL (given the .pyd extension) for Python extensions on Windows, or a Java class file for Jython extensions. (Note that currently, the Distutils only handles C/C++ extensions for Python.)

**package**
a module that contains other modules; typically contained in a directory in the filesystem and distinguished from other directories by the presence of a file __init__.py.

**root package**
the root of the hierarchy of packages. (This isn't really a package, since it doesn't have an __init__.py file. But we have to call it something.) The vast majority of the standard library is in the root package, as are many small, standalone third-party modules that don't belong to a larger module collection. Unlike regular packages, modules in the root package can be found in many directories: in fact, every directory listed in sys.path
contributes modules to the root package.
1.4 Distutils-specific terminology

The following terms apply more specifically to the domain of distributing Python modules using the Distutils:

**module distribution**

A collection of Python modules distributed together as a single downloadable resource and meant to be installed *en masse*. Examples of some well-known module distributions are Numeric Python, PyXML, PIL (the Python Imaging Library), or mxBase. (This would be called a *package*, except that term is already taken in the Python context: a single module distribution may contain zero, one, or many Python packages.)

**pure module distribution**

A module distribution that contains only pure Python modules and packages. Sometimes referred to as a ``pure distribution."

**non-pure module distribution**

A module distribution that contains at least one extension module. Sometimes referred to as a ``non-pure distribution."

**distribution root**

The top-level directory of your source tree (or source distribution); the directory where *setup.py* exists. Generally *setup.py* will be run from this directory.

---

*Previous:* 1.3 General Python terminology  *Up:* 1. An Introduction to  *Next:* 2. Writing the Setup

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
2. Writing the Setup Script

The setup script is the centre of all activity in building, distributing, and installing modules using the Distutils. The main purpose of the setup script is to describe your module distribution to the Distutils, so that the various commands that operate on your modules do the right thing. As we saw in section 1.2 above, the setup script consists mainly of a call to setup(), and most information supplied to the Distutils by the module developer is supplied as keyword arguments to setup().

Here's a slightly more involved example, which we'll follow for the next couple of sections: the Distutils' own setup script. (Keep in mind that although the Distutils are included with Python 1.6 and later, they also have an independent existence so that Python 1.5.2 users can use them to install other module distributions. The Distutils' own setup script, shown here, is used to install the package into Python 1.5.2.)

```python
#!/usr/bin/env python

from distutils.core import setup

setup(name='Distutils',
      version='1.0',
      description='Python Distribution Utilities',
      author='Greg Ward',
      author_email='gward@python.net',
      url='http://www.python.org/sigs/distutils-sig/',
      packages=['distutils', 'distutils.command'],
)
```

There are only two differences between this and the trivial one-file distribution presented in section 1.2: more metadata, and the specification of pure Python modules by package, rather than by module. This is important since the Distutils consist of a couple of dozen modules split into (so far) two packages; an explicit list of every module would be tedious to generate and difficult to maintain. For more information on the additional meta-data, see section 2.8.

Note that any pathnames (files or directories) supplied in the setup script should be written using the UNIX convention, i.e. slash-separated. The Distutils will take care of converting this platform-neutral representation into whatever is
appropriate on your current platform before actually using the pathname. This makes your setup script portable across operating systems, which of course is one of the major goals of the Distutils. In this spirit, all pathnames in this document are slash-separated. (Mac OS 9 programmers should keep in mind that the absence of a leading slash indicates a relative path, the opposite of the Mac OS convention with colons.)

This, of course, only applies to pathnames given to Distutils functions. If you, for example, use standard Python functions such as `glob.glob()` or `os.listdir()` to specify files, you should be careful to write portable code instead of hardcoding path separators:

```python
glob.glob(os.path.join('mydir', 'subdir', '*.html'))
o.listdir(os.path.join('mydir', 'subdir'))
```

2.1 Listing whole packages

The packages option tells the Distutils to process (build, distribute, install, etc.) all pure Python modules found in each package mentioned in the packages list. In order to do this, of course, there has to be a correspondence between package names and directories in the filesystem. The default correspondence is the most obvious one, i.e. package distutils is found in the directory distutils relative to the distribution root. Thus, when you say packages = ['foo'] in your setup script, you are promising that the Distutils will find a file foo/__init__.py (which might be spelled differently on your system, but you get the idea) relative to the directory where your setup script lives. If you break this promise, the Distutils will issue a warning but still process the broken package anyways.

If you use a different convention to lay out your source directory, that's no problem: you just have to supply the package_dir option to tell the Distutils about your convention. For example, say you keep all Python source under lib, so that modules in the "root package" (i.e., not in any package at all) are in lib, modules in the foo package are in lib/foo, and so forth. Then you would put

```
package_dir = {'': 'lib'}
```

in your setup script. The keys to this dictionary are package names, and an empty package name stands for the root package. The values are directory names relative to your distribution root. In this case, when you say packages = ['foo'], you are promising that the file lib/foo/__init__.py exists.

Another possible convention is to put the foo package right in lib, the foo.bar package in lib/bar, etc. This would be written in the setup script as

```
package_dir = {'foo': 'lib'}
```

A package: dir entry in the package_dir dictionary implicitly applies to all packages below package, so the foo.bar case is automatically handled here. In this example, having packages = ['foo', 'foo.bar'] tells the Distutils to look for lib/__init__.py and lib/bar/__init__.py. (Keep in mind that although package_dir applies recursively, you must explicitly list all packages in packages: the Distutils will not recursively scan your source tree looking for
any directory with an __init__.py file.)
2.2 Listing individual modules

For a small module distribution, you might prefer to list all modules rather than listing packages--especially the case of a single module that goes in the ``root package'' (i.e., no package at all). This simplest case was shown in section 1.2; here is a slightly more involved example:

   py_modules = ['mod1', 'pkg.mod2']

This describes two modules, one of them in the ``root'' package, the other in the pkg package. Again, the default package/directory layout implies that these two modules can be found in mod1.py and pkg/mod2.py, and that pkg/__init__.py exists as well. And again, you can override the package/directory correspondence using the package_dir option.
Subsections

- 2.3.1 Extension names and packages
- 2.3.2 Extension source files
- 2.3.3 Preprocessor options
- 2.3.4 Library options
- 2.3.5 Other options
2.3 Describing extension modules

Just as writing Python extension modules is a bit more complicated than writing pure Python modules, describing them to the Distutils is a bit more complicated. Unlike pure modules, it's not enough just to list modules or packages and expect the Distutils to go out and find the right files; you have to specify the extension name, source file(s), and any compile/link requirements (include directories, libraries to link with, etc.).

All of this is done through another keyword argument to setup(), the ext_modules option. ext_modules is just a list of Extension instances, each of which describes a single extension module. Suppose your distribution includes a single extension, called foo and implemented by foo.c. If no additional instructions to the compiler/linker are needed, describing this extension is quite simple:

```
Extension('foo', ['foo.c'])
```

The Extension class can be imported from distutils.core along with setup(). Thus, the setup script for a module distribution that contains only this one extension and nothing else might be:

```
from distutils.core import setup, Extension
setup(name='foo',
       version='1.0',
       ext_modules=[Extension('foo', ['foo.c'])],
)
```

The Extension class (actually, the underlying extension-building machinery implemented by the build_ext command) supports a great deal of flexibility in describing Python extensions, which is explained in the following sections.
2.3.1 Extension names and packages

The first argument to the \texttt{Extension} constructor is always the name of the extension, including any package names. For example,

\begin{verbatim}
    Extension('foo', ['src/foo1.c', 'src/foo2.c'])
\end{verbatim}

describes an extension that lives in the root package, while

\begin{verbatim}
    Extension('pkg.foo', ['src/foo1.c', 'src/foo2.c'])
\end{verbatim}

describes the same extension in the \texttt{pkg} package. The source files and resulting object code are identical in both cases; the only difference is where in the filesystem (and therefore where in Python's namespace hierarchy) the resulting extension lives.

If you have a number of extensions all in the same package (or all under the same base package), use the \texttt{ext\_package} keyword argument to \texttt{setup(\)}. For example,

\begin{verbatim}
    setup(...
        ext\_package='pkg',
        ext\_modules=[Extension('foo', ['foo.c']),
                       Extension('subpkg.bar', ['bar.c'])],
    )
\end{verbatim}

will compile \texttt{foo.c} to the extension \texttt{pkg.foo}, and \texttt{bar.c} to \texttt{pkg.subpkg.bar}.
2.3.2 Extension source files

The second argument to the `Extension` constructor is a list of source files. Since the Distutils currently only support C, C++, and Objective-C extensions, these are normally C/C++/Objective-C source files. (Be sure to use appropriate extensions to distinguish C++ source files: `.cc` and `.cpp` seem to be recognized by both UNIX and Windows compilers.)

However, you can also include SWIG interface (.i) files in the list; the `build_ext` command knows how to deal with SWIG extensions: it will run SWIG on the interface file and compile the resulting C/C++ file into your extension.

**SWIG support is rough around the edges and largely untested; especially SWIG support for C++ extensions! Explain in more detail here when the interface firms up.**

On some platforms, you can include non-source files that are processed by the compiler and included in your extension. Currently, this just means Windows message text (.mc) files and resource definition (.rc) files for Visual C++. These will be compiled to binary resource (.res) files and linked into the executable.
2.3.3 Preprocessor options

Three optional arguments to `Extension` will help if you need to specify include directories to search or preprocessor macros to define/undefine: `include_dirs`, `define_macros`, and `undef_macros`.

For example, if your extension requires header files in the `include` directory under your distribution root, use the `include_dirs` option:

   Extension('foo', ['foo.c'], include_dirs=['include'])

You can specify absolute directories there; if you know that your extension will only be built on UNIX systems with X11R6 installed to `/usr`, you can get away with

   Extension('foo', ['foo.c'], include_dirs=['/usr/include/X11'])

You should avoid this sort of non-portable usage if you plan to distribute your code: it's probably better to write C code like

   #include <X11/Xlib.h>

If you need to include header files from some other Python extension, you can take advantage of the fact that header files are installed in a consistent way by the Distutils `install_header` command. For example, the Numerical Python header files are installed (on a standard UNIX installation) to `/usr/local/include/python1.5/Numerical`. (The exact location will differ according to your platform and Python installation.) Since the Python include directory--`/usr/local/include/python1.5` in this case--is always included in the search path when building Python extensions, the best approach is to write C code like

   #include <Numerical/arrayobject.h>

If you must put the Numerical include directory right into your header search path, though, you can find that directory using the Distutils `distutils.sysconfig` module:

   from distutils.sysconfig import get_python_inc
   incdir = os.path.join(get_python_inc(plat_specific=1), 'Numerical')
Even though this is quite portable--it will work on any Python installation, regardless of platform--it's probably easier to just write your C code in the sensible way.

You can define and undefine pre-processor macros with the `define_macros` and `undef_macros` options. `define_macros` takes a list of (name, value) tuples, where name is the name of the macro to define (a string) and value is its value: either a string or `None`. (Defining a macro `FOO` to `None` is the equivalent of a bare `#define FOO` in your C source: with most compilers, this sets `FOO` to the string 1.) `undef_macros` is just a list of macros to undefine.

For example:

```python
setup(...,
    Extension(..., include_dirs=[incdir]),
)

 Extension(...,
             define_macros=[('NDEBUG', '1'),
                            ('HAVE_STRFTIME', None)],
             undef_macros=['HAVE_FOO', 'HAVE_BAR'])
```

is the equivalent of having this at the top of every C source file:

```
#define NDEBUG 1
#define HAVE_STRFTIME
#undef HAVE_FOO
#undef HAVE_BAR
```
2.3.4 Library options

You can also specify the libraries to link against when building your extension, and the directories to search for those libraries. The libraries option is a list of libraries to link against, library_dirs is a list of directories to search for libraries at link-time, and runtime_library_dirs is a list of directories to search for shared (dynamically loaded) libraries at run-time.

For example, if you need to link against libraries known to be in the standard library search path on target systems

```python
Extension(...,
    libraries=['gdbm', 'readline'])
```

If you need to link with libraries in a non-standard location, you'll have to include the location in library_dirs:

```python
Extension(...,
    library_dirs=['/usr/X11R6/lib'],
    libraries=['X11', 'Xt'])
```

(Again, this sort of non-portable construct should be avoided if you intend to distribute your code.)

** Should mention clib libraries here or somewhere else! **
2.3.5 Other options

There are still some other options which can be used to handle special cases.

The extra_objects option is a list of object files to be passed to the linker. These files must not have extensions, as the default extension for the compiler is used.

extra_compile_args and extra_link_args can be used to specify additional command line options for the respective compiler and linker command lines.

export_symbols is only useful on Windows. It can contain a list of symbols (functions or variables) to be exported. This option is not needed when building compiled extensions: Distutils will automatically add initmodule to the list of exported symbols.
2.4 Relationships between Distributions and Packages

A distribution may relate to packages in three specific ways:

1. It can require packages or modules.
2. It can provide packages or modules.
3. It can obsolete packages or modules.

These relationships can be specified using keyword arguments to the `distutils.core.setup()` function.

Dependencies on other Python modules and packages can be specified by supplying the `requires` keyword argument to `setup()`. The value must be a list of strings. Each string specifies a package that is required, and optionally what versions are sufficient.

To specify that any version of a module or package is required, the string should consist entirely of the module or package name. Examples include 'mymodule' and 'xml.parsers.expat'.

If specific versions are required, a sequence of qualifiers can be supplied in parentheses. Each qualifier may consist of a comparison operator and a version number. The accepted comparison operators are:

```
<  >  ==
<=  >=  !=
```

These can be combined by using multiple qualifiers separated by commas (and optional whitespace). In this case, all of the qualifiers must be matched; a logical AND is used to combine the evaluations.

Let's look at a bunch of examples:

<table>
<thead>
<tr>
<th>Requires</th>
<th>Explanation</th>
</tr>
</thead>
</table>
### Expression

<table>
<thead>
<tr>
<th>Expression</th>
<th>Explanation</th>
</tr>
</thead>
<tbody>
<tr>
<td>( \equiv 1.0 )</td>
<td>Only version 1.0 is compatible</td>
</tr>
<tr>
<td>( &gt;1.0, \neq 1.5.1, &lt;2.0 )</td>
<td>Any version after 1.0 and before 2.0 is compatible, except 1.5.1</td>
</tr>
</tbody>
</table>

Now that we can specify dependencies, we also need to be able to specify what we provide that other distributions can require. This is done using the *provides* keyword argument to `setup()`. The value for this keyword is a list of strings, each of which names a Python module or package, and optionally identifies the version. If the version is not specified, it is assumed to match that of the distribution.

Some examples:

<table>
<thead>
<tr>
<th>Provides</th>
<th>Explanation</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>mymod</code></td>
<td>Provide <code>mymod</code>, using the distribution version</td>
</tr>
<tr>
<td><code>mymod (1.1</code></td>
<td>Provide <code>mymod</code> version 1.1, regardless of the distribution version</td>
</tr>
</tbody>
</table>

A package can declare that it obsoletes other packages using the *obsoletes* keyword argument. The value for this is similar to that of the *requires* keyword: a list of strings giving module or package specifiers. Each specifier consists of a module or package name optionally followed by one or more version qualifiers. Version qualifiers are given in parentheses after the module or package name.

The versions identified by the qualifiers are those that are obsoleted by the distribution being described. If no qualifiers are given, all versions of the named module or package are understood to be obsoleted.
2.5 Installing Scripts

So far we have been dealing with pure and non-pure Python modules, which are usually not run by themselves but imported by scripts.

Scripts are files containing Python source code, intended to be started from the command line. Scripts don't require Distutils to do anything very complicated. The only clever feature is that if the first line of the script starts with `#!` and contains the word `python`, the Distutils will adjust the first line to refer to the current interpreter location. By default, it is replaced with the current interpreter location. The `--executable` (or `-e`) option will allow the interpreter path to be explicitly overridden.

The `scripts` option simply is a list of files to be handled in this way. From the PyXML setup script:

```python
setup(...
    scripts=['scripts/xmlproc_parse', 'scripts/xmlproc_val']
)
```

Release 2.5, documentation updated on 19th September, 2006.
See [About this document...](#) for information on suggesting changes.
2.6 Installing Package Data

Often, additional files need to be installed into a package. These files are often data that's closely related to the package's implementation, or text files containing documentation that might be of interest to programmers using the package. These files are called *package data*.

Package data can be added to packages using the `package_data` keyword argument to the `setup()` function. The value must be a mapping from package name to a list of relative path names that should be copied into the package. The paths are interpreted as relative to the directory containing the package (information from the `package_dir` mapping is used if appropriate); that is, the files are expected to be part of the package in the source directories. They may contain glob patterns as well.

The path names may contain directory portions; any necessary directories will be created in the installation.

For example, if a package should contain a subdirectory with several data files, the files can be arranged like this in the source tree:

```plaintext
setup.py
src/
    mypkg/
        __init__.py
        module.py
        data/
            tables.dat
            spoons.dat
            forks.dat
```

The corresponding call to `setup()` might be:

```python
setup(...,
    packages=['mypkg'],
    package_dir={'mypkg': 'src/mypkg'},
    package_data={'mypkg': ['data/*.dat']},
)
```

New in version 2.4.
2.7 Installing Additional Files

The data_files option can be used to specify additional files needed by the module distribution: configuration files, message catalogs, data files, anything which doesn't fit in the previous categories.

data_files specifies a sequence of (directory, files) pairs in the following way:

```python
setup(...
    data_files=[('bitmaps', ['bm/b1.gif', 'bm/b2.gif']),
                ('config', ['cfg/data.cfg']),
                ('/etc/init.d', ['init-script'])]
)
```

Note that you can specify the directory names where the data files will be installed, but you cannot rename the data files themselves.

Each (directory, files) pair in the sequence specifies the installation directory and the files to install there. If directory is a relative path, it is interpreted relative to the installation prefix (Python's `sys.prefix` for pure-Python packages, `sys.exec_prefix` for packages that contain extension modules). Each file name in files is interpreted relative to the `setup.py` script at the top of the package source distribution. No directory information from files is used to determine the final location of the installed file; only the name of the file is used.

You can specify the data_files options as a simple sequence of files without specifying a target directory, but this is not recommended, and the install command will print a warning in this case. To install data files directly in the target directory, an empty string should be given as the directory.
## 2.8 Additional meta-data

The setup script may include additional meta-data beyond the name and version. This information includes:

<table>
<thead>
<tr>
<th>Meta-Data</th>
<th>Description</th>
<th>Value</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>name</td>
<td>name of the package</td>
<td>short string</td>
<td>(1)</td>
</tr>
<tr>
<td>version</td>
<td>version of this release</td>
<td>short string</td>
<td>(1)(2)</td>
</tr>
<tr>
<td>author</td>
<td>package author's name</td>
<td>short string</td>
<td>(3)</td>
</tr>
<tr>
<td>author_email</td>
<td>email address of the package author</td>
<td>email address</td>
<td>(3)</td>
</tr>
<tr>
<td>maintainer</td>
<td>package maintainer's name</td>
<td>short string</td>
<td>(3)</td>
</tr>
<tr>
<td>maintainer_email</td>
<td>email address of the package maintainer</td>
<td>email address</td>
<td>(3)</td>
</tr>
<tr>
<td>url</td>
<td>home page for the package</td>
<td>URL</td>
<td>(1)</td>
</tr>
<tr>
<td>description</td>
<td>short, summary description of the package</td>
<td>short string</td>
<td></td>
</tr>
<tr>
<td>long_description</td>
<td>longer description of the package</td>
<td>long string</td>
<td></td>
</tr>
<tr>
<td>download_url</td>
<td>location where the package may be downloaded</td>
<td>URL</td>
<td>(4)</td>
</tr>
<tr>
<td>classifiers</td>
<td>a list of classifiers</td>
<td>list of strings</td>
<td>(4)</td>
</tr>
</tbody>
</table>

Notes:

(1) These fields are required.
(2) It is recommended that versions take the form major.minor[.patch[.sub]].
(3)
Either the author or the maintainer must be identified.

These fields should not be used if your package is to be compatible with Python versions prior to 2.2.3 or 2.3. The list is available from the PyPI website.

'short string'
A single line of text, not more than 200 characters.

'long string'
Multiple lines of plain text in reStructuredText format (see http://docutils.sf.net/).

'list of strings'
See below.

None of the string values may be Unicode.

Encoding the version information is an art in itself. Python packages generally adhere to the version format major.minor[.patch][sub]. The major number is 0 for initial, experimental releases of software. It is incremented for releases that represent major milestones in a package. The minor number is incremented when important new features are added to the package. The patch number increments when bug-fix releases are made. Additional trailing version information is sometimes used to indicate sub-releases. These are "a1,a2,...,aN" (for alpha releases, where functionality and API may change), "b1,b2,...,bN" (for beta releases, which only fix bugs) and "pr1,pr2,...,prN" (for final pre-release release testing). Some examples:

0.1.0
the first, experimental release of a package

1.0.1a2
the second alpha release of the first patch version of 1.0

classifiers are specified in a python list:

```python
setup(
    classifiers=[
        'Development Status :: 4 - Beta',
        'Environment :: Console',
        'Environment :: Web Environment',
        'Intended Audience :: End Users/Desktop',
        'Intended Audience :: Developers',
    ]
```
If you wish to include classifiers in your setup.py file and also wish to remain backwards-compatible with Python releases prior to 2.2.3, then you can include the following code fragment in your setup.py before the setup() call.

```
# patch distutils if it can't cope with the "classifiers" or
# "download_url" keywords
from sys import version
if version < '2.2.3':
    from distutils.dist import DistributionMetadata
    DistributionMetadata.classifiers = None
    DistributionMetadata.download_url = None
```

Distributing Python Modules

Previous: 2.7 Installing Additional Files  Up: 2. Writing the Setup  Next: 2.9 Debugging the setup

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
2.9 Debugging the setup script

Sometimes things go wrong, and the setup script doesn't do what the developer wants.

Distutils catches any exceptions when running the setup script, and print a simple error message before the script is terminated. The motivation for this behaviour is to not confuse administrators who don't know much about Python and are trying to install a package. If they get a big long traceback from deep inside the guts of Distutils, they may think the package or the Python installation is broken because they don't read all the way down to the bottom and see that it's a permission problem.

On the other hand, this doesn't help the developer to find the cause of the failure. For this purpose, the DISTUTILS_DEBUG environment variable can be set to anything except an empty string, and distutils will now print detailed information what it is doing, and prints the full traceback in case an exception occurs.
3. Writing the Setup Configuration File

Often, it's not possible to write down everything needed to build a distribution \textit{a priori}: you may need to get some information from the user, or from the user's system, in order to proceed. As long as that information is fairly simple--a list of directories to search for C header files or libraries, for example--then providing a configuration file, \texttt{setup.cfg}, for users to edit is a cheap and easy way to solicit it. Configuration files also let you provide default values for any command option, which the installer can then override either on the command-line or by editing the config file.

The setup configuration file is a useful middle-ground between the setup script--which, ideally, would be opaque to installers\textsuperscript{31}--and the command-line to the setup script, which is outside of your control and entirely up to the installer. In fact, \texttt{setup.cfg} (and any other Distutils configuration files present on the target system) are processed after the contents of the setup script, but before the command-line. This has several useful consequences:

- installers can override some of what you put in \texttt{setup.py} by editing \texttt{setup.cfg}
- you can provide non-standard defaults for options that are not easily set in \texttt{setup.py}
- installers can override anything in \texttt{setup.cfg} using the command-line options to \texttt{setup.py}

The basic syntax of the configuration file is simple:

```
[command]
option=value
...
```

where \textit{command} is one of the Distutils commands (e.g. \texttt{build\_py}, \texttt{install}), and \textit{option} is one of the options that command supports. Any number of options can be supplied for each command, and any number of command sections can be included in the file. Blank lines are ignored, as are comments, which run from a "#" character until the end of the line. Long option values can be split across
multiple lines simply by indenting the continuation lines.

You can find out the list of options supported by a particular command with the universal \texttt{--help} option, e.g.

\begin{verbatim}
> python setup.py --help build_ext
[...]
Options for 'build_ext' command:
  --build-lib (-b) directory for compiled extension modules
  --build-temp (-t) directory for temporary files (build by-produ
  --inplace (-i) ignore build-lib and put compiled extensions
    source directory alongside your pure Python m
  --include-dirs (-I) list of directories to search for header file
  --define (-D) C preprocessor macros to define
  --undef (-U) C preprocessor macros to undefine
[...]
\end{verbatim}

Note that an option spelled \texttt{--foo-bar} on the command-line is spelled \texttt{foo_bar} in configuration files.

For example, say you want your extensions to be built ``in-place''--that is, you have an extension \texttt{pkg.ext}, and you want the compiled extension file (\texttt{ext.so} on UNIX, say) to be put in the same source directory as your pure Python modules \texttt{pkg.mod1} and \texttt{pkg.mod2}. You can always use the \texttt{--inplace} option on the command-line to ensure this:

\begin{verbatim}
python setup.py build_ext --inplace
\end{verbatim}

But this requires that you always specify the \texttt{build_ext} command explicitly, and remember to provide \texttt{--inplace}. An easier way is to ``set and forget'' this option, by encoding it in \texttt{setup.cfg}, the configuration file for this distribution:

\begin{verbatim}
[build_ext]
inplace=1
\end{verbatim}

This will affect all builds of this module distribution, whether or not you explicitly specify \texttt{build_ext}. If you include \texttt{setup.cfg} in your source distribution, it will also affect end-user builds--which is probably a bad idea for this option, since always building extensions in-place would break installation of the module distribution. In certain peculiar cases, though, modules are built right in their installation directory, so this is conceivably a useful ability. (Distributing extensions that expect to be built in their installation directory is almost always a bad idea, though.)
Another example: certain commands take a lot of options that don't change from run to run; for example, `bdist_rpm` needs to know everything required to generate a ``spec'' file for creating an RPM distribution. Some of this information comes from the setup script, and some is automatically generated by the Distutils (such as the list of files installed). But some of it has to be supplied as options to `bdist_rpm`, which would be very tedious to do on the command-line for every run. Hence, here is a snippet from the Distutils' own `setup.cfg`:

```ini
[bdist_rpm]
release = 1
packager = Greg Ward <gward@python.net>
doc_files = CHANGES.txt
            README.txt
            USAGE.txt
            doc/
            examples/
```

Note that the `doc_files` option is simply a whitespace-separated string split across multiple lines for readability.

More information on the configuration files is available in the manual for system administrators.

### Footnotes

... installers\footnote{3.1}{This ideal probably won't be achieved until auto-configuration is fully supported by the Distutils.}
Creating a Source

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
4. Creating a Source Distribution

As shown in section 1.2, you use the sdist command to create a source distribution. In the simplest case,

```
python setup.py sdist
```

(assuming you haven't specified any sdist options in the setup script or config file), sdist creates the archive of the default format for the current platform. The default format is a gzip'ed tar file (.tar.gz) on UNIX, and ZIP file on Windows.

You can specify as many formats as you like using the `--formats` option, for example:

```
python setup.py sdist --formats=gztar,zip
```

to create a gzipped tarball and a zip file. The available formats are:

<table>
<thead>
<tr>
<th>Format</th>
<th>Description</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>zip</td>
<td>zip file (.zip)</td>
<td>(1),(3)</td>
</tr>
<tr>
<td>gztar</td>
<td>gzip'ed tar file (.tar.gz)</td>
<td>(2),(4)</td>
</tr>
<tr>
<td>bztar</td>
<td>bzip2'ed tar file (.tar.bz2)</td>
<td>(4)</td>
</tr>
<tr>
<td>ztar</td>
<td>compressed tar file (.tar.Z)</td>
<td>(4)</td>
</tr>
<tr>
<td>tar</td>
<td>tar file (.tar)</td>
<td>(4)</td>
</tr>
</tbody>
</table>

Notes:

(1) default on Windows
(2) default on UNIX
(3) requires either external `zip` utility or `zipfile` module (part of the standard Python library since Python 1.6)
(4) requires external utilities: `tar` and possibly one of `gzip`, `bzip2`, or `compress`
Subsections

- 4.1 Specifying the files to distribute
- 4.2 Manifest-related options

Distributing Python Modules

Previous: 3. Writing the Setup Up: Distributing Python Modules Next: 4.1 Specifying the files

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
4.1 Specifying the files to distribute

If you don't supply an explicit list of files (or instructions on how to generate one), the sdist command puts a minimal default set into the source distribution:

- all Python source files implied by the py_modules and packages options
- all C source files mentioned in the ext_modules or libraries options (**
getting C library sources currently broken--no
get_source_files() method in build_clib.py! **)  
- scripts identified by the scripts option
- anything that looks like a test script: test/test*.py (currently, the Distutils don't do anything with test scripts except include them in source distributions, but in the future there will be a standard for testing Python module distributions)
- README.txt (or README), setup.py (or whatever you called your setup script), and setup.cfg

Sometimes this is enough, but usually you will want to specify additional files to distribute. The typical way to do this is to write a manifest template, called MANIFEST.in by default. The manifest template is just a list of instructions for how to generate your manifest file, MANIFEST, which is the exact list of files to include in your source distribution. The sdist command processes this template and generates a manifest based on its instructions and what it finds in the filesystem.

If you prefer to roll your own manifest file, the format is simple: one filename per line, regular files (or symlinks to them) only. If you do supply your own MANIFEST, you must specify everything: the default set of files described above does not apply in this case.

The manifest template has one command per line, where each command specifies a set of files to include or exclude from the source distribution. For an example, again we turn to the Distutils' own manifest template:

```
include *.txt
recursive-include examples *.txt *.py
prune examples/sample?/build
```
The meanings should be fairly clear: include all files in the distribution root matching *.txt, all files anywhere under the examples directory matching *.txt or *.py, and exclude all directories matching examples/sample?/build. All of this is done after the standard include set, so you can exclude files from the standard set with explicit instructions in the manifest template. (Or, you can use the --no-defaults option to disable the standard set entirely.) There are several other commands available in the manifest template mini-language; see section 10.2.

The order of commands in the manifest template matters: initially, we have the list of default files as described above, and each command in the template adds to or removes from that list of files. Once we have fully processed the manifest template, we remove files that should not be included in the source distribution:

- all files in the Distutils ``build'' tree (default build/)
- all files in directories named RCS, CVS or .svn

Now we have our complete list of files, which is written to the manifest for future reference, and then used to build the source distribution archive(s).

You can disable the default set of included files with the --no-defaults option, and you can disable the standard exclude set with --no-prune.

Following the Distutils' own manifest template, let's trace how the sdist command builds the list of files to include in the Distutils source distribution:

1. include all Python source files in the distutils and distutils/command subdirectories (because packages corresponding to those two directories were mentioned in the packages option in the setup script--see section 2)
2. include README.txt, setup.py, and setup.cfg (standard files)
3. include test/test*.py (standard files)
4. include *.txt in the distribution root (this will find README.txt a second time, but such redundancies are weeded out later)
5. include anything matching *.txt or *.py in the sub-tree under examples,
6. exclude all files in the sub-trees starting at directories matching examples/sample?/build--this may exclude files included by the previous two steps, so it's important that the prune command in the manifest template comes after the recursive-include command
7. exclude the entire build tree, and any RCS, CVS and .svn directories
Just like in the setup script, file and directory names in the manifest template should always be slash-separated; the Distutils will take care of converting them to the standard representation on your platform. That way, the manifest template is portable across operating systems.
4.2 Manifest-related options

The normal course of operations for the sdist command is as follows:

- if the manifest file, MANIFEST doesn't exist, read MANIFEST.in and create the manifest
- if neither MANIFEST nor MANIFEST.in exist, create a manifest with just the default file set
- if either MANIFEST.in or the setup script (setup.py) are more recent than MANIFEST, recreate MANIFEST by reading MANIFEST.in
- use the list of files now in MANIFEST (either just generated or read in) to create the source distribution archive(s)

There are a couple of options that modify this behaviour. First, use the --no-defaults and --no-prune to disable the standard ``include'' and ``exclude'' sets.

Second, you might want to force the manifest to be regenerated--for example, if you have added or removed files or directories that match an existing pattern in the manifest template, you should regenerate the manifest:

```
python setup.py sdist --force-manifest
```

Or, you might just want to (re)generate the manifest, but not create a source distribution:

```
python setup.py sdist --manifest-only
```

`--manifest-only` implies `--force-manifest`. `-o` is a shortcut for `--manifest-only`, and `-f` for `--force-manifest`.

Distributing Python Modules

Previous: 4.1 Specifying the files  Up: 4. Creating a Source  Next: 5. Creating Built Distributions

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
5. Creating Built Distributions

A "built distribution" is what you're probably used to thinking of either as a "binary package" or an "installer" (depending on your background). It's not necessarily binary, though, because it might contain only Python source code and/or byte-code; and we don't call it a package, because that word is already spoken for in Python. (And "installer" is a term specific to the world of mainstream desktop systems.)

A built distribution is how you make life as easy as possible for installers of your module distribution: for users of RPM-based Linux systems, it's a binary RPM; for Windows users, it's an executable installer; for Debian-based Linux users, it's a Debian package; and so forth. Obviously, no one person will be able to create built distributions for every platform under the sun, so the Distutils are designed to enable module developers to concentrate on their specialty--writing code and creating source distributions--while an intermediary species called packagers springs up to turn source distributions into built distributions for as many platforms as there are packagers.

Of course, the module developer could be his own packager; or the packager could be a volunteer "out there" somewhere who has access to a platform which the original developer does not; or it could be software periodically grabbing new source distributions and turning them into built distributions for as many platforms as the software has access to. Regardless of who they are, a packager uses the setup script and the bdist command family to generate built distributions.

As a simple example, if I run the following command in the Distutils source tree:

```
python setup.py bdist
```

then the Distutils builds my module distribution (the Distutils itself in this case), does a "fake" installation (also in the build directory), and creates the default type of built distribution for my platform. The default format for built distributions is a "dumb" tar file on UNIX, and a simple executable installer on Windows. (That tar file is considered "dumb" because it has to be unpacked in a specific location to work.)
Thus, the above command on a UNIX system creates Distutils-1.0.plat.tar.gz; unpacking this tarball from the right place installs the Distutils just as though you had downloaded the source distribution and run `python setup.py install`. (The "right place" is either the root of the filesystem or Python's `prefix` directory, depending on the options given to the `bdist_dumb` command; the default is to make dumb distributions relative to `prefix`.)

Obviously, for pure Python distributions, this isn't any simpler than just running `python setup.py install`—but for non-pure distributions, which include extensions that would need to be compiled, it can mean the difference between someone being able to use your extensions or not. And creating "smart" built distributions, such as an RPM package or an executable installer for Windows, is far more convenient for users even if your distribution doesn't include any extensions.

The `bdist` command has a `--formats` option, similar to the `sdist` command, which you can use to select the types of built distribution to generate: for example,

```
python setup.py bdist --format=zip
```

would, when run on a UNIX system, create Distutils-1.0.plat.zip—again, this archive would be unpacked from the root directory to install the Distutils.

The available formats for built distributions are:

<table>
<thead>
<tr>
<th>Format</th>
<th>Description</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>gztar</td>
<td>gzipped tar file (.tar.gz)</td>
<td>(1),(3)</td>
</tr>
<tr>
<td>ztar</td>
<td>compressed tar file (.tar.Z)</td>
<td>(3)</td>
</tr>
<tr>
<td>tar</td>
<td>tar file (.tar)</td>
<td>(3)</td>
</tr>
<tr>
<td>zip</td>
<td>zip file (.zip)</td>
<td>(4)</td>
</tr>
<tr>
<td>rpm</td>
<td>RPM</td>
<td>(5)</td>
</tr>
<tr>
<td>pkgtool</td>
<td>Solaris pkgtool</td>
<td></td>
</tr>
<tr>
<td>sdux</td>
<td>HP-UX <code>swinstall</code></td>
<td></td>
</tr>
<tr>
<td>rpm</td>
<td>RPM</td>
<td>(5)</td>
</tr>
<tr>
<td>wininst</td>
<td>self-extracting ZIP file for Windows</td>
<td>(2),(4)</td>
</tr>
</tbody>
</table>

Notes:
default on **Unix**

default on Windows **to-do!**

requires external utilities: **tar** and possibly one of **gzip**, **bzip2**, or **compress**

requires either external **zip** utility or **zipfile** module (part of the standard Python library since Python 1.6)

requires external **rpm** utility, version 3.0.4 or better (use **rpm --version** to find out which version you have)

You don't have to use the **bdist** command with the **--formats** option; you can also use the command that directly implements the format you're interested in. Some of these **bdist** ``sub-commands'' actually generate several similar formats; for instance, the **bdist_dumb** command generates all the ``dumb'' archive formats (**tar**, **ztar**, **gztar**, and **zip**), and **bdist_rpm** generates both binary and source RPMs. The **bdist** sub-commands, and the formats generated by each, are:

<table>
<thead>
<tr>
<th>Command</th>
<th>Formats</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>bdist_dumb</strong></td>
<td><strong>tar</strong>, <strong>ztar</strong>, <strong>gztar</strong>, <strong>zip</strong></td>
</tr>
<tr>
<td><strong>bdist_rpm</strong></td>
<td><strong>rpm</strong>, <strong>srpm</strong></td>
</tr>
<tr>
<td><strong>bdist_wininst</strong></td>
<td><strong>wininst</strong></td>
</tr>
</tbody>
</table>

The following sections give details on the individual **bdist_*** commands.

5.1 Creating dumb built distributions

** Need to document absolute vs. prefix-relative packages here, but first I have to implement it! **

---

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
5.2 Creating RPM packages

The RPM format is used by many popular Linux distributions, including Red Hat, SuSE, and Mandrake. If one of these (or any of the other RPM-based Linux distributions) is your usual environment, creating RPM packages for other users of that same distribution is trivial. Depending on the complexity of your module distribution and differences between Linux distributions, you may also be able to create RPMs that work on different RPM-based distributions.

The usual way to create an RPM of your module distribution is to run the `bdist_rpm` command:

```
python setup.py bdist_rpm
```

or the `bdist` command with the `--format` option:

```
python setup.py bdist --formats=rpm
```

The former allows you to specify RPM-specific options; the latter allows you to easily specify multiple formats in one run. If you need to do both, you can explicitly specify multiple `bdist_*` commands and their options:

```
python setup.py bdist_rpm --packager="John Doe <jdoe@example.org>" \
bdist_wininst --target_version="2.0"
```

Creating RPM packages is driven by a `.spec` file, much as using the Distutils is driven by the setup script. To make your life easier, the `bdist_rpm` command normally creates a `.spec` file based on the information you supply in the setup script, on the command line, and in any Distutils configuration files. Various options and sections in the `.spec` file are derived from options in the setup script as follows:

<table>
<thead>
<tr>
<th>RPM <code>.spec</code> file option or section</th>
<th>Distutils setup script option</th>
</tr>
</thead>
<tbody>
<tr>
<td>Name</td>
<td>name</td>
</tr>
<tr>
<td>Summary (in preamble)</td>
<td>description</td>
</tr>
<tr>
<td>Version</td>
<td>version</td>
</tr>
<tr>
<td>Vendor</td>
<td>author and author_email, or &amp; maintainer and maintainer_email</td>
</tr>
</tbody>
</table>
Additionally, there are many options in `.spec` files that don't have corresponding options in the setup script. Most of these are handled through options to the `bdist_rpm` command as follows:

<table>
<thead>
<tr>
<th>RPM .spec file option or section</th>
<th>bdist_rpm option</th>
<th>default value</th>
</tr>
</thead>
<tbody>
<tr>
<td>Release</td>
<td>release</td>
<td><code>1</code></td>
</tr>
<tr>
<td>Group</td>
<td>group</td>
<td><code>Development/Libraries</code></td>
</tr>
<tr>
<td>Vendor</td>
<td>vendor</td>
<td>(see above)</td>
</tr>
<tr>
<td>Packager</td>
<td>packager</td>
<td>(none)</td>
</tr>
<tr>
<td>Provides</td>
<td>provides</td>
<td>(none)</td>
</tr>
<tr>
<td>Requires</td>
<td>requires</td>
<td>(none)</td>
</tr>
<tr>
<td>Conflicts</td>
<td>conflicts</td>
<td>(none)</td>
</tr>
<tr>
<td>Obsoletes</td>
<td>obsoletes</td>
<td>(none)</td>
</tr>
<tr>
<td>Distribution</td>
<td>distribution_name</td>
<td>(none)</td>
</tr>
<tr>
<td>BuildRequires</td>
<td>buildRequires</td>
<td>(none)</td>
</tr>
<tr>
<td>Icon</td>
<td>icon</td>
<td>(none)</td>
</tr>
</tbody>
</table>

Obviously, supplying even a few of these options on the command-line would be tedious and error-prone, so it's usually best to put them in the setup configuration file, `setup.cfg`—see section 3. If you distribute or package many Python module distributions, you might want to put options that apply to all of them in your personal Distutils configuration file (~/.pydistutils.cfg).

There are three steps to building a binary RPM package, all of which are handled automatically by the Distutils:

1. create a `.spec` file, which describes the package (analogous to the Distutils setup script; in fact, much of the information in the setup script winds up in the `.spec` file)
2. create the source RPM
3. create the ```binary``` RPM (which may or may not contain binary code, depending on whether your module distribution contains Python
Normally, RPM bundles the last two steps together; when you use the Distutils, all three steps are typically bundled together.

If you wish, you can separate these three steps. You can use the \texttt{--spec-only} option to make \texttt{bdist\_rpm} just create the \texttt{.spec} file and exit; in this case, the \texttt{.spec} file will be written to the \texttt{``distribution directory''} -- normally \texttt{dist/}, but customizable with the \texttt{--dist-dir} option. (Normally, the \texttt{.spec} file winds up deep in the \texttt{``build tree,''} in a temporary directory created by \texttt{bdist\_rpm}.)

Subsections

- 5.3.1 The Postinstallation script
5.3 Creating Windows Installers

Executable installers are the natural format for binary distributions on Windows. They display a nice graphical user interface, display some information about the module distribution to be installed taken from the metadata in the setup script, let the user select a few options, and start or cancel the installation.

Since the metadata is taken from the setup script, creating Windows installers is usually as easy as running:

    python setup.py bdist_wininst

or the bdist command with the --formats option:

    python setup.py bdist --formats=wininst

If you have a pure module distribution (only containing pure Python modules and packages), the resulting installer will be version independent and have a name like foo-1.0.win32.exe. These installers can even be created on UNIX or Mac OS platforms.

If you have a non-pure distribution, the extensions can only be created on a Windows platform, and will be Python version dependent. The installer filename will reflect this and now has the form foo-1.0.win32-py2.0.exe. You have to create a separate installer for every Python version you want to support.

The installer will try to compile pure modules into bytecode after installation on the target system in normal and optimizing mode. If you don't want this to happen for some reason, you can run the bdist_wininst command with the --no-target-compile and/or the --no-target-optimize option.

By default the installer will display the cool "Python Powered" logo when it is run, but you can also supply your own bitmap which must be a Windows .bmp file with the --bitmap option.

The installer will also display a large title on the desktop background window when it is run, which is constructed from the name of your distribution and the version number. This can be changed to another text by using the --title option.
The installer file will be written to the ``distribution directory'' -- normally `dist/`, but customizable with the `--dist-dir` option.
5.3.1 The Postinstallation script

Starting with Python 2.3, a postinstallation script can be specified which the --install-script option. The basename of the script must be specified, and the script filename must also be listed in the scripts argument to the setup function.

This script will be run at installation time on the target system after all the files have been copied, with argv[1] set to -install, and again at uninstallation time before the files are removed with argv[1] set to -remove.

The installation script runs embedded in the windows installer, every output (sys.stdout, sys.stderr) is redirected into a buffer and will be displayed in the GUI after the script has finished.

Some functions especially useful in this context are available as additional built-in functions in the installation script.

**directory_created**(path)

**file_created**(path)

These functions should be called when a directory or file is created by the postinstall script at installation time. It will register path with the uninstaller, so that it will be removed when the distribution is uninstalled. To be safe, directories are only removed if they are empty.

**get_special_folder_path**(csidl_string)

This function can be used to retrieve special folder locations on Windows like the Start Menu or the Desktop. It returns the full path to the folder. csidl_string must be one of the following strings:

"CSIDL_APPDATA"

"CSIDL_COMMON_STARTMENU"
"CSIDL_STARTMENU"

"CSIDL_COMMON_DESKTOPDIRECTORY"
"CSIDL_DESKTOPDIRECTORY"

"CSIDL_COMMON_STARTUP"
"CSIDL_STARTUP"
"CSIDL_COMMON_PROGRAMS"
"CSIDL_PROGRAMS"
"CSIDL_FONTS"

If the folder cannot be retrieved, 

\texttt{OSError} is raised.

Which folders are available depends on the exact Windows version, and probably also the configuration. For details refer to Microsoft's documentation of the \texttt{SHGetSpecialFolderPath()} function.

\texttt{create\_shortcut( target, description, filename[, arguments[, workdir[, iconpath[, iconindex]]]]])}

This function creates a shortcut. \texttt{target} is the path to the program to be started by the shortcut. \texttt{description} is the description of the shortcut. \texttt{filename} is the title of the shortcut that the user will see. \texttt{arguments} specifies the command line arguments, if any. \texttt{workdir} is the working directory for the program. \texttt{iconpath} is the file containing the icon for the shortcut, and \texttt{iconindex} is the index of the icon in the file \texttt{iconpath}. Again, for details consult the Microsoft documentation for the \texttt{IShellLink} interface.
6. Registering with the Package Index

The Python Package Index (PyPI) holds meta-data describing distributions packaged with distutils. The distutils command register is used to submit your distribution's meta-data to the index. It is invoked as follows:

```python
python setup.py register
```

Distutils will respond with the following prompt:

```
running register
We need to know who you are, so please choose either:
1. use your existing login,
2. register as a new user,
3. have the server generate a new password for you (and email it to you),
4. quit
Your selection [default 1]:
```

Note: if your username and password are saved locally, you will not see this menu.

If you have not registered with PyPI, then you will need to do so now. You should choose option 2, and enter your details as required. Soon after submitting your details, you will receive an email which will be used to confirm your registration.

Once you are registered, you may choose option 1 from the menu. You will be prompted for your PyPI username and password, and register will then submit your meta-data to the index.

You may submit any number of versions of your distribution to the index. If you alter the meta-data for a particular version, you may submit it again and the index will be updated.

PyPI holds a record for each (name, version) combination submitted. The first user to submit information for a given name is designated the Owner of that name. They may submit changes through the register command or through the web interface. They may also designate other users as Owners or Maintainers.
Maintainers may edit the package information, but not designate other Owners or Maintainers.

By default PyPI will list all versions of a given package. To hide certain versions, the Hidden property should be set to yes. This must be edited through the web interface.

---

Subsections

- [6.1 The .pypirc file](#)
6.1 The .pypirc file

The format of the .pypirc file is formatted as follows:

```
[server-login]
repository: <repository-url>
username: <username>
password: <password>
```

`repository` can be omitted and defaults to http://www.python.org/pypi.
7. Uploading Packages to the Package Index

New in version 2.5.

The Python Package Index (PyPI) not only stores the package info, but also the package data if the author of the package wishes to. The distutils command upload pushes the distribution files to PyPI.

The command is invoked immediately after building one or more distribution files. For example, the command

```
python setup.py sdist bdist_wininst upload
```

will cause the source distribution and the Windows installer to be uploaded to PyPI. Note that these will be uploaded even if they are built using an earlier invocation of setup.py, but that only distributions named on the command line for the invocation including the upload command are uploaded.

The upload command uses the username, password, and repository URL from the $HOME/.pypirc file (see section 6.1 for more on this file).

You can use the --sign option to tell upload to sign each uploaded file using GPG (GNU Privacy Guard). The gpg program must be available for execution on the system PATH. You can also specify which key to use for signing using the --identity=name option.

Other upload options include --repository=url (which lets you override the repository setting from $HOME/.pypirc), and --show-response (which displays the full response text from the PyPI server for help in debugging upload problems).
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
8. Examples

This chapter provides a number of basic examples to help get started with distutils. Additional information about using distutils can be found in the Distutils Cookbook.

Distutils Cookbook
Collection of recipes showing how to achieve more control over distutils.

Subsections

- 8.1 Pure Python distribution (by module)
- 8.2 Pure Python distribution (by package)
- 8.3 Single extension module
8.1 Pure Python distribution (by module)

If you're just distributing a couple of modules, especially if they don't live in a particular package, you can specify them individually using the \texttt{py\_modules} option in the setup script.

In the simplest case, you'll have two files to worry about: a setup script and the single module you're distributing, \texttt{foo.py} in this example:

\begin{verbatim}
<root>/
    setup.py
    foo.py
\end{verbatim}

(In all diagrams in this section, \texttt{<root>} will refer to the distribution root directory.) A minimal setup script to describe this situation would be:

\begin{verbatim}
from distutils.core import setup
setup(name='foo',
      version='1.0',
      py_modules=['foo'],
)
\end{verbatim}

Note that the name of the distribution is specified independently with the \texttt{name} option, and there's no rule that says it has to be the same as the name of the sole module in the distribution (although that's probably a good convention to follow). However, the distribution name is used to generate filenames, so you should stick to letters, digits, underscores, and hyphens.

Since \texttt{py\_modules} is a list, you can of course specify multiple modules, eg. if you're distributing modules \texttt{foo} and \texttt{bar}, your setup might look like this:

\begin{verbatim}
<root>/
    setup.py
    foo.py
    bar.py
\end{verbatim}

and the setup script might be

\begin{verbatim}
from distutils.core import setup
setup(name='foobaz',
      version='1.0',
)
\end{verbatim}
You can put module source files into another directory, but if you have enough modules to do that, it's probably easier to specify modules by package rather than listing them individually.
8.2 Pure Python distribution (by package)

If you have more than a couple of modules to distribute, especially if they are in multiple packages, it's probably easier to specify whole packages rather than individual modules. This works even if your modules are not in a package; you can just tell the Distutils to process modules from the root package, and that works the same as any other package (except that you don't have to have an __init__.py file).

The setup script from the last example could also be written as

```python
from distutils.core import setup
setup(name='foobar',
      version='1.0',
      packages=[''],
      )
```

(The empty string stands for the root package.)

If those two files are moved into a subdirectory, but remain in the root package, e.g.:

```
<root>/
  setup.py
  src/
    foo.py
    bar.py
```

then you would still specify the root package, but you have to tell the Distutils where source files in the root package live:

```python
from distutils.core import setup
setup(name='foobar',
      version='1.0',
      package_dir={'': 'src'},
      packages=[''],
      )
```

More typically, though, you will want to distribute multiple modules in the same package (or in sub-packages). For example, if the foo and bar modules belong in package foobar, one way to layout your source tree is
This is in fact the default layout expected by the Distutils, and the one that requires the least work to describe in your setup script:

```python
from distutils.core import setup
setup(name='foobar',
      version='1.0',
      packages=['foobar'],
)
```

If you want to put modules in directories not named for their package, then you need to use the `package_dir` option again. For example, if the `src` directory holds modules in the `foobar` package:

```python
from distutils.core import setup
setup(name='foobar',
      version='1.0',
      package_dir={'foobar': 'src'},
      packages=['foobar'],
)
```

Or, you might put modules from your main package right in the distribution root:

```python
from distutils.core import setup
setup(name='foobar',
      version='1.0',
      package_dir={'foobar': ''},
      packages=['foobar'],
)
```
packages=['foobar'],
)

(The empty string also stands for the current directory.)

If you have sub-packages, they must be explicitly listed in packages, but any entries in package_dir automatically extend to sub-packages. (In other words, the Distutils does not scan your source tree, trying to figure out which directories correspond to Python packages by looking for __init__.py files.) Thus, if the default layout grows a sub-package:

```
<root>/
    setup.py
    foobar/
        __init__.py
        foo.py
        bar.py
    subfoo/
        __init__.py
        blah.py
```

then the corresponding setup script would be

```
from distutils.core import setup
setup(name='foobar',
    version='1.0',
    packages=['foobar', 'foobar.subfoo'],
)
```

(Again, the empty string in package_dir stands for the current directory.)
8.3 Single extension module

Extension modules are specified using the `ext_modules` option. `package_dir` has no effect on where extension source files are found; it only affects the source for pure Python modules. The simplest case, a single extension module in a single C source file, is:

```python
<root>/
    setup.py
    foo.c
```

If the `foo` extension belongs in the root package, the setup script for this could be

```python
from distutils.core import setup
from distutils.extension import Extension
setup(name='foobar',
      version='1.0',
      ext_modules=[Extension('foo', ['foo.c'])],
)
```

If the extension actually belongs in a package, say `foopkg`, then

With exactly the same source tree layout, this extension can be put in the `foopkg` package simply by changing the name of the extension:

```python
from distutils.core import setup
from distutils.extension import Extension
setup(name='foobar',
      version='1.0',
      ext_modules=[Extension('foopkg.foo', ['foo.c'])],
)
```
9. Extending Distutils

Distutils can be extended in various ways. Most extensions take the form of new commands or replacements for existing commands. New commands may be written to support new types of platform-specific packaging, for example, while replacements for existing commands may be made to modify details of how the command operates on a package.

Most extensions of the distutils are made within setup.py scripts that want to modify existing commands; many simply add a few file extensions that should be copied into packages in addition to .py files as a convenience.

Most distutils command implementations are subclasses of the Command class from distutils.cmd. New commands may directly inherit from Command, while replacements often derive from Command indirectly, directly subclassing the command they are replacing. Commands are required to derive from Command.

---

Subsections

- [9.1 Integrating new commands](#)
- [9.2 Adding new distribution types](#)

---

Release 2.5, documentation updated on 19th September, 2006.
See [About this document...](#) for information on suggesting changes.
9.1 Integrating new commands

There are different ways to integrate new command implementations into distutils. The most difficult is to lobby for the inclusion of the new features in distutils itself, and wait for (and require) a version of Python that provides that support. This is really hard for many reasons.

The most common, and possibly the most reasonable for most needs, is to include the new implementations with your setup.py script, and cause the distutils.core.setup() function use them:

```python
from distutils.command.build_py import build_py as _build_py
from distutils.core import setup

class build_py(_build_py):
    """Specialized Python source builder."""

        # implement whatever needs to be different...

setup(cmdclass={'build_py': build_py},
     ...
```

This approach is most valuable if the new implementations must be used to use a particular package, as everyone interested in the package will need to have the new command implementation.

Beginning with Python 2.4, a third option is available, intended to allow new commands to be added which can support existing setup.py scripts without requiring modifications to the Python installation. This is expected to allow third-party extensions to provide support for additional packaging systems, but the commands can be used for anything distutils commands can be used for. A new configuration option, command_packages (command-line option --command-packages), can be used to specify additional packages to be searched for modules implementing commands. Like all distutils options, this can be specified on the command line or in a configuration file. This option can only be set in the [global] section of a configuration file, or before any commands on the command line. If set in a configuration file, it can be overridden from the command line; setting it to an empty string on the command line causes the default to be used. This should never be set in a configuration file provided with a package.
This new option can be used to add any number of packages to the list of packages searched for command implementations; multiple package names should be separated by commas. When not specified, the search is only performed in the distutils.command package. When setup.py is run with the option --command-packages distcmds,buildcmds, however, the packages distutils.command, distcmds, and buildcmds will be searched in that order. New commands are expected to be implemented in modules of the same name as the command by classes sharing the same name. Given the example command line option above, the command bdist_openpkg could be implemented by the class distcmds.bdist_openpkg.bdist_openpkg or buildcmds.bdist_openpkg.bdist_openpkg.
9.2 Adding new distribution types

Commands that create distributions (files in the dist/ directory) need to add
(command, filename) pairs to self.distribution.dist_files so
that upload can upload it to PyPI. The filename in the pair contains no path
information, only the name of the file itself. In dry-run mode, pairs should still
be added to represent what would have been created.
10. Command Reference

Subsections

- 10.1 Installing modules: the `install` command family
  - 10.1.1 `install_data`
  - 10.1.2 `install_scripts`
- 10.2 Creating a source distribution: the `sdist` command

Distributing Python Modules

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
Subsections

- 10.1.1 install data
- 10.1.2 install scripts
10.1 Installing modules: the `install` command family

The `install` command ensures that the build commands have been run and then runs the subcommands `install_lib`, `install_data` and `install_scripts`. 
10.1.1 install_data

This command installs all data files provided with the distribution.
10.1.2 install_scripts

This command installs all (Python) scripts in the distribution.
10.2 Creating a source distribution: the \texttt{sdist} command

** fragment moved down from above: needs context! **

The manifest template commands are:

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>\texttt{include} pat1 pat2 ...</td>
<td>include all files matching any of the listed patterns</td>
</tr>
<tr>
<td>\texttt{exclude} pat1 pat2 ...</td>
<td>exclude all files matching any of the listed patterns</td>
</tr>
<tr>
<td>\texttt{recursive-include} dir pat1 pat2 ...</td>
<td>include all files under \textit{dir} matching any of the listed patterns</td>
</tr>
<tr>
<td>\texttt{recursive-exclude} dir pat1 pat2 ...</td>
<td>exclude all files under \textit{dir} matching any of the listed patterns</td>
</tr>
<tr>
<td>\texttt{global-include} pat1 pat2 ...</td>
<td>include all files anywhere in the source tree matching &amp; any of the listed patterns</td>
</tr>
<tr>
<td>\texttt{global-exclude} pat1 pat2 ...</td>
<td>exclude all files anywhere in the source tree matching &amp; any of the listed patterns</td>
</tr>
<tr>
<td>\texttt{prune} dir</td>
<td>exclude all files under \textit{dir}</td>
</tr>
<tr>
<td>\texttt{graft} dir</td>
<td>include all files under \textit{dir}</td>
</tr>
</tbody>
</table>

The patterns here are \texttt{UNIX}-style ``glob'' patterns: * matches any sequence of regular filename characters, ? matches any single regular filename character, and \texttt{[range]} matches any of the characters in \textit{range} (e.g., a-z, a-zA-Z, a-f0-9_.). The definition of ``regular filename character'' is platform-specific: on \texttt{UNIX} it is anything except slash; on Windows anything except backslash or colon; on Mac OS 9 anything except colon.

** Windows support not there yet **
Release 2.5, documentation updated on 19th September, 2006.

**Distributing Python Modules**

Previous: **10.2 Creating a source**  Up: Distributing Python Modules  Next: **11.1 distutils.core**

*Release 2.5, documentation updated on 19th September, 2006.*
See About this document... for information on suggesting changes.
11.1 distutils.core -- Core Distutils functionality

The distutils.core module is the only module that needs to be installed to use the Distutils. It provides the \texttt{setup()} (which is called from the setup script). Indirectly provides the \texttt{distutils.dist.Distribution} and \texttt{distutils.cmd.Command} class.

\texttt{setup( arguments)}

The basic do-everything function that does most everything you could ever ask for from a Distutils method. See XXXXX

The setup function takes a large number of arguments. These are laid out in the following table.

<table>
<thead>
<tr>
<th>argument name</th>
<th>value</th>
<th>type</th>
</tr>
</thead>
<tbody>
<tr>
<td>name</td>
<td>The name of the package</td>
<td>a string</td>
</tr>
<tr>
<td>version</td>
<td>The version number of the package</td>
<td>See \texttt{distutils.version}</td>
</tr>
<tr>
<td>description</td>
<td>A single line describing the package</td>
<td>a string</td>
</tr>
<tr>
<td>long_description</td>
<td>Longer description of the package</td>
<td>a string</td>
</tr>
<tr>
<td>author</td>
<td>The name of the package author</td>
<td>a string</td>
</tr>
<tr>
<td>author_email</td>
<td>The email address of the package author</td>
<td>a string</td>
</tr>
<tr>
<td>maintainer</td>
<td>The name of the package author</td>
<td>a string</td>
</tr>
<tr>
<td>Variable</td>
<td>Description</td>
<td>Type</td>
</tr>
<tr>
<td>--------------</td>
<td>------------------------------------------------------------------------------</td>
<td>--------------------</td>
</tr>
<tr>
<td>maintainer_email</td>
<td>The email address of the current maintainer, if different from the author.</td>
<td>The email address of the current maintainer, if different from the author.</td>
</tr>
<tr>
<td>url</td>
<td>A URL for the package (homepage)</td>
<td>A URL</td>
</tr>
<tr>
<td>download_url</td>
<td>A URL to download the package</td>
<td>A URL</td>
</tr>
<tr>
<td>packages</td>
<td>A list of Python packages that distutils will manipulate</td>
<td>A list of strings</td>
</tr>
<tr>
<td>py_modules</td>
<td>A list of Python modules that distutils will manipulate</td>
<td>A list of strings</td>
</tr>
<tr>
<td>scripts</td>
<td>A list of standalone script files to be built and installed</td>
<td>A list of strings</td>
</tr>
<tr>
<td>ext_modules</td>
<td>A list of Python extensions to be built</td>
<td>A list of instances of distutils.</td>
</tr>
<tr>
<td>classifiers</td>
<td>A list of categories for the package</td>
<td>The list of available categorizations</td>
</tr>
<tr>
<td>distclass</td>
<td>the Distribution class to use</td>
<td>A subclass of distutils.core.</td>
</tr>
</tbody>
</table>
**script_name** | The name of the setup.py script - defaults to `sys.argv[0]` | a string
---|---|---
**script_args** | Arguments to supply to the setup script | a list of strings
**options** | default options for the setup script | a string
**license** | The license for the package |  
**keywords** | Descriptive metadata. See PEP 314 |  
**platforms** |  
**cmdclass** | A mapping of command names to Command subclasses | a dictionary

**run_setup**(script_name[, script_args=None, stop_after='run'])

Run a setup script in a somewhat controlled environment, and return the `distutils.dist.Distribution` instance that drives things. This is useful if you need to find out the distribution meta-data (passed as keyword args from `script` to `setup()`), or the contents of the config files or command-line.

**script_name** is a file that will be run with `execfile()` `sys.argv[0]` will be replaced with `script` for the duration of the call. **script_args** is a list of strings; if supplied, `sys.argv[1:]` will be replaced by **script_args** for the duration of the call.

**stop_after** tells `setup()` when to stop processing; possible values:

<table>
<thead>
<tr>
<th>value</th>
<th>description</th>
</tr>
</thead>
<tbody>
<tr>
<td>init</td>
<td>Stop after the <code>Distribution</code> instance has been created</td>
</tr>
</tbody>
</table>
and populated with the keyword arguments to setup()

<table>
<thead>
<tr>
<th>config</th>
<th>Stop after config files have been parsed (and their data stored in the Distribution instance)</th>
</tr>
</thead>
<tbody>
<tr>
<td>cmdline</td>
<td>Stop after the command-line (sys.argv[1:] or script_args) have been parsed (and the data stored in the Distribution instance.)</td>
</tr>
<tr>
<td>run</td>
<td>Stop after all commands have been run (the same as if setup() had been called in the usual way). This is the default value.</td>
</tr>
</tbody>
</table>

In addition, the distutils.core module exposed a number of classes that live elsewhere.

- Extension from distutils.extension
- Command from distutils.cmd
- Distribution from distutils.dist

A short description of each of these follows, but see the relevant module for the full reference.

**class Extension**

The Extension class describes a single C or C++ extension module in a setup script. It accepts the following keyword arguments in its constructor

<table>
<thead>
<tr>
<th>argument name</th>
<th>value</th>
<th>type</th>
</tr>
</thead>
<tbody>
<tr>
<td>name</td>
<td>the full name of the extension, including any packages -- ie. not a filename or pathname, but Python dotted name</td>
<td>string</td>
</tr>
<tr>
<td>sources</td>
<td>list of source filenames, relative to the distribution root (where the setup script lives), in Unix form (slash-separated) for portability. Source files may be C, C++, SWIG (.i), platform-specific resource files, or whatever else is recognized by the build_ext</td>
<td>string</td>
</tr>
</tbody>
</table>
command as source for a Python extension.

<table>
<thead>
<tr>
<th>Key</th>
<th>Description</th>
<th>Type</th>
</tr>
</thead>
<tbody>
<tr>
<td>include_dirs</td>
<td>list of directories to search for C/C++ header files (in UNIX form for portability)</td>
<td>string</td>
</tr>
<tr>
<td>define_macros</td>
<td>list of macros to define; each macro is defined using a 2-tuple, where 'value' is either the string to define it to or None to define it without a particular value (equivalent of <code>#define FOO</code> in source or <code>-DFOO</code> on UNIX C compiler command line)</td>
<td>(string,string) tuple or (name,None)</td>
</tr>
<tr>
<td>undef_macros</td>
<td>list of macros to undefine explicitly</td>
<td>string</td>
</tr>
<tr>
<td>library_dirs</td>
<td>list of directories to search for C/C++ libraries at link time</td>
<td>string</td>
</tr>
<tr>
<td>libraries</td>
<td>list of library names (not filenames or paths) to link against</td>
<td>string</td>
</tr>
<tr>
<td>runtime_library_dirs</td>
<td>list of directories to search for C/C++ libraries at run time (for shared extensions, this is when the extension is loaded)</td>
<td>string</td>
</tr>
<tr>
<td>extra_objects</td>
<td>list of extra files to link with (eg. object files not implied by 'sources', static library that must be explicitly specified, binary resource files, etc.)</td>
<td>string</td>
</tr>
<tr>
<td>extra_compile_args</td>
<td>any extra platform- and compiler-specific information to use when compiling the source files in 'sources'. For platforms and compilers where a command line makes sense, this is typically a list of command-line arguments, but for other platforms it could be anything.</td>
<td>string</td>
</tr>
</tbody>
</table>
extra_link_args | any extra platform- and compiler-specific information to use when linking object files together to create the extension (or to create a new static Python interpreter). Similar interpretation as for 'extra_compile_args'. | string
---|---|---
export_symbols | list of symbols to be exported from a shared extension. Not used on all platforms, and not generally necessary for Python extensions, which typically export exactly one symbol: init + extension_name. | string
depends | list of files that the extension depends on | string
language | extension language (i.e. 'c', 'c++', 'objc'). Will be detected from the source extensions if not provided. | string

**class Distribution**

A Distribution describes how to build, install and package up a Python software package.

See the setup() function for a list of keyword arguments accepted by the Distribution constructor. setup() creates a Distribution instance.

**class Command**

A Command class (or rather, an instance of one of its subclasses) implement a single distutils command.
11.2 distutils.ccompiler -- CCompiler base class

This module provides the abstract base class for the CCompiler classes. A CCompiler instance can be used for all the compile and link steps needed to build a single project. Methods are provided to set options for the compiler -- macro definitions, include directories, link path, libraries and the like.

This module provides the following functions.

**gen_lib_options**(*compiler*, *library_dirs*, *runtime_library_dirs*, *libraries*)
Generate linker options for searching library directories and linking with specific libraries. *libraries* and *library_dirs* are, respectively, lists of library names (not filenames!) and search directories. Returns a list of command-line options suitable for use with some compiler (depending on the two format strings passed in).

**gen_preprocess_options**(*macros*, *include_dirs*)
Generate C pre-processor options (-D, -U, -I) as used by at least two types of compilers: the typical UNIX compiler and Visual C++. *macros* is the usual thing, a list of 1- or 2-tuples, where (*name*, ) means undefine (-U) macro *name*, and (*name*, *value*) means define (-D) macro *name* to *value*. *include_dirs* is just a list of directory names to be added to the header file search path (-I). Returns a list of command-line options suitable for either UNIX compilers or Visual C++.

**get_default_compiler**(*osname*, *platform*)
Determine the default compiler to use for the given platform.

*osname* should be one of the standard Python OS names (i.e. the ones returned by *os.name*) and *platform* the common value returned by *sys.platform* for the platform in question.

The default values are *os.name* and *sys.platform* in case the parameters are not given.
new_compiler( plat=None, compiler=None, verbose=0, dry_run=0, force=0)

Factory function to generate an instance of some CCompiler subclass for
the supplied platform/compiler combination. plat defaults to os.name (eg.
'posix', 'nt'), and compiler defaults to the default compiler for that
platform. Currently only 'posix' and 'nt' are supported, and the
default compilers are "traditional UNIX interface" (UnixCCompiler
class) and Visual C++(MSVCCompiler class). Note that it's perfectly
possible to ask for a UNIX compiler object under Windows, and a Microsoft
compiler object under UNIX--if you supply a value for compiler, plat is
ignored.

show_compilers()

Print list of available compilers (used by the --help-compiler options to
build, build_ext, build_clib).

class CCompiler([verbose=0, dry_run=0, force=0])

The abstract base class CCompiler defines the interface that must be
implemented by real compiler classes. The class also has some utility
methods used by several compiler classes.

The basic idea behind a compiler abstraction class is that each instance can
be used for all the compile/link steps in building a single project. Thus,
attributes common to all of those compile and link steps -- include
directories, macros to define, libraries to link against, etc. -- are attributes of
the compiler instance. To allow for variability in how individual files are
treated, most of those attributes may be varied on a per-compilation or per-
link basis.

The constructor for each subclass creates an instance of the Compiler
object. Flags are verbose (show verbose output), dry_run (don't actually
execute the steps) and force (rebuild everything, regardless of
dependencies). All of these flags default to 0 (off). Note that you probably
don't want to instantiate CCompiler or one of its subclasses directly - use
the distutils.CCompiler.new_compiler() factory function
instead.
The following methods allow you to manually alter compiler options for the instance of the Compiler class.

**add_include_dir** (*dir*)
Add *dir* to the list of directories that will be searched for header files. The compiler is instructed to search directories in the order in which they are supplied by successive calls to `add_include_dir()`.

**set_include_dirs** (*dirs*)
Set the list of directories that will be searched to *dirs* (a list of strings). Overrides any preceding calls to `add_include_dir()`; subsequent calls to `add_include_dir()` add to the list passed to `set_include_dirs()`. This does not affect any list of standard include directories that the compiler may search by default.

**add_library** (*libname*)
Add *libname* to the list of libraries that will be included in all links driven by this compiler object. Note that *libname* should *not* be the name of a file containing a library, but the name of the library itself: the actual filename will be inferred by the linker, the compiler, or the compiler class (depending on the platform).

The linker will be instructed to link against libraries in the order they were supplied to `add_library()` and/or `set_libraries()`. It is perfectly valid to duplicate library names; the linker will be instructed to link against libraries as many times as they are mentioned.

**set_libraries** (*libnames*)
Set the list of libraries to be included in all links driven by this compiler object to *libnames* (a list of strings). This does not affect any standard system libraries that the linker may include by default.

**add_library_dir** (*dir*)
Add *dir* to the list of directories that will be searched for libraries specified to `add_library()` and `set_libraries()`. The linker will be instructed to search for libraries in the order they are supplied
to add_library_dir() and/or set_library_dirs().

**set_library_dirs(dirs)**
Set the list of library search directories to *dirs* (a list of strings). This does not affect any standard library search path that the linker may search by default.

**add_runtime_library_dir(dir)**
Add *dir* to the list of directories that will be searched for shared libraries at runtime.

**set_runtime_library_dirs(dirs)**
Set the list of directories to search for shared libraries at runtime to *dirs* (a list of strings). This does not affect any standard search path that the runtime linker may search by default.

**define_macro(name[, value=None])**
Define a preprocessor macro for all compilations driven by this compiler object. The optional parameter *value* should be a string; if it is not supplied, then the macro will be defined without an explicit value and the exact outcome depends on the compiler used (XXX true? does ANSI say anything about this?)

**undefine_macro(name)**
Undefine a preprocessor macro for all compilations driven by this compiler object. If the same macro is defined by define_macro() and undefined by undefine_macro() the last call takes precedence (including multiple redefinitions or undefinitions). If the macro is redefined/undefined on a per-compilation basis (ie. in the call to compile()), then that takes precedence.

**add_link_object(object)**
Add *object* to the list of object files (or analogues, such as explicitly named library files or the output of \"resource compilers\") to be included in every link driven by this compiler object.

**set_link_objects(objects)**
Set the list of object files (or analogues) to be included in every link to objects. This does not affect any standard object files that the linker may include by default (such as system libraries).

The following methods implement methods for autodetection of compiler options, providing some functionality similar to GNU autoconf.

**detect_language** *(sources)*
Detect the language of a given file, or list of files. Uses the instance attributes `language_map` (a dictionary), and `language_order` (a list) to do the job.

**find_library_file** *(dirs, lib[, debug=\theta]*)
Search the specified list of directories for a static or shared library file `lib` and return the full path to that file. If `debug` is true, look for a debugging version (if that makes sense on the current platform). Return None if `lib` wasn't found in any of the specified directories.

**has_function** *(funcname [, includes=\texttt{None}, include_dirs=\texttt{None}, libraries=\texttt{None}, library_dirs=\texttt{None}])*  
Return a boolean indicating whether `funcname` is supported on the current platform. The optional arguments can be used to augment the compilation environment by providing additional include files and paths and libraries and paths.

**library_dir_option** *(dir)*
Return the compiler option to add `dir` to the list of directories searched for libraries.

**library_option** *(lib)*
Return the compiler option to add `dir` to the list of libraries linked into the shared library or executable.

**runtime_library_dir_option** *(dir)*
Return the compiler option to add `dir` to the list of directories searched for runtime libraries.
**set_executables( **args**)

Define the executables (and options for them) that will be run to perform the various stages of compilation. The exact set of executables that may be specified here depends on the compiler class (via the 'executables' class attribute), but most will have:

<table>
<thead>
<tr>
<th>attribute</th>
<th>description</th>
</tr>
</thead>
<tbody>
<tr>
<td>compiler</td>
<td>the C/C++ compiler</td>
</tr>
<tr>
<td>linker_so</td>
<td>linker used to create shared objects and libraries</td>
</tr>
<tr>
<td>linker_exe</td>
<td>linker used to create binary executables</td>
</tr>
<tr>
<td>archiver</td>
<td>static library creator</td>
</tr>
</tbody>
</table>

On platforms with a command-line (UNIX, DOS/Windows), each of these is a string that will be split into executable name and (optional) list of arguments. (Splitting the string is done similarly to how UNIX shells operate: words are delimited by spaces, but quotes and backslashes can override this. See distutils.util.split_quoted().)

The following methods invoke stages in the build process.

```python
compile( sources[, output_dir=None, macros=None, include_dirs=None, debug=0, extra_preargs=None, extra_postargs=None, depends=None])
```

Compile one or more source files. Generates object files (e.g. transforms a .c file to a .o file.)

*sources* must be a list of filenames, most likely C/C++ files, but in reality anything that can be handled by a particular compiler and compiler class (eg. MSVCCompiler can handle resource files in *sources*). Return a list of object filenames, one per source filename in *sources*. Depending on the implementation, not all source files will necessarily be compiled, but all corresponding object filenames will be returned.

If *output_dir* is given, object files will be put under it, while retaining their original path component. That is, foo/bar.c normally compiles to foo/bar.o (for a UNIX implementation); if *output_dir* is *build*, then it
would compile to `build/foo/bar.o`.

*macros*, if given, must be a list of macro definitions. A macro definition is either a `(name, value)` 2-tuple or a `(name,)` 1-tuple. The former defines a macro; if the value is `None`, the macro is defined without an explicit value. The 1-tuple case undefines a macro. Later definitions/redefinitions/undefinitions take precedence.

*include_dirs*, if given, must be a list of strings, the directories to add to the default include file search path for this compilation only.

*debug* is a boolean; if true, the compiler will be instructed to output debug symbols in (or alongside) the object file(s).

*extra_pareargs* and *extra_postargs* are implementation-dependent. On platforms that have the notion of a command-line (e.g. UNIX, DOS/Windows), they are most likely lists of strings: extra command-line arguments to prepend/append to the compiler command line. On other platforms, consult the implementation class documentation. In any event, they are intended as an escape hatch for those occasions when the abstract compiler framework doesn't cut the mustard.

*depends*, if given, is a list of filenames that all targets depend on. If a source file is older than any file in depends, then the source file will be recompiled. This supports dependency tracking, but only at a coarse granularity.

Raises `CompileError` on failure.

```
create_static_lib(objects, output_libname[, output_dir=None, debug=0, target_lang=None])
```

Link a bunch of stuff together to create a static library file. The "bunch of stuff" consists of the list of object files supplied as `objects`, the extra object files supplied to `add_link_object()` and/or `set_link_objects()`, the libraries supplied to `add_library()` and/or `set_libraries()`, and the libraries supplied as `libraries` (if any).

`output_libname` should be a library name, not a filename; the filename
will be inferred from the library name. *output_dir* is the directory where the library file will be put. XXX defaults to what?

*debug* is a boolean; if true, debugging information will be included in the library (note that on most platforms, it is the compile step where this matters: the *debug* flag is included here just for consistency).

*target_lang* is the target language for which the given objects are being compiled. This allows specific linkage time treatment of certain languages.

Raises *LibError* on failure.

```python
link(target_desc, objects, output_filename[, output_dir=None, libraries=None, library_dirs=None, runtime_library_dirs=None, export_symbols=None, debug=0, extra_preargs=None, extra_postargs=None, build_temp=None, target_lang=None])
```

Link a bunch of stuff together to create an executable or shared library file.

The ``bunch of stuff`` consists of the list of object files supplied as *objects*. *output_filename* should be a filename. If *output_dir* is supplied, *output_filename* is relative to it (i.e. *output_filename* can provide directory components if needed).

*libraries* is a list of libraries to link against. These are library names, not filenames, since they’re translated into filenames in a platform-specific way (eg. *foo* becomes *libfoo.a* on *UNIX* and *foo.lib* on DOS/Windows). However, they can include a directory component, which means the linker will look in that specific directory rather than searching all the normal locations.

*library_dirs*, if supplied, should be a list of directories to search for libraries that were specified as bare library names (ie. no directory component). These are on top of the system default and those supplied to *add_library_dir() and/or set_library_dirs()*.

*runtime_library_dirs* is a list of directories that will be embedded into the shared library and used to search for other shared libraries that *it* depends on at run-time. (This may only be relevant on *UNIX.*).
export_symbols is a list of symbols that the shared library will export. (This appears to be relevant only on Windows.)

debug is as for compile() and create_static_lib(), with the slight distinction that it actually matters on most platforms (as opposed to create_static_lib(), which includes a debug flag mostly for form's sake).

extra_preargs and extra_postargs are as for compile() (except of course that they supply command-line arguments for the particular linker being used).

target_lang is the target language for which the given objects are being compiled. This allows specific linkage time treatment of certain languages.

Raises LinkError on failure.

```
link_executable(objects, output_progname[, output_dir=’None’,
libraries=’None’, library_dirs=’None’,
runtime_library_dirs=’None’, debug=0,
extra_preargs=’None’, extra_postargs=’None’,
target_lang=’None’])
```

Link an executable. output_progname is the name of the file executable, while objects are a list of object filenames to link in. Other arguments are as for the link method.

```
link_shared_lib(objects, output_libname[, output_dir=’None’,
libraries=’None’, library_dirs=’None’,
runtime_library_dirs=’None’,
export_symbols=’None’, debug=0,
extra_preargs=’None’, extra_postargs=’None’,
build_temp=’None’, target_lang=’None’])
```

Link a shared library. output_libname is the name of the output library, while objects is a list of object filenames to link in. Other arguments are as for the link method.
Link a shared object. `output_filename` is the name of the shared object that will be created, while `objects` is a list of object filenames to link in. Other arguments are as for the `link` method.

Preprocess a single C/C++ source file, named in `source`. Output will be written to file named `output_file`, or `stdout` if `output_file` not supplied. `macros` is a list of macro definitions as for `compile()`, which will augment the macros set with `define_macro()` and `undefine_macro()`. `include_dirs` is a list of directory names that will be added to the default list, in the same way as `add_include_dir()`.

Raises `PreprocessError` on failure.

The following utility methods are defined by the `CCompiler` class, for use by the various concrete subclasses.

Returns the filename of the executable for the given `basename`. Typically for non-Windows platforms this is the same as the basename, while Windows will get a `.exe` added.

Returns the filename for the given library name on the current platform. On UNIX a library with `lib_type` of 'static' will typically be of the form `liblibname.a`, while a `lib_type` of 'dynamic' will be of the form `liblibname.so`. 
**object_filenames** *source_filenames*[ , *strip_dir=0, output_dir=' ']*)

Returns the name of the object files for the given source files.  
*source_filenames* should be a list of filenames.

**shared_object_filename** *

Returns the name of a shared object file for the given file name *basename*.

**execute** *(func, args[, msg=None, level=1])*

Invokes *distutils.util.execute()* This method invokes a Python function *func* with the given arguments *args*, after logging and taking into account the *dry_run* flag.  XXX see also.

**spawn** *(cmd)*

Invokes *distutils.util.spawn()* This invokes an external process to run the given command.  XXX see also.

**mkpath** *(name[, mode=511])*

Invokes *distutils.dir_util.mkpath()* This creates a directory and any missing ancestor directories.  XXX see also.

**move_file** *(src, dst)*

Invokes *distutils.file_util.move_file()* Renames *src* to *dst*.  XXX see also.

**announce** *(msg[, level=1])*

Write a message using *distutils.log.debug()* XXX see also.

**warn** *(msg)*

Write a warning message *msg* to standard error.

**debug_print** *(msg)*

If the *debug* flag is set on this CCompiler instance, print *msg* to standard output, otherwise do nothing.
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
11.3 distutils.unixccompiler -- Unix C Compiler

This module provides the UnixCCompiler class, a subclass of CCompiler that handles the typical UNIX-style command-line C compiler:

- macros defined with `-Dname[=value]`
- macros undefined with `-Uname`
- include search directories specified with `-Idir`
- libraries specified with `-l` `lib`
- library search directories specified with `-L` `dir`
- compile handled by `cc` (or similar) executable with `-c` option: compiles `.c` to `.o`
- link static library handled by `ar` command (possibly with `ranlib`)
- link shared library handled by `cc -shared`

---

**Distributing Python Modules**

Previous: 11.2 distutils.ccompiler Up: 11. API Reference Next: 11.4 distutils.msvccompiler

Release 2.5, documentation updated on 19th September, 2006. See About this document... for information on suggesting changes.
11.4 distutils.msvccompiler -- Microsoft Compiler

This module provides MsvcCompiler, an implementation of the abstract CCompiler class for Microsoft Visual Studio. Typically, extension modules need to be compiled with the same compiler that was used to compile Python. For Python 2.3 and earlier, the compiler was Visual Studio 6. For Python 2.4 and 2.5, the compiler is Visual Studio .NET 2003. The AMD64 and Itanium binaries are created using the Platform SDK.

MsvcCompiler will normally choose the right compiler, linker etc. on its own. To override this choice, the environment variables DISTUTILS_USE_SDK and MSSdk must be both set. MSSdk indicates that the current environment has been setup by the SDK's SetEnv.Cmd script, or that the environment variables had been registered when the SDK was installed; DISTUTILS_USE_SDK indicates that the distutils user has made an explicit choice to override the compiler selection by MsvcCompiler.

Distributing Python Modules

Previous: 11.3 distutils.unixccompiler Up: 11. API Reference Next: 11.5 distutils.bcppcompiler

Release 2.5, documentation updated on 19th September, 2006. See About this document... for information on suggesting changes.
11.5 distutils.bcppcompiler -- Borland Compiler

This module provides BorlandCCompiler, a subclass of the abstract CCompiler class for the Borland C++ compiler.

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
11.6 distutils.cygwincompiler -- Cygwin Compiler

This module provides the CygwinCCompiler class, a subclass of UnixCCompiler that handles the Cygwin port of the GNU C compiler to Windows. It also contains the Mingw32CCompiler class which handles the mingw32 port of GCC (same as cygwin in no-cygwin mode).
11.7 distutils.emxccompiler -- OS/2 EMX Compiler

This module provides the EMXCCompiler class, a subclass of UnixCCompiler that handles the EMX port of the GNU C compiler to OS/2.

Release 2.5, documentation updated on 19th September, 2006. See About this document... for information on suggesting changes.
11.8 distutils.mwerkscompiler -- Metrowerks CodeWarrior support

Contains MWerksCompiler, an implementation of the abstract CCompiler class for MetroWerks CodeWarrior on the pre-Mac OS X Macintosh. Needs work to support CW on Windows or Mac OS X.
11.9 distutils.archive_util -- Archiving utilities

This module provides a few functions for creating archive files, such as tarballs or zipfiles.

```
make_archive(base_name, format[, root_dir=None, base_dir=None, verbose=0, dry_run=0])
```

Create an archive file (eg. zip or tar). base_name is the name of the file to create, minus any format-specific extension; format is the archive format: one of zip, tar, ztar, or gztar. root_dir is a directory that will be the root directory of the archive; ie. we typically chdir into root_dir before creating the archive. base_dir is the directory where we start archiving from; ie. base_dir will be the common prefix of all files and directories in the archive. root_dir and base_dir both default to the current directory. Returns the name of the archive file.

**Warning:** This should be changed to support bz2 files

```
make_tarball(base_name, base_dir[, compress='gzip', verbose=0, dry_run=0])
```

'Create an (optional compressed) archive as a tar file from all files in and under base_dir. compress must be 'gzip' (the default), 'compress', 'bzip2', or None. Both tar and the compression utility named by compress must be on the default program search path, so this is probably UNIX-specific. The output tar file will be named base_dir.tar, possibly plus the appropriate compression extension (.gz, .bz2 or .Z). Return the output filename.

**Warning:** This should be replaced with calls to the tarfile module.

```
make_zipfile(base_name, base_dir[, verbose=0, dry_run=0])
```

Create a zip file from all files in and under base_dir. The output zip file will be named base_dir + .zip. Uses either the zipfile Python module (if
available) or the InfoZIP zip utility (if installed and found on the default search path). If neither tool is available, raises DistutilsExecError. Returns the name of the output zip file.
11.10 distutils.dep_util --
Dependency checking

This module provides functions for performing simple, timestamp-based
dependency of files and groups of files; also, functions based entirely on such
timestamp dependency analysis.

**newer**(*source*, *target*)

Return true if *source* exists and is more recently modified than *target*, or if
*source* exists and *target* doesn't. Return false if both exist and *target* is the
same age or newer than *source*. Raise *DistutilsFileError* if *source*
does not exist.

**newer_pairwise**(*sources*, *targets*)

Walk two filename lists in parallel, testing if each source is newer than its
 corresponding target. Return a pair of lists (*sources*, *targets*) where source
is newer than target, according to the semantics of *newer()*

**newer_group**(*sources*, *target*, *missing*='error')

Return true if *target* is out-of-date with respect to any file listed in *sources*
In other words, if *target* exists and is newer than every file in *sources*,
return false; otherwise return true. *missing* controls what we do when a
source file is missing; the default ('error') is to blow up with an
*OSError* from inside *os.stat()*. if it is 'ignore', we silently drop
any missing source files; if it is 'newer', any missing source files make
us assume that *target* is out-of-date (this is handy in ``dry-run" mode: it'll
make you pretend to carry out commands that wouldn't work because inputs
are missing, but that doesn't matter because you're not actually going to run
the commands).
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
11.11 distutils.dir_util --
Directory tree operations

This module provides functions for operating on directories and trees of
directories.

**mkpath**( `name[, mode=0777, verbose=0, dry_run=0]`)  
Create a directory and any missing ancestor directories. If the directory already exists (or if `name` is the empty string, which means the current directory, which of course exists), then do nothing. Raise `DistutilsFileError` if unable to create some directory along the way (e.g. some sub-path exists, but is a file rather than a directory). If `verbose` is true, print a one-line summary of each mkdir to stdout. Return the list of
directories actually created.

**create_tree**( `base_dir, files[, mode=0777, verbose=0, dry_run=0]`)  
Create all the empty directories under `base_dir` needed to put `files` there. 
`base_dir` is just the a name of a directory which doesn't necessarily exist yet; `files` is a list of filenames to be interpreted relative to `base_dir`. 
`base_dir` + the directory portion of every file in `files` will be created if it doesn't already exist. `mode`, `verbose` and `dry_run` flags are as for `mkpath()`.

**copy_tree**( `src, dst[ preserve_mode=1, preserve_times=1, 
    preserve_symlinks=0, update=0, verbose=0, dry_run=0 ]`)  
Copy an entire directory tree `src` to a new location `dst`. Both `src` and `dst` must be directory names. If `src` is not a directory, raise `DistutilsFileError`. If `dst` does not exist, it is created with `mkpath()`. The end result of the copy is that every file in `src` is copied to 
`dst`, and directories under `src` are recursively copied to `dst`. Return the list of
files that were copied or might have been copied, using their output name. 
The return value is unaffected by `update` or `dry_run`: it is simply the list of
all files under `src`, with the names changed to be under `dst`. 

preserve_mode and preserve_times are the same as for copy_file in distutils.file_util; note that they only apply to regular files, not to directories. If preserve_symlinks is true, symlinks will be copied as symlinks (on platforms that support them!); otherwise (the default), the destination of the symlink will be copied. update and verbose are the same as for copy_file.

** Some of this could be replaced with the shutil module? **

remove_tree(directory[verbose=0, dry_run=0])
Recursively remove directory and all files and directories underneath it. Any errors are ignored (apart from being reported to sys.stdout if verbose is true).

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
11.12 distutils.file_util -- Single file operations

This module contains some utility functions for operating on individual files.

```
copy_file( src, dst[preserve_mode=1, preserve_times=1, update=0,  
    link=None, verbose=0, dry_run=0])
```

Copy file `src` to `dst`. If `dst` is a directory, then `src` is copied there with the same name; otherwise, it must be a filename. (If the file exists, it will be ruthlessly clobbered.) If `preserve_mode` is true (the default), the file's mode (type and permission bits, or whatever is analogous on the current platform) is copied. If `preserve_times` is true (the default), the last-modified and last-access times are copied as well. If `update` is true, `src` will only be copied if `dst` does not exist, or if `dst` does exist but is older than `src`.

`link` allows you to make hard links (using `os.link`) or symbolic links (using `os.symlink`) instead of copying: set it to 'hard' or 'sym'; if it is `None` (the default), files are copied. Don't set `link` on systems that don't support it: `copy_file()` doesn't check if hard or symbolic linking is available. It uses `_copy_file_contents()` to copy file contents.

Return a tuple "(dest_name, copied)": `dest_name` is the actual name of the output file, and `copied` is true if the file was copied (or would have been copied, if `dry_run` true).

```
move_file( src, dst[verbose, dry_run])
```

Move file `src` to `dst`. If `dst` is a directory, the file will be moved into it with the same name; otherwise, `src` is just renamed to `dst`. Returns the new full name of the file. **Warning:** Handles cross-device moves on UNIX using `copy_file()`. What about other systems???

```
write_file( filename, contents)
```

Create a file called `filename` and write `contents` (a sequence of strings without line terminators) to it.
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
11.13 distutils.util -- Miscellaneous other utility functions

This module contains other assorted bits and pieces that don't fit into any other utility module.

get_platform()

Return a string that identifies the current platform. This is used mainly to distinguish platform-specific build directories and platform-specific built distributions. Typically includes the OS name and version and the architecture (as supplied by 'os.uname()'), although the exact information included depends on the OS; eg. for IRIX the architecture isn't particularly important (IRIX only runs on SGI hardware), but for Linux the kernel version isn't particularly important.

Examples of returned values:

- linux-i586
- linux-alpha
- solaris-2.6-sun4u
- irix-5.3
- irix64-6.2

For non-POSIX platforms, currently just returns sys.platform.

convert_path(pathname)

Return 'pathname' as a name that will work on the native filesystem, i.e. split it on '/' and put it back together again using the current directory separator. Needed because filenames in the setup script are always supplied in UNIX style, and have to be converted to the local convention before we can actually use them in the filesystem. Raises ValueError on non-UNIX-ish systems if pathname either starts or ends with a slash.

change_root(new_root, pathname)

Return pathname with new_root prepended. If pathname is relative, this is
equivalent to "os.path.join(new_root, pathname)"
Otherwise, it requires making pathname relative and then joining the two, which is tricky on DOS/Windows.

**check_environ()**
Ensure that 'os.environ' has all the environment variables we guarantee that users can use in config files, command-line options, etc. Currently this includes:
- **HOME** - user's home directory (UNIX only)
- **PLAT** - description of the current platform, including hardware and OS
  (see get_platform())

**subst_vars(s, local_vars)**
Perform shell/Perl-style variable substitution on s. Every occurrence of $ followed by a name is considered a variable, and variable is substituted by the value found in the local_vars dictionary, or in os.environ if it's not in local_vars. os.environ is first checked/augmented to guarantee that it contains certain values: see check_environ(). Raise ValueError for any variables not found in either local_vars or os.environ.

Note that this is not a fully-fledged string interpolation function. A valid $variable can consist only of upper and lower case letters, numbers and an underscore. No { } or style quoting is available.

**grok_environment_error(exc[, prefix=\texttt{tex2html_deferred}{'error:}]]
Generate a useful error message from an EnvironmentError (IOError or OSError) exception object. Handles Python 1.5.1 and later styles, and does what it can to deal with exception objects that don't have a filename (which happens when the error is due to a two-file operation, such as rename() or link()). Returns the error message as a string prefixed with prefix.

**split_quoted(s)**
Split a string up according to UNIX shell-like rules for quotes and backslashes. In short: words are delimited by spaces, as long as those spaces are not escaped by a backslash, or inside a quoted string. Single and
double quotes are equivalent, and the quote characters can be backslash-escaped. The backslash is stripped from any two-character escape sequence, leaving only the escaped character. The quote characters are stripped from any quoted string. Returns a list of words.

**execute**(*func*, *args*[*, *msg=None*, *verbose=0*, *dry_run=0]*)

Perform some action that affects the outside world (for instance, writing to the filesystem). Such actions are special because they are disabled by the `dry_run` flag. This method takes care of all that bureaucracy for you; all you have to do is supply the function to call and an argument tuple for it (to embody the "external action" being performed), and an optional message to print.

**strtobool**(*val*)

Convert a string representation of truth to true (1) or false (0).

True values are *y*, *yes*, *t*, *true*, *on* and 1; false values are *n*, *no*, *f*, *false*, *off* and 0. Raises *ValueError* if *val* is anything else.

**byte_compile**(*py_files*[*, *optimize=0*, *force=0*, *prefix=None*, *base_dir=None*, *verbose=1*, *dry_run=0*, *direct=None]*)

Byte-compile a collection of Python source files to either .pyc or .pyo files in the same directory. *py_files* is a list of files to compile; any files that don't end in .py are silently skipped. optimize must be one of the following:

- 0 - don't optimize (generate .pyc)
- 1 - normal optimization (like "python -O")
- 2 - extra optimization (like "python -OO")

If force is true, all files are recompiled regardless of timestamps.

The source filename encoded in each bytecode file defaults to the filenames listed in *py_files*; you can modify these with prefix and basedir. prefix is a string that will be stripped off of each source filename, and basedir is a directory name that will be prepended (after prefix is stripped). You can supply either or both (or neither) of prefix and basedir, as you wish.

If dry_run is true, doesn't actually do anything that would affect the filesystem.
Byte-compilation is either done directly in this interpreter process with the standard `py_compile` module, or indirectly by writing a temporary script and executing it. Normally, you should let `byte_compile()` figure out to use direct compilation or not (see the source for details). The `direct` flag is used by the script generated in indirect mode; unless you know what you're doing, leave it set to `None`.

**rfc822_escape( header)**

Return a version of `header` escaped for inclusion in an RFC 822 header, by ensuring there are 8 spaces space after each newline. Note that it does no other modification of the string.
11.14 distutils.dist -- The Distribution class

This module provides the Distribution class, which represents the module distribution being built/installed/distributed.
11.15 distutils.extension -- The Extension class

This module provides the Extension class, used to describe C/C++ extension modules in setup scripts.
11.16 distutils.debug -- Distutils debug mode

This module provides the DEBUG flag.
11.17 distutils.errors -- Distutils exceptions

Provides exceptions used by the Distutils modules. Note that Distutils modules may raise standard exceptions; in particular, SystemExit is usually raised for errors that are obviously the end-user's fault (eg. bad command-line arguments).

This module is safe to use in "from ... import *" mode; it only exports symbols whose names start with Distutils and end with Error.

Distributing Python Modules

Previous: 11.16 distutils.debug  Up: 11. API Reference  Next: 11.18 distutils.fancy_getopt

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
11.18 distutils.fancy_getopt --
Wrapper around the standard getopt module

This module provides a wrapper around the standard getopt module that provides the following additional features:

- short and long options are tied together
- options have help strings, so `fancy_getopt` could potentially create a complete usage summary
- options set attributes of a passed-in object
- boolean options can have ``negative aliases'' -- eg. if `--quiet` is the ``negative alias'' of `--verbose`, then `--quiet` on the command line sets `verbose` to false.

** Should be replaced with optik (which is also now known as optrparase in Python 2.3 and later). **

`fancy_getopt(options, negative_opt, object, args)`
Wrapper function. `options` is a list of ``(long_option, short_option, help_string)`` 3-tuples as described in the constructor for FancyGetopt. `negative_opt` should be a dictionary mapping option names to option names, both the key and value should be in the `options` list. `object` is an object which will be used to store values (see the getopt() method of the FancyGetopt class). `args` is the argument list. Will use `sys.argv[1:]` if you pass `None` as `args`.

`wrap_text(text, width)`
Wraps `text` to less than `width` wide.

**Warning:** Should be replaced with textwrap (which is available in Python 2.3 and later).

`class FancyGetopt([option_table=None])`
The option_table is a list of 3-tuples: "(long_option, short_option, help_string)"

If an option takes an argument, its long_option should have '=' appended; short_option should just be a single character, no ':' in any case. short_option should be None if a long_option doesn't have a corresponding short_option. All option tuples must have long options.

The FancyGetopt class provides the following methods:

getopt([args=None, object=None])
Parse command-line options in args. Store as attributes on object.

If args is None or not supplied, uses sys.argv[1:]. If object is None or not supplied, creates a new OptionDummy instance, stores option values there, and returns a tuple "(args, object)". If object is supplied, it is modified in place and getopt() just returns args; in both cases, the returned args is a modified copy of the passed-in args list, which is left untouched.

get_option_order()
Returns the list of "(option, value)" tuples processed by the previous run of getopt() Raises RuntimeError if getopt() hasn't been called yet.

generate_help([header=None])
Generate help text (a list of strings, one per suggested line of output) from the option table for this FancyGetopt object.

If supplied, prints the supplied header at the top of the help.
11.19 distutils.filelist -- The FileList class

This module provides the FileList class, used for poking about the filesystem and building lists of files.
11.20 distutils.log -- Simple PEP 282-style logging

**Warning:** Should be replaced with standard **logging** module.

Release 2.5, documentation updated on 19th September, 2006.
See [About this document...](...) for information on suggesting changes.
11.21 distutils.spawn -- Spawn a sub-process

This module provides the `spawn()` function, a front-end to various platform-specific functions for launching another program in a sub-process. Also provides `find_executable()` to search the path for a given executable name.
11.22 distutils.sysconfig -- System configuration information

The distutils.sysconfig module provides access to Python's low-level configuration information. The specific configuration variables available depend heavily on the platform and configuration. The specific variables depend on the build process for the specific version of Python being run; the variables are those found in the Makefile and configuration header that are installed with Python on UNIX systems. The configuration header is called pyconfig.h for Python versions starting with 2.2, and config.h for earlier versions of Python.

Some additional functions are provided which perform some useful manipulations for other parts of the distutils package.

**PREFIX**

The result of os.path.normpath(sys.prefix).

**EXEC_PREFIX**

The result of os.path.normpath(sys.exec_prefix).

**get_config_var(name)**

Return the value of a single variable. This is equivalent to get_config_vars().get(name).

**get_config_vars(…)**

Return a set of variable definitions. If there are no arguments, this returns a dictionary mapping names of configuration variables to values. If arguments are provided, they should be strings, and the return value will be a sequence giving the associated values. If a given name does not have a corresponding value, None will be included for that variable.

**get_config_h_filename()**

Return the full path name of the configuration header. For UNIX, this will be the header generated by the configure script; for other platforms the header will have been supplied directly by the Python source distribution. The file
is a platform-specific text file.

**get_makefile_filename()**

Return the full path name of the Makefile used to build Python. For UNIX, this will be a file generated by the `configure` script; the meaning for other platforms will vary. The file is a platform-specific text file, if it exists. This function is only useful on POSIX platforms.

**get_python_inc([plat_specific[, prefix]])**

Return the directory for either the general or platform-dependent C include files. If `plat_specific` is true, the platform-dependent include directory is returned; if false or omitted, the platform-independent directory is returned. If `prefix` is given, it is used as either the prefix instead of `PREFIX`, or as the exec-prefix instead of `EXEC_PREFIX` if `plat_specific` is true.

**get_python_lib([plat_specific[, standard_lib[, prefix]]])**

Return the directory for either the general or platform-dependent library installation. If `plat_specific` is true, the platform-dependent include directory is returned; if false or omitted, the platform-independent directory is returned. If `prefix` is given, it is used as either the prefix instead of `PREFIX`, or as the exec-prefix instead of `EXEC_PREFIX` if `plat_specific` is true. If `standard_lib` is true, the directory for the standard library is returned rather than the directory for the installation of third-party extensions.

The following function is only intended for use within the `distutils` package.

**customize_compiler(compiler)**

Do any platform-specific customization of a `distutils.ccompiler.CCompiler` instance.

This function is only needed on UNIX at this time, but should be called consistently to support forward-compatibility. It inserts the information that varies across UNIX flavors and is stored in Python's `Makefile`. This information includes the selected compiler, compiler and linker options, and the extension used by the linker for shared objects.

This function is even more special-purpose, and should only be used from
Python's own build procedures.

**set_python_build()**

Inform the `distutils.sysconfig` module that it is being used as part of the build process for Python. This changes a lot of relative locations for files, allowing them to be located in the build area rather than in an installed Python.
11.23 distutils.text_file -- The TextFile class

This module provides the TextFile class, which gives an interface to text files that (optionally) takes care of stripping comments, ignoring blank lines, and joining lines with backslashes.

**class TextFile([filename=None, file=None, **options])**

This class provides a file-like object that takes care of all the things you commonly want to do when processing a text file that has some line-by-line syntax: strip comments (as long as # is your comment character), skip blank lines, join adjacent lines by escaping the newline (ie. backslash at end of line), strip leading and/or trailing whitespace. All of these are optional and independently controllable.

The class provides a `warn()` method so you can generate warning messages that report physical line number, even if the logical line in question spans multiple physical lines. Also provides `unreadline()` for implementing line-at-a-time lookahead.

TextFile instances are create with either `filename`, `file`, or both. `RuntimeError` is raised if both are `None`. `filename` should be a string, and `file` a file object (or something that provides `readline()` and `close()` methods). It is recommended that you supply at least `filename`, so that TextFile can include it in warning messages. If `file` is not supplied, TextFile creates its own using the `open()` built-in function.

The options are all boolean, and affect the values returned by `readline()`

<table>
<thead>
<tr>
<th>option name</th>
<th>description</th>
<th>default</th>
</tr>
</thead>
<tbody>
<tr>
<td>strip from # to end-of-line, as well as any whitespace leading up to the #--unless it is escaped by a backslash</td>
<td>true</td>
<td></td>
</tr>
<tr>
<td>strip leading whitespace from each line before returning it</td>
<td>false</td>
<td></td>
</tr>
<tr>
<td>strip trailing whitespace (including line terminator!) from each line before returning it.</td>
<td>true</td>
<td></td>
</tr>
<tr>
<td>skip lines that are empty <em>after</em> stripping comments and whitespace. (If both lstrip_ws and rstrip_ws are false, then some lines may consist of solely whitespace: these will <em>not</em> be skipped, even if skip_blanks is true.)</td>
<td>true</td>
<td></td>
</tr>
<tr>
<td>if a backslash is the last non-newline character on a line after stripping comments and whitespace, join the following line to it to form one logical line; if N consecutive lines end with a backslash, then N+1 physical lines will be joined to form one logical line.</td>
<td>false</td>
<td></td>
</tr>
<tr>
<td>strip leading whitespace from lines that are joined to their predecessor; only matters if &quot;(join_lines and not lstrip_ws)&quot;</td>
<td>false</td>
<td></td>
</tr>
</tbody>
</table>

Note that since rstrip_ws can strip the trailing newline, the semantics of readline() must differ from those of the built-in file object's readline() method! In particular, readline() returns None for end-of-file: an empty string might just be a blank line (or an all-whitespace line), if rstrip_ws is true but skip_blanks is not.

**open( filename )**

Open a new file filename. This overrides any file or filename constructor arguments.

**close()**

Close the current file and forget everything we know about it (including the filename and the current line number).

**warn( msg[, line=None] )**

Print (to stderr) a warning message tied to the current logical line in the current file. If the current logical line in the file spans multiple physical lines, the warning refers to the whole range, such as ":lines 3-5". If line is supplied, it overrides the current line
number; it may be a list or tuple to indicate a range of physical lines, or an integer for a single physical line.

**readline()**

Read and return a single logical line from the current file (or from an internal buffer if lines have previously been ``unread'' with unreadline()). If the join_lines option is true, this may involve reading multiple physical lines concatenated into a single string. Updates the current line number, so calling warn() after readline() emits a warning about the physical line(s) just read. Returns None on end-of-file, since the empty string can occur if rstrip_ws is true but strip_blanks is not.

**readlines()**

Read and return the list of all logical lines remaining in the current file. This updates the current line number to the last line of the file.

**unreadline( line)**

Push line (a string) onto an internal buffer that will be checked by future readline() calls. Handy for implementing a parser with line-at-a-time lookahead. Note that lines that are ``unread'' with unreadline are not subsequently re-cleansed (whitespace stripped, or whatever) when read with readline. If multiple calls are made to unreadline before a call to readline, the lines will be returned most in most recent first order.

11.25 distutils.cmd -- Abstract base class for Distutils commands

This module supplies the abstract base class Command.

```python
class Command(dist)
    Abstract base class for defining command classes, the ``worker bees'' of the Distutils. A useful analogy for command classes is to think of them as subroutines with local variables called options. The options are declared in initialize_options() and defined (given their final values) in finalize_options(), both of which must be defined by every command class. The distinction between the two is necessary because option values might come from the outside world (command line, config file, ...), and any options dependent on other options must be computed after these outside influences have been processed -- hence finalize_options(). The body of the subroutine, where it does all its work based on the values of its options, is the run() method, which must also be implemented by every command class.

The class constructor takes a single argument dist, a Distribution instance.
```

Distributing Python Modules

Previous: 11.44 distutils.command.install_scripts  Up: 11. API Reference  Next: 11.46 Creating a new

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
11.46 Creating a new Distutils command

This section outlines the steps to create a new Distutils command.

A new command lives in a module in the distutils.command package. There is a sample template in that directory called command_template. Copy this file to a new module with the same name as the new command you're implementing. This module should implement a class with the same name as the module (and the command). So, for instance, to create the command peel_banana (so that users can run "setup.py peel_banana"), you'd copy command_template to distutils/command/peel_banana.py, then edit it so that it's implementing the class peel_banana, a subclass of distutils.cmd.Command.

Subclasses of Command must define the following methods.

initialize_options()

Set default values for all the options that this command supports. Note that these defaults may be overridden by other commands, by the setup script, by config files, or by the command-line. Thus, this is not the place to code dependencies between options; generally, initialize_options() implementations are just a bunch of "self.foo = None" assignments.

finalize_options()

Set final values for all the options that this command supports. This is always called as late as possible, i.e. after any option assignments from the command-line or from other commands have been done. Thus, this is the place to to code option dependencies: if foo depends on bar, then it is safe to set foo from bar as long as foo still has the same value it was assigned in initialize_options().

run()

A command's raison d'être: carry out the action it exists to perform, controlled by the options initialized in initialize_options(),
customized by other commands, the setup script, the command-line, and config files, and finalized in `finalize_options()`. All terminal output and filesystem interaction should be done by `run()`.

`sub_commands` formalizes the notion of a ``family'' of commands, eg. `install` as the parent with sub-commands `install_lib`, `install_headers`, etc. The parent of a family of commands defines `sub_commands` as a class attribute; it's a list of 2-tuples "(command_name, predicate)", with `command_name` a string and `predicate` an unbound method, a string or None. `predicate` is a method of the parent command that determines whether the corresponding command is applicable in the current situation. (Eg. we `install_headers` is only applicable if we have any C header files to install.) If `predicate` is None, that command is always applicable.

`sub_commands` is usually defined at the *end* of a class, because predicates can be unbound methods, so they must already have been defined. The canonical example is the `install` command.

About this document...
Release 1.0.
See About this document... for information on suggesting changes.
This article explains the new features in Python 2.5. The final release of Python 2.5 is scheduled for August 2006; PEP 356 describes the planned release schedule.

The changes in Python 2.5 are an interesting mix of language and library improvements. The library enhancements will be more important to Python's user community, I think, because several widely-useful packages were added. New modules include ElementTree for XML processing (section 13.2), the
SQLite database module (section 13.4), and the ctypes module for calling C functions (section 13.1).

The language changes are of middling significance. Some pleasant new features were added, but most of them aren't features that you'll use every day. Conditional expressions were finally added to the language using a novel syntax; see section 1. The new 'with' statement will make writing cleanup code easier (section 8). Values can now be passed into generators (section 7). Imports are now visible as either absolute or relative (section 4). Some corner cases of exception handling are handled better (section 6). All these improvements are worthwhile, but they're improvements to one specific language feature or another; none of them are broad modifications to Python's semantics.

As well as the language and library additions, other improvements and bugfixes were made throughout the source tree. A search through the SVN change logs finds there were 353 patches applied and 458 bugs fixed between Python 2.4 and 2.5. (Both figures are likely to be underestimates.)

This article doesn't try to be a complete specification of the new features; instead changes are briefly introduced using helpful examples. For full details, you should always refer to the documentation for Python 2.5 at http://docs.python.org. If you want to understand the complete implementation and design rationale, refer to the PEP for a particular new feature.

Comments, suggestions, and error reports for this document are welcome; please e-mail them to the author or open a bug in the Python bug tracker.

This document was generated using the LaTeX2HTML translator.

The application of LaTeX2HTML to the Python documentation has been heavily tailored by Fred L. Drake, Jr. Original navigation icons were contributed by Christopher Petrilli.
Comments and Questions

General comments and questions regarding this document should be sent by email to docs@python.org. If you find specific errors in this document, either in the content or the presentation, please report the bug at the Python Bug Tracker at SourceForge. If you are able to provide suggested text, either to replace existing incorrect or unclear material, or additional text to supplement what's already available, we'd appreciate the contribution. There's no need to worry about text markup; our documentation team will gladly take care of that.

Questions regarding how to use the information in this document should be sent to the Python news group, comp.lang.python, or the Python mailing list (which is gated to the newsgroup and carries the same content).

For any of these channels, please be sure not to send HTML email. Thanks.
16 Acknowledgements

The author would like to thank the following people for offering suggestions, corrections and assistance with various drafts of this article: Georg Brandl, Nick Coghlan, Phillip J. Eby, Lars Gustäbel, Raymond Hettinger, Ralf W. Grosse-Kunstleve, Kent Johnson, Iain Lowe, Martin von Löwis, Fredrik Lundh, Andrew McNamara, Skip Montanaro, Gustavo Niemeyer, Paul Prescod, James Pryor, Mike Rovner, Scott Weikart, Barry Warsaw, Thomas Wouters.
Abstract:

Python is an easy to learn, powerful programming language. It has efficient high-level data structures and a simple but effective approach to object-oriented programming. Python's elegant syntax and dynamic typing, together with its interpreted nature, make it an ideal language for scripting and rapid application development in many areas on most platforms.

The Python interpreter and the extensive standard library are freely available in source or binary form for all major platforms from the Python Web site, http://www.python.org/, and may be freely distributed. The same site also contains distributions of and pointers to many free third party Python modules, programs and tools, and additional documentation.

The Python interpreter is easily extended with new functions and data types implemented in C or C++ (or other languages callable from C). Python is also suitable as an extension language for customizable applications.

This tutorial introduces the reader informally to the basic concepts and features of the Python language and system. It helps to have a Python interpreter handy for hands-on experience, but all examples are self-contained, so the tutorial can be read off-line as well.

For a description of standard objects and modules, see the Python Library.
Reference document. The Python Reference Manual gives a more formal definition of the language. To write extensions in C or C++, read Extending and Embedding the Python Interpreter and Python/C API Reference. There are also several books covering Python in depth.

This tutorial does not attempt to be comprehensive and cover every single feature, or even every commonly used feature. Instead, it introduces many of Python's most noteworthy features, and will give you a good idea of the language's flavor and style. After reading it, you will be able to read and write Python modules and programs, and you will be ready to learn more about the various Python library modules described in the Python Library Reference.

9.8 Exceptions Are Classes Too
9.9 Iterators
9.10 Generators
9.11 Generator Expressions

10. Brief Tour of the Standard Library
  10.1 Operating System Interface
  10.2 File Wildcards
  10.3 Command Line Arguments
  10.4 Error Output Redirection and Program Termination
  10.5 String Pattern Matching
  10.6 Mathematics
  10.7 Internet Access
  10.8 Dates and Times
  10.9 Data Compression
  10.10 Performance Measurement
  10.11 Quality Control
  10.12 Batteries Included

11. Brief Tour of the Standard Library - Part II
  11.1 Output Formatting
  11.2 Templating
  11.3 Working with Binary Data Record Layouts
  11.4 Multi-threading
  11.5 Logging
  11.6 Weak References
  11.7 Tools for Working with Lists
  11.8 Decimal Floating Point Arithmetic

12. What Now?
  A. Interactive Input Editing and History Substitution
    A.1 Line Editing
    A.2 History Substitution
    A.3 Key Bindings
    A.4 Commentary
  B. Floating Point Arithmetic: Issues and Limitations
B.1 Representation Error

C. History and License
- C.1 History of the software
- C.2 Terms and conditions for accessing or otherwise using Python
- C.3 Licenses and Acknowledgements for Incorporated Software
  - C.3.1 Mersenne Twister
  - C.3.2 Sockets
  - C.3.3 Floating point exception control
  - C.3.4 MD5 message digest algorithm
  - C.3.5 Asynchronous socket services
  - C.3.6 Cookie management
  - C.3.7 Profiling
  - C.3.8 Execution tracing
  - C.3.9 UUencode and UUdecode functions
  - C.3.10 XML Remote Procedure Calls

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
About this document ...

Python Tutorial, 19th September, 2006, Release 2.5

This document was generated using the LaTeX2HTML translator.

The application of LaTeX2HTML to the Python documentation has been heavily tailored by Fred L. Drake, Jr. Original navigation icons were contributed by Christopher Petrilli.
Comments and Questions

General comments and questions regarding this document should be sent by email to docs@python.org. If you find specific errors in this document, either in the content or the presentation, please report the bug at the Python Bug Tracker at SourceForge. If you are able to provide suggested text, either to replace existing incorrect or unclear material, or additional text to supplement what's already available, we'd appreciate the contribution. There's no need to worry about text markup; our documentation team will gladly take care of that.

Questions regarding how to use the information in this document should be sent to the Python news group, comp.lang.python, or the Python mailing list (which is gated to the newsgroup and carries the same content).

For any of these channels, please be sure not to send HTML email. Thanks.

Abstract:

Python is an extensible, interpreted, object-oriented programming language. It supports a wide range of applications, from simple text processing scripts to interactive Web browsers.

While the Python Reference Manual describes the exact syntax and semantics of the language, it does not describe the standard library that is distributed with the language, and which greatly enhances its immediate usability. This library contains built-in modules (written in C) that provide access to system functionality such as file I/O that would otherwise be inaccessible to Python programmers, as well as modules written in Python that provide standardized solutions for many problems that occur in everyday programming. Some of these modules are explicitly designed to encourage and enhance the portability of Python programs.

This library reference manual documents Python's standard library, as well as many optional library modules (which may or may not be available, depending on whether the underlying platform supports them and on the configuration choices made at compile time). It also documents the standard types of the language and its built-in functions and exceptions, many of which are not or incompletely documented in the Reference Manual.

This manual assumes basic knowledge about the Python language. For an
informal introduction to Python, see the Python Tutorial; the Python Reference Manual remains the highest authority on syntactic and semantic questions. Finally, the manual entitled Extending and Embedding the Python Interpreter describes how to add new extensions to Python and how to embed it in other applications.
Contents

• 1. Introduction
• 2. Built-in Objects
  ○ 2.1 Built-in Functions
  ○ 2.2 Non-essential Built-in Functions
  ○ 2.3 Built-in Exceptions
  ○ 2.4 Built-in Constants
• 3. Built-in Types
  ○ 3.1 Truth Value Testing
  ○ 3.2 Boolean Operations -- and, or, not
  ○ 3.3 Comparisons
  ○ 3.4 Numeric Types -- int, float, long, complex
    ■ 3.4.1 Bit-string Operations on Integer Types
  ○ 3.5 Iterator Types
  ○ 3.6 Sequence Types -- str, unicode, list, tuple, buffer, xrange
    ■ 3.6.1 String Methods
    ■ 3.6.2 String Formatting Operations
    ■ 3.6.3 XRange Type
    ■ 3.6.4 Mutable Sequence Types
  ○ 3.7 Set Types -- set, frozenset
  ○ 3.8 Mapping Types -- dict
  ○ 3.9 File Objects
  ○ 3.10 Context Manager Types
  ○ 3.11 Other Built-in Types
    ■ 3.11.1 Modules
    ■ 3.11.2 Classes and Class Instances
    ■ 3.11.3 Functions
    ■ 3.11.4 Methods
    ■ 3.11.5 Code Objects
    ■ 3.11.6 Type Objects
    ■ 3.11.7 The Null Object
    ■ 3.11.8 The Ellipsis Object
    ■ 3.11.9 Boolean Values
    ■ 3.11.10 Internal Objects
  ○ 3.12 Special Attributes
• 4. String Services
4.1 string -- Common string operations
   4.1.1 String constants
   4.1.2 Template strings
   4.1.3 String functions
   4.1.4 Deprecated string functions
4.2 re -- Regular expression operations
   4.2.1 Regular Expression Syntax
   4.2.2 Matching vs Searching
   4.2.3 Module Contents
   4.2.4 Regular Expression Objects
   4.2.5 Match Objects
   4.2.6 Examples
4.3 struct -- Interpret strings as packed binary data
4.4 difflib -- Helpers for computing deltas
   4.4.1 SequenceMatcher Objects
   4.4.2 SequenceMatcher Examples
   4.4.3 Differ Objects
   4.4.4 Differ Example
4.5 StringIO -- Read and write strings as files
4.6 cStringIO -- Faster version of StringIO
4.7 textwrap -- Text wrapping and filling
4.8 codecs -- Codec registry and base classes
   4.8.1 Codec Base Classes
   4.8.2 Encodings and Unicode
   4.8.3 Standard Encodings
   4.8.4 encodings.idna -- Internationalized Domain Names in Applications
   4.8.5 encodings.utf_8_sig -- UTF-8 codec with BOM signature
4.9 unicodedata -- Unicode Database
4.10 stringprep -- Internet String Preparation
4.11 ffpformat -- Floating point conversions

5. Data Types
5.1 datetime -- Basic date and time types
   5.1.1 Available Types
   5.1.2 timedelta Objects
   5.1.3 date Objects
   5.1.4 datetime Objects
   5.1.5 time Objects
   5.1.6 tzinfo Objects
- 5.1.7 strftime() Behavior
- 5.1.8 Examples

- 5.2 calendar -- General calendar-related functions
- 5.3 collections -- High-performance container datatypes
  - 5.3.1 deque objects
  - 5.3.2 defaultdict objects
- 5.4 heapq -- Heap queue algorithm
  - 5.4.1 Theory
- 5.5 bisect -- Array bisection algorithm
  - 5.5.1 Examples
- 5.6 array -- Efficient arrays of numeric values
- 5.7 sets -- Unordered collections of unique elements
  - 5.7.1 Set Objects
  - 5.7.2 Example
  - 5.7.3 Protocol for automatic conversion to immutable
  - 5.7.4 Comparison to the built-in set types
- 5.8 sched -- Event scheduler
  - 5.8.1 Scheduler Objects
- 5.9 mutex -- Mutual exclusion support
  - 5.9.1 Mutex Objects
- 5.10 Queue -- A synchronized queue class
  - 5.10.1 Queue Objects
- 5.11 weakref -- Weak references
  - 5.11.1 Weak Reference Objects
  - 5.11.2 Example
- 5.12 UserDict -- Class wrapper for dictionary objects
- 5.13 UserList -- Class wrapper for list objects
- 5.14 UserString -- Class wrapper for string objects
- 5.15 types -- Names for built-in types
- 5.16 new -- Creation of runtime internal objects
- 5.17 copy -- Shallow and deep copy operations
- 5.18 pprint -- Data pretty printer
  - 5.18.1 PrettyPrinter Objects
- 5.19 repr -- Alternate repr() implementation
  - 5.19.1 Repr Objects
  - 5.19.2 Subclassing Repr Objects

- 6. Numeric and Mathematical Modules
  - 6.1 math -- Mathematical functions
  - 6.2 cmath -- Mathematical functions for complex numbers
6.3 decimal -- Decimal floating point arithmetic
   - 6.3.1 Quick-start Tutorial
   - 6.3.2 Decimal objects
   - 6.3.3 Context objects
   - 6.3.4 Signals
   - 6.3.5 Floating Point Notes
   - 6.3.6 Working with threads
   - 6.3.7 Recipes
   - 6.3.8 Decimal FAQ

6.4 random -- Generate pseudo-random numbers

6.5 itertools -- Functions creating iterators for efficient looping
   - 6.5.1 Itertool functions
   - 6.5.2 Examples
   - 6.5.3 Recipes

6.6 functools -- Higher order functions and operations on callable objects.
   - 6.6.1 partial Objects

6.7 operator -- Standard operators as functions.
   - 6.7.1 Mapping Operators to Functions

7. Internet Data Handling
   - 7.1 email -- An email and MIME handling package
     - 7.1.1 Representing an email message
     - 7.1.2 Parsing email messages
     - 7.1.3 Generating MIME documents
     - 7.1.4 Creating email and MIME objects from scratch
     - 7.1.5 Internationalized headers
     - 7.1.6 Representing character sets
     - 7.1.7 Encoders
     - 7.1.8 Exception and Defect classes
     - 7.1.9 Miscellaneous utilities
     - 7.1.10 Iterators
     - 7.1.11 Package History
     - 7.1.12 Differences from mimelib
     - 7.1.13 Examples
   - 7.2 mailcap -- Mailcap file handling.
   - 7.3 mailbox -- Manipulate mailboxes in various formats
     - 7.3.1 Mailbox objects
     - 7.3.2 Message objects
     - 7.3.3 Exceptions
7.3.4 Deprecated classes and methods
7.3.5 Examples

7.4 mhlib -- Access to MH mailboxes
  7.4.1 MH Objects
  7.4.2 Folder Objects
  7.4.3 Message Objects

7.5 mimeTools -- Tools for parsing MIME messages
  7.5.1 Additional Methods of Message Objects

7.6 mimeTypes -- Map filenames to MIME types
  7.6.1 MimeTypes Objects

7.7 MimeWriter -- Generic MIME file writer
  7.7.1 MimeWriter Objects

7.8 mimify -- MIME processing of mail messages

7.9 multiFile -- Support for files containing distinct parts
  7.9.1 MultiFile Objects
  7.9.2 MultiFile Example

7.10 rfc822 -- Parse RFC 2822 mail headers
  7.10.1 Message Objects
  7.10.2 AddressList Objects

7.11 base64 -- RFC 3548: Base16, Base32, Base64 Data Encodings

7.12 binhex -- Encode and decode binhex4 files
  7.12.1 Notes

7.13 binascii -- Convert between binary and ASCII

7.14 quopri -- Encode and decode MIME quoted-printable data

7.15 uu -- Encode and decode uuencode files

8. Structured Markup Processing Tools
  8.1 HTMLParser -- Simple HTML and XHTML parser
    8.1.1 Example HTML Parser Application
  8.2 sgmllib -- Simple SGML parser
  8.3 htmllib -- A parser for HTML documents
    8.3.1 HTMLParser Objects
  8.4 htmlentitydefs -- Definitions of HTML general entities
  8.5 xml.parsers.expat -- Fast XML parsing using Expat
    8.5.1 XMLParser Objects
    8.5.2 ExpatError Exceptions
    8.5.3 Example
    8.5.4 Content Model Descriptions
    8.5.5 Expat error constants
  8.6 xml.dom -- The Document Object Model API
8.6.1 Module Contents
8.6.2 Objects in the DOM
8.6.3 Conformance
8.7 xml.dom.minidom -- Lightweight DOM implementation
  8.7.1 DOM Objects
  8.7.2 DOM Example
  8.7.3 minidom and the DOM standard
8.8 xml.dom.pulldom -- Support for building partial DOM trees
  8.8.1 DOMEventStream Objects
8.9 xml.sax -- Support for SAX2 parsers
  8.9.1 SAXException Objects
8.10 xml.sax.handler -- Base classes for SAX handlers
  8.10.1 ContentHandler Objects
  8.10.2 DTDHandler Objects
  8.10.3 EntityResolver Objects
  8.10.4 ErrorHandler Objects
8.11 xml.sax.saxutils -- SAX Utilities
8.12 xml.sax.xmlreader -- Interface for XML parsers
  8.12.1 XMLReader Objects
  8.12.2 IncrementalParser Objects
  8.12.3 Locator Objects
  8.12.4 InputSource Objects
  8.12.5 The Attributes Interface
  8.12.6 The AttributesNS Interface
8.13 xml.etree.ElementTree -- The ElementTree XML API
  8.13.1 Functions
  8.13.2 ElementTree Objects
  8.13.3 QName Objects
  8.13.4 TreeBuilder Objects
  8.13.5 XMLTreeBuilder Objects
9. File Formats
  9.1 csv -- CSV File Reading and Writing
    9.1.1 Module Contents
    9.1.2 Dialects and Formatting Parameters
    9.1.3 Reader Objects
    9.1.4 Writer Objects
    9.1.5 Examples
  9.2 ConfigParser -- Configuration file parser
    9.2.1 RawConfigParser Objects
9.2.2 ConfigParser Objects
9.2.3 SafeConfigParser Objects
9.3 robotparser -- Parser for robots.txt
9.4 netrc -- netrc file processing
  9.4.1 netrc Objects
9.5 xdrlib -- Encode and decode XDR data
  9.5.1 Packer Objects
  9.5.2 Unpacker Objects
  9.5.3 Exceptions
10. Cryptographic Services
  10.1 hashlib -- Secure hashes and message digests
  10.2 hmac -- Keyed-Hashing for Message Authentication
  10.3 md5 -- MD5 message digest algorithm
  10.4 sha -- SHA-1 message digest algorithm
11. File and Directory Access
  11.1 os.path -- Common pathname manipulations
  11.2 fileinput -- Iterate over lines from multiple input streams
  11.3 stat -- Interpreting stat() results
  11.4 statvfs -- Constants used with os.statvfs()
  11.5 filecmp -- File and Directory Comparisons
    11.5.1 The dircmp class
  11.6 tempfile -- Generate temporary files and directories
  11.7 glob -- Unix style pathname pattern expansion
  11.8 fnmatch -- Unix filename pattern matching
  11.9 linecache -- Random access to text lines
  11.10 shutil -- High-level file operations
    11.10.1 Example
  11.11 dircache -- Cached directory listings
12. Data Compression and Archiving
  12.1 zlib -- Compression compatible with gzip
  12.2 gzip -- Support for gzip files
  12.3 bz2 -- Compression compatible with bzip2
    12.3.1 (De)compression of files
    12.3.2 Sequential (de)compression
    12.3.3 One-shot (de)compression
  12.4 zipfile -- Work with ZIP archives
    12.4.1 ZipFile Objects
    12.4.2 PyZipFile Objects
    12.4.3 ZipInfo Objects
12.5 tarfile -- Read and write tar archive files
   - 12.5.1 TarFile Objects
   - 12.5.2 TarInfo Objects
   - 12.5.3 Examples

13. Data Persistence
   - 13.1 pickle -- Python object serialization
     - 13.1.1 Relationship to other Python modules
     - 13.1.2 Data stream format
     - 13.1.3 Usage
     - 13.1.4 What can be pickled and unpickled?
     - 13.1.5 The pickle protocol
     - 13.1.6 Subclassing Unpicklers
     - 13.1.7 Example
   - 13.2 cPickle -- A faster pickle
   - 13.3 copy_reg -- Register pickle support functions
   - 13.4 shelve -- Python object persistence
     - 13.4.1 Restrictions
     - 13.4.2 Example
   - 13.5 marshal -- Internal Python object serialization
   - 13.6 anydbm -- Generic access to DBM-style databases
   - 13.7 whichdb -- Guess which DBM module created a database
   - 13.8 dbm -- Simple ``database'' interface
   - 13.9 gdbm -- GNU's reinterpretation of dbm
   - 13.10 dbhash -- DBM-style interface to the BSD database library
     - 13.10.1 Database Objects
   - 13.11 bsddb -- Interface to Berkeley DB library
     - 13.11.1 Hash, BTree and Record Objects
   - 13.12 dumbdbm -- Portable DBM implementation
     - 13.12.1 Dumbdbm Objects
   - 13.13 sqlite3 -- DB-API 2.0 interface for SQLite databases
     - 13.13.1 Module functions and constants
     - 13.13.2 Connection Objects
     - 13.13.3 Cursor Objects
     - 13.13.4 SQLite and Python types
     - 13.13.5 Controlling Transactions
     - 13.13.6 Using pysqlite efficiently

14. Generic Operating System Services
   - 14.1 os -- Miscellaneous operating system interfaces
     - 14.1.1 Process Parameters
14.1.2 File Object Creation
14.1.3 File Descriptor Operations
14.1.4 Files and Directories
14.1.5 Process Management
14.1.6 Miscellaneous System Information
14.1.7 Miscellaneous Functions

14.2 time -- Time access and conversions
14.3 optparse -- More powerful command line option parser
  14.3.1 Background
  14.3.2 Tutorial
  14.3.3 Reference Guide
  14.3.4 Option Callbacks
  14.3.5 Extending optparse

14.4 getopt -- Parser for command line options
14.5 logging -- Logging facility for Python
  14.5.1 Logger Objects
  14.5.2 Basic example
  14.5.3 Logging to multiple destinations
  14.5.4 Sending and receiving logging events across a network
  14.5.5 Handler Objects
  14.5.6 Formatter Objects
  14.5.7 Filter Objects
  14.5.8 LogRecord Objects
  14.5.9 Thread Safety
  14.5.10 Configuration

14.6 getpass -- Portable password input
14.7 curses -- Terminal handling for character-cell displays
  14.7.1 Functions
  14.7.2 Window Objects
  14.7.3 Constants

14.8 curses.textpad -- Text input widget for curses programs
  14.8.1 Textbox objects
14.9 curses.wrapper -- Terminal handler for curses programs
14.10 curses.ascii -- Utilities for ASCII characters
14.11 curses.panel -- A panel stack extension for curses.
  14.11.1 Functions
  14.11.2 Panel Objects

14.12 platform -- Access to underlying platform's identifying data
  14.12.1 Cross Platform
14.12.2 Java Platform
14.12.3 Windows Platform
14.12.4 Mac OS Platform
14.12.5 Unix Platforms

14.13 errno -- Standard errno system symbols
14.14 ctypes -- A foreign function library for Python.
  14.14.1 ctypes tutorial
  14.14.2 ctypes reference

15. Optional Operating System Services
  15.1 select -- Waiting for I/O completion
    15.1.1 Polling Objects
  15.2 thread -- Multiple threads of control
  15.3 threading -- Higher-level threading interface
    15.3.1 Lock Objects
    15.3.2 RLock Objects
    15.3.3 Condition Objects
    15.3.4 Semaphore Objects
    15.3.5 Event Objects
    15.3.6 Thread Objects
    15.3.7 Timer Objects
    15.3.8 Using locks, conditions, and semaphores in the with statement
  15.4 dummy_thread -- Drop-in replacement for the thread module
  15.5 dummy_threading -- Drop-in replacement for the threading module
  15.6 mmap -- Memory-mapped file support
  15.7 readline -- GNU readline interface
    15.7.1 Example
  15.8 rlcompleter -- Completion function for GNU readline
    15.8.1 Completer Objects

16. Unix Specific Services
  16.1 posix -- The most common POSIX system calls
    16.1.1 Large File Support
    16.1.2 Module Contents
  16.2 pwd -- The password database
  16.3 spwd -- The shadow password database
  16.4 grp -- The group database
  16.5 crypt -- Function to check Unix passwords
  16.6 dl -- Call C functions in shared objects
16.6.1 D1 Objects

16.7 termios -- POSIX style tty control
   16.7.1 Example

16.8 tty -- Terminal control functions

16.9 pty -- Pseudo-terminal utilities

16.10 fcntl -- The fcntl() and ioctl() system calls

16.11 pipes -- Interface to shell pipelines
   16.11.1 Template Objects

16.12 posixfile -- File-like objects with locking support

16.13 resource -- Resource usage information
   16.13.1 Resource Limits
   16.13.2 Resource Usage

16.14 nis -- Interface to Sun's NIS (Yellow Pages)

16.15 syslog -- Unix syslog library routines

16.16 commands -- Utilities for running commands

17. Interprocess Communication and Networking

17.1 subprocess -- Subprocess management
   17.1.1 Using the subprocess Module
   17.1.2 Popen Objects
   17.1.3 Replacing Older Functions with the subprocess Module

17.2 socket -- Low-level networking interface
   17.2.1 Socket Objects
   17.2.2 SSL Objects
   17.2.3 Example

17.3 signal -- Set handlers for asynchronous events
   17.3.1 Example

17.4 popen2 -- Subprocesses with accessible I/O streams
   17.4.1 Popen3 and Popen4 Objects
   17.4.2 Flow Control Issues

17.5 asyncore -- Asynchronous socket handler
   17.5.1 asyncore Example basic HTTP client

17.6 asynchat -- Asynchronous socket command/response handler
   17.6.1 asynchat - Auxiliary Classes and Functions
   17.6.2 asynchat Example

18. Internet Protocols and Support

18.1 webbrowser -- Convenient Web-browser controller
   18.1.1 Browser Controller Objects

18.2 cgi -- Common Gateway Interface support
   18.2.1 Introduction
18.2.2 Using the cgi module
18.2.3 Higher Level Interface
18.2.4 Old classes
18.2.5 Functions
18.2.6 Caring about security
18.2.7 Installing your CGI script on a Unix system
18.2.8 Testing your CGI script
18.2.9 Debugging CGI scripts
18.2.10 Common problems and solutions

18.3 cgitb -- Traceback manager for CGI scripts

18.4 wsgiref -- WSGI Utilities and Reference Implementation
18.4.1 wsgiref.util - WSGI environment utilities
18.4.2 wsgiref.headers - WSGI response header tools
18.4.3 wsgiref.simple_server - a simple WSGI HTTP server
18.4.4 wsgiref.validate - WSGI conformance checker
18.4.5 wsgiref.handlers - server/gateway base classes

18.5 urllib -- Open arbitrary resources by URL
18.5.1 URLopener Objects
18.5.2 Examples

18.6 urllib2 -- extensible library for opening URLs
18.6.1 Request Objects
18.6.2 OpenerDirector Objects
18.6.3 BaseHandler Objects
18.6.4 HTTPRedirectHandler Objects
18.6.5 HTTPCookieProcessor Objects
18.6.6 ProxyHandler Objects
18.6.7 HTTPPasswordMgr Objects
18.6.8 AbstractBasicAuthHandler Objects
18.6.9 HTTPBasicAuthHandler Objects
18.6.10 ProxyBasicAuthHandler Objects
18.6.11 AbstractDigestAuthHandler Objects
18.6.12 HTTPDigestAuthHandler Objects
18.6.13 ProxyDigestAuthHandler Objects
18.6.14 HTTPHandler Objects
18.6.15 HTTPSHandler Objects
18.6.16 FileHandler Objects
18.6.17 FTPHandler Objects
18.6.18 CacheFTPHandler Objects
18.6.19 GopherHandler Objects
18.6.20 UnknownHandler Objects
18.6.21 HTTPErrorProcessor Objects
18.6.22 Examples

18.7 httplib -- HTTP protocol client
18.7.1 HTTPConnection Objects
18.7.2 HTTPResponse Objects
18.7.3 Examples

18.8 ftplib -- FTP protocol client
18.8.1 FTP Objects

18.9 gopherlib -- Gopher protocol client

18.10 poplib -- POP3 protocol client
18.10.1 POP3 Objects
18.10.2 POP3 Example

18.11 imaplib -- IMAP4 protocol client
18.11.1 IMAP4 Objects
18.11.2 IMAP4 Example

18.12 nntplib -- NNTP protocol client
18.12.1 NNTP Objects

18.13 smtplib -- SMTP protocol client
18.13.1 SMTP Objects
18.13.2 SMTP Example

18.14 smtpd -- SMTP Server
18.14.1 SMTPServer Objects
18.14.2 DebuggingServer Objects
18.14.3 PureProxy Objects
18.14.4 MailmanProxy Objects

18.15 telnetlib -- Telnet client
18.15.1 Telnet Objects
18.15.2 Telnet Example

18.16 uuid -- UUID objects according to RFC 4122
18.16.1 Example

18.17 urlparse -- Parse URLs into components
18.17.1 Results of urlparse() and urlsplit()

18.18 SocketServer -- A framework for network servers
18.18.1 Server Creation Notes
18.18.2 Server Objects
18.18.3 RequestHandler Objects

18.19 BaseHTTPServer -- Basic HTTP server

18.20 SimpleHTTPServer -- Simple HTTP request handler
18.21 CGIHTTPServer -- CGI-capable HTTP request handler
18.22 cookielib -- Cookie handling for HTTP clients
  18.22.1 CookieJar and FileCookieJar Objects
  18.22.2 FileCookieJar subclasses and co-operation with web browsers
  18.22.3 CookiePolicy Objects
  18.22.4 DefaultCookiePolicy Objects
  18.22.5 Cookie Objects
  18.22.6 Examples
18.23 Cookie -- HTTP state management
  18.23.1 Cookie Objects
  18.23.2 Morsel Objects
  18.23.3 Example
18.24 xmlrpclib -- XML-RPC client access
  18.24.1 ServerProxy Objects
  18.24.2 Boolean Objects
  18.24.3 DateTime Objects
  18.24.4 Binary Objects
  18.24.5 Fault Objects
  18.24.6 ProtocolError Objects
  18.24.7 MultiCall Objects
  18.24.8 Convenience Functions
  18.24.9 Example of Client Usage
18.25 SimpleXMLRPCServer -- Basic XML-RPC server
  18.25.1 SimpleXMLRPCServer Objects
  18.25.2 CGIXMLRPCRequestHandler
18.26 DocXMLRPCServer -- Self-documenting XML-RPC server
  18.26.1 DocXMLRPCServer Objects
  18.26.2 DocCGIXMLRPCRequestHandler

19. Multimedia Services
19.1 audioop -- Manipulate raw audio data
19.2 imageop -- Manipulate raw image data
19.3 aifc -- Read and write AIFF and AIFC files
19.4 sunau -- Read and write Sun AU files
  19.4.1 AU_read Objects
  19.4.2 AU_write Objects
19.5 wave -- Read and write WAV files
  19.5.1 Wave_read Objects
  19.5.2 Wave_write Objects
• **19.6** chunk -- Read IFF chunked data
• **19.7** colorsys -- Conversions between color systems
• **19.8** rgbimg -- Read and write ``SGI RGB'' files
• **19.9** imghdr -- Determine the type of an image
• **19.10** sndhdr -- Determine type of sound file
• **19.11** ossaudiodev -- Access to OSS-compatible audio devices
  - 19.11.1 Audio Device Objects
  - 19.11.2 Mixer Device Objects
• **20.** Graphical User Interfaces with Tk
  - **20.1** Tkinter -- Python interface to Tcl/Tk
    - 20.1.1 Tkinter Modules
    - 20.1.2 Tkinter Life Preserver
    - 20.1.3 A (Very) Quick Look at Tcl/Tk
    - 20.1.4 Mapping Basic Tk into Tkinter
    - 20.1.5 How Tk and Tkinter are Related
    - 20.1.6 Handy Reference
  - **20.2** Tix -- Extension widgets for Tk
    - 20.2.1 Using Tix
    - 20.2.2 Tix Widgets
    - 20.2.3 Tix Commands
  - **20.3** ScrolledText -- Scrolled Text Widget
  - **20.4** turtle -- Turtle graphics for Tk
    - 20.4.1 Turtle, Pen and RawPen Objects
  - **20.5** Idle
    - 20.5.1 Menus
    - 20.5.2 Basic editing and navigation
    - 20.5.3 Syntax colors
  - **20.6** Other Graphical User Interface Packages
• **21.** Internationalization
  - **21.1** gettext -- Multilingual internationalization services
    - 21.1.1 GNU gettext API
    - 21.1.2 Class-based API
    - 21.1.3 Internationalizing your programs and modules
    - 21.1.4 Acknowledgements
  - **21.2** locale -- Internationalization services
    - 21.2.1 Background, details, hints, tips and caveats
    - 21.2.2 For extension writers and programs that embed Python
    - 21.2.3 Access to message catalogs
• **22.** Program Frameworks
22.1 cmd -- Support for line-oriented command interpreters
  - 22.1.1 Cmd Objects
22.2 shlex -- Simple lexical analysis
  - 22.2.1 shlex Objects
  - 22.2.2 Parsing Rules

23. Development Tools

23.1 pydoc -- Documentation generator and online help system
23.2 doctest -- Test interactive Python examples
  - 23.2.1 Simple Usage: Checking Examples in Docstrings
  - 23.2.2 Simple Usage: Checking Examples in a Text File
  - 23.2.3 How It Works

About this document ...

Python Library Reference, 19th September, 2006, Release 2.5

This document was generated using the \LaTeX2HTML translator.

The application of \LaTeX2HTML to the Python documentation has been heavily tailored by Fred L. Drake, Jr. Original navigation icons were contributed by Christopher Petrilli.
Comments and Questions

General comments and questions regarding this document should be sent by email to docs@python.org. If you find specific errors in this document, either in the content or the presentation, please report the bug at the Python Bug Tracker at SourceForge. If you are able to provide suggested text, either to replace existing incorrect or unclear material, or additional text to supplement what's already available, we'd appreciate the contribution. There's no need to worry about text markup; our documentation team will gladly take care of that.

Questions regarding how to use the information in this document should be sent to the Python news group, comp.lang.python, or the Python mailing list (which is gated to the newsgroup and carries the same content).

For any of these channels, please be sure not to send HTML email. Thanks.

Release 2.5, documentation updated on 19th September, 2006. See About this document... for information on suggesting changes.
4.8.1.1 Codec Objects

The Codec class defines these methods which also define the function interfaces of the stateless encoder and decoder:

**encode**(*input*, *errors*)

Encodes the object *input* and returns a tuple (output object, length consumed). While codecs are not restricted to use with Unicode, in a Unicode context, encoding converts a Unicode object to a plain string using a particular character set encoding (e.g., cp1252 or iso-8859-1).

*errors* defines the error handling to apply. It defaults to 'strict' handling.

The method may not store state in the Codec instance. Use StreamCodec for codecs which have to keep state in order to make encoding/decoding efficient.

The encoder must be able to handle zero length input and return an empty object of the output object type in this situation.

**decode**(*input*, *errors*)

Decodes the object *input* and returns a tuple (output object, length consumed). In a Unicode context, decoding converts a plain string encoded using a particular character set encoding to a Unicode object.

*input* must be an object which provides the **bf_getreadbuf** buffer slot. Python strings, buffer objects and memory mapped files are examples of objects providing this slot.

*errors* defines the error handling to apply. It defaults to 'strict' handling.

The method may not store state in the Codec instance. Use StreamCodec for codecs which have to keep state in order to make
encoding/decoding efficient.

The decoder must be able to handle zero length input and return an empty object of the output object type in this situation.

The IncrementalEncoder and IncrementalDecoder classes provide the basic interface for incremental encoding and decoding. Encoding/decoding the input isn't done with one call to the stateless encoder/decoder function, but with multiple calls to the encode/decode method of the incremental encoder/decoder. The incremental encoder/decoder keeps track of the encoding/decoding process during method calls.

The joined output of calls to the encode/decode method is the same as if all the single inputs were joined into one, and this input was encoded/decoded with the stateless encoder/decoder.
4.8.1.2 IncrementalEncoder Objects

New in version 2.5.

The IncrementalEncoder class is used for encoding an input in multiple steps. It defines the following methods which every incremental encoder must define in order to be compatible with the Python codec registry.

```python
class IncrementalEncoder([errors])
```

Constructor for an IncrementalEncoder instance.

All incremental encoders must provide this constructor interface. They are free to add additional keyword arguments, but only the ones defined here are used by the Python codec registry.

The IncrementalEncoder may implement different error handling schemes by providing the errors keyword argument. These parameters are predefined:

- 'strict' Raise ValueError (or a subclass); this is the default.
- 'ignore' Ignore the character and continue with the next.
- 'replace' Replace with a suitable replacement character
- 'xmlcharrefreplace' Replace with the appropriate XML character reference
- 'backslashreplace' Replace with backslashed escape sequences.

The errors argument will be assigned to an attribute of the same name. Assigning to this attribute makes it possible to switch between different error handling strategies during the lifetime of the IncrementalEncoder object.

The set of allowed values for the errors argument can be extended with register_error().
encode(object[, final])

Encodes object (taking the current state of the encoder into account) and returns the resulting encoded object. If this is the last call to encode final must be true (the default is false).

reset()

Reset the encoder to the initial state.
4.8.1.3 IncrementalDecoder Objects

The Incremental Decoder class is used for decoding an input in multiple steps. It defines the following methods which every incremental decoder must define in order to be compatible with the Python codec registry.

```python
class IncrementalDecoder([errors])
    Constructor for an IncrementalDecoder instance.
```

All incremental decoders must provide this constructor interface. They are free to add additional keyword arguments, but only the ones defined here are used by the Python codec registry.

The IncrementalDecoder may implement different error handling schemes by providing the errors keyword argument. These parameters are predefined:

- 'strict' Raise ValueError (or a subclass); this is the default.
- 'ignore' Ignore the character and continue with the next.
- 'replace' Replace with a suitable replacement character.

The errors argument will be assigned to an attribute of the same name. Assigning to this attribute makes it possible to switch between different error handling strategies during the lifetime of the IncrementalEncoder object.

The set of allowed values for the errors argument can be extended with register_error().

```python
decode(object[, final])
    Decodes object (taking the current state of the decoder into account) and returns the resulting decoded object. If this is the last call to decode final must be true (the default is false). If final is true the decoder must decode the input completely and must flush all buffers. If this isn't possible (e.g. because of incomplete byte sequences at the end of the input) it must
initiate error handling just like in the stateless case (which might raise an exception).

**reset()**
Reset the decoder to the initial state.

The StreamWriter and StreamReader classes provide generic working interfaces which can be used to implement new encoding submodules very easily. See `encodings.utf_8` for an example of how this is done.
4.8.1.4 StreamWriter Objects

The StreamWriter class is a subclass of Codec and defines the following methods which every stream writer must define in order to be compatible with the Python codec registry.

```python
class StreamWriter(stream[, errors])
    Constructor for a StreamWriter instance.
```

All stream writers must provide this constructor interface. They are free to add additional keyword arguments, but only the ones defined here are used by the Python codec registry.

*stream* must be a file-like object open for writing binary data.

The StreamWriter may implement different error handling schemes by providing the *errors* keyword argument. These parameters are predefined:

- 'strict' Raise ValueError (or a subclass); this is the default.
- 'ignore' Ignore the character and continue with the next.
- 'replace' Replace with a suitable replacement character
- 'xmlcharrefreplace' Replace with the appropriate XML character reference
- 'backslashreplace' Replace with backslashed escape sequences.

The *errors* argument will be assigned to an attribute of the same name. Assigning to this attribute makes it possible to switch between different error handling strategies during the lifetime of the StreamWriter object.

The set of allowed values for the *errors* argument can be extended with `register_error()`.

```python
write(object)
    Writes the object's contents encoded to the stream.
```
**writelines**( *list*)

Writes the concatenated list of strings to the stream (possibly by reusing the `write()` method).

**reset()**

Flushes and resets the codec buffers used for keeping state.

Calling this method should ensure that the data on the output is put into a clean state that allows appending of new fresh data without having to rescan the whole stream to recover state.

In addition to the above methods, the `StreamWriter` must also inherit all other methods and attributes from the underlying stream.
### 4.8.1.5 StreamReader Objects

The `StreamReader` class is a subclass of `Codec` and defines the following methods which every stream reader must define in order to be compatible with the Python codec registry.

```python
class StreamReader(stream[, errors])
```

Constructor for a `StreamReader` instance.

All stream readers must provide this constructor interface. They are free to add additional keyword arguments, but only the ones defined here are used by the Python codec registry.

*stream* must be a file-like object open for reading (binary) data.

The `StreamReader` may implement different error handling schemes by providing the `errors` keyword argument. These parameters are defined:

- `'strict'` Raise `ValueError` (or a subclass); this is the default.
- `'ignore'` Ignore the character and continue with the next.
- `'replace'` Replace with a suitable replacement character.

The `errors` argument will be assigned to an attribute of the same name. Assigning to this attribute makes it possible to switch between different error handling strategies during the lifetime of the `StreamReader` object.

The set of allowed values for the `errors` argument can be extended with `register_error()`.

```python
read([size[, chars[, firstline]]])
```

Decodes data from the stream and returns the resulting object.

*chars* indicates the number of characters to read from the stream. `read()` will never return more than `chars` characters, but it might return less, if there are not enough characters available.
size indicates the approximate maximum number of bytes to read from the stream for decoding purposes. The decoder can modify this setting as appropriate. The default value -1 indicates to read and decode as much as possible. size is intended to prevent having to decode huge files in one step.

firstline indicates that it would be sufficient to only return the first line, if there are decoding errors on later lines.

The method should use a greedy read strategy meaning that it should read as much data as is allowed within the definition of the encoding and the given size, e.g. if optional encoding endings or state markers are available on the stream, these should be read too.

Changed in version 2.4: chars argument added. Changed in version 2.4.2: firstline argument added.

**readline**([size[, keepends]])

Read one line from the input stream and return the decoded data.

size, if given, is passed as size argument to the stream's readline() method.

If keepends is false line-endings will be stripped from the lines returned.

Changed in version 2.4: keepends argument added.

**readlines**([sizehint[, keepends]])

Read all lines available on the input stream and return them as a list of lines.

Line-endings are implemented using the codec's decoder method and are included in the list entries if keepends is true.

sizehint, if given, is passed as the size argument to the stream's read() method.

**reset**()

Resets the codec buffers used for keeping state.
Note that no stream repositioning should take place. This method is primarily intended to be able to recover from decoding errors.

In addition to the above methods, the `StreamReader` must also inherit all other methods and attributes from the underlying stream.

The next two base classes are included for convenience. They are not needed by the codec registry, but may provide useful in practice.
4.8.1.6 StreamReaderWriter Objects

The StreamReaderWriter allows wrapping streams which work in both read and write modes.

The design is such that one can use the factory functions returned by the `lookup()` function to construct the instance.

```python
class StreamReaderWriter(stream, Reader, Writer, errors)
```

Creates a `StreamReaderWriter` instance. `stream` must be a file-like object. `Reader` and `Writer` must be factory functions or classes providing the `StreamReader` and `StreamWriter` interface resp. Error handling is done in the same way as defined for the stream readers and writers.

`StreamReaderWriter` instances define the combined interfaces of `StreamReader` and `StreamWriter` classes. They inherit all other methods and attributes from the underlying stream.
4.8.1.7 StreamRecoder Objects

The StreamRecoder provide a frontend - backend view of encoding data which is sometimes useful when dealing with different encoding environments.

The design is such that one can use the factory functions returned by the lookup() function to construct the instance.

class StreamRecoder(stream, encode, decode, Reader, Writer, errors)

Creates a StreamRecoder instance which implements a two-way conversion: encode and decode work on the frontend (the input to read() and output of write()) while Reader and Writer work on the backend (reading and writing to the stream).

You can use these objects to do transparent direct recodings from e.g. Latin-1 to UTF-8 and back.

stream must be a file-like object.

encode, decode must adhere to the Codec interface. Reader, Writer must be factory functions or classes providing objects of the StreamReader and StreamWriter interface respectively.

encode and decode are needed for the frontend translation, Reader and Writer for the backend translation. The intermediate format used is determined by the two sets of codecs, e.g. the Unicode codecs will use Unicode as the intermediate encoding.

Error handling is done in the same way as defined for the stream readers and writers.

StreamRecoder instances define the combined interfaces of StreamReader and StreamWriter classes. They inherit all other methods and attributes from the underlying stream.
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
5.1.8.1 Creating Datetime Objects from Formatted Strings

The `datetime` class does not directly support parsing formatted time strings. You can use `time.strptime` to do the parsing and create a `datetime` object from the tuple it returns:

```python
>>> s = "2005-12-06T12:13:14"
>>> from datetime import datetime
>>> from time import strptime
>>> datetime(*strptime(s, "%Y-%m-%dT%H:%M:%S"))[0:6])
datetime.datetime(2005, 12, 6, 12, 13, 14)
```
5.3.1.1 Recipes

This section shows various approaches to working with deques.

The `rotate()` method provides a way to implement deque slicing and deletion. For example, a pure python implementation of `del d[n]` relies on the `rotate()` method to position elements to be popped:

```python
def delete_nth(d, n):
    d.rotate(-n)
    d.popleft()
    d.rotate(n)
```

To implement deque slicing, use a similar approach applying `rotate()` to bring a target element to the left side of the deque. Remove old entries with `popleft()`, add new entries with `extend()`, and then reverse the rotation.

With minor variations on that approach, it is easy to implement Forth style stack manipulations such as `dup`, `drop`, `swap`, `over`, `pick`, `rot`, and `roll`.

A roundrobin task server can be built from a `deque` using `popleft()` to select the current task and `append()` to add it back to the tasklist if the input stream is not exhausted:

```python
def roundrobin(*iterables):
    pending = deque(iter(i) for i in iterables)
    while pending:
        task = pending.popleft()
        try:
            yield task.next()
        except StopIteration:
            continue
        pending.append(task)
```

```bash
>>> for value in roundrobin('abc', 'd', 'efgh'):
...    print value

a
d
```
Multi-pass data reduction algorithms can be succinctly expressed and efficiently coded by extracting elements with multiple calls to `popleft()`, applying the reduction function, and calling `append()` to add the result back to the queue.

For example, building a balanced binary tree of nested lists entails reducing two adjacent nodes into one by grouping them in a list:

```python
def maketree(iterable):
    d = deque(iterable)
    while len(d) > 1:
        pair = [d.popleft(), d.popleft()]
        d.append(pair)
    return list(d)
```

```python
>>> print maketree('abcdefgh')
[[[['a', 'b'], ['c', 'd']], [['e', 'f'], ['g', 'h']]]]
```
5.3.2.1 defaultdict Examples

Using list as the default_factory, it is easy to group a sequence of key-value pairs into a dictionary of lists:

```python
>>> s = [('yellow', 1), ('blue', 2), ('yellow', 3), ('blue', 4), ('red', 1)]
>>> d = defaultdict(list)
>>> for k, v in s:
    d[k].append(v)

>>> d.items()
[('blue', [2, 4]), ('red', [1]), ('yellow', [1, 3])]
```

When each key is encountered for the first time, it is not already in the mapping; so an entry is automatically created using the default_factory function which returns an empty list. The list.append() operation then attaches the value to the new list. When keys are encountered again, the look-up proceeds normally (returning the list for that key) and the list.append() operation adds another value to the list. This technique is simpler and faster than an equivalent technique using dict.setdefault():

```python
>>> d = {}
>>> for k, v in s:
    d.setdefault(k, []).append(v)

>>> d.items()
[('blue', [2, 4]), ('red', [1]), ('yellow', [1, 3])]
```

Setting the default_factory to int makes the defaultdict useful for counting (like a bag or multiset in other languages):

```python
>>> s = 'mississippi'
>>> d = defaultdict(int)
>>> for k in s:
    d[k] += 1

>>> d.items()
[('i', 4), ('p', 2), ('s', 4), ('m', 1)]
```

When a letter is first encountered, it is missing from the mapping, so the default_factory function calls int() to supply a default count of zero.
The increment operation then builds up the count for each letter. This technique makes counting simpler and faster than an equivalent technique using `dict.get()`:

```python
>>> d = {}
>>> for k in s:
    d[k] = d.get(k, 0) + 1

>>> d.items()
[('i', 4), ('p', 2), ('s', 4), ('m', 1)]
```

Setting the `default_factory` to `set` makes the `defaultdict` useful for building a dictionary of sets:

```python
>>> s = [('red', 1), ('blue', 2), ('red', 3), ('blue', 4), ('red', 1
>>> d = defaultdict(set)
>>> for k, v in s:
    d[k].add(v)

>>> d.items()
[('blue', set([2, 4])), ('red', set([1, 3]))]
```
6.3.5.1 Mitigating round-off error with increased precision

The use of decimal floating point eliminates decimal representation error (making it possible to represent 0.1 exactly); however, some operations can still incur round-off error when non-zero digits exceed the fixed precision.

The effects of round-off error can be amplified by the addition or subtraction of nearly offsetting quantities resulting in loss of significance. Knuth provides two instructive examples where rounded floating point arithmetic with insufficient precision causes the breakdown of the associative and distributive properties of addition:

```python
# Examples from Seminumerical Algorithms, Section 4.2.2.
>>> from decimal import Decimal, getcontext
>>> getcontext().prec = 8

>>> u, v, w = Decimal(11111113), Decimal(-11111111), Decimal('7.51111111')
>>> (u + v) + w
Decimal("9.5111111")
>>> u + (v + w)
Decimal("10")

>>> u, v, w = Decimal(20000), Decimal(-6), Decimal('6.0000003')
>>> (u*v) + (u*w)
Decimal("0.01")
>>> u * (v+w)
Decimal("0.0060000")
```

The `decimal` module makes it possible to restore the identities by expanding the precision sufficiently to avoid loss of significance:

```python
>>> getcontext().prec = 20
>>> u, v, w = Decimal(11111113), Decimal(-11111111), Decimal('7.51111111')
>>> (u + v) + w
Decimal("9.51111111")
>>> u + (v + w)
Decimal("9.51111111")

>>> u, v, w = Decimal(20000), Decimal(-6), Decimal('6.00000003')
>>> (u*v) + (u*w)
Decimal("0.0060000")
>>> u * (v+w)
```
Decimal("0.0060000")

Previous: 6.3.5 Floating Point Notes  Up: 6.3.5 Floating Point Notes  Next: 6.3.5.2 Special values

Release 2.5, documentation updated on 19th September, 2006.  See About this document... for information on suggesting changes.
6.3.5.2 Special values

The number system for the `decimal` module provides special values including `NaN`, `sNaN`, `-Infinity`, `Infinity`, and two zeroes, `+0` and `-0`.

Infinities can be constructed directly with: `Decimal('Infinity')`. Also, they can arise from dividing by zero when the `DivisionByZero` signal is not trapped. Likewise, when the `Overflow` signal is not trapped, infinity can result from rounding beyond the limits of the largest representable number.

The infinities are signed (affine) and can be used in arithmetic operations where they get treated as very large, indeterminate numbers. For instance, adding a constant to infinity gives another infinite result.

Some operations are indeterminate and return `NaN`, or if the `InvalidOperation` signal is trapped, raise an exception. For example, `0/0` returns `NaN` which means ``not a number``. This variety of `NaN` is quiet and, once created, will flow through other computations always resulting in another `NaN`. This behavior can be useful for a series of computations that occasionally have missing inputs -- it allows the calculation to proceed while flagging specific results as invalid.

A variant is `sNaN` which signals rather than remaining quiet after every operation. This is a useful return value when an invalid result needs to interrupt a calculation for special handling.

The signed zeros can result from calculations that underflow. They keep the sign that would have resulted if the calculation had been carried out to greater precision. Since their magnitude is zero, both positive and negative zeros are treated as equal and their sign is informational.

In addition to the two signed zeros which are distinct yet equal, there are various representations of zero with differing precisions yet equivalent in value. This takes a bit of getting used to. For an eye accustomed to normalized floating point representations, it is not immediately obvious that the following calculation
returns a value equal to zero:

```python
>>> 1 / Decimal('Infinity')
Decimal("0E-1000000026")
```
7.1.2.1 FeedParser API

New in version 2.4.

The FeedParser, imported from the email.feedparser module, provides an API that is conducive to incremental parsing of email messages, such as would be necessary when reading the text of an email message from a source that can block (e.g. a socket). The FeedParser can of course be used to parse an email message fully contained in a string or a file, but the classic Parser API may be more convenient for such use cases. The semantics and results of the two parser APIs are identical.

The FeedParser's API is simple; you create an instance, feed it a bunch of text until there's no more to feed it, then close the parser to retrieve the root message object. The FeedParser is extremely accurate when parsing standards-compliant messages, and it does a very good job of parsing non-compliant messages, providing information about how a message was deemed broken. It will populate a message object's defects attribute with a list of any problems it found in a message. See the email.errors module for the list of defects that it can find.

Here is the API for the FeedParser:

```python
class FeedParser([_factory])

Create a FeedParser instance. Optional _factory is a no-argument callable that will be called whenever a new message object is needed. It defaults to the email.message.Message class.

feed(data)

Feed the FeedParser some more data. data should be a string containing one or more lines. The lines can be partial and the FeedParser will stitch such partial lines together properly. The lines in the string can have any of the common three line endings, carriage return, newline, or carriage return and newline (they can even be mixed).
```
close()

Closing a FeedParser completes the parsing of all previously fed data, and returns the root message object. It is undefined what happens if you feed more data to a closed FeedParser.
The `Parser` class, imported from the `email.parser` module, provides an API that can be used to parse a message when the complete contents of the message are available in a string or file. The `email.parser` module also provides a second class, called `HeaderParser` which can be used if you're only interested in the headers of the message. `HeaderParser` can be much faster in these situations, since it does not attempt to parse the message body, instead setting the payload to the raw body as a string. `HeaderParser` has the same API as the `Parser` class.

**class Parser([_class])**

The constructor for the `Parser` class takes an optional argument `_class`. This must be a callable factory (such as a function or a class), and it is used whenever a sub-message object needs to be created. It defaults to `Message` (see `email.message`). The factory will be called without arguments.

The optional `strict` flag is ignored.

**Deprecated since release 2.4.** Because the `Parser` class is a backward compatible API wrapper around the new-in-Python 2.4 `FeedParser`, _all_ parsing is effectively non-strict. You should simply stop passing a `strict` flag to the `Parser` constructor.

Changed in version 2.2.2: The `strict` flag was added. Changed in version 2.4: The `strict` flag was deprecated.

The other public `Parser` methods are:

**parse(fp[, headersonly])**

Read all the data from the file-like object `fp`, parse the resulting text, and return the root message object. `fp` must support both the `readline()` and the `read()` methods on file-like objects.
The text contained in \texttt{fp} must be formatted as a block of RFC\,2822 style headers and header continuation lines, optionally preceded by a envelope header. The header block is terminated either by the end of the data or by a blank line. Following the header block is the body of the message (which may contain MIME-encoded subparts).

Optional \texttt{headersonly} is as with the \texttt{parse()} method.

Changed in version 2.2.2: The \texttt{headersonly} flag was added.

\texttt{parsestr(\text{text}[\text{, headersonly}])}

Similar to the \texttt{parse()} method, except it takes a string object instead of a file-like object. Calling this method on a string is exactly equivalent to wrapping \texttt{text} in a \texttt{StringIO} instance first and calling \texttt{parse()}.

Optional \texttt{headersonly} is a flag specifying whether to stop parsing after reading the headers or not. The default is \texttt{False}, meaning it parses the entire contents of the file.

Changed in version 2.2.2: The \texttt{headersonly} flag was added.

Since creating a message object structure from a string or a file object is such a common task, two functions are provided as a convenience. They are available in the top-level \texttt{email} package namespace.

\texttt{message\_from\_string(s[, \_class[, strict]])}

Return a message object structure from a string. This is exactly equivalent to \texttt{Parser().parsestr(s)}. Optional \texttt{\_class} and \texttt{strict} are interpreted as with the \texttt{Parser} class constructor.

Changed in version 2.2.2: The \texttt{strict} flag was added.

\texttt{message\_from\_file(fp[, \_class[, strict]])}

Return a message object structure tree from an open file object. This is exactly equivalent to \texttt{Parser().parse(fp)}. Optional \texttt{\_class} and \texttt{strict} are interpreted as with the \texttt{Parser} class constructor.

Changed in version 2.2.2: The \texttt{strict} flag was added.
Here's an example of how you might use this at an interactive Python prompt:

```python
>>> import email
>>> msg = email.message_from_string(myString)
```
7.1.2.3 Additional notes

Here are some notes on the parsing semantics:

- Most non-multipart type messages are parsed as a single message object with a string payload. These objects will return `False` for `is_multipart()`. Their `get_payload()` method will return a string object.

- All multipart type messages will be parsed as a container message object with a list of sub-message objects for their payload. The outer container message will return `True` for `is_multipart()` and their `get_payload()` method will return the list of Message subparts.

- Most messages with a content type of `message/*` (e.g. `message/delivery-status` and `message/rfc822`) will also be parsed as container object containing a list payload of length 1. Their `is_multipart()` method will return `True`. The single element in the list payload will be a sub-message object.

- Some non-standards compliant messages may not be internally consistent about their multipart-edness. Such messages may have a Content-Type: header of type `multipart`, but their `is_multipart()` method may return `False`. If such messages were parsed with the `FeedParser`, they will have an instance of the `MultipartInvariantViolationDefect` class in their `defects` attribute list. See `email.errors` for details.
7.3.1.1 Maildir

class Maildir(dirname[, factory=rfc822.Message[, create=True]])

A subclass of Mailbox for mailboxes in Maildir format. Parameter factory is a callable object that accepts a file-like message representation (which behaves as if opened in binary mode) and returns a custom representation. If factory is None, MaildirMessage is used as the default message representation. If create is True, the mailbox is created if it does not exist.

It is for historical reasons that factory defaults to rfc822.Message and that dirname is named as such rather than path. For a Maildir instance that behaves like instances of other Mailbox subclasses, set factory to None.

Maildir is a directory-based mailbox format invented for the qmail mail transfer agent and now widely supported by other programs. Messages in a Maildir mailbox are stored in separate files within a common directory structure. This design allows Maildir mailboxes to be accessed and modified by multiple unrelated programs without data corruption, so file locking is unnecessary.

Maildir mailboxes contain three subdirectories, namely: tmp, new, and cur. Messages are created momentarily in the tmp subdirectory and then moved to the new subdirectory to finalize delivery. A mail user agent may subsequently move the message to the cur subdirectory and store information about the state of the message in a special "info" section appended to its file name.

Folders of the style introduced by the Courier mail transfer agent are also supported. Any subdirectory of the main mailbox is considered a folder if "." is the first character in its name. Folder names are represented by Maildir without the leading ".". Each folder is itself a Maildir mailbox but should not contain other folders. Instead, a logical nesting is indicated using "." to delimit levels, e.g., "Archived.2005.07".

Note: The Maildir specification requires the use of a colon ("::") in certain message file names. However, some operating
systems do not permit this character in file names, If you wish to
use a Maildir-like format on such an operating system, you
should specify another character to use instead. The exclamation
point ("!") is a popular choice. For example:

```
import mailbox
mailbox.Maildir.colon = '!
```

The colon attribute may also be set on a per-instance basis.

Maildir instances have all of the methods of Mailbox in addition to the
following:

**list_folders()**
Return a list of the names of all folders.

**get_folder(folder)**
Return a Maildir instance representing the folder whose name is `folder`.
A NoSuchMailboxError exception is raised if the folder does not exist.

**add_folder(folder)**
Create a folder whose name is `folder` and return a Maildir instance
representing it.

**remove_folder(folder)**
Delete the folder whose name is `folder`. If the folder contains any messages,
aNotEmptyError exception will be raised and the folder will not be
deleted.

**clean()**
Delete temporary files from the mailbox that have not been accessed in the
last 36 hours. The Maildir specification says that mail-reading programs
should do this occasionally.

Some Mailbox methods implemented by Maildir deserve special remarks:

**add(message)**

**__setitem__(key, message)**
update( arg)

Warning: These methods generate unique file names based upon the current process ID. When using multiple threads, undetected name clashes may occur and cause corruption of the mailbox unless threads are coordinated to avoid using these methods to manipulate the same mailbox simultaneously.

flush()

All changes to Maildir mailboxes are immediately applied, so this method does nothing.

lock()

unlock()

Maildir mailboxes do not support (or require) locking, so these methods do nothing.

close()

Maildir instances do not keep any open files and the underlying mailboxes do not support locking, so this method does nothing.

get_file( key)

Depending upon the host platform, it may not be possible to modify or remove the underlying message while the returned file remains open.

Another specification of the format. Describes a common extension for supporting folders.
### 7.3.1.2 mbox

**class mbox**( *path*, *factory=None*, *create=True*)

A subclass of Mailbox for mailboxes in mbox format. Parameter *factory* is a callable object that accepts a file-like message representation (which behaves as if opened in binary mode) and returns a custom representation. If *factory* is *None*, *mboxMessage* is used as the default message representation. If *create* is *True*, the mailbox is created if it does not exist.

The mbox format is the classic format for storing mail on UNIX systems. All messages in an mbox mailbox are stored in a single file with the beginning of each message indicated by a line whose first five characters are "From ".

Several variations of the mbox format exist to address perceived shortcomings in the original. In the interest of compatibility, *mbox* implements the original format, which is sometimes referred to as *mboxo*. This means that the Content-Length: header, if present, is ignored and that any occurrences of "From " at the beginning of a line in a message body are transformed to ">From " when storing the message, although occurrences of ">From " are not transformed to "From " when reading the message.

Some Mailbox methods implemented by *mbox* deserve special remarks:

**get_file**( *key*)

Using the file after calling flush() or close() on the *mbox* instance may yield unpredictable results or raise an exception.

**lock()**

**unlock()**

Three locking mechanisms are used--dot locking and, if available, the flock() and lockf() system calls.

---

Another specification of the format, with details on locking.

Configuring Netscape Mail on UNIX: Why The Content-Length Format is Bad
An argument for using the original mbox format rather than a variation.

"mbox" is a family of several mutually incompatible mailbox formats
A history of mbox variations.
7.3.1.3 MH

class MH( path[, factory=None[, create=True]])

A subclass of Mailbox for mailboxes in MH format. Parameter factory is a callable object that accepts a file-like message representation (which behaves as if opened in binary mode) and returns a custom representation. If factory is None, MHMessage is used as the default message representation. If create is True, the mailbox is created if it does not exist.

MH is a directory-based mailbox format invented for the MH Message Handling System, a mail user agent. Each message in an MH mailbox resides in its own file. An MH mailbox may contain other MH mailboxes (called folders) in addition to messages. Folders may be nested indefinitely. MH mailboxes also support sequences, which are named lists used to logically group messages without moving them to sub-folders. Sequences are defined in a file called .mh_sequences in each folder.

The MH class manipulates MH mailboxes, but it does not attempt to emulate all of mh's behaviors. In particular, it does not modify and is not affected by the context or .mh_profile files that are used by mh to store its state and configuration.

MH instances have all of the methods of Mailbox in addition to the following:

list_folders()

Return a list of the names of all folders.

get_folder( folder)

Return an MH instance representing the folder whose name is folder. A NoSuchMailboxError exception is raised if the folder does not exist.

add_folder( folder)

Create a folder whose name is folder and return an MH instance representing it.
**remove_folder**( *folder*)
Delete the folder whose name is *folder*. If the folder contains any messages, a **NotEmptyError** exception will be raised and the folder will not be deleted.

**get_sequences()**
Return a dictionary of sequence names mapped to key lists. If there are no sequences, the empty dictionary is returned.

**set_sequences**( *sequences*)
Re-define the sequences that exist in the mailbox based upon *sequences*, a dictionary of names mapped to key lists, like returned by **get_sequences()**.

**pack()**
Rename messages in the mailbox as necessary to eliminate gaps in numbering. Entries in the sequences list are updated correspondingly. **Note:** Already-issued keys are invalidated by this operation and should not be subsequently used.

Some **Mailbox** methods implemented by **MH** deserve special remarks:

**remove**( *key*)

**__delitem__**( *key*)

**discard**( *key*)
These methods immediately delete the message. The **MH** convention of marking a message for deletion by prepending a comma to its name is not used.

**lock()**

**unlock()**
Three locking mechanisms are used--dot locking and, if available, the **flock()** and **lockf()** system calls. For **MH** mailboxes, locking the mailbox means locking the **.mh_sequences** file and, only for the duration of any operations that affect them, locking individual message files.

**get_file**( *key*)
Depending upon the host platform, it may not be possible to remove the underlying message while the returned file remains open.

**flush()**
All changes to MH mailboxes are immediately applied, so this method does nothing.

**close()**
MH instances do not keep any open files, so this method is equivalent to `unlock()`.

---

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
7.3.1.4 Babyl

class Babyl(path[, factory=None, create=True]):

A subclass of Mailbox for mailboxes in Babyl format. Parameter factory
is a callable object that accepts a file-like message representation (which
behaves as if opened in binary mode) and returns a custom representation.
If factory is None, BabylMessage is used as the default message
representation. If create is True, the mailbox is created if it does not exist.

Babyl is a single-file mailbox format used by the Rmail mail user agent included
with Emacs. The beginning of a message is indicated by a line containing the
two characters Control-Underscore ("\037") and Control-L ("\014"). The end
of a message is indicated by the start of the next message or, in the case of the
last message, a line containing a Control-Underscore ("\037") character.

Messages in a Babyl mailbox have two sets of headers, original headers and so-
called visible headers. Visible headers are typically a subset of the original
headers that have been reformatted or abridged to be more attractive. Each
message in a Babyl mailbox also has an accompanying list of labels, or short
strings that record extra information about the message, and a list of all user-
defined labels found in the mailbox is kept in the Babyl options section.

Babyl instances have all of the methods of Mailbox in addition to the
following:

get_labels()

Return a list of the names of all user-defined labels used in the mailbox.
Note: The actual messages are inspected to determine which labels exist in
the mailbox rather than consulting the list of labels in the Babyl options
section, but the Babyl section is updated whenever the mailbox is modified.

Some Mailbox methods implemented by Babyl deserve special remarks:

get_file(key)

In Babyl mailboxes, the headers of a message are not stored contiguously
with the body of the message. To generate a file-like representation, the headers and body are copied together into a `StringIO` instance (from the `StringIO` module), which has an API identical to that of a file. As a result, the file-like object is truly independent of the underlying mailbox but does not save memory compared to a string representation.

```python
lock()
unlock()
```

Three locking mechanisms are used--dot locking and, if available, the `flock()` and `lockf()` system calls.

  A specification of the Babyl format.

- [Reading Mail with Rmail](#)
  The Rmail manual, with some information on Babyl semantics.
7.3.1.5 MMDF

```python
class MMDF(path[, factory=None[, create=True]])
```
A subclass of `Mailbox` for mailboxes in MMDF format. Parameter `factory` is a callable object that accepts a file-like message representation (which behaves as if opened in binary mode) and returns a custom representation. If `factory` is `None`, `MMDFMessage` is used as the default message representation. If `create` is `True`, the mailbox is created if it does not exist.

MMDF is a single-file mailbox format invented for the Multichannel Memorandum Distribution Facility, a mail transfer agent. Each message is in the same form as an mbox message but is bracketed before and after by lines containing four Control-A ("\001") characters. As with the mbox format, the beginning of each message is indicated by a line whose first five characters are "From ", but additional occurrences of "From " are not transformed to ">From " when storing messages because the extra message separator lines prevent mistaking such occurrences for the starts of subsequent messages.

Some `Mailbox` methods implemented by `MMDF` deserve special remarks:

- `get_file(key)`
  Using the file after calling `flush()` or `close()` on the `MMDF` instance may yield unpredictable results or raise an exception.

- `lock()`
- `unlock()`

Three locking mechanisms are used--dot locking and, if available, the `flock()` and `lockf()` system calls.

A Wikipedia article describing the Multichannel Memorandum Distribution Facility.
7.3.2.1 MaildirMessage

class MaildirMessage([message])

A message with Maildir-specific behaviors. Parameter message has the same meaning as with the Message constructor.

Typically, a mail user agent application moves all of the messages in the new subdirectory to the cur subdirectory after the first time the user opens and closes the mailbox, recording that the messages are old whether or not they've actually been read. Each message in cur has an "info" section added to its file name to store information about its state. (Some mail readers may also add an "info" section to messages in new.) The "info" section may take one of two forms: it may contain "2," followed by a list of standardized flags (e.g., "2,FR") or it may contain "1," followed by so-called experimental information. Standard flags for Maildir messages are as follows:

<table>
<thead>
<tr>
<th>Flag</th>
<th>Meaning</th>
<th>Explanation</th>
</tr>
</thead>
<tbody>
<tr>
<td>D</td>
<td>Draft</td>
<td>Under composition</td>
</tr>
<tr>
<td>F</td>
<td>Flagged</td>
<td>Marked as important</td>
</tr>
<tr>
<td>P</td>
<td>Passed</td>
<td>Forwarded, resent, or bounced</td>
</tr>
<tr>
<td>R</td>
<td>Replied</td>
<td>Replied to</td>
</tr>
<tr>
<td>S</td>
<td>Seen</td>
<td>Read</td>
</tr>
<tr>
<td>T</td>
<td>Trashed</td>
<td>Marked for subsequent deletion</td>
</tr>
</tbody>
</table>

MaildirMessage instances offer the following methods:

get_subdir()

Return either "new" (if the message should be stored in the new subdirectory) or "cur" (if the message should be stored in the cur subdirectory). **Note:** A message is typically moved from new to cur after its mailbox has been accessed, whether or not the message is has been read. A message msg has been read if "S" not in msg.get_flags() is True.
set_subdir(subdir)

Set the subdirectory the message should be stored in. Parameter subdir must be either "new" or "cur".

get_flags()

Return a string specifying the flags that are currently set. If the message complies with the standard Maildir format, the result is the concatenation in alphabetical order of zero or one occurrence of each of "D", "F", "P", "R", "S", and "T". The empty string is returned if no flags are set or if "info" contains experimental semantics.

set_flags(flags)

Set the flags specified by flags and unset all others.

add_flag(flag)

Set the flag(s) specified by flag without changing other flags. To add more than one flag at a time, flag may be a string of more than one character. The current "info" is overwritten whether or not it contains experimental information rather than flags.

remove_flag(flag)

Unset the flag(s) specified by flag without changing other flags. To remove more than one flag at a time, flag may be a string of more than one character. If "info" contains experimental information rather than flags, the current "info" is not modified.

get_date()

Return the delivery date of the message as a floating-point number representing seconds since the epoch.

set_date(date)

Set the delivery date of the message to date, a floating-point number representing seconds since the epoch.

get_info()

Return a string containing the "info" for a message. This is useful for accessing and modifying "info" that is experimental (i.e., not a list of flags).
**set_info**( `info` )

Set "info" to `info`, which should be a string.

When a `MaildirMessage` instance is created based upon an `mboxMessage` or `MMDFMessage` instance, the `Status:` and `X-Status:` headers are omitted and the following conversions take place:

<table>
<thead>
<tr>
<th>Resulting state</th>
<th><code>mboxMessage</code> or <code>MMDFMessage</code> state</th>
</tr>
</thead>
<tbody>
<tr>
<td>&quot;cur&quot; subdirectory</td>
<td>O flag</td>
</tr>
<tr>
<td>F flag</td>
<td>F flag</td>
</tr>
<tr>
<td>R flag</td>
<td>A flag</td>
</tr>
<tr>
<td>S flag</td>
<td>R flag</td>
</tr>
<tr>
<td>T flag</td>
<td>D flag</td>
</tr>
</tbody>
</table>

When a `MaildirMessage` instance is created based upon an `MHMessage` instance, the following conversions take place:

<table>
<thead>
<tr>
<th>Resulting state</th>
<th><code>MHMessage</code> state</th>
</tr>
</thead>
<tbody>
<tr>
<td>&quot;cur&quot; subdirectory</td>
<td>&quot;unseen&quot; sequence</td>
</tr>
<tr>
<td>&quot;cur&quot; subdirectory and S flag</td>
<td>no &quot;unseen&quot; sequence</td>
</tr>
<tr>
<td>F flag</td>
<td>&quot;flagged&quot; sequence</td>
</tr>
<tr>
<td>R flag</td>
<td>&quot;replied&quot; sequence</td>
</tr>
</tbody>
</table>

When a `MaildirMessage` instance is created based upon a `BabylMessage` instance, the following conversions take place:

<table>
<thead>
<tr>
<th>Resulting state</th>
<th><code>BabylMessage</code> state</th>
</tr>
</thead>
<tbody>
<tr>
<td>&quot;cur&quot; subdirectory</td>
<td>&quot;unseen&quot; label</td>
</tr>
<tr>
<td>&quot;cur&quot; subdirectory and S flag</td>
<td>no &quot;unseen&quot; label</td>
</tr>
<tr>
<td>P flag</td>
<td>&quot;forwarded&quot; or &quot;resent&quot; label</td>
</tr>
<tr>
<td>R flag</td>
<td>&quot;answered&quot; label</td>
</tr>
<tr>
<td>T flag</td>
<td>&quot;deleted&quot; label</td>
</tr>
</tbody>
</table>
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
7.3.2.2 mboxMessage

```
class mboxMessage([message])
    A message with mbox-specific behaviors. Parameter message has the same meaning as with the Message constructor.
```

Messages in an mbox mailbox are stored together in a single file. The sender's envelope address and the time of delivery are typically stored in a line beginning with "From " that is used to indicate the start of a message, though there is considerable variation in the exact format of this data among mbox implementations. Flags that indicate the state of the message, such as whether it has been read or marked as important, are typically stored in Status: and X-Status: headers.

Conventional flags for mbox messages are as follows:

<table>
<thead>
<tr>
<th>Flag</th>
<th>Meaning</th>
<th>Explanation</th>
</tr>
</thead>
<tbody>
<tr>
<td>R</td>
<td>Read</td>
<td>Read</td>
</tr>
<tr>
<td>O</td>
<td>Old</td>
<td>Previously detected by MUA</td>
</tr>
<tr>
<td>D</td>
<td>Deleted</td>
<td>Marked for subsequent deletion</td>
</tr>
<tr>
<td>F</td>
<td>Flagged</td>
<td>Marked as important</td>
</tr>
<tr>
<td>A</td>
<td>Answered</td>
<td>Replied to</td>
</tr>
</tbody>
</table>

The "R" and "O" flags are stored in the Status: header, and the "D", "F", and "A" flags are stored in the X-Status: header. The flags and headers typically appear in the order mentioned.

mboxMessage instances offer the following methods:

```python
get_from()
    Return a string representing the "From " line that marks the start of the message in an mbox mailbox. The leading "From " and the trailing newline are excluded.
```
set_from(from_, time_=None)
Set the "From " line to from_, which should be specified without a leading
"From " or trailing newline. For convenience, time_ may be specified and
will be formatted appropriately and appended to from_. If time_ is
specified, it should be a struct_time instance, a tuple suitable for
passing to time.strftime(), or True (to use time.gmtime()).

get_flags()
Return a string specifying the flags that are currently set. If the message
complies with the conventional format, the result is the concatenation in the
following order of zero or one occurrence of each of "R", "O", "D", "F", and
"A".

set_flags(flags)
Set the flags specified by flags and unset all others. Parameter flags should
be the concatenation in any order of zero or more occurrences of each of
"R", "O", "D", "F", and "A".

add_flag(flag)
Set the flag(s) specified by flag without changing other flags. To add more
than one flag at a time, flag may be a string of more than one character.

remove_flag(flag)
Unset the flag(s) specified by flag without changing other flags. To remove
more than one flag at a time, flag maybe a string of more than one
character.

When an mboxMessage instance is created based upon a MaildirMessage
instance, a "From " line is generated based upon the MaildirMessage
instance's delivery date, and the following conversions take place:

<table>
<thead>
<tr>
<th>Resulting state</th>
<th>MaildirMessage state</th>
</tr>
</thead>
<tbody>
<tr>
<td>R flag</td>
<td>S flag</td>
</tr>
<tr>
<td>O flag</td>
<td>&quot;cur&quot; subdirectory</td>
</tr>
<tr>
<td>D flag</td>
<td>T flag</td>
</tr>
<tr>
<td>F flag</td>
<td>F flag</td>
</tr>
<tr>
<td>A flag</td>
<td>R flag</td>
</tr>
</tbody>
</table>
When an `mboxMessage` instance is created based upon an `MHMessage` instance, the following conversions take place:

<table>
<thead>
<tr>
<th>Resulting state</th>
<th>MHMessage state</th>
</tr>
</thead>
<tbody>
<tr>
<td>R flag and O flag</td>
<td>no &quot;unseen&quot; sequence</td>
</tr>
<tr>
<td>O flag</td>
<td>&quot;unseen&quot; sequence</td>
</tr>
<tr>
<td>F flag</td>
<td>&quot;flagged&quot; sequence</td>
</tr>
<tr>
<td>A flag</td>
<td>&quot;replied&quot; sequence</td>
</tr>
</tbody>
</table>

When an `mboxMessage` instance is created based upon a `BabylMessage` instance, the following conversions take place:

<table>
<thead>
<tr>
<th>Resulting state</th>
<th>BabylMessage state</th>
</tr>
</thead>
<tbody>
<tr>
<td>R flag and O flag</td>
<td>no &quot;unseen&quot; label</td>
</tr>
<tr>
<td>O flag</td>
<td>&quot;unseen&quot; label</td>
</tr>
<tr>
<td>D flag</td>
<td>&quot;deleted&quot; label</td>
</tr>
<tr>
<td>A flag</td>
<td>&quot;answered&quot; label</td>
</tr>
</tbody>
</table>

When a `Message` instance is created based upon an `MMDFMessage` instance, the "From " line is copied and all flags directly correspond:

<table>
<thead>
<tr>
<th>Resulting state</th>
<th>MMDFMessage state</th>
</tr>
</thead>
<tbody>
<tr>
<td>R flag</td>
<td>R flag</td>
</tr>
<tr>
<td>O flag</td>
<td>O flag</td>
</tr>
<tr>
<td>D flag</td>
<td>D flag</td>
</tr>
<tr>
<td>F flag</td>
<td>F flag</td>
</tr>
<tr>
<td>A flag</td>
<td>A flag</td>
</tr>
</tbody>
</table>
7.3.2.3 MHMessage

**class MHMessage([message])**

A message with MH-specific behaviors. Parameter *message* has the same meaning as with the Message constructor.

MH messages do not support marks or flags in the traditional sense, but they do support sequences, which are logical groupings of arbitrary messages. Some mail reading programs (although not the standard `mh` and `nmh`) use sequences in much the same way flags are used with other formats, as follows:

<table>
<thead>
<tr>
<th>Sequence</th>
<th>Explanation</th>
</tr>
</thead>
<tbody>
<tr>
<td>unseen</td>
<td>Not read, but previously detected by MUA</td>
</tr>
<tr>
<td>replied</td>
<td>Replied to</td>
</tr>
<tr>
<td>flagged</td>
<td>Marked as important</td>
</tr>
</tbody>
</table>

MHMessage instances offer the following methods:

**get_sequences()**

Return a list of the names of sequences that include this message.

**set_sequences(sequences)**

Set the list of sequences that include this message.

**add_sequence(sequence)**

Add *sequence* to the list of sequences that include this message.

**remove_sequence(sequence)**

Remove *sequence* from the list of sequences that include this message.

When an MHMessage instance is created based upon a MaildirMessage instance, the following conversions take place:

<table>
<thead>
<tr>
<th>Resulting state</th>
<th>MaildirMessage state</th>
</tr>
</thead>
</table>

Previous: 7.3.2.2 mboxMessage Up: 7.3.2 Message objects Next: 7.3.2.4 BabylMessage
<p>| | |</p>
<table>
<thead>
<tr>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>&quot;unseen&quot; sequence</td>
<td>no S flag</td>
</tr>
<tr>
<td>&quot;replied&quot; sequence</td>
<td>R flag</td>
</tr>
<tr>
<td>&quot;flagged&quot; sequence</td>
<td>F flag</td>
</tr>
</tbody>
</table>

When an `MHMessage` instance is created based upon an `mboxMessage` or `MMDFMessage` instance, the `Status:` and `X-Status:` headers are omitted and the following conversions take place:

<table>
<thead>
<tr>
<th>Resulting state</th>
<th><code>mboxMessage</code> or <code>MMDFMessage</code> state</th>
</tr>
</thead>
<tbody>
<tr>
<td>&quot;unseen&quot; sequence</td>
<td>no R flag</td>
</tr>
<tr>
<td>&quot;replied&quot; sequence</td>
<td>A flag</td>
</tr>
<tr>
<td>&quot;flagged&quot; sequence</td>
<td>F flag</td>
</tr>
</tbody>
</table>

When an `MHMessage` instance is created based upon a `BabylMessage` instance, the following conversions take place:

<table>
<thead>
<tr>
<th>Resulting state</th>
<th><code>BabylMessage</code> state</th>
</tr>
</thead>
<tbody>
<tr>
<td>&quot;unseen&quot; sequence</td>
<td>&quot;unseen&quot; label</td>
</tr>
<tr>
<td>&quot;replied&quot; sequence</td>
<td>&quot;answered&quot; label</td>
</tr>
</tbody>
</table>

Release 2.5, documentation updated on 19th September, 2006. See About this document... for information on suggesting changes.
7.3.2.4 BabylMessage

**class BabylMessage**([*message*])

A message with Babyl-specific behaviors. Parameter *message* has the same meaning as with the `Message` constructor.

Certain message labels, called *attributes*, are defined by convention to have special meanings. The attributes are as follows:

<table>
<thead>
<tr>
<th>Label</th>
<th>Explanation</th>
</tr>
</thead>
<tbody>
<tr>
<td>unseen</td>
<td>Not read, but previously detected by MUA</td>
</tr>
<tr>
<td>deleted</td>
<td>Marked for subsequent deletion</td>
</tr>
<tr>
<td>filed</td>
<td>Copied to another file or mailbox</td>
</tr>
<tr>
<td>answered</td>
<td>Replied to</td>
</tr>
<tr>
<td>forwarded</td>
<td>Forwarded</td>
</tr>
<tr>
<td>edited</td>
<td>Modified by the user</td>
</tr>
<tr>
<td>resent</td>
<td>Resent</td>
</tr>
</tbody>
</table>

By default, Rmail displays only visible headers. The `BabylMessage` class, though, uses the original headers because they are more complete. Visible headers may be accessed explicitly if desired.

`BabylMessage` instances offer the following methods:

**get_labels()**

Return a list of labels on the message.

**set_labels**( *labels*)

Set the list of labels on the message to *labels*.

**add_label**( *label*)

Add *label* to the list of labels on the message.
**remove_label(label)**
Remove *label* from the list of labels on the message.

**get_visible()**
Return an *Message* instance whose headers are the message's visible headers and whose body is empty.

**set_visible(visible)**
Set the message's visible headers to be the same as the headers in *message*. Parameter *visible* should be a *Message* instance, an *email.Message.Message* instance, a string, or a file-like object (which should be open in text mode).

**update_visible()**
When a *BabylMessage* instance's original headers are modified, the visible headers are not automatically modified to correspond. This method updates the visible headers as follows: each visible header with a corresponding original header is set to the value of the original header, each visible header without a corresponding original header is removed, and any of *Date:*, *From:*, *Reply-To:*, *To:*, *CC:*, and *Subject:* that are present in the original headers but not the visible headers are added to the visible headers.

When a *BabylMessage* instance is created based upon a *MaildirMessage* instance, the following conversions take place:

<table>
<thead>
<tr>
<th>Resulting state</th>
<th>MaildirMessage state</th>
</tr>
</thead>
<tbody>
<tr>
<td>&quot;unseen&quot; label</td>
<td>no S flag</td>
</tr>
<tr>
<td>&quot;deleted&quot; label</td>
<td>T flag</td>
</tr>
<tr>
<td>&quot;answered&quot; label</td>
<td>R flag</td>
</tr>
<tr>
<td>&quot;forwarded&quot; label</td>
<td>P flag</td>
</tr>
</tbody>
</table>

When a *BabylMessage* instance is created based upon an *mboxMessage* or *MMDFMessage* instance, the *Status:* and *X-Status:* headers are omitted and the following conversions take place:

<table>
<thead>
<tr>
<th>Resulting state</th>
<th>mboxMessage or MMDFMessage state</th>
</tr>
</thead>
<tbody>
<tr>
<td>&quot;unseen&quot; label</td>
<td>no R flag</td>
</tr>
</tbody>
</table>
When a `BabylMessage` instance is created based upon an `MHMessage` instance, the following conversions take place:

<table>
<thead>
<tr>
<th>Resulting state</th>
<th>MHMessage state</th>
</tr>
</thead>
<tbody>
<tr>
<td>&quot;unseen&quot; label</td>
<td>&quot;unseen&quot; sequence</td>
</tr>
<tr>
<td>&quot;answered&quot; label</td>
<td>&quot;replied&quot; sequence</td>
</tr>
</tbody>
</table>

Python Library Reference

Previous: 7.3.2.3 `MHMessage` Up: 7.3.2 `Message objects` Next: 7.3.2.5 `MMDFMessage`

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
7.3.2.5 MMDFMessage

**class MMDFMessage([message])**

A message with MMDF-specific behaviors. Parameter *message* has the same meaning as with the *Message* constructor.

As with message in an mbox mailbox, MMDF messages are stored with the sender's address and the delivery date in an initial line beginning with "From ". Likewise, flags that indicate the state of the message are typically stored in Status: and X-Status: headers.

Conventional flags for MMDF messages are identical to those of mbox message and are as follows:

<table>
<thead>
<tr>
<th>Flag</th>
<th>Meaning</th>
<th>Explanation</th>
</tr>
</thead>
<tbody>
<tr>
<td>R</td>
<td>Read</td>
<td>Read</td>
</tr>
<tr>
<td>O</td>
<td>Old</td>
<td>Previously detected by MUA</td>
</tr>
<tr>
<td>D</td>
<td>Deleted</td>
<td>Marked for subsequent deletion</td>
</tr>
<tr>
<td>F</td>
<td>Flagged</td>
<td>Marked as important</td>
</tr>
<tr>
<td>A</td>
<td>Answered</td>
<td>Replied to</td>
</tr>
</tbody>
</table>

The "R" and "O" flags are stored in the Status: header, and the "D", "F", and "A" flags are stored in the X-Status: header. The flags and headers typically appear in the order mentioned.

**MMDFMessage** instances offer the following methods, which are identical to those offered by *mboxMessage*:

**get_from()**

Return a string representing the "From " line that marks the start of the message in an mbox mailbox. The leading "From " and the trailing newline are excluded.

**set_from(from[, time_=None])**
Set the "From " line to \texttt{from}_, which should be specified without a leading "From " or trailing newline. For convenience, \texttt{time}_ may be specified and will be formatted appropriately and appended to \texttt{from}_. If \texttt{time}_ is specified, it should be a \texttt{struct\_time} instance, a tuple suitable for passing to \texttt{time.strftime()}, or \texttt{True} (to use \texttt{time.gmtime()}).

\texttt{get\_flags()} 
Return a string specifying the flags that are currently set. If the message complies with the conventional format, the result is the concatenation in the following order of zero or one occurrence of each of "R", "O", "D", "F", and "A".

\texttt{set\_flags(\texttt{flags})} 
Set the flags specified by \texttt{flags} and unset all others. Parameter \texttt{flags} should be the concatenation in any order of zero or more occurrences of each of "R", "O", "D", "F", and "A".

\texttt{add\_flag(\texttt{flag})} 
Set the flag(s) specified by \texttt{flag} without changing other flags. To add more than one flag at a time, \texttt{flag} may be a string of more than one character.

\texttt{remove\_flag(\texttt{flag})} 
Unset the flag(s) specified by \texttt{flag} without changing other flags. To remove more than one flag at a time, \texttt{flag} maybe a string of more than one character.

When an \texttt{MMDFMessage} instance is created based upon a \texttt{MaildirMessage} instance, a "From " line is generated based upon the \texttt{MaildirMessage} instance's delivery date, and the following conversions take place:

<table>
<thead>
<tr>
<th>Resulting state</th>
<th>MaildirMessage state</th>
</tr>
</thead>
<tbody>
<tr>
<td>R flag</td>
<td>S flag</td>
</tr>
<tr>
<td>O flag</td>
<td>&quot;cur&quot; subdirectory</td>
</tr>
<tr>
<td>D flag</td>
<td>T flag</td>
</tr>
<tr>
<td>F flag</td>
<td>F flag</td>
</tr>
<tr>
<td>A flag</td>
<td>R flag</td>
</tr>
</tbody>
</table>
When an `MMDFMessage` instance is created based upon an `MHMessage` instance, the following conversions take place:

<table>
<thead>
<tr>
<th>Resulting state</th>
<th>MHMessage state</th>
</tr>
</thead>
<tbody>
<tr>
<td>R flag and O flag</td>
<td>no &quot;unseen&quot; sequence</td>
</tr>
<tr>
<td>O flag</td>
<td>&quot;unseen&quot; sequence</td>
</tr>
<tr>
<td>F flag</td>
<td>&quot;flagged&quot; sequence</td>
</tr>
<tr>
<td>A flag</td>
<td>&quot;replied&quot; sequence</td>
</tr>
</tbody>
</table>

When an `MMDFMessage` instance is created based upon a `BabylMessage` instance, the following conversions take place:

<table>
<thead>
<tr>
<th>Resulting state</th>
<th>BabylMessage state</th>
</tr>
</thead>
<tbody>
<tr>
<td>R flag and O flag</td>
<td>no &quot;unseen&quot; label</td>
</tr>
<tr>
<td>O flag</td>
<td>&quot;unseen&quot; label</td>
</tr>
<tr>
<td>D flag</td>
<td>&quot;deleted&quot; label</td>
</tr>
<tr>
<td>A flag</td>
<td>&quot;answered&quot; label</td>
</tr>
</tbody>
</table>

When an `MMDFMessage` instance is created based upon an `mboxMessage` instance, the "From " line is copied and all flags directly correspond:

<table>
<thead>
<tr>
<th>Resulting state</th>
<th>mboxMessage state</th>
</tr>
</thead>
<tbody>
<tr>
<td>R flag</td>
<td>R flag</td>
</tr>
<tr>
<td>O flag</td>
<td>O flag</td>
</tr>
<tr>
<td>D flag</td>
<td>D flag</td>
</tr>
<tr>
<td>F flag</td>
<td>F flag</td>
</tr>
<tr>
<td>A flag</td>
<td>A flag</td>
</tr>
</tbody>
</table>
8.6.2.1 DOMImplementation Objects

The DOMImplementation interface provides a way for applications to determine the availability of particular features in the DOM they are using. DOM Level 2 added the ability to create new Document and DocumentType objects using the DOMImplementation as well.

hasFeature(feature, version)
  Return true if the feature identified by the pair of strings feature and version is implemented.

createDocument(namespaceUri, qualifiedName, doctype)
  Return a new Document object (the root of the DOM), with a child Element object having the given namespaceUri and qualifiedName. The doctype must be a DocumentType object created by createDocumentType(), or None. In the Python DOM API, the first two arguments can also be None in order to indicate that no Element child is to be created.

cREATEDocumentType(qualifiedName, publicId, systemId)
  Return a new DocumentType object that encapsulates the given qualifiedName, publicId, and systemId strings, representing the information contained in an XML document type declaration.
8.6.2.2 Node Objects

All of the components of an XML document are subclasses of Node.

**nodeType**
An integer representing the node type. Symbolic constants for the types are on the Node object: ELEMENT_NODE, ATTRIBUTE_NODE, TEXT_NODE, CDATA_SECTION_NODE, ENTITY_NODE, PROCESSING_INSTRUCTION_NODE, COMMENT_NODE, DOCUMENT_NODE, DOCUMENT_TYPE_NODE, NOTATION_NODE. This is a read-only attribute.

**parentNode**
The parent of the current node, or None for the document node. The value is always a Node object or None. For Element nodes, this will be the parent element, except for the root element, in which case it will be the Document object. For Attr nodes, this is always None. This is a read-only attribute.

**attributes**
A NamedNodeMap of attribute objects. Only elements have actual values for this; others provide None for this attribute. This is a read-only attribute.

**previousSibling**
The node that immediately precedes this one with the same parent. For instance the element with an end-tag that comes just before the self element's start-tag. Of course, XML documents are made up of more than just elements so the previous sibling could be text, a comment, or something else. If this node is the first child of the parent, this attribute will be None. This is a read-only attribute.

**nextSibling**
The node that immediately follows this one with the same parent. See also previousSibling. If this is the last child of the parent, this attribute will be None. This is a read-only attribute.
childNodes
   A list of nodes contained within this node. This is a read-only attribute.

firstChild
   The first child of the node, if there are any, or None. This is a read-only attribute.

lastChild
   The last child of the node, if there are any, or None. This is a read-only attribute.

localName
   The part of the tagName following the colon if there is one, else the entire tagName. The value is a string.

prefix
   The part of the tagName preceding the colon if there is one, else the empty string. The value is a string, or None

namespaceURI
   The namespace associated with the element name. This will be a string or None. This is a read-only attribute.

nodeName
   This has a different meaning for each node type; see the DOM specification for details. You can always get the information you would get here from another property such as the tagName property for elements or the name property for attributes. For all node types, the value of this attribute will be either a string or None. This is a read-only attribute.

nodeValue
   This has a different meaning for each node type; see the DOM specification for details. The situation is similar to that with nodeName. The value is a string or None.

hasAttributes()
   Returns true if the node has any attributes.

hasChildNodes()
Returns true if the node has any child nodes.

**isSameNode**( other)

Returns true if `other` refers to the same node as this node. This is especially useful for DOM implementations which use any sort of proxy architecture (because more than one object can refer to the same node).

**Note:** This is based on a proposed DOM Level 3 API which is still in the “working draft” stage, but this particular interface appears uncontroversial. Changes from the W3C will not necessarily affect this method in the Python DOM interface (though any new W3C API for this would also be supported).

**appendChild**( newChild)

Add a new child node to this node at the end of the list of children, returning `newChild`.

**insertBefore**( newChild, refChild)

Insert a new child node before an existing child. It must be the case that `refChild` is a child of this node; if not, `ValueError` is raised. `newChild` is returned. If `refChild` is `None`, it inserts `newChild` at the end of the children's list.

**removeChild**( oldChild)

Remove a child node. `oldChild` must be a child of this node; if not, `ValueError` is raised. `oldChild` is returned on success. If `oldChild` will not be used further, its `unlink()` method should be called.

**replaceChild**( newChild, oldChild)

Replace an existing node with a new node. It must be the case that `oldChild` is a child of this node; if not, `ValueError` is raised.

**normalize**( )

Join adjacent text nodes so that all stretches of text are stored as single `Text` instances. This simplifies processing text from a DOM tree for many
applications. New in version 2.1.

**cloneNode** *(deep)*

Clone this node. Setting *deep* means to clone all child nodes as well. This returns the clone.
8.6.2.3 NodeList Objects

A NodeList represents a sequence of nodes. These objects are used in two ways in the DOM Core recommendation: the Element objects provides one as its list of child nodes, and the getElementsByTagName() and getElementsByTagNameNS() methods of Node return objects with this interface to represent query results.

The DOM Level 2 recommendation defines one method and one attribute for these objects:

item(i)
Return the i'th item from the sequence, if there is one, or None. The index i is not allowed to be less then zero or greater than or equal to the length of the sequence.

length
The number of nodes in the sequence.

In addition, the Python DOM interface requires that some additional support is provided to allow NodeList objects to be used as Python sequences. All NodeList implementations must include support for __len__() and __getitem__(); this allows iteration over the NodeList in for statements and proper support for the len() built-in function.

If a DOM implementation supports modification of the document, the NodeList implementation must also support the __setitem__() and __delitem__() methods.
See About this document... for information on suggesting changes.
8.6.2.4 DocumentType Objects

Information about the notations and entities declared by a document (including the external subset if the parser uses it and can provide the information) is available from a DocumentType object. The DocumentType for a document is available from the Document object's doctype attribute; if there is no DOCTYPE declaration for the document, the document's doctype attribute will be set to None instead of an instance of this interface.

DocumentType is a specialization of Node, and adds the following attributes:

publicId
The public identifier for the external subset of the document type definition. This will be a string or None.

systemId
The system identifier for the external subset of the document type definition. This will be a URI as a string, or None.

internalSubset
A string giving the complete internal subset from the document. This does not include the brackets which enclose the subset. If the document has no internal subset, this should be None.

name
The name of the root element as given in the DOCTYPE declaration, if present.

entities
This is a NamedNodeMap giving the definitions of external entities. For entity names defined more than once, only the first definition is provided (others are ignored as required by the XML recommendation). This may be None if the information is not provided by the parser, or if no entities are defined.
notations

This is a NamedNodeMap giving the definitions of notations. For notation names defined more than once, only the first definition is provided (others are ignored as required by the XML recommendation). This may be None if the information is not provided by the parser, or if no notations are defined.
8.6.2.5 Document Objects

A Document represents an entire XML document, including its constituent elements, attributes, processing instructions, comments etc. Remember that it inherits properties from Node.

documentElement
  The one and only root element of the document.

createElement( tagName)
  Create and return a new element node. The element is not inserted into the document when it is created. You need to explicitly insert it with one of the other methods such as insertBefore() or appendChild().

createElementNS( namespaceURI, tagName)
  Create and return a new element with a namespace. The tagName may have a prefix. The element is not inserted into the document when it is created. You need to explicitly insert it with one of the other methods such as insertBefore() or appendChild().

createTextNode( data)
  Create and return a text node containing the data passed as a parameter. As with the other creation methods, this one does not insert the node into the tree.

createComment( data)
  Create and return a comment node containing the data passed as a parameter. As with the other creation methods, this one does not insert the node into the tree.

createProcessingInstruction( target, data)
  Create and return a processing instruction node containing the target and data passed as parameters. As with the other creation methods, this one does not insert the node into the tree.
**createAttribute**(*name*)
Create and return an attribute node. This method does not associate the attribute node with any particular element. You must use `setAttributeNode()` on the appropriate `Element` object to use the newly created attribute instance.

**createAttributeNS**(*namespaceURI, qualifiedName*)
Create and return an attribute node with a namespace. The `tagName` may have a prefix. This method does not associate the attribute node with any particular element. You must use `setAttributeNode()` on the appropriate `Element` object to use the newly created attribute instance.

**getElementsByTagName**(*tagName*)
Search for all descendants (direct children, children's children, etc.) with a particular element type name.

**getElementsByTagNameNS**(*namespaceURI, localName*)
Search for all descendants (direct children, children's children, etc.) with a particular namespace URI and localname. The localname is the part of the namespace after the prefix.
8.6.2.6 Element Objects

Element is a subclass of Node, so inherits all the attributes of that class.

tagName
The element type name. In a namespace-using document it may have colons in it. The value is a string.

getElementsByTagName(tagName)
Same as equivalent method in the Document class.

getElementsByTagNameNS(tagName)
Same as equivalent method in the Document class.

hasAttribute(name)
Returns true if the element has an attribute named by name.

hasAttributeNS(namespaceURI, localName)
Returns true if the element has an attribute named by namespaceURI and localName.

getAttribute(name)
Return the value of the attribute named by name as a string. If no such attribute exists, an empty string is returned, as if the attribute had no value.

getAttributeNode(attrname)
Return the Attr node for the attribute named by attrname.

getAttributeNS(namespaceURI, localName)
Return the value of the attribute named by namespaceURI and localName as a string. If no such attribute exists, an empty string is returned, as if the attribute had no value.

getAttributeNodeNS(namespaceURI, localName)
Return an attribute value as a node, given a namespaceURI and localName.

**removeAttribute**(name)
Remove an attribute by name. No exception is raised if there is no matching attribute.

**removeAttributeNode**(oldAttr)
Remove and return oldAttr from the attribute list, if present. If oldAttr is not present, NotFoundErr is raised.

**removeAttributeNS**(namespaceURI, localName)
Remove an attribute by name. Note that it uses a localName, not a qname. No exception is raised if there is no matching attribute.

**setAttribute**(name, value)
Set an attribute value from a string.

**setAttributeNode**(newAttr)
Add a new attribute node to the element, replacing an existing attribute if necessary if the name attribute matches. If a replacement occurs, the old attribute node will be returned. If newAttr is already in use, InuseAttributeErr will be raised.

**setAttributeNodeNS**(newAttr)
Add a new attribute node to the element, replacing an existing attribute if necessary if the namespaceURI and localName attributes match. If a replacement occurs, the old attribute node will be returned. If newAttr is already in use, InuseAttributeErr will be raised.

**setAttributeNS**(namespaceURI, qname, value)
Set an attribute value from a string, given a namespaceURI and a qname. Note that a qname is the whole attribute name. This is different than above.
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
8.6.2.7 Attr Objects

Attr inherits from Node, so inherits all its attributes.

name
The attribute name. In a namespace-using document it may have colons in it.

localName
The part of the name following the colon if there is one, else the entire name. This is a read-only attribute.

prefix
The part of the name preceding the colon if there is one, else the empty string.
8.6.2.8 NamedNodeMap Objects

NamedNodeMap does not inherit from Node.

length
The length of the attribute list.

item(index)
Return an attribute with a particular index. The order you get the attributes in is arbitrary but will be consistent for the life of a DOM. Each item is an attribute node. Get its value with the value attribute.

There are also experimental methods that give this class more mapping behavior. You can use them or you can use the standardized getAttribute*() family of methods on the Element objects.
8.6.2.9 Comment Objects

Comment represents a comment in the XML document. It is a subclass of Node, but cannot have child nodes.

data
The content of the comment as a string. The attribute contains all characters between the leading <!- - - and trailing - - >, but does not include them.

---

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
8.6.2.10 Text and CDATASection Objects

The Text interface represents text in the XML document. If the parser and DOM implementation support the DOM's XML extension, portions of the text enclosed in CDATA marked sections are stored in CDATASection objects. These two interfaces are identical, but provide different values for the nodeType attribute.

These interfaces extend the Node interface. They cannot have child nodes.

**data**

The content of the text node as a string.

**Note:** The use of a CDATASection node does not indicate that the node represents a complete CDATA marked section, only that the content of the node was part of a CDATA section. A single CDATA section may be represented by more than one node in the document tree. There is no way to determine whether two adjacent CDATASection nodes represent different CDATA marked sections.
8.6.2.11 ProcessingInstruction Objects

Represents a processing instruction in the XML document; this inherits from the Node interface and cannot have child nodes.

**target**
The content of the processing instruction up to the first whitespace character. This is a read-only attribute.

**data**
The content of the processing instruction following the first whitespace character.
8.6.2.12 Exceptions

New in version 2.1.

The DOM Level 2 recommendation defines a single exception, DOMException, and a number of constants that allow applications to determine what sort of error occurred. DOMException instances carry a code attribute that provides the appropriate value for the specific exception.

The Python DOM interface provides the constants, but also expands the set of exceptions so that a specific exception exists for each of the exception codes defined by the DOM. The implementations must raise the appropriate specific exception, each of which carries the appropriate value for the code attribute.

**exception DOMException**

Base exception class used for all specific DOM exceptions. This exception class cannot be directly instantiated.

**exception DomstringSizeErr**

Raised when a specified range of text does not fit into a string. This is not known to be used in the Python DOM implementations, but may be received from DOM implementations not written in Python.

**exception HierarchyRequestErr**

Raised when an attempt is made to insert a node where the node type is not allowed.

**exception IndexSizeErr**

Raised when an index or size parameter to a method is negative or exceeds the allowed values.

**exception InuseAttributeErr**

Raised when an attempt is made to insert an Attr node that is already present elsewhere in the document.

**exception InvalidAccessErr**
Raised if a parameter or an operation is not supported on the underlying object.

**exception InvalidCharacterErr**
This exception is raised when a string parameter contains a character that is not permitted in the context it's being used in by the XML 1.0 recommendation. For example, attempting to create an `Element` node with a space in the element type name will cause this error to be raised.

**exception InvalidModificationErr**
Raised when an attempt is made to modify the type of a node.

**exception InvalidStateErr**
Raised when an attempt is made to use an object that is not defined or is no longer usable.

**exception NamespaceErr**
If an attempt is made to change any object in a way that is not permitted with regard to the *Namespaces in XML* recommendation, this exception is raised.

**exception NotFoundErr**
Exception when a node does not exist in the referenced context. For example, `NamedNodeMap.removeNamedItem()` will raise this if the node passed in does not exist in the map.

**exception NotSupportedErr**
Raised when the implementation does not support the requested type of object or operation.

**exception NoDataAllowedErr**
This is raised if data is specified for a node which does not support data.

**exception NoModificationAllowedErr**
Raised on attempts to modify an object where modifications are not allowed (such as for read-only nodes).

**exception SyntaxErr**
Raised when an invalid or illegal string is specified.
**exception WrongDocumentErr**

Raised when a node is inserted in a different document than it currently belongs to, and the implementation does not support migrating the node from one document to the other.

The exception codes defined in the DOM recommendation map to the exceptions described above according to this table:

<table>
<thead>
<tr>
<th>Constant</th>
<th>Exception</th>
</tr>
</thead>
<tbody>
<tr>
<td>DOMSTRING_SIZE_ERR</td>
<td>DomstringSizeErr</td>
</tr>
<tr>
<td>HIERARCHY_REQUEST_ERR</td>

8.6.3.1 Type Mapping

The primitive IDL types used in the DOM specification are mapped to Python types according to the following table.

<table>
<thead>
<tr>
<th>IDL Type</th>
<th>Python Type</th>
</tr>
</thead>
<tbody>
<tr>
<td>boolean</td>
<td>IntegerType (with a value of 0 or 1)</td>
</tr>
<tr>
<td>int</td>
<td>IntegerType</td>
</tr>
<tr>
<td>long int</td>
<td>IntegerType</td>
</tr>
<tr>
<td>unsigned int</td>
<td>IntegerType</td>
</tr>
</tbody>
</table>

Additionally, the DOMString defined in the recommendation is mapped to a Python string or Unicode string. Applications should be able to handle Unicode whenever a string is returned from the DOM.

The IDL null value is mapped to None, which may be accepted or provided by the implementation whenever null is allowed by the API.
The mapping from OMG IDL to Python defines accessor functions for IDL attribute declarations in much the way the Java mapping does. Mapping the IDL declarations

```idl
readonly attribute string someValue;
attribute string anotherValue;
```

yields three accessor functions: a `"get" method for `someValue` (_get_someValue()), and `"get" and `"set" methods for `anotherValue` (_get_anotherValue() and _set_anotherValue()). The mapping, in particular, does not require that the IDL attributes are accessible as normal Python attributes: `object.someValue` is not required to work, and may raise an `AttributeError`.

The Python DOM API, however, does require that normal attribute access work. This means that the typical surrogates generated by Python IDL compilers are not likely to work, and wrapper objects may be needed on the client if the DOM objects are accessed via CORBA. While this does require some additional consideration for CORBA DOM clients, the implementers with experience using DOM over CORBA from Python do not consider this a problem. Attributes that are declared `readonly` may not restrict write access in all DOM implementations.

In the Python DOM API, accessor functions are not required. If provided, they should take the form defined by the Python IDL mapping, but these methods are considered unnecessary since the attributes are accessible directly from Python. `"Set" accessors should never be provided for `readonly` attributes.

The IDL definitions do not fully embody the requirements of the W3C DOM API, such as the notion of certain objects, such as the return value of `getElementsByTagName()`, being `"live". The Python DOM API does not require implementations to enforce such requirements.

13.1.5.1 Pickling and unpickling normal class instances

When a pickled class instance is unpickled, its __init__() method is normally *not* invoked. If it is desirable that the __init__() method be called on unpickling, an old-style class can define a method __getinitargs__(), which should return a *tuple* containing the arguments to be passed to the class constructor (__init__() for example). The __getinitargs__() method is called at pickle time; the tuple it returns is incorporated in the pickle for the instance.

New-style types can provide a __getnewargs__() method that is used for protocol 2. Implementing this method is needed if the type establishes some internal invariants when the instance is created, or if the memory allocation is affected by the values passed to the __new__() method for the type (as it is for tuples and strings). Instances of a new-style type C are created using

```
obj = c.__new__(c, *args)
```

where *args* is the result of calling __getnewargs__() on the original object; if there is no __getnewargs__() method, an empty tuple is assumed.

Classes can further influence how their instances are pickled; if the class defines the method __getstate__(), it is called and the return state is pickled as the contents for the instance, instead of the contents of the instance's dictionary. If there is no __getstate__() method, the instance's __dict__ is pickled.

Upon unpickling, if the class also defines the method __setstate__(), it is called with the unpickled state. If there is no __setstate__() method, the pickled state must be a dictionary and its items are assigned to the new instance's dictionary. If a class defines both __getstate__() and __setstate__(), the state object needn't be a dictionary and these methods can do what they want.
**Warning:** For new-style classes, if `__getstate__()` returns a false value, the `__setstate__()` method will not be called.

---

**Footnotes**

... state.\(^{13.5}\)
These methods can also be used to implement copying class instances.

... want.\(^{13.6}\)
This protocol is also used by the shallow and deep copying operations defined in the `copy` module.

---

*Previous:* 13.1.5 The pickle protocol  *Up:* 13.1.5 The pickle protocol  *Next:* 13.1.5.2 Pickling and unpickling

Release 2.5, documentation updated on 19th September, 2006.
See *About this document...* for information on suggesting changes.
13.1.5.2 Pickling and unpickling extension types

When the Pickler encounters an object of a type it knows nothing about -- such as an extension type -- it looks in two places for a hint of how to pickle it. One alternative is for the object to implement a \_reduce\_ method. If provided, at pickling time \_reduce\_ will be called with no arguments, and it must return either a string or a tuple.

If a string is returned, it names a global variable whose contents are pickled as normal. The string returned by \_reduce\_ should be the object's local name relative to its module; the pickle module searches the module namespace to determine the object's module.

When a tuple is returned, it must be between two and five elements long. Optional elements can either be omitted, or None can be provided as their value. The semantics of each element are:

- A callable object that will be called to create the initial version of the object. The next element of the tuple will provide arguments for this callable, and later elements provide additional state information that will subsequently be used to fully reconstruct the pickled date.

  In the unpickling environment this object must be either a class, a callable registered as a "safe constructor" (see below), or it must have an attribute \_safe_for unpickling\_ with a true value. Otherwise, an UnpicklingError will be raised in the unpickling environment. Note that as usual, the callable itself is pickled by name.

- A tuple of arguments for the callable object. Changed in version 2.5: Formerly, this argument could also be None.

- Optionally, the object's state, which will be passed to the object's \_setstate\_ method as described in section 13.1.5. If the object has no \_setstate\_ method, then, as above, the value must be a dictionary and it will be added to the object's __dict__. 

• Optionally, an iterator (and not a sequence) yielding successive list items. These list items will be pickled and appended to the object using either `obj.append(item)` or `obj.extend(list_of_items)`. This is primarily used for list subclasses, but may be used by other classes as long as they have `append()` and `extend()` methods with the appropriate signature. (Whether `append()` or `extend()` is used depends on which pickle protocol version is used as well as the number of items to append, so both must be supported.)

• Optionally, an iterator (not a sequence) yielding successive dictionary items, which should be tuples of the form `(key, value)`. These items will be pickled and stored to the object using `obj[key] = value`. This is primarily used for dictionary subclasses, but may be used by other classes as long as they implement `__setitem__`.

It is sometimes useful to know the protocol version when implementing `__reduce__`. This can be done by implementing a method named `__reduce_ex__` instead of `__reduce__`. `__reduce_ex__`, when it exists, is called in preference over `__reduce__` (you may still provide `__reduce__` for backwards compatibility). The `__reduce_ex__` method will be called with a single integer argument, the protocol version.

The `object` class implements both `__reduce__` and `__reduce_ex__`; however, if a subclass overrides `__reduce__` but not `__reduce_ex__`, the `__reduce_ex__` implementation detects this and calls `__reduce__`.

An alternative to implementing a `__reduce__()` method on the object to be pickled, is to register the callable with the `copy_reg` module. This module provides a way for programs to register "reduction functions" and constructors for user-defined types. Reduction functions have the same semantics and interface as the `__reduce__()` method described above, except that they are called with a single argument, the object to be pickled.

The registered constructor is deemed a "safe constructor" for purposes of unpickling as described above.
13.1.5.3 Pickling and unpickling external objects

For the benefit of object persistence, the pickle module supports the notion of a reference to an object outside the pickled data stream. Such objects are referenced by a ``persistent id'', which is just an arbitrary string of printable ASCII characters. The resolution of such names is not defined by the pickle module; it will delegate this resolution to user defined functions on the pickler and unpickler.\textsuperscript{13.7}

To define external persistent id resolution, you need to set the \texttt{persistent\_id} attribute of the pickler object and the \texttt{persistent\_load} attribute of the unpickler object.

To pickle objects that have an external persistent id, the pickler must have a custom \texttt{persistent\_id()} method that takes an object as an argument and returns either \texttt{None} or the persistent id for that object. When \texttt{None} is returned, the pickler simply pickles the object as normal. When a persistent id string is returned, the pickler will pickle that string, along with a marker so that the unpickler will recognize the string as a persistent id.

To unpickle external objects, the unpickler must have a custom \texttt{persistent\_load()} function that takes a persistent id string and returns the referenced object.

Here's a silly example that \textit{might} shed more light:

```python
import pickle
from cStringIO import StringIO

src = StringIO()
p = pickle.Pickler(src)

def persistent_id(obj):
    if hasattr(obj, 'x'):
        return 'the value %d' % obj.x
    else:
        return None

p.persistent_id = persistent_id
```
class Integer:
    def __init__(self, x):
        self.x = x
    def __str__(self):
        return 'My name is integer %d' % self.x

i = Integer(7)
print i
p.dump(i)

datastream = src.getvalue()
print repr(datastream)
dst = StringIO(datastream)

up = pickle.Unpickler(dst)

class FancyInteger(Integer):
    def __str__(self):
        return 'I am the integer %d' % self.x

    def persistent_load(persid):
        if persid.startswith('the value '):
            value = int(persid.split()[2])
            return FancyInteger(value)
        else:
            raise pickle.UnpicklingError, 'Invalid persistent id'

up.persistent_load = persistent_load

j = up.load()
print j

In the cPickle module, the unpickler's persistent_load attribute can also be set to a Python list, in which case, when the unpickler reaches a persistent id, the persistent id string will simply be appended to this list. This functionality exists so that a pickle data stream can be ``sniffed'' for object references without actually instantiating all the objects in a pickle. Setting persistent_load to a list is usually used in conjunction with the noload() method on the Unpickler.

Footnotes

13.7 The actual mechanism for associating these user defined functions is
slightly different for pickle and cPickle. The description given here works the same for both implementations. Users of the pickle module could also use subclassing to effect the same results, overriding the persistent_id() and persistent_load() methods in the derived classes.

... pickle.\[13.8\]

We’ll leave you with the image of Guido and Jim sitting around sniffing pickles in their living rooms.
13.13.4.1 Introduction

SQLite natively supports the following types: NULL, INTEGER, REAL, TEXT, BLOB.

The following Python types can thus be sent to SQLite without any problem:

<table>
<thead>
<tr>
<th>Python type</th>
<th>SQLite type</th>
</tr>
</thead>
<tbody>
<tr>
<td>None</td>
<td>NULL</td>
</tr>
<tr>
<td>int</td>
<td>INTEGER</td>
</tr>
<tr>
<td>long</td>
<td>INTEGER</td>
</tr>
<tr>
<td>float</td>
<td>REAL</td>
</tr>
<tr>
<td>str (UTF8-encoded)</td>
<td>TEXT</td>
</tr>
<tr>
<td>unicode</td>
<td>TEXT</td>
</tr>
<tr>
<td>buffer</td>
<td>BLOB</td>
</tr>
</tbody>
</table>

This is how SQLite types are converted to Python types by default:

<table>
<thead>
<tr>
<th>SQLite type</th>
<th>Python type</th>
</tr>
</thead>
<tbody>
<tr>
<td>NULL</td>
<td>None</td>
</tr>
<tr>
<td>INTEGER</td>
<td>int or long, depending on size</td>
</tr>
<tr>
<td>REAL</td>
<td>float</td>
</tr>
<tr>
<td>TEXT</td>
<td>depends on text_factory, unicode by default</td>
</tr>
<tr>
<td>BLOB</td>
<td>buffer</td>
</tr>
</tbody>
</table>

The type system of the sqlite3 module is extensible in two ways: you can store additional Python types in a SQLite database via object adaptation, and you can let the sqlite3 module convert SQLite types to different Python types via converters.
13.13.4.2 Using adapters to

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
As described before, SQLite supports only a limited set of types natively. To use other Python types with SQLite, you must adapt them to one of the sqlite3 module's supported types for SQLite: one of NoneType, int, long, float, str, unicode, buffer.

The sqlite3 module uses Python object adaptation, as described in PEP 246 for this. The protocol to use is PrepareProtocol.

There are two ways to enable the sqlite3 module to adapt a custom Python type to one of the supported ones.

### 13.13.4.2.1 Letting your object adapt itself

This is a good approach if you write the class yourself. Let's suppose you have a class like this:

```python
class Point(object):
    def __init__(self, x, y):
        self.x, self.y = x, y
```

Now you want to store the point in a single SQLite column. First you'll have to choose one of the supported types first to be used for representing the point. Let's just use str and separate the coordinates using a semicolon. Then you need to give your class a method `__conform__` which must return the converted value. The parameter `protocol` will be PrepareProtocol.
**13.13.4.2.2 Registering an adapter callable**

The other possibility is to create a function that converts the type to the string representation and register the function with `register_adapter`.

**Note:** The type/class to adapt must be a new-style class, i.e. it must have `object` as one of its bases.
The `sqlite3` module has two default adapters for Python's built-in `datetime.date` and `datetime.datetime` types. Now let's suppose we want to store `datetime.datetime` objects not in ISO representation, but as a UNIX timestamp.

```python
import sqlite3
import datetime, time

def adapt_datetime(ts):
    return time.mktime(ts.timetuple())

sqlite3.register_adapter(datetime.datetime, adapt_datetime)

con = sqlite3.connect(":memory:")
cur = con.cursor()

now = datetime.datetime.now()
cur.execute("select ?", (now,))
print cur.fetchone()[0]
```

Download as text (original file name: `sqlite3/adapter_datetime.py`).
13.13.4.3 Converting SQLite values to custom Python types

Writing an adapter lets you send custom Python types to SQLite. But to make it really useful we need to make the Python to SQLite to Python roundtrip work.

Enter converters.

Let's go back to the `Point` class. We stored the x and y coordinates separated via semicolons as strings in SQLite.

First, we'll define a converter function that accepts the string as a parameter and constructs a `Point` object from it.

```python
def convert_point(s):
    x, y = map(float, s.split(';'))
    return Point(x, y)
```

Now you need to make the `sqlite3` module know that what you select from the database is actually a point. There are two ways of doing this:

- Implicitly via the declared type
- Explicitly via the column name

Both ways are described in `Module Constants`, section 13.13.1, in the entries for the constants `PARSE_DECLTYPES` and `PARSE_COLNAMES`.

The following example illustrates both approaches.
```python
import sqlite3

class Point(object):
    def __init__(self, x, y):
        self.x, self.y = x, y

    def __repr__(self):
        return "(%f;%f)" % (self.x, self.y)

def adapt_point(point):
    return "%f;%f" % (point.x, point.y)

def convert_point(s):
    x, y = map(float, s.split(";"))
    return Point(x, y)

# Register the adapter
sqlite3.register_adapter(Point, adapt_point)

# Register the converter
sqlite3.register_converter("point", convert_point)

p = Point(4.0, -3.2)

# 1) Using declared types
con = sqlite3.connect(":memory:", detect_types=sqlite3.PARSE_DECLTYPES)
cur = con.cursor()
cur.execute("create table test(p point)")

cur.execute("insert into test(p) values (?)", (p,))
cur.execute("select p from test")
print "with declared types:", cur.fetchone()[0]
cur.close()
con.close()

# 1) Using column names
con = sqlite3.connect(":memory:", detect_types=sqlite3.PARSE_COLNAME)
cur = con.cursor()
cur.execute("create table test(p)")

cur.execute("insert into test(p) values (?)", (p,))
cur.execute('select p as "p [point]" as "p [point]" from test')
print "with column names:", cur.fetchone()[0]
cur.close()
con.close()
```

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
13.13.4.4 Default adapters and converters

There are default adapters for the date and datetime types in the datetime module. They will be sent as ISO dates/ISO timestamps to SQLite.

The default converters are registered under the name "date" for `datetime.date` and under the name "timestamp" for `datetime.datetime`.

This way, you can use date/timestamps from Python without any additional fiddling in most cases. The format of the adapters is also compatible with the experimental SQLite date/time functions.

The following example demonstrates this.

```python
import sqlite3
import datetime

con = sqlite3.connect(':memory:', detect_types=sqlite3.PARSE_DECLTYPES|sqlite3.PARSE_COLNAMES)
cur = con.cursor()
cur.execute("create table test(d date, ts timestamp)"

today = datetime.date.today()
own = datetime.datetime.now()

cur.execute("insert into test(d, ts) values (?, ?)", (today, now))
cur.execute("select d, ts from test")
row = cur.fetchone()
print today, "=>", row[0], type(row[0])
print now, "=>", row[1], type(row[1])

cur.execute('select current_date as "d [date]", current_timestamp as "ts [timestamp]"')
row = cur.fetchone()
print "current_date", row[0], type(row[0])
print "current_timestamp", row[1], type(row[1])
```

Download as text (original file name: sqlite3/pysqlite_datetime.py).
Release 2.5, documentation updated on 19th September, 2006. See About this document... for information on suggesting changes.
13.13.6.1 Using shortcut methods

Using the nonstandard `execute`, `executemany` and `executescript` methods of the `Connection` object, your code can be written more concisely because you don't have to create the (often superfluous) `Cursor` objects explicitly. Instead, the `Cursor` objects are created implicitly and these shortcut methods return the cursor objects. This way, you can execute a SELECT statement and iterate over it directly using only a single call on the `Connection` object.

```python
import sqlite3

persons = [
    ("Hugo", "Boss"),
    ("Calvin", "Klein")
]

con = sqlite3.connect(":memory:"

# Create the table
con.execute("create table person(firstname, lastname)"

# Fill the table
con.executemany("insert into person(firstname, lastname) values (?,

# Print the table contents
for row in con.execute("select firstname, lastname from person"):
    print row

# Using a dummy WHERE clause to not let SQLite take the shortcut tab
print "I just deleted", con.execute("delete from person where 1=1").
```

Download as text (original file name: sqlite3/shortcut_methods.py).
13.13.6.2 Accessing columns by name instead of by index

One useful feature of the sqlite3 module is the builtin sqlite3.Row class designed to be used as a row factory.

Rows wrapped with this class can be accessed both by index (like tuples) and case-insensitively by name:

```python
import sqlite3
con = sqlite3.connect("mydb")
con.row_factory = sqlite3.Row

cur = con.cursor()
cur.execute("select name_last, age from people")
for row in cur:
    assert row[0] == row["name_last"]
    assert row["name_last"] == row["nAmE_lAsT"]
    assert row[1] == row["age"]
    assert row[1] == row["AgE"]
```

Download as text (original file name: sqlite3/rowclass.py).
14.3.1.1 Terminology

**Argument**

A string entered on the command-line, and passed by the shell to `exec1()` or `execv()`. In Python, arguments are elements of `sys.argv[1:]` (`sys.argv[0]` is the name of the program being executed). UNIX shells also use the term "word".

It is occasionally desirable to substitute an argument list other than `sys.argv[1:]`, so you should read "argument" as "an element of `sys.argv[1:]`, or of some other list provided as a substitute for `sys.argv[1:]".

**Option**

An argument used to supply extra information to guide or customize the execution of a program. There are many different syntaxes for options; the traditional UNIX syntax is a hyphen (`-`) followed by a single letter, e.g. "-x" or "-F". Also, traditional UNIX syntax allows multiple options to be merged into a single argument, e.g. "-x -F" is equivalent to "-xF". The GNU project introduced "-" followed by a series of hyphen-separated words, e.g. "-file" or "-dry-run". These are the only two option syntaxes provided by `optparse`.

Some other option syntaxes that the world has seen include:

- A hyphen followed by a few letters, e.g. "-pf" (this is not the same as multiple options merged into a single argument)

- A hyphen followed by a whole word, e.g. "-file" (this is technically equivalent to the previous syntax, but they aren't usually seen in the same program)

- A plus sign followed by a single letter, or a few letters, or a word, e.g. "+f", "+rgb"
• a slash followed by a letter, or a few letters, or a word, e.g. "/f", "/file"

These option syntaxes are not supported by optparse, and they never will be. This is deliberate: the first three are non-standard on any environment, and the last only makes sense if you're exclusively targeting VMS, MS-DOS, and/or Windows.

**option argument**

an argument that follows an option, is closely associated with that option, and is consumed from the argument list when that option is. With optparse, option arguments may either be in a separate argument from their option:

```
-f foo
--file foo
```

or included in the same argument:

```
-ffoo
--file=foo
```

Typically, a given option either takes an argument or it doesn't. Lots of people want an "optional option arguments" feature, meaning that some options will take an argument if they see it, and won't if they don't. This is somewhat controversial, because it makes parsing ambiguous: if "-a" takes an optional argument and "-b" is another option entirely, how do we interpret "-ab"? Because of this ambiguity, optparse does not support this feature.

**positional argument**

something leftover in the argument list after options have been parsed, i.e. after options and their arguments have been parsed and removed from the argument list.

**required option**

an option that must be supplied on the command-line; note that the phrase "required option" is self-contradictory in English. optparse doesn't prevent you from implementing required options, but doesn't give you much help at it either. See examples/required_1.py and examples/required_2.py in the optparse source distribution for
two ways to implement required options with `optparse`.

For example, consider this hypothetical command-line:

```
prog -v --report /tmp/report.txt foo bar
```

"-v" and "--report" are both options. Assuming that `--report` takes one argument, "/tmp/report.txt" is an option argument. "foo" and "bar" are positional arguments.
14.3.1.2 What are options for?

Options are used to provide extra information to tune or customize the execution of a program. In case it wasn't clear, options are usually optional. A program should be able to run just fine with no options whatsoever. (Pick a random program from the Unix or GNU toolsets. Can it run without any options at all and still make sense? The main exceptions are find, tar, and dd--all of which are mutant oddballs that have been rightly criticized for their non-standard syntax and confusing interfaces.)

Lots of people want their programs to have "required options". Think about it. If it's required, then it's not optional! If there is a piece of information that your program absolutely requires in order to run successfully, that's what positional arguments are for.

As an example of good command-line interface design, consider the humble cp utility, for copying files. It doesn't make much sense to try to copy files without supplying a destination and at least one source. Hence, cp fails if you run it with no arguments. However, it has a flexible, useful syntax that does not require any options at all:

```
cp SOURCE DEST
cp SOURCE ... DEST-DIR
```

You can get pretty far with just that. Most cp implementations provide a bunch of options to tweak exactly how the files are copied: you can preserve mode and modification time, avoid following symlinks, ask before clobbering existing files, etc. But none of this distracts from the core mission of cp, which is to copy either one file to another, or several files to another directory.
See About this document... for information on suggesting changes.
14.3.1.3 What are positional arguments for?

Positional arguments are for those pieces of information that your program absolutely, positively requires to run.

A good user interface should have as few absolute requirements as possible. If your program requires 17 distinct pieces of information in order to run successfully, it doesn't much matter how you get that information from the user--most people will give up and walk away before they successfully run the program. This applies whether the user interface is a command-line, a configuration file, or a GUI: if you make that many demands on your users, most of them will simply give up.

In short, try to minimize the amount of information that users are absolutely required to supply--use sensible defaults whenever possible. Of course, you also want to make your programs reasonably flexible. That's what options are for. Again, it doesn't matter if they are entries in a config file, widgets in the `Preferences` dialog of a GUI, or command-line options--the more options you implement, the more flexible your program is, and the more complicated its implementation becomes. Too much flexibility has drawbacks as well, of course; too many options can overwhelm users and make your code much harder to maintain.
14.3.2.1 Understanding option actions

Actions tell optparse what to do when it encounters an option on the command line. There is a fixed set of actions hard-coded into optparse; adding new actions is an advanced topic covered in section 14.3.5, Extending optparse. Most actions tell optparse to store a value in some variable—for example, take a string from the command line and store it in an attribute of options.

If you don't specify an option action, optparse defaults to store.
14.3.2.2 The store action

The most common option action is store, which tells optparse to take the next argument (or the remainder of the current argument), ensure that it is of the correct type, and store it to your chosen destination.

For example:

```python
parser.add_option("-f", "--file",
                 action="store", type="string", dest="filename")
```

Now let's make up a fake command line and ask optparse to parse it:

```python
args = ["-f", "foo.txt"]
(options, args) = parser.parse_args(args)
```

When optparse sees the option string "-f", it consumes the next argument, "foo.txt", and stores it in options.filename. So, after this call to parse_args(), options.filename is "foo.txt".

Some other option types supported by optparse are int and float. Here's an option that expects an integer argument:

```python
parser.add_option("-n", type="int", dest="num")
```

Note that this option has no long option string, which is perfectly acceptable. Also, there's no explicit action, since the default is store.

Let's parse another fake command-line. This time, we'll jam the option argument right up against the option: since "-n42" (one argument) is equivalent to "-n 42" (two arguments), the code

```python
(options, args) = parser.parse_args(["-n42"])
print options.num
```

will print "42".

If you don't specify a type, optparse assumes string. Combined with the
fact that the default action is \texttt{store}, that means our first example can be a lot shorter:

\begin{verbatim}
parser.add_option("-f", "--file", dest="filename")
\end{verbatim}

If you don't supply a destination, \texttt{optparse} figures out a sensible default from the option strings: if the first long option string is "-foo-bar", then the default destination is \texttt{foo_bar}. If there are no long option strings, \texttt{optparse} looks at the first short option string: the default destination for "-f" is \texttt{f}.

\texttt{optparse} also includes built-in \texttt{long} and \texttt{complex} types. Adding types is covered in section 14.3.5, Extending \texttt{optparse}.
14.3.2.3 Handling boolean (flag) options

Flag options--set a variable to true or false when a particular option is seen--are quite common. optparse supports them with two separate actions, store_true and store_false. For example, you might have a verbose flag that is turned on with "-v" and off with "-q":

```
pARSER.add_option("-v", action="store_true", dest="verbose")
pARSER.add_option("-q", action="store_false", dest="verbose")
```

Here we have two different options with the same destination, which is perfectly OK. (It just means you have to be a bit careful when setting default values--see below.)

When optparse encounters "-v" on the command line, it sets options.verbose to True; when it encounters "-q", options.verbose is set to False.
14.3.2.4 Other actions

Some other actions supported by `optparse` are:

- `store_const`: store a constant value
- `append`: append this option's argument to a list
- `count`: increment a counter by one
- `callback`: call a specified function

These are covered in section 14.3.3, Reference Guide and section 14.3.4, Option Callbacks.
14.3.2.5 Default values

All of the above examples involve setting some variable (the "destination") when certain command-line options are seen. What happens if those options are never seen? Since we didn't supply any defaults, they are all set to None. This is usually fine, but sometimes you want more control. optparse lets you supply a default value for each destination, which is assigned before the command line is parsed.

First, consider the verbose/quiet example. If we want optparse to set verbose to True unless "-q" is seen, then we can do this:

```python
parser.add_option("-v", action="store_true", dest="verbose", default=True)
parser.add_option("-q", action="store_false", dest="verbose")
```

Since default values apply to the destination rather than to any particular option, and these two options happen to have the same destination, this is exactly equivalent:

```python
parser.add_option("-v", action="store_true", dest="verbose")
parser.add_option("-q", action="store_false", dest="verbose", default=True)
```

Consider this:

```python
parser.add_option("-v", action="store_true", dest="verbose", default=True)
parser.add_option("-q", action="store_false", dest="verbose", default=False)
```

Again, the default value for verbose will be True: the last default value supplied for any particular destination is the one that counts.

A clearer way to specify default values is the set_defaults() method of OptionParser, which you can call at any time before calling parse_args():

```python
parser.set_defaults(verbos=True)
parser.add_option(...)  
(options, args) = parser.parse_args()
```

As before, the last value specified for a given option destination is the one that
counts. For clarity, try to use one method or the other of setting default values, not both.
14.3.2.6 Generating help

`optparse`'s ability to generate help and usage text automatically is useful for creating user-friendly command-line interfaces. All you have to do is supply a `help` value for each option, and optionally a short usage message for your whole program. Here's an OptionParser populated with user-friendly (documented) options:

```python
usage = "usage: %prog [options] arg1 arg2"
parser = OptionParser(usage=usage)
parsers.add_option("-v", "--verbose",
                 action="store_true", dest="verbose", default=True,
                 help="make lots of noise [default]"
) parsers.add_option("-q", "--quiet",
                  action="store_false", dest="verbose",
                  help="be vewwy quiet (I'm hunting wabbits)"
) parsers.add_option("-f", "--filename",
                metavar="FILE", help="write output to FILE"
) parsers.add_option("-m", "--mode",
            default="intermediate",
            help="interaction mode: novice, intermediate, "
            "or expert [default: %default]"
)
```

If `optparse` encounters either "-h" or "-help" on the command-line, or if you just call `parser.print_help()`, it prints the following to standard output:

```
usage: <yourscript> [options] arg1 arg2

options:
  -h, --help                     show this help message and exit
  -v, --verbose                  make lots of noise [default]
  -q, --quiet                    be vewwy quiet (I'm hunting wabbits)
  -f FILE, --filename=FILE       write output to FILE
  -m MODE, --mode=MODE           interaction mode: novice, intermediate, or
                                 expert [default: intermediate]
```

(If the help output is triggered by a help option, `optparse` exits after printing the help text.)

There's a lot going on here to help `optparse` generate the best possible help
the script defines its own usage message:

   usage = "usage: %prog [options] arg1 arg2"

optparse expands "%prog" in the usage string to the name of the current program, i.e. os.path.basename(sys.argv[0]). The expanded string is then printed before the detailed option help.

If you don't supply a usage string, optparse uses a bland but sensible default: ``usage: %prog [options]'', which is fine if your script doesn't take any positional arguments.

- every option defines a help string, and doesn't worry about line-wrapping--optparse takes care of wrapping lines and making the help output look good.

- options that take a value indicate this fact in their automatically-generated help message, e.g. for the ``mode'' option:

   -m MODE, --mode=MODE

Here, ``MODE'' is called the meta-variable: it stands for the argument that the user is expected to supply to -m/--mode. By default, optparse converts the destination variable name to uppercase and uses that for the meta-variable. Sometimes, that's not what you want--for example, the --filename option explicitly sets metavar="FILE", resulting in this automatically-generated option description:

   -f FILE, --filename=FILE

This is important for more than just saving space, though: the manually written help text uses the meta-variable ``FILE'' to clue the user in that there's a connection between the semi-formal syntax ``-f FILE'' and the informal semantic description ``write output to FILE''. This is a simple but effective way to make your help text a lot clearer and more useful for end users.

- options that have a default value can include %default in the help string-
  -optparse will replace it with str() of the option's default value. If an
option has no default value (or the default value is None), %default expands to none.
14.3.2.7 Printing a version string

Similar to the brief usage string, optparse can also print a version string for your program. You have to supply the string as the version argument to OptionParser:

```python
def main():
    parser = OptionParser(usage="%prog [-f] [-q]", version="%prog 1.0")
```

"%prog" is expanded just like it is in usage. Apart from that, version can contain anything you like. When you supply it, optparse automatically adds a "-version" option to your parser. If it encounters this option on the command line, it expands your version string (by replacing "%prog"), prints it to stdout, and exits.

For example, if your script is called /usr/bin/foo:

```bash
$ /usr/bin/foo --version
foo 1.0
```
14.3.2.8 How optparse handles errors

There are two broad classes of errors that optparse has to worry about: programmer errors and user errors. Programmer errors are usually erroneous calls to parser.add_option(), e.g. invalid option strings, unknown option attributes, missing option attributes, etc. These are dealt with in the usual way: raise an exception (either optparse.OptionError or TypeError) and let the program crash.

Handling user errors is much more important, since they are guaranteed to happen no matter how stable your code is. optparse can automatically detect some user errors, such as bad option arguments (passing "-n 4x" where -n takes an integer argument), missing arguments ("-n" at the end of the command line, where -n takes an argument of any type). Also, you can call parser.error() to signal an application-defined error condition:

```python
(options, args) = parser.parse_args()
[...]
if options.a and options.b:
    parser.error("options -a and -b are mutually exclusive")
```

In either case, optparse handles the error the same way: it prints the program's usage message and an error message to standard error and exits with error status 2.

Consider the first example above, where the user passes "4x" to an option that takes an integer:

```
$ /usr/bin/foo -n 4x
usage: foo [options]

foo: error: option -n: invalid integer value: '4x'
```

Or, where the user fails to pass a value at all:

```
$ /usr/bin/foo -n
usage: foo [options]
```
foo: error: -n option requires an argument

optparse-generated error messages take care always to mention the option involved in the error; be sure to do the same when calling \texttt{parser.error()} from your application code.

If \texttt{optparse}'s default error-handling behaviour does not suite your needs, you'll need to subclass \texttt{OptionParser} and override \texttt{exit()} and/or \texttt{error()}.
14.3.2.9 Putting it all together

Here's what `optparse`-based scripts usually look like:

```python
from optparse import OptionParser

def main():
    usage = "usage: %prog [options] arg"
    parser = OptionParser(usage)
    parser.add_option(""'-f", "'--file", dest="filename",
                     help="read data from FILENAME")
    parser.add_option(""'-v", "'--verbose",
                     action="store_true", dest="verbose")
    parser.add_option(""'-q", "'--quiet",
                     action="store_false", dest="verbose")
    [...]
    (options, args) = parser.parse_args()
    if len(args) != 1:
        parser.error("incorrect number of arguments")
    if options.verbose:
        print "reading %s..." % options.filename
    [...]
    if __name__ == "__main__":
        main()
```

Python Library Reference
14.3.3.1 Creating the parser

The first step in using `optparse` is to create an OptionParser instance:

```python
parser = OptionParser(...)  
```

The OptionParser constructor has no required arguments, but a number of optional keyword arguments. You should always pass them as keyword arguments, i.e. do not rely on the order in which the arguments are declared.

**usage** (default: "%prog [options]")

The usage summary to print when your program is run incorrectly or with a help option. When `optparse` prints the usage string, it expands `%prog` to `os.path.basename(sys.argv[0])` (or to `prog` if you passed that keyword argument). To suppress a usage message, pass the special value `optparse.SUPPRESS_USAGE`.

**option_list** (default: `[]`)

A list of `Option` objects to populate the parser with. The options in `option_list` are added after any options in `standard_option_list` (a class attribute that may be set by OptionParser subclasses), but before any version or help options. Deprecated; use `add_option()` after creating the parser instead.

**option_class** (default: `optparse.Option`)

Class to use when adding options to the parser in `add_option()`.

**version** (default: `None`)

A version string to print when the user supplies a version option. If you supply a true value for `version`, `optparse` automatically adds a version option with the single option string "-version". The substring "%prog" is expanded the same as for `usage`.

**conflict_handler** (default: "error")

Specifies what to do when options with conflicting option strings are added to the parser; see section 14.3.3, Conflicts between options.

**description** (default: `None`)

A paragraph of text giving a brief overview of your program. `optparse` reformats this paragraph to fit the current terminal width and prints it when
the user requests help (after usage, but before the list of options).

**formatter (default: a new IndentedHelpFormatter)**

An instance of optparse.HelpFormatter that will be used for printing help text. optparse provides two concrete classes for this purpose: IndentedHelpFormatter and TitledHelpFormatter.

**add_help_option (default: True)**

If true, optparse will add a help option (with option strings "-h" and "-help") to the parser.

**prog**

The string to use when expanding "%prog" in usage and version instead of os.path.basename(sys.argv[0]).
14.3.3.2 Populating the parser

There are several ways to populate the parser with options. The preferred way is by using `OptionParser.add_option()`, as shown in section 14.3.2, the tutorial. `add_option()` can be called in one of two ways:

- pass it an Option instance (as returned by `make_option()`)
- pass it any combination of positional and keyword arguments that are acceptable to `make_option()` (i.e., to the Option constructor), and it will create the Option instance for you

The other alternative is to pass a list of pre-constructed Option instances to the OptionParser constructor, as in:

```python
option_list = [
    make_option("-f", "--filename",
                action="store", type="string", dest="filename"),
    make_option("-q", "--quiet",
                action="store_false", dest="verbose"),
]
parser = OptionParser(option_list=option_list)
```

(`make_option()` is a factory function for creating Option instances; currently it is an alias for the Option constructor. A future version of `optparse` may split Option into several classes, and `make_option()` will pick the right class to instantiate. Do not instantiate Option directly.)
14.3.3.3 Defining options

Each Option instance represents a set of synonymous command-line option strings, e.g. `-f` and `--file`. You can specify any number of short or long option strings, but you must specify at least one overall option string.

The canonical way to create an Option instance is with the `add_option()` method of `OptionParser`:

```
parser.add_option(opt_str[, ...], attr=value, ...)
```

To define an option with only a short option string:

```
parser.add_option("-f", attr=value, ...)
```

And to define an option with only a long option string:

```
parser.add_option("--foo", attr=value, ...)
```

The keyword arguments define attributes of the new Option object. The most important option attribute is `action`, and it largely determines which other attributes are relevant or required. If you pass irrelevant option attributes, or fail to pass required ones, `optparse` raises an OptionError exception explaining your mistake.

An option's `action` determines what `optparse` does when it encounters this option on the command-line. The standard option actions hard-coded into `optparse` are:

- **store**
  - store this option's argument (default)
- **store_const**
  - store a constant value
- **store_true**
  - store a true value
- **store_false**
  - store a false value
append
   append this option's argument to a list
append_const
   append a constant value to a list
count
   increment a counter by one
callback
   call a specified function
help
   print a usage message including all options and the documentation for them

(If you don't supply an action, the default is store. For this action, you may also supply type and dest option attributes; see below.)

As you can see, most actions involve storing or updating a value somewhere. optparse always creates a special object for this, conventionally called options (it happens to be an instance of optparse.Values). Option arguments (and various other values) are stored as attributes of this object, according to the dest (destination) option attribute.

For example, when you call

    parser.parse_args()

one of the first things optparse does is create the options object:

    options = Values()

If one of the options in this parser is defined with

    parser.add_option("-f", "--file", action="store", type="string", dest

and the command-line being parsed includes any of the following:

    -ffoo
    -f foo
    --file=foo
    --file foo

then optparse, on seeing this option, will do the equivalent of

    options.filename = "foo"
The type and dest option attributes are almost as important as action, but action is the only one that makes sense for all options.
The various option actions all have slightly different requirements and effects. Most actions have several relevant option attributes which you may specify to guide optparse's behaviour; a few have required attributes, which you must specify for any option using that action.

- **store** [relevant: `type`, `dest`, `nargs`, `choices`]

  The option must be followed by an argument, which is converted to a value according to `type` and stored in `dest`. If `nargs > 1`, multiple arguments will be consumed from the command line; all will be converted according to `type` and stored to `dest` as a tuple. See the ``Option types'' section below.

  If `choices` is supplied (a list or tuple of strings), the type defaults to `choice`.

  If `type` is not supplied, it defaults to `string`.

  If `dest` is not supplied, `optparse` derives a destination from the first long option string (e.g., "-foo-bar" implies `foo_bar`). If there are no long option strings, `optparse` derives a destination from the first short option string (e.g., "-f" implies `f`).

Example:

```
parser.add_option("-f")
parser.add_option("-p", type="float", nargs=3, dest="point")
```

As it parses the command line

```
-f foo.txt -p 1 -3.5 4 -fbar.txt
```

`optparse` will set

```
options.f = "foo.txt"
```
options.point = (1.0, -3.5, 4.0)
options.f = "bar.txt"

- **store_const** [required: const; relevant: dest]

  The value `const` is stored in `dest`.

  Example:

  ```python
  parser.add_option("-q", "--quiet",
                   action="store_const", const=0, dest="verbose");
  parser.add_option("-v", "--verbose",
                   action="store_const", const=1, dest="verbose");
  parser.add_option("--noisy",
                   action="store_const", const=2, dest="verbose");
  ```

  If "-noisy" is seen, `optparse` will set

  ```python
  options.verbose = 2
  ```

- **store_true** [relevant: dest]

  A special case of `store_const` that stores a true value to `dest`.

- **store_false** [relevant: dest]

  Like `store_true`, but stores a false value.

  Example:

  ```python
  parser.add_option("--clobber", action="store_true", dest="clobber")
  parser.add_option("--no-clobber", action="store_false", dest="clobber")
  ```

- **append** [relevant: type, dest, nargs, choices]

  The option must be followed by an argument, which is appended to the list in `dest`. If no default value for `dest` is supplied, an empty list is automatically created when `optparse` first encounters this option on the command-line. If `nargs > 1`, multiple arguments are consumed, and a tuple of length `nargs` is appended to `dest`.

  The defaults for `type` and `dest` are the same as for the `store` action.
Example:

```python
caller.add_option("-t", "--tracks", action="append", type="int")
```

If "-t3" is seen on the command-line, `optparse` does the equivalent of:

```python
options.tracks = []
options.tracks.append(int("3"))
```

If, a little later on, "-tracks=4" is seen, it does:

```python
options.tracks.append(int("4"))
```

- **append_const [required: const; relevant: dest]**

  Like `store_const`, but the value `const` is appended to `dest`; as with `append`, `dest` defaults to `None`, and an an empty list is automatically created the first time the option is encountered.

- **count [relevant: dest]**

  Increment the integer stored at `dest`. If no default value is supplied, `dest` is set to zero before being incremented the first time.

  Example:

  ```python
  parser.add_option("-v", action="count", dest="verbosity")
  ```

  The first time "-v" is seen on the command line, `optparse` does the equivalent of:

  ```python
  options.verbosity = 0
  options.verbosity += 1
  ```

  Every subsequent occurrence of "-v" results in

  ```python
  options.verbosity += 1
  ```

- **callback [required: callback; relevant: type, nargs, callback_args, callback_kwargs]**

  Call the function specified by `callback`, which is called as
func(option, opt_str, value, parser, *args, **kwargs)

See section 14.3.4, Option Callbacks for more detail.

- help

Prints a complete help message for all the options in the current option parser. The help message is constructed from the usage string passed to OptionParser's constructor and the help string passed to every option.

If no help string is supplied for an option, it will still be listed in the help message. To omit an option entirely, use the special value optparse.SUPPRESS_HELP.

optparse automatically adds a help option to all OptionParsers, so you do not normally need to create one.

Example:

```python
from optparse import OptionParser, SUPPRESS_HELP

parser = OptionParser()
parser.add_option("-h", "--help", action="help"),
parser.add_option("-v", action="store_true", dest="verbose",
    help="Be moderately verbose")
parser.add_option("--file", dest="filename",
    help="Input file to read data from")
parser.add_option("--secret", help=SUPPRESS_HELP)
```

If optparse sees either "-h" or "-help" on the command line, it will print something like the following help message to stdout (assuming sys.argv[0] is "foo.py"):

```plaintext
usage: foo.py [options]

options:
  -h, --help            Show this help message and exit
  -v                   Be moderately verbose
  --file=FILENAME      Input file to read data from
```

After printing the help message, optparse terminates your process with sys.exit(0).

- version
Prints the version number supplied to the OptionParser to stdout and exits. The version number is actually formatted and printed by the `print_version()` method of OptionParser. Generally only relevant if the `version` argument is supplied to the OptionParser constructor. As with help options, you will rarely create `version` options, since `optparse` automatically adds them when needed.
14.3.3.5 Option attributes

The following option attributes may be passed as keyword arguments to `parser.add_option()`. If you pass an option attribute that is not relevant to a particular option, or fail to pass a required option attribute, `optparse` raises OptionError.

- **action** (default: "store")

  Determines `optparse`'s behaviour when this option is seen on the command line; the available options are documented above.

- **type** (default: "string")

  The argument type expected by this option (e.g., "string" or "int"); the available option types are documented below.

- **dest** (default: derived from option strings)

  If the option's action implies writing or modifying a value somewhere, this tells `optparse` where to write it: `dest` names an attribute of the `options` object that `optparse` builds as it parses the command line.

- **default** (deprecated)

  The value to use for this option's destination if the option is not seen on the command line. Deprecated; use `parser.set_defaults()` instead.

- **nargs** (default: 1)

  How many arguments of type `type` should be consumed when this option is seen. If > 1, `optparse` will store a tuple of values to `dest`.

- **const**

  For actions that store a constant value, the constant value to store.
• **choices**

  For options of type "choice", the list of strings the user may choose from.

• **callback**

  For options with action "callback", the callable to call when this option is seen. See section [14.3.4](#), Option Callbacks for detail on the arguments passed to callable.

• **callback_args**, **callback_kwargs**

  Additional positional and keyword arguments to pass to callback after the four standard callback arguments.

• **help**

  Help text to print for this option when listing all available options after the user supplies a help option (such as "-help"). If no help text is supplied, the option will be listed without help text. To hide this option, use the special value `SUPPRESS_HELP`.

• **metavar** (default: derived from option strings)

  Stand-in for the option argument(s) to use when printing help text. See section [14.3.2](#), the tutorial for an example.
14.3.3.6 Standard option types

`optparse` has six built-in option types: `string`, `int`, `long`, `choice`, `float` and `complex`. If you need to add new option types, see section 14.3.5, Extending `optparse`.

Arguments to string options are not checked or converted in any way: the text on the command line is stored in the destination (or passed to the callback) as-is.

Integer arguments (type `int` or `long`) are parsed as follows:

- if the number starts with `0x`, it is parsed as a hexadecimal number
- if the number starts with `0`, it is parsed as an octal number
- if the number starts with `0b`, is is parsed as a binary number
- otherwise, the number is parsed as a decimal number

The conversion is done by calling either `int()` or `long()` with the appropriate base (2, 8, 10, or 16). If this fails, so will `optparse`, although with a more useful error message.

`float` and `complex` option arguments are converted directly with `float()` and `complex()`, with similar error-handling.

`choice` options are a subtype of `string` options. The `choices` option attribute (a sequence of strings) defines the set of allowed option arguments. `optparse.check_choice()` compares user-supplied option arguments against this master list and raises `OptionValueError` if an invalid string is given.
Release 2.5, documentation updated on 19th September, 2006. See About this document... for information on suggesting changes.
14.3.3.7 Parsing arguments

The whole point of creating and populating an OptionParser is to call its `parse_args()` method:

```python
(options, args) = parser.parse_args(args=None, options=None)
```

where the input parameters are

- **args**
  - the list of arguments to process (default: `sys.argv[1:]`)
- **options**
  - object to store option arguments in (default: a new instance of `optparse.Values`)

and the return values are

- **options**
  - the same object that was passed in as `options`, or the `optparse.Values` instance created by `optparse`
- **args**
  - the leftover positional arguments after all options have been processed

The most common usage is to supply neither keyword argument. If you supply `options`, it will be modified with repeated `setattr()` calls (roughly one for every option argument stored to an option destination) and returned by `parse_args()`.

If `parse_args()` encounters any errors in the argument list, it calls the OptionParser's `error()` method with an appropriate end-user error message. This ultimately terminates your process with an exit status of 2 (the traditional UNIX exit status for command-line errors).
14.3.3.8 Querying and manipulating

Release 2.5, documentation updated on 19th September, 2006. See About this document... for information on suggesting changes.
14.3.3.8 Querying and manipulating your option parser

Sometimes, it's useful to poke around your option parser and see what's there. OptionParser provides a couple of methods to help you out:

**has_option(opt_str)**
Return true if the OptionParser has an option with option string `opt_str` (e.g., "-q" or "-verbose").

**get_option(opt_str)**
Returns the Option instance with the option string `opt_str`, or None if no options have that option string.

**remove_option(opt_str)**
If the OptionParser has an option corresponding to `opt_str`, that option is removed. If that option provided any other option strings, all of those option strings become invalid. If `opt_str` does not occur in any option belonging to this OptionParser, raises ValueError.
14.3.3.9 Conflicts between options

If you're not careful, it's easy to define options with conflicting option strings:

```
    parser.add_option("-n", "--dry-run", ...)  
    [...]  
    parser.add_option("-n", "--noisy", ...)  
```

(This is particularly true if you've defined your own OptionParser subclass with some standard options.)

Every time you add an option, `optparse` checks for conflicts with existing options. If it finds any, it invokes the current conflict-handling mechanism. You can set the conflict-handling mechanism either in the constructor:

```
    parser = OptionParser(..., conflict_handler=handler)
```

or with a separate call:

```
    parser.set_conflict_handler(handler)
```

The available conflict handlers are:

**error** *(default)*

- assume option conflicts are a programming error and raise `OptionConflictError`

**resolve**

- resolve option conflicts intelligently (see below)

As an example, let's define an OptionParser that resolves conflicts intelligently and add conflicting options to it:

```
    parser = OptionParser(conflict_handler="resolve")  
    parser.add_option("-n", "--dry-run", ..., help="do no harm")  
    parser.add_option("-n", "--noisy", ..., help="be noisy")
```

At this point, `optparse` detects that a previously-added option is already using the "-n" option string. Since `conflict_handler` is "resolve", it
resolves the situation by removing "-n" from the earlier option's list of option strings. Now "-dry-run" is the only way for the user to activate that option. If the user asks for help, the help message will reflect that:

```python
options:
    --dry-run     do no harm
    [...]        
    -n, --noisy  be noisy
```

It's possible to whittle away the option strings for a previously-added option until there are none left, and the user has no way of invoking that option from the command-line. In that case, `optparse` removes that option completely, so it doesn't show up in help text or anywhere else. Carrying on with our existing OptionParser:

```python
parser.add_option("--dry-run", ..., help="new dry-run option")
```

At this point, the original `-n/-dry-run` option is no longer accessible, so `optparse` removes it, leaving this help text:

```python
options:
    [...]        
    -n, --noisy  be noisy
    --dry-run    new dry-run option
```

---

**Python Library Reference**

Previous: [14.3.3.8 Querying and manipulating](#)  
Up: [14.3.3 Reference Guide](#)  
Next: [14.3.3.10 Cleanup](#)  

Release 2.5, documentation updated on 19th September, 2006.  
See [About this document...](#) for information on suggesting changes.
14.3.3.10 Cleanup

OptionParser instances have several cyclic references. This should not be a problem for Python's garbage collector, but you may wish to break the cyclic references explicitly by calling `destroy()` on your OptionParser once you are done with it. This is particularly useful in long-running applications where large object graphs are reachable from your OptionParser.
14.3.3.11 Other methods

OptionParser supports several other public methods:

- **set_usage(usage)**

  Set the usage string according to the rules described above for the usage constructor keyword argument. Passing `None` sets the default usage string; use `SUPPRESS_USAGE` to suppress a usage message.

- **enable_interspersed_args()**, **disable_interspersed_args()**

  Enable/disable positional arguments interspersed with options, similar to GNU getopt (enabled by default). For example, if "-a" and "-b" are both simple options that take no arguments, optparse normally accepts this syntax:

  ```
  prog -a arg1 -b arg2
  ```

  and treats it as equivalent to

  ```
  prog -a -b arg1 arg2
  ```

  To disable this feature, call `disable_interspersed_args()`. This restores traditional UNIX syntax, where option parsing stops with the first non-option argument.

- **set_defaults(dest=value, ...)**

  Set default values for several option destinations at once. Using `set_defaults()` is the preferred way to set default values for options, since multiple options can share the same destination. For example, if several "mode" options all set the same destination, any one of them can set the default, and the last one wins:

  ```python
  parser.add_option("--advanced", action="store_const",
  ```
To avoid this confusion, use `set_defaults()`:

```python
default="advanced")  # overridden below
parser.add_option("--advanced", action="store_const",
dest="mode", const="advanced")  # overrides above setting

parser.set_defaults(mode="advanced")
parser.add_option("--advanced", action="store_const",
dest="mode", const="advanced")
parser.add_option("--novice", action="store_const",
dest="mode", const="novice")
```
14.3.4.1 Defining a callback option

As always, the easiest way to define a callback option is by using the `parser.add_option()` method. Apart from `action`, the only option attribute you must specify is `callback`, the function to call:

```python
parser.add_option("-c", action="callback", callback=my_callback)
```

callback is a function (or other callable object), so you must have already defined `my_callback()` when you create this callback option. In this simple case, `optparse` doesn't even know if `-c` takes any arguments, which usually means that the option takes no arguments--the mere presence of `-c` on the command-line is all it needs to know. In some circumstances, though, you might want your callback to consume an arbitrary number of command-line arguments. This is where writing callbacks gets tricky; it's covered later in this section.

`optparse` always passes four particular arguments to your callback, and it will only pass additional arguments if you specify them via `callback_args` and `callback_kwargs`. Thus, the minimal callback function signature is:

```python
def my_callback(option, opt, value, parser):
```

The four arguments to a callback are described below.

There are several other option attributes that you can supply when you define a callback option:

**type**

has its usual meaning: as with the `store` or `append` actions, it instructs `optparse` to consume one argument and convert it to `type`. Rather than storing the converted value(s) anywhere, though, `optparse` passes it to your callback function.

**nargs**

also has its usual meaning: if it is supplied and > 1, `optparse` will consume `nargs` arguments, each of which must be convertible to `type`. It then passes a tuple of converted values to your callback.
callback_args
   a tuple of extra positional arguments to pass to the callback

callback_kwargs
   a dictionary of extra keyword arguments to pass to the callback
14.3.4.2 How callbacks are called

All callbacks are called as follows:

```
func(option, opt_str, value, parser, *args, **kwargs)
```

where

**option**

is the Option instance that's calling the callback

**opt_str**

is the option string seen on the command-line that's triggering the callback. (If an abbreviated long option was used, **opt_str** will be the full, canonical option string--e.g. if the user puts "-foo" on the command-line as an abbreviation for "-foobar", then **opt_str** will be "-foobar".)

**value**

is the argument to this option seen on the command-line. **optparse** will only expect an argument if **type** is set; the type of **value** will be the type implied by the option's type. If **type** for this option is **None** (no argument expected), then **value** will be **None**. If **nargs** > 1, **value** will be a tuple of values of the appropriate type.

**parser**

is the OptionParser instance driving the whole thing, mainly useful because you can access some other interesting data through its instance attributes:

**parser.largs**

the current list of leftover arguments, i.e. arguments that have been consumed but are neither options nor option arguments. Feel free to modify **parser.largs**, e.g. by adding more arguments to it. (This list will become **args**, the second return value of **parse_args()**.)

**parser.rargs**

the current list of remaining arguments, i.e. with **opt_str** and **value** (if applicable) removed, and only the arguments following them still there. Feel free to modify **parser.rargs**, e.g. by consuming more arguments.

**parser.values**
the object where option values are by default stored (an instance of optparse.OptionValues). This lets callbacks use the same mechanism as the rest of optparse for storing option values; you don't need to mess around with globals or closures. You can also access or modify the value(s) of any options already encountered on the command-line.

**args**

is a tuple of arbitrary positional arguments supplied via the callback_args option attribute.

**kwargs**

is a dictionary of arbitrary keyword arguments supplied via callback_kwargs.
14.3.4.3 Raising errors in a callback

The callback function should raise OptionValueError if there are any problems with the option or its argument(s). optparse catches this and terminates the program, printing the error message you supply to stderr. Your message should be clear, concise, accurate, and mention the option at fault. Otherwise, the user will have a hard time figuring out what he did wrong.
14.3.4.4 Callback example 1: trivial callback

Here's an example of a callback option that takes no arguments, and simply records that the option was seen:

```python
def record_foo_seen(option, opt_str, value, parser):
    parser.saw_foo = True

parser.add_option("--foo", action="callback", callback=record_foo_seen)
```

Of course, you could do that with the `store_true` action.
14.3.4.5 Callback example 2: check option order

Here's a slightly more interesting example: record the fact that "-a" is seen, but blow up if it comes after "-b" in the command-line.

```python
def check_order(option, opt_str, value, parser):
    if parser.values.b:
        raise OptionValueError("can't use -a after -b")
    parser.values.a = 1

[...]
parser.add_option("-a", action="callback", callback=check_order)
parser.add_option("-b", action="store_true", dest="b")
```

See About this document... for information on suggesting changes.
14.3.4.6 Callback example 3: check option order (generalized)

If you want to re-use this callback for several similar options (set a flag, but blow up if "-b" has already been seen), it needs a bit of work: the error message and the flag that it sets must be generalized.

```python
def check_order(option, opt_str, value, parser):
    if parser.values.b:
        raise OptionValueError("can't use %s after -b" % opt_str)
    setattr(parser.values, option.dest, 1)

parser.add_option("-a", action="callback", callback=check_order, dest='a')
parser.add_option("-b", action="store_true", dest="b")
parser.add_option("-c", action="callback", callback=check_order, dest=
```

Release 2.5, documentation updated on 19th September, 2006.

See About this document... for information on suggesting changes.
14.3.4.7 Callback example 4: check arbitrary condition

Of course, you could put any condition in there--you're not limited to checking the values of already-defined options. For example, if you have options that should not be called when the moon is full, all you have to do is this:

```python
def check_moon(option, opt_str, value, parser):
    if is_moon_full():
        raise OptionValueError("%s option invalid when moon is full" % opt_str)
    setattr(parser.values, option.dest, 1)
[[...]
parser.add_option("--foo",
    action="callback", callback=check_moon, dest="foo"
)
```

(The definition of is_moon_full() is left as an exercise for the reader.)
14.3.4.8 Callback example 5: fixed arguments

Things get slightly more interesting when you define callback options that take a fixed number of arguments. Specifying that a callback option takes arguments is similar to defining a store or append option: if you define type, then the option takes one argument that must be convertible to that type; if you further define nargs, then the option takes nargs arguments.

Here's an example that just emulates the standard store action:

```python
def store_value(option, opt_str, value, parser):
    setattr(parser.values, option.dest, value)

[...]
parsed.add_option("--foo",
    action="callback", callback=store_value,
    type="int", nargs=3, dest="foo")
```

Note that optparse takes care of consuming 3 arguments and converting them to integers for you; all you have to do is store them. (Or whatever; obviously you don't need a callback for this example.)
14.3.4.9 Callback example 6: variable arguments

Things get hairy when you want an option to take a variable number of arguments. For this case, you must write a callback, as optparse doesn't provide any built-in capabilities for it. And you have to deal with certain intricacies of conventional UNIX command-line parsing that optparse normally handles for you. In particular, callbacks should implement the conventional rules for bare "-" and "-" arguments:

- either "-" or "-" can be option arguments
- bare "-" (if not the argument to some option): halt command-line processing and discard the "-"
- bare "-" (if not the argument to some option): halt command-line processing but keep the "-" (append it to parser.largs)

If you want an option that takes a variable number of arguments, there are several subtle, tricky issues to worry about. The exact implementation you choose will be based on which trade-offs you're willing to make for your application (which is why optparse doesn't support this sort of thing directly).

Nevertheless, here's a stab at a callback for an option with variable arguments:

```python
def vararg_callback(option, opt_str, value, parser):
    assert value is None
    done = 0
    value = []
    rargs = parser.rargs
    while rargs:
        arg = rargs[0]
        # Stop if we hit an arg like "--foo", ":a", ":fx", ":file=f
        # etc. Note that this also stops on ":3" or ":3.0", so if
        # your option takes numeric values, you will need to handle
        # this.
        if ((arg[2:] == "--" and len(arg) > 2) or
            (arg[1:] == "-" and len(arg) > 1 and arg[1] != ":")): break
```
else:
    value.append(arg)
    del rargs[0]

    setattr(parser.values, option.dest, value)

    [...]  
    parser.add_option("-c", "--callback",
                      action="callback", callback=varargs)

The main weakness with this particular implementation is that negative numbers in the arguments following "-c" will be interpreted as further options (probably causing an error), rather than as arguments to "-c". Fixing this is left as an exercise for the reader.
14.3.5.1 Adding new types

To add new types, you need to define your own subclass of `optparse`'s Option class. This class has a couple of attributes that define `optparse`'s types: TYPES and TYPE_CHECKER.

TYPES is a tuple of type names; in your subclass, simply define a new tuple TYPES that builds on the standard one.

TYPE_CHECKER is a dictionary mapping type names to type-checking functions. A type-checking function has the following signature:

```python
def check_mytype(option, opt, value)
```

where option is an Option instance, opt is an option string (e.g., "-f"), and value is the string from the command line that must be checked and converted to your desired type. check_mytype() should return an object of the hypothetical type mytype. The value returned by a type-checking function will wind up in the OptionValues instance returned by OptionParser.parse_args(), or be passed to a callback as the value parameter.

Your type-checking function should raise OptionValueError if it encounters any problems. OptionValueError takes a single string argument, which is passed as-is to OptionParser's error() method, which in turn prepends the program name and the string "error:" and prints everything to stderr before terminating the process.

Here's a silly example that demonstrates adding a complex option type to parse Python-style complex numbers on the command line. (This is even sillier than it used to be, because optparse 1.3 added built-in support for complex numbers, but never mind.)

First, the necessary imports:

```python
from copy import copy
```
You need to define your type-checker first, since it's referred to later (in the TYPE_CHECKER class attribute of your Option subclass):

```python
def check_complex(option, opt, value):
    try:
        return complex(value)
    except ValueError:
        raise OptionValueError(
            "option %s: invalid complex value: %r" % (opt, value))
```

Finally, the Option subclass:

```python
class MyOption (Option):
    TYPES = Option.TYPES + ("complex",)
    TYPE_CHECKER = copy(Option.TYPE_CHECKER)
    TYPE_CHECKER["complex"] = check_complex
```

(If we didn't make a copy() of Option.TYPE_CHECKER, we would end up modifying the TYPE_CHECKER attribute of optparse's Option class. This being Python, nothing stops you from doing that except good manners and common sense.)

That's it! Now you can write a script that uses the new option type just like any other optparse-based script, except you have to instruct your OptionParser to use MyOption instead of Option:

```python
parser = OptionParser(option_class=MyOption)
presenter.add_option("-c", type="complex")
```

Alternately, you can build your own option list and pass it to OptionParser; if you don't use add_option() in the above way, you don't need to tell OptionParser which option class to use:

```python
option_list = [MyOption("-c", action="store", type="complex", dest="
```

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
14.3.5.2 Adding new actions

Adding new actions is a bit trickier, because you have to understand that `optparse` has a couple of classifications for actions:

``store'' actions
  actions that result in `optparse` storing a value to an attribute of the current `OptionValues` instance; these options require a `dest` attribute to be supplied to the `Option` constructor

``typed'' actions
  actions that take a value from the command line and expect it to be of a certain type; or rather, a string that can be converted to a certain type. These options require a `type` attribute to the `Option` constructor.

These are overlapping sets: some default ```store''` actions are `store`, `store_const`, `append`, and `count`, while the default ```typed''` actions are `store`, `append`, and `callback`.

When you add an action, you need to categorize it by listing it in at least one of the following class attributes of `Option` (all are lists of strings):

**ACTIONS**
  all actions must be listed in `ACTIONS`

**STORE_ACTIONS**
  ```store''` actions are additionally listed here

**TYPED_ACTIONS**
  ```typed''` actions are additionally listed here

**ALWAYS_TYPED_ACTIONS**
  actions that always take a type (i.e. whose options always take a value) are additionally listed here. The only effect of this is that `optparse` assigns the default type, `string`, to options with no explicit type whose action is listed in `ALWAYS_TYPED_ACTIONS`.

In order to actually implement your new action, you must override `Option`'s `take_action()` method and add a case that recognizes your action.
For example, let’s add an `extend` action. This is similar to the standard `append` action, but instead of taking a single value from the command-line and appending it to an existing list, `extend` will take multiple values in a single comma-delimited string, and extend an existing list with them. That is, if `-names` is an `extend` option of type `string`, the command line

```
--names=foo,bar --names blah --names ding,dong
```

would result in a list

```
["foo", "bar", "blah", "ding", "dong"]
```

Again we define a subclass of `Option`:

```
class MyOption (Option):

    ACTIONS = Option.ACTIONS + ("extend",)
    STORE_ACTIONS = Option.STORE_ACTIONS + ("extend",)
    TYPED_ACTIONS = Option.TYPED_ACTIONS + ("extend",)
    ALWAYS_TYPED_ACTIONS = Option.ALWAYS_TYPED_ACTIONS + ("extend",)

    def take_action(self, action, dest, opt, value, values, parser):
        if action == "extend":
            lvalue = value.split(",")
            values.ensure_value(dest, []).extend(lvalue)
        else:
            Option.take_action(
                self, action, dest, opt, value, values, parser)
```

Features of note:

- `extend` both expects a value on the command-line and stores that value somewhere, so it goes in both `STORE_ACTIONS` and `TYPED_ACTIONS`

- to ensure that `optparse` assigns the default type of `string` to `extend` actions, we put the `extend` action in `ALWAYS_TYPED_ACTIONS` as well

- `MyOption.take_action()` implements just this one new action, and passes control back to `Option.take_action()` for the standard `optparse` actions

- `values` is an instance of the `optparse_parser.Values` class, which provides the very useful `ensure_value()` method. `ensure_value()` is
essentially `getattr()` with a safety valve; it is called as

```
values.ensure_value(attr, value)
```

If the `attr` attribute of `values` doesn't exist or is `None`, then
`ensure_value()` first sets it to `value`, and then returns `value`. This is very
handy for actions like `extend`, `append`, and `count`, all of which
accumulate data in a variable and expect that variable to be of a certain type
(a list for the first two, an integer for the latter). Using `ensure_value()`
means that scripts using your action don't have to worry about setting a
default value for the option destinations in question; they can just leave the
default as `None` and `ensure_value()` will take care of getting it right
when it's needed.
14.5.5.1 StreamHandler

The StreamHandler class, located in the core logging package, sends logging output to streams such as sys.stdout, sys.stderr or any file-like object (or, more precisely, any object which supports write() and flush() methods).

```python
class StreamHandler([strm])
    Returns a new instance of the StreamHandler class. If strm is specified, the instance will use it for logging output; otherwise, sys.stderr will be used.

emit(record)
    If a formatter is specified, it is used to format the record. The record is then written to the stream with a trailing newline. If exception information is present, it is formatted using traceback.print_exception() and appended to the stream.

flush()
    Flushes the stream by calling its flush() method. Note that the close() method is inherited from Handler and so does nothing, so an explicit flush() call may be needed at times.
```
14.5.5.2 FileHandler

The FileHandler class, located in the core logging package, sends logging output to a disk file. It inherits the output functionality from StreamHandler.

```python
class FileHandler(filename[, mode])
```

Returns a new instance of the FileHandler class. The specified file is opened and used as the stream for logging. If mode is not specified, 'a' is used. By default, the file grows indefinitely.

```python
close()
```

Closes the file.

```python
emit(record)
```

Outputs the record to the file.
14.5.5.3 RotatingFileHandler

The RotatingFileHandler class, located in the logging.handlers module, supports rotation of disk log files.

```python
class RotatingFileHandler( filename[, mode[, maxBytes[, backupCount]]])
```

Returns a new instance of the RotatingFileHandler class. The specified file is opened and used as the stream for logging. If mode is not specified, 'a' is used. By default, the file grows indefinitely.

You can use the maxBytes and backupCount values to allow the file to rollover at a predetermined size. When the size is about to be exceeded, the file is closed and a new file is silently opened for output. Rollover occurs whenever the current log file is nearly maxBytes in length; if maxBytes is zero, rollover never occurs. If backupCount is non-zero, the system will save old log files by appending the extensions ".1", ".2" etc., to the filename. For example, with a backupCount of 5 and a base file name of app.log, you would get app.log, app.log.1, app.log.2, up to app.log.5. The file being written to is always app.log. When this file is filled, it is closed and renamed to app.log.1, and if files app.log.1, app.log.2, etc. exist, then they are renamed to app.log.2, app.log.3 etc. respectively.

doRollover()

Does a rollover, as described above.

emit(record)

Outputs the record to the file, catering for rollover as described previously.
14.5.5.4 TimedRotatingFileHandler

The `TimedRotatingFileHandler` class, located in the `logging.handlers` module, supports rotation of disk log files at certain timed intervals.

```python
class TimedRotatingFileHandler(filename [,when [,interval [,backupCount]]])
```

Returns a new instance of the `TimedRotatingFileHandler` class. The specified file is opened and used as the stream for logging. On rotating it also sets the filename suffix. Rotating happens based on the product of `when` and `interval`.

You can use the `when` to specify the type of `interval`. The list of possible values is, note that they are not case sensitive:

<table>
<thead>
<tr>
<th>Value</th>
<th>Type of interval</th>
</tr>
</thead>
<tbody>
<tr>
<td>S</td>
<td>Seconds</td>
</tr>
<tr>
<td>M</td>
<td>Minutes</td>
</tr>
<tr>
<td>H</td>
<td>Hours</td>
</tr>
<tr>
<td>D</td>
<td>Days</td>
</tr>
<tr>
<td>W</td>
<td>Week day (0=Monday)</td>
</tr>
<tr>
<td>midnight</td>
<td>Roll over at midnight</td>
</tr>
</tbody>
</table>

If `backupCount` is non-zero, the system will save old log files by appending extensions to the filename. The extensions are date-and-time based, using the strftime format `%Y-%m-%d_%H-%M-%S` or a leading portion thereof, depending on the rollover interval. At most `backupCount` files will be kept, and if more would be created when rollover occurs, the oldest one is deleted.

```python
doRollover()
```

Does a rollover, as described above.
**emit** (*record*)

Outputs the record to the file, catering for rollover as described above.
14.5.5.5 SocketHandler

The SocketHandler class, located in the logging.handlers module, sends logging output to a network socket. The base class uses a TCP socket.

```python
class SocketHandler(host, port)
    Returns a new instance of the SocketHandler class intended to communicate with a remote machine whose address is given by host and port.

close()
    Closes the socket.

handleError()

emit()
    Pickles the record's attribute dictionary and writes it to the socket in binary format. If there is an error with the socket, silently drops the packet. If the connection was previously lost, re-establishes the connection. To unpickle the record at the receiving end into a LogRecord, use the makeLogRecord() function.

handleError()
    Handles an error which has occurred during emit(). The most likely cause is a lost connection. Closes the socket so that we can retry on the next event.

makeSocket()
    This is a factory method which allows subclasses to define the precise type of socket they want. The default implementation creates a TCP socket (socket.SOCK_STREAM).

makePickle(record)
```
Pickles the record's attribute dictionary in binary format with a length prefix, and returns it ready for transmission across the socket.

**send**(*packet*)

Send a pickled string *packet* to the socket. This function allows for partial sends which can happen when the network is busy.
14.5.5.6 DatagramHandler

The DatagramHandler class, located in the logging.handlers module, inherits from SocketHandler to support sending logging messages over UDP sockets.

class DatagramHandler( host, port)

    Returns a new instance of the DatagramHandler class intended to communicate with a remote machine whose address is given by host and port.

emit()

    Pickles the record's attribute dictionary and writes it to the socket in binary format. If there is an error with the socket, silently drops the packet. To unpickle the record at the receiving end into a LogRecord, use the makeLogRecord() function.

makeSocket()

    The factory method of SocketHandler is here overridden to create a UDP socket (socket.SOCK_DGRAM).

send(s)

    Send a pickled string to a socket.
14.5.5.7 SysLogHandler

The SysLogHandler class, located in the logging.handlers module, supports sending logging messages to a remote or local UNIX syslog.

```python
class SysLogHandler([address[, facility]])
    Returns a new instance of the SysLogHandler class intended to communicate with a remote UNIX machine whose address is given by address in the form of a (host, port) tuple. If address is not specified, ('localhost', 514) is used. The address is used to open a UDP socket. If facility is not specified, LOG_USER is used.

close()
    Closes the socket to the remote host.

emit(record)
    The record is formatted, and then sent to the syslog server. If exception information is present, it is not sent to the server.

encodePriority(facility, priority)
    Encodes the facility and priority into an integer. You can pass in strings or integers - if strings are passed, internal mapping dictionaries are used to convert them to integers.
```
14.5.5.8 NTEventLogHandler

The NTEventLogHandler class, located in the logging.handlers module, supports sending logging messages to a local Windows NT, Windows 2000 or Windows XP event log. Before you can use it, you need Mark Hammond's Win32 extensions for Python installed.

class NTEventLogHandler( appname[, dllname[, logtype]])

Returns a new instance of the NTEventLogHandler class. The appname is used to define the application name as it appears in the event log. An appropriate registry entry is created using this name. The dllname should give the fully qualified pathname of a .dll or .exe which contains message definitions to hold in the log (if not specified, 'win32service.pyd' is used - this is installed with the Win32 extensions and contains some basic placeholder message definitions. Note that use of these placeholders will make your event logs big, as the entire message source is held in the log. If you want slimmer logs, you have to pass in the name of your own .dll or .exe which contains the message definitions you want to use in the event log). The logtype is one of 'Application', 'System' or 'Security', and defaults to 'Application'.

close()

At this point, you can remove the application name from the registry as a source of event log entries. However, if you do this, you will not be able to see the events as you intended in the Event Log Viewer - it needs to be able to access the registry to get the .dll name. The current version does not do this (in fact it doesn't do anything).

emit( record)

Determines the message ID, event category and event type, and then logs the message in the NT event log.

getEventCategory( record)

Returns the event category for the record. Override this if you want to
specify your own categories. This version returns 0.

**getEventType**( record )

Returns the event type for the record. Override this if you want to specify your own types. This version does a mapping using the handler's typemap attribute, which is set up in `__init__()` to a dictionary which contains mappings for DEBUG, INFO, WARNING, ERROR and CRITICAL. If you are using your own levels, you will either need to override this method or place a suitable dictionary in the handler's typemap attribute.

**getMessageID**( record )

Returns the message ID for the record. If you are using your own messages, you could do this by having the *msg* passed to the logger being an ID rather than a format string. Then, in here, you could use a dictionary lookup to get the message ID. This version returns 1, which is the base message ID in win32service.pyd.
The **SMTPHandler** class, located in the `logging.handlers` module, supports sending logging messages to an email address via SMTP.

```python
class SMTPHandler( mailhost, fromaddr, toaddrs, subject )
```

Returns a new instance of the `SMTPHandler` class. The instance is initialized with the from and to addresses and subject line of the email. The `toaddrs` should be a list of strings. To specify a non-standard SMTP port, use the (host, port) tuple format for the `mailhost` argument. If you use a string, the standard SMTP port is used.

```python
emit( record )
```

Formats the record and sends it to the specified addressees.

```python
getSubject( record )
```

If you want to specify a subject line which is record-dependent, override this method.
14.5.5.10 MemoryHandler

The MemoryHandler class, located in the logging.handlers module, supports buffering of logging records in memory, periodically flushing them to a target handler. Flushing occurs whenever the buffer is full, or when an event of a certain severity or greater is seen.

MemoryHandler is a subclass of the more general BufferingHandler, which is an abstract class. This buffers logging records in memory. Whenever each record is added to the buffer, a check is made by calling shouldFlush() to see if the buffer should be flushed. If it should, then flush() is expected to do the needful.

class BufferingHandler(capacity)
  Initializes the handler with a buffer of the specified capacity.

class MemoryHandler(capacity[, flushLevel [, target]])
  Returns a new instance of the MemoryHandler class. The instance is initialized with a buffer size of capacity. If flushLevel is not specified, ERROR is used. If no target is specified, the target will need to be set using setTarget() before this handler does anything useful.
close()
    Calls flush(), sets the target to None and clears the buffer.

flush()
    For a MemoryHandler, flushing means just sending the buffered records
    to the target, if there is one. Override if you want different behavior.

setTarget( target)
    Sets the target handler for this handler.

shouldFlush( record)
    Checks for buffer full or a record at the flushLevel or higher.
The HTTPHandler class, located in the logging.handlers module, supports sending logging messages to a Web server, using either "GET" or "POST" semantics.

```
class HTTPHandler( host, url[, method])

    Returns a new instance of the HTTPHandler class. The instance is initialized with a host address, url and HTTP method. The host can be of the form host:port, should you need to use a specific port number. If no method is specified, "GET" is used.
```

```
emit( record)

    Sends the record to the Web server as an URL-encoded dictionary.
```
14.5.10.1 Configuration functions

The following functions configure the logging module. They are located in the `logging.config` module. Their use is optional -- you can configure the logging module using these functions or by making calls to the main API (defined in `logging` itself) and defining handlers which are declared either in `logging` or `logging.handlers`.

`fileConfig(fname[, defaults])`

Reads the logging configuration from a ConfigParser-format file named `fname`. This function can be called several times from an application, allowing an end user the ability to select from various pre-canned configurations (if the developer provides a mechanism to present the choices and load the chosen configuration). Defaults to be passed to ConfigParser can be specified in the `defaults` argument.

`listen([port])`

Starts up a socket server on the specified port, and listens for new configurations. If no port is specified, the module's default `DEFAULT_LOGGING_CONFIG_PORT` is used. Logging configurations will be sent as a file suitable for processing by `fileConfig()`. Returns a `Thread` instance on which you can call `start()` to start the server, and which you can `join()` when appropriate. To stop the server, call `stopListening()`. To send a configuration to the socket, read in the configuration file and send it to the socket as a string of bytes preceded by a four-byte length packed in binary using `struct.pack('>L', n)`.

`stopListening()`

Stops the listening server which was created with a call to `listen()`. This is typically called before calling `join()` on the return value from `listen()`.
Release 2.5, documentation updated on 19th September, 2006. 
See About this document... for information on suggesting changes.
14.5.10.2 Configuration file format

The configuration file format understood by `fileConfig()` is based on ConfigParser functionality. The file must contain sections called `[loggers]`, `[handlers]` and `[formatters]` which identify by name the entities of each type which are defined in the file. For each such entity, there is a separate section which identified how that entity is configured. Thus, for a logger named `log01` in the `[loggers]` section, the relevant configuration details are held in a section `[logger_log01]`. Similarly, a handler called `hand01` in the `[handlers]` section will have its configuration held in a section called `[handler_hand01]`, while a formatter called `form01` in the `[formatters]` section will have its configuration specified in a section called `[formatter_form01]`. The root logger configuration must be specified in a section called `[logger_root]`.

Examples of these sections in the file are given below.

```
[loggers]
keys=root,log02,log03,log04,log05,log06,log07

[handlers]
keys=hand01,hand02,hand03,hand04,hand05,hand06,hand07,hand08,hand09

[formatters]
keys=form01,form02,form03,form04,form05,form06,form07,form08,form09
```

The root logger must specify a level and a list of handlers. An example of a root logger section is given below.

```
[logger_root]
level=NOTSET
handlers=hand01
```

The `level` entry can be one of `DEBUG`, `INFO`, `WARNING`, `ERROR`, `CRITICAL` or `NOTSET`. For the root logger only, `NOTSET` means that all messages will be logged. Level values are evaluated in the context of the `logging` package's namespace.
The **handlers** entry is a comma-separated list of handler names, which must appear in the [handlers] section. These names must appear in the [handlers] section and have corresponding sections in the configuration file.

For loggers other than the root logger, some additional information is required. This is illustrated by the following example.

```
[logger_parser]
level=DEBUG
handlers=hand01
propagate=1
qualname=compiler.parser
```

The **level** and **handlers** entries are interpreted as for the root logger, except that if a non-root logger's level is specified as **NOTSET**, the system consults loggers higher up the hierarchy to determine the effective level of the logger. The **propagate** entry is set to 1 to indicate that messages must propagate to handlers higher up the logger hierarchy from this logger, or 0 to indicate that messages are **not** propagated to handlers up the hierarchy. The **qualname** entry is the hierarchical channel name of the logger, that is to say the name used by the application to get the logger.

Sections which specify handler configuration are exemplified by the following.

```
[handler_hand01]
class=StreamHandler
level=NOTSET
formatter=form01
args=(sys.stdout,)
```

The **class** entry indicates the handler's class (as determined by eval() in the logging package's namespace). The **level** is interpreted as for loggers, and **NOTSET** is taken to mean "log everything".

The **formatter** entry indicates the key name of the formatter for this handler. If blank, a default formatter (**logging._defaultFormatter**) is used. If a name is specified, it must appear in the [formatters] section and have a corresponding section in the configuration file.

The **args** entry, when eval()uated in the context of the logging package's namespace, is the list of arguments to the constructor for the handler class. Refer to the constructors for the relevant handlers, or to the examples below, to see
how typical entries are constructed.

[handler_hand02]
class=FileHandler
level=DEBUG
formatter=form02
args=('python.log', 'w')

[handler_hand03]
class=handlers.SocketHandler
level=INFO
formatter=form03
args=('localhost', handlers.DEFAULT_TCP_LOGGING_PORT)

[handler_hand04]
class=handlers.DatagramHandler
level=WARN
formatter=form04
args=('localhost', handlers.DEFAULT_UDP_LOGGING_PORT)

[handler_hand05]
class=handlers.SysLogHandler
level=ERROR
formatter=form05
args=(("localhost", handlers.SYSLOG_UDP_PORT), handlers.SysLogHandler

[handler_hand06]
class=handlers.NTEventLogHandler
level=CRITICAL
formatter=form06
args=('Python Application', '', 'Application')

[handler_hand07]
class=handlers.SMTPHandler
level=WARN
formatter=form07
args=('localhost', 'from@abc', ['user1@abc', 'user2@xyz'], 'Logger S

[handler_hand08]
class=handlers.MemoryHandler
level=NOTSET
formatter=form08
target=
args=(10, ERROR)

[handler_hand09]
class=handlers.HTTPHandler
level=NOTSET
formatter=form09
args=('localhost:9022', '/log', 'GET')
Sections which specify formatter configuration are typified by the following.

```
[formatter_form01]
format=F1 %(asctime)s %(levelname)s %(message)s
datefmt=
class=logging.Formatter
```

The `format` entry is the overall format string, and the `datefmt` entry is the `strftime()`-compatible date/time format string. If empty, the package substitutes ISO8601 format date/times, which is almost equivalent to specifying the date format string "The ISO8601 format also specifies milliseconds, which are appended to the result of using the above format string, with a comma separator. An example time in ISO8601 format is 2003-01-23 00:29:50,411.

The `class` entry is optional. It indicates the name of the formatter's class (as a dotted module and class name.) This option is useful for instantiating a `Formatter` subclass. Subclasses of `Formatter` can present exception traces in an expanded or condensed format.
14.12.3.1 Win95/98 specific

`popen(cmd, mode='r', bufsize=None)`

Portable `popen()` interface. Find a working `popen` implementation preferring `win32pipe.popen()`. On Windows NT, `win32pipe.popen()` should work; on Windows 9x it hangs due to bugs in the MS C library.
14.14.1.1 Loading dynamic link libraries

c\texttt{types} exports the \texttt{dll}, and on Windows also \texttt{windll} and \texttt{oledll} objects to load dynamic link libraries.

You load libraries by accessing them as attributes of these objects. \texttt{dll} loads libraries which export functions using the standard \texttt{cdecl} calling convention, while \texttt{windll} libraries call functions using the \texttt{stdcall} calling convention. \texttt{oledll} also uses the \texttt{stdcall} calling convention, and assumes the functions return a Windows \texttt{HRESULT} error code. The error code is used to automatically raise \texttt{WindowsError} Python exceptions when the function call fails.

Here are some examples for Windows, note that \texttt{msvcrt} is the MS standard C library containing most standard C functions, and uses the cdecl calling convention:

\begin{verbatim}
>>> from ctypes import *
>>> print windll.kernel32 # doctest: +WINDOWS
<WinDLL 'kernel32', handle ... at ...>
>>> print cdll.msvcrt # doctest: +WINDOWS
<CDLL 'msvcrt', handle ... at ...>
>>> libc = cdll.msvcrt # doctest: +WINDOWS
>>> Windows\ appendsthe usual '.dll' file suffix automatically.

On Linux, it is required to specify the filename \texttt{including} the extension to load a library, so attribute access does not work. Either the \texttt{LoadLibrary} method of the dll loaders should be used, or you should load the library by creating an instance of CDLL by calling the constructor:

\begin{verbatim}
>>> cdll.LoadLibrary("libc.so.6") # doctest: +LINUX
<CDLL 'libc.so.6', handle ... at ...>
>>> libc = CDLL("libc.so.6")  # doctest: +LINUX
>>> libc # doctest: +LINUX
<CDLL 'libc.so.6', handle ... at ...>
>>> \end{verbatim}
Accessing functions from

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
14.14.1.2 Accessing functions from loaded dlls

Functions are accessed as attributes of dll objects:

```python
>>> from ctypes import *
>>> libc.printf
<_FuncPtr object at 0x...>
>>> print windll.kernel32.GetModuleHandleA # doctest: +WINDOWS
<_FuncPtr object at 0x...>
>>> print windll.kernel32.MyOwnFunction # doctest: +WINDOWS
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
  File "ctypes.py", line 239, in __getattr__
    func = _StdcallFuncPtr(name, self)
AttributeError: function 'MyOwnFunction' not found
```n
Note that win32 system dlls like kernel32 and user32 often export ANSI as well as UNICODE versions of a function. The UNICODE version is exported with an W appended to the name, while the ANSI version is exported with an A appended to the name. The win32 GetModuleHandle function, which returns a module handle for a given module name, has the following C prototype, and a macro is used to expose one of them as GetModuleHandle depending on whether UNICODE is defined or not:

```c
/* ANSI version */
HMODULE GetModuleHandleA(LPCSTR lpModuleName);
/* UNICODE version */
HMODULE GetModuleHandleW(LPCWSTR lpModuleName);
```

windll does not try to select one of them by magic, you must access the version you need by specifying GetModuleHandleA or GetModuleHandleW explicitly, and then call it with normal strings or unicode strings respectively.

Sometimes, dlls export functions with names which aren't valid Python identifiers, like "??2@YAPAXI@Z". In this case you have to use getattr to retrieve the function:

```python
>>> getattr(cdll.msvcrt, "??2@YAPAXI@Z") # doctest: +WINDOWS
<_FuncPtr object at 0x...>
```
On Windows, some dlls export functions not by name but by ordinal. These functions can be accessed by indexing the dll object with the ordinal number:

```python
>>> cdll.kernel32[1] # doctest: +WINDOWS
<_FuncPtr object at 0x...>
>>> cdll.kernel32[0] # doctest: +WINDOWS
Traceback (most recent call last):
  File "<stdin>", line 1, in 
  File "ctypes.py", line 310, in __getitem__
    func = _StdcallFuncPtr(name, self)
AttributeError: function ordinal 0 not found
>>>```

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
14.14.1.3 Calling functions

You can call these functions like any other Python callable. This example uses the `time()` function, which returns system time in seconds since the UNIX epoch, and the `GetModuleHandleA()` function, which returns a win32 module handle.

This example calls both functions with a NULL pointer (None should be used as the NULL pointer):

```python
>>> print libc.time(None) # doctest: +SKIP
1150640792
>>> print hex(windll.kernel32.GetModuleHandleA(None)) # doctest: +WIN
0x1d000000
>>>
```

curses tries to protect you from calling functions with the wrong number of arguments or the wrong calling convention. Unfortunately this only works on Windows. It does this by examining the stack after the function returns, so although an error is raised the function has been called:

```python
>>> windll.kernel32.GetModuleHandleA() # doctest: +WINDOWS
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
ValueError: Procedure probably called with not enough arguments (4 b
>>> windll.kernel32.GetModuleHandleA(0, 0) # doctest: +WINDOWS
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
ValueError: Procedure probably called with too many arguments (4 byt
>>> 
```

The same exception is raised when you call an stdcall function with the cdecl calling convention, or vice versa:

```python
>>> cdll.kernel32.GetModuleHandleA(0) # doctest: +WINDOWS
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
ValueError: Procedure probably called with not enough arguments (4 b
>>> 
>>> windll.msvcrt.printf("spam") # doctest: +WINDOWS
```
To find out the correct calling convention you have to look into the C header file or the documentation for the function you want to call.

On Windows, ctypes uses win32 structured exception handling to prevent crashes from general protection faults when functions are called with invalid argument values:

```python
>>> windll.kernel32.GetModuleHandleA(32)  # doctest: +WINDOWS
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
WindowsError: exception: access violation reading 0x00000020
```

There are, however, enough ways to crash Python with ctypes, so you should be careful anyway.

None, integers, longs, byte strings and unicode strings are the only native Python objects that can directly be used as parameters in these function calls. None is passed as a C NULL pointer, byte strings and unicode strings are passed as pointer to the memory block that contains their data (char * or wchar_t *). Python integers and Python longs are passed as the platforms default C int type, their value is masked to fit into the C type.

Before we move on calling functions with other parameter types, we have to learn more about ctypes data types.
### 14.14.1.4 Fundamental data types

`ctypes` defines a number of primitive C compatible data types:

<table>
<thead>
<tr>
<th>ctypes type</th>
<th>C type</th>
<th>Python type</th>
</tr>
</thead>
<tbody>
<tr>
<td>c_char</td>
<td>char</td>
<td>1-character string</td>
</tr>
<tr>
<td>c_wchar</td>
<td>wchar_t</td>
<td>1-character unicode string</td>
</tr>
<tr>
<td>c_byte</td>
<td>char</td>
<td>int/long</td>
</tr>
<tr>
<td>c_ubyte</td>
<td>unsigned char</td>
<td>int/long</td>
</tr>
<tr>
<td>c_short</td>
<td>short</td>
<td>int/long</td>
</tr>
<tr>
<td>c_ushort</td>
<td>unsigned short</td>
<td>int/long</td>
</tr>
<tr>
<td>c_int</td>
<td>int</td>
<td>int/long</td>
</tr>
<tr>
<td>c_uint</td>
<td>unsigned int</td>
<td>int/long</td>
</tr>
<tr>
<td>c_long</td>
<td>long</td>
<td>int/long</td>
</tr>
<tr>
<td>c_ulong</td>
<td>unsigned long</td>
<td>int/long</td>
</tr>
<tr>
<td>c_longlong</td>
<td>__int64 or long long</td>
<td>int/long</td>
</tr>
<tr>
<td>c_ulonglong</td>
<td>unsigned __int64 or unsigned long long</td>
<td>int/long</td>
</tr>
<tr>
<td>c_float</td>
<td>float</td>
<td>float</td>
</tr>
<tr>
<td>c_double</td>
<td>double</td>
<td>float</td>
</tr>
<tr>
<td>c_char_p</td>
<td>char * (NUL terminated)</td>
<td>string or None</td>
</tr>
<tr>
<td>c_wchar_p</td>
<td>wchar_t * (NUL terminated)</td>
<td>unicode or None</td>
</tr>
<tr>
<td>c_void_p</td>
<td>void *</td>
<td>int/long or None</td>
</tr>
</tbody>
</table>

All these types can be created by calling them with an optional initializer of the correct type and value:

```python
globals() c_int() c_long(0)
globals() c_char_p("Hello, World") c_char_p('Hello, World')
globals() c_ushort(-3) c_ushort(65533)
globals()```
Since these types are mutable, their value can also be changed afterwards:

```python
>>> i = c_int(42)
>>> print i
c_long(42)
>>> print i.value
42
>>> i.value = -99
>>> print i.value
-99
```

Assigning a new value to instances of the pointer types `c_char_p`, `c_wchar_p`, and `c_void_p` changes the memory location they point to, *not the contents* of the memory block (of course not, because Python strings are immutable):

```python
>>> s = "Hello, World"
>>> c_s = c_char_p(s)
>>> print c_s
'Hello, World'
>>> c_s.value = "Hi, there"
>>> print c_s
'Hi, there'
>>> print s  # first string is unchanged
Hello, World
```

You should be careful, however, not to pass them to functions expecting pointers to mutable memory. If you need mutable memory blocks, ctypes has a `create_string_buffer` function which creates these in various ways. The current memory block contents can be accessed (or changed) with the `raw` property, if you want to access it as NUL terminated string, use the `string` property:

```python
>>> from ctypes import *
>>> p = create_string_buffer(3)  # create a 3 byte buffer, initialized to NUL bytes
>>> print sizeof(p), repr(p.raw)
3 '\x00\x00\x00'
>>> p = create_string_buffer("Hello")  # create a buffer containing a NUL terminated string
>>> print sizeof(p), repr(p.raw)
6 'Hello\x00'
>>> print repr(p.value)
'Hello'
>>> p = create_string_buffer("Hello", 10)  # create a 10 byte buffer
```
>>> print sizeof(p), repr(p.raw)
10 'Hello\x00\x00\x00\x00\x00'
>>> p.value = "Hi"
>>> print sizeof(p), repr(p.raw)
10 'Hi\x00lo\x00\x00\x00\x00\x00'

The create_string_buffer function replaces the c_buffer function (which is still available as an alias), as well as the c_string function from earlier ctypes releases. To create a mutable memory block containing unicode characters of the C type wchar_t use the create_unicode_buffer function.
14.14.1.5 Calling functions, continued

Note that `printf` prints to the real standard output channel, not to `sys.stdout`, so these examples will only work at the console prompt, not from within `IDLE` or `PythonWin`:

```python
>>> printf = libc.printf
>>> printf("Hello, %s\n", "World!")
Hello, World!
14
>>> printf("Hello, %S", u"World!")
Hello, World!
13
>>> printf("%d bottles of beer\n", 42)
42 bottles of beer
19
>>> printf("%f bottles of beer\n", 42.5)
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
ArgumentError: argument 2: exceptions.TypeError: Don't know how to c
>>> 
```

As has been mentioned before, all Python types except integers, strings, and unicode strings have to be wrapped in their corresponding `ctypes` type, so that they can be converted to the required C data type:

```python
>>> printf("An int %d, a double %f\n", 1234, c_double(3.14))
Integer 1234, double 3.1400001049
31
>>> 
```
14.14.1.6 Calling functions with your own custom data types

You can also customize ctypes argument conversion to allow instances of your own classes be used as function arguments. ctypes looks for an _as_parameter_ attribute and uses this as the function argument. Of course, it must be one of integer, string, or unicode:

```python
>>> class Bottles(object):
...     def __init__(self, number):
...         self._as_parameter_ = number
... >>> bottles = Bottles(42)
>>> printf("%d bottles of beer\n", bottles)
42 bottles of beer
19
```  

If you don't want to store the instance's data in the _as_parameter_ instance variable, you could define a property which makes the data available.
14.14.1.7 Specifying the required argument types (function prototypes)

It is possible to specify the required argument types of functions exported from DLLs by setting the `argtypes` attribute.

`argtypes` must be a sequence of C data types (the `printf` function is probably not a good example here, because it takes a variable number and different types of parameters depending on the format string, on the other hand this is quite handy to experiment with this feature):

```python
>>> printf.argtypes = [c_char_p, c_char_p, c_int, c_double]
>>> printf("String '%s', Int %d, Double %f\n", "Hi", 10, 2.2)
String 'Hi', Int 10, Double 2.200000
37
```

Specifying a format protects against incompatible argument types (just as a prototype for a C function), and tries to convert the arguments to valid types:

```python
>>> printf("%d %d %d", 1, 2, 3)
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
ArgumentError: argument 2: exceptions.TypeError: wrong type
>>> printf("%s %d %f", "X", 2, 3)
X 2 3.00000012
12
```

If you have defined your own classes which you pass to function calls, you have to implement a `from_param` class method for them to be able to use them in the `argtypes` sequence. The `from_param` class method receives the Python object passed to the function call, it should do a typecheck or whatever is needed to make sure this object is acceptable, and then return the object itself, it's `_as_parameter_` attribute, or whatever you want to pass as the C function argument in this case. Again, the result should be an integer, string, unicode, a `ctypes` instance, or something having the `_as_parameter_` attribute.
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
14.14.1.8 Return types

By default functions are assumed to return the C int type. Other return types can be specified by setting the restype attribute of the function object.

Here is a more advanced example, it uses the strchr function, which expects a string pointer and a char, and returns a pointer to a string:

```python
>>> strchr = libc.strchr
>>> strchr("abcdef", ord("d")) # doctest: +SKIP
8059983
>>> strchr.restype = c_char_p # c_char_p is a pointer to a string
>>> strchr("abcdef", ord("d"))
'def'
>>> print strchr("abcdef", ord("x"))
None
```

If you want to avoid the `ord("x")` calls above, you can set the argtypes attribute, and the second argument will be converted from a single character Python string into a C char:

```python
>>> strchr.restype = c_char_p
>>> strchr.argtypes = [c_char_p, c_char]
>>> strchr("abcdef", "d")
'def'
>>> strchr("abcdef", "def")
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
ArgumentError: argument 2: exceptions.TypeError: one character string expected
>>> print strchr("abcdef", "x")
None
>>> strchr("abcdef", "d")
'def'
```

You can also use a callable Python object (a function or a class for example) as the restype attribute, if the foreign function returns an integer. The callable will be called with the integer the C function returns, and the result of this call will be used as the result of your function call. This is useful to check for error return values and automatically raise an exception:
>>> GetModuleHandle = windll.kernel32.GetModuleHandleA # doctest: +W
>>> def ValidHandle(value):
...     if value == 0:
...         raise WinError()
...     return value
... >>>
>>> GetModuleHandle().restype = ValidHandle # doctest: +W
>>> GetModuleHandle(None) # doctest: +W
486539264
>>> GetModuleHandle("something silly") # doctest: +W
WindowsError: [Errno 126] The specified module could not be found.

WinError is a function which will call Windows FormatMessage() api to get the string representation of an error code, and returns an exception. WinError takes an optional error code parameter, if no one is used, it calls GetLastError() to retrieve it.

Please note that a much more powerful error checking mechanism is available through the errcheck attribute; see the reference manual for details.
14.14.1.9 Passing pointers (or: passing parameters by reference)

Sometimes a C api function expects a pointer to a data type as parameter, probably to write into the corresponding location, or if the data is too large to be passed by value. This is also known as passing parameters by reference.

ctypes exports the byref function which is used to pass parameters by reference. The same effect can be achieved with the pointer function, although pointer does a lot more work since it constructs a real pointer object, so it is faster to use byref if you don't need the pointer object in Python itself:

```python
>>> i = c_int()
>>> f = c_float()
>>> s = create_string_buffer('\000' * 32)
>>> print i.value, f.value, repr(s.value)
0 0.0 ''
>>> libc.sscanf("1 3.14 Hello", "%d %f %s", ...          byref(i), byref(f), s)
3
>>> print i.value, f.value, repr(s.value)
1 3.14000001049 'Hello'
```
Structures and unions must derive from the `Structure` and `Union` base classes which are defined in the `ctypes` module. Each subclass must define a `_fields_` attribute. `_fields_` must be a list of 2-tuples, containing a field name and a field type.

The field type must be a `ctypes` type like `c_int`, or any other derived `ctypes` type: structure, union, array, pointer.

Here is a simple example of a `POINT` structure, which contains two integers named `x` and `y`, and also shows how to initialize a structure in the constructor:

```python
>>> from ctypes import *
>>> class POINT(Structure):
...     _fields_ = ["x", c_int],
...     ("y", c_int)]
...
>>> point = POINT(10, 20)
>>> print point.x, point.y
10 20
>>> point = POINT(y=5)
>>> print point.x, point.y
0 5
>>> POINT(1, 2, 3)
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
ValueError: too many initializers
>>>
```

You can, however, build much more complicated structures. Structures can itself contain other structures by using a structure as a field type.

Here is a `RECT` structure which contains two `POINTs` named `upperleft` and `lowerright`:

```python
>>> class RECT(Structure):
...     _fields_ = ["upperleft", POINT],
...     ("lowerright", POINT)]
...
>>> rc = RECT(point)
```
Nested structures can also be initialized in the constructor in several ways:

```python
>>> r = RECT(POINT(1, 2), POINT(3, 4))
>>> r = RECT((1, 2), (3, 4))
```

Fields descriptors can be retrieved from the class, they are useful for debugging because they can provide useful information:

```python
>>> print POINT.x
<Field type=c_long, ofs=0, size=4>
```
14.14.1.11 Structure/union alignment and byte order

By default, Structure and Union fields are aligned in the same way the C compiler does it. It is possible to override this behaviour by specifying a _pack_ class attribute in the subclass definition. This must be set to a positive integer and specifies the maximum alignment for the fields. This is what #pragma pack(n) also does in MSVC.

ctypes uses the native byte order for Structures and Unions. To build structures with non-native byte order, you can use one of the BigEndianStructure, LittleEndianStructure, BigEndianUnion, and LittleEndianUnion base classes. These classes cannot contain pointer fields.
14.14.1.12 Bit fields in structures and unions

It is possible to create structures and unions containing bit fields. Bit fields are only possible for integer fields, the bit width is specified as the third item in the _fields_ tuples:

```python
>>> class Int(Structure):
...     _fields_ = ["first_16", c_int, 16],
...     ("second_16", c_int, 16]
... >>> print Int.first_16
<Field type=c_long, ofs=0:0, bits=16>
>>> print Int.second_16
<Field type=c_long, ofs=0:16, bits=16>
```
14.14.1.13 Arrays

Arrays are sequences, containing a fixed number of instances of the same type.

The recommended way to create array types is by multiplying a data type with a positive integer:

```
TenPointsArrayType = POINT * 10
```

Here is an example of an somewhat artificial data type, a structure containing 4 POINTs among other stuff:

```
>>> from ctypes import *
>>> class POINT(Structure):
...    _fields_ = ("x", c_int), ("y", c_int)
...    ...
>>> class MyStruct(Structure):
...    _fields_ = ["a", c_int],
...                ("b", c_float),
...                ("point_array", POINT * 4)
>>> print len(MyStruct().point_array)
4
```

Instances are created in the usual way, by calling the class:

```
arr = TenPointsArrayType()
for pt in arr:
    print pt.x, pt.y
```

The above code print a series of 0 0 lines, because the array contents is initialized to zeros.

Initializers of the correct type can also be specified:

```
>>> from ctypes import *
>>> TenIntegers = c_int * 10
>>> ii = TenIntegers(1, 2, 3, 4, 5, 6, 7, 8, 9, 10)
>>> for i in ii: print i,
<__main__.c_long_Array_10 object at 0x...>
```

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
14.14.14 Pointers

Pointer instances are created by calling the `pointer` function on a `ctypes` type:

```python
>>> from ctypes import *
>>> i = c_int(42)
>>> pi = pointer(i)

>>> pi.contents
<5000000000
```

Pointer instances have a `contents` attribute which returns the object to which the pointer points, the `i` object above:

```python
>>> pi.contents
<5000000000
```

Note that `ctypes` does not have OOR (original object return), it constructs a new, equivalent object each time you retrieve an attribute:

```python
>>> pi.contents is i
False
>>> pi.contents is pi.contents
False
```

Assigning another `c_int` instance to the pointer's `contents` attribute would cause the pointer to point to the memory location where this is stored:

```python
>>> i = c_int(99)
>>> pi.contents = i
>>> pi.contents
<5000000000
```

Pointer instances can also be indexed with integers:

```python
>>> pi[0]
99
```
Assigning to an integer index changes the pointed to value:

```python
>>> print i
c_long(99)
>>> pi[0] = 22
>>> print i
c_long(22)
```

It is also possible to use indexes different from 0, but you must know what you're doing, just as in C: You can access or change arbitrary memory locations. Generally you only use this feature if you receive a pointer from a C function, and you know that the pointer actually points to an array instead of a single item.

Behind the scenes, the `pointer` function does more than simply create pointer instances, it has to create pointer types first. This is done with the `POINTER` function, which accepts any `ctypes` type, and returns a new type:

```python
>>> PI = POINTER(c_int)
>>> PI
<class 'ctypes.LP_c_long'>
>>> PI(42)
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
TypeError: expected c_long instead of int
>>> PI(c_int(42))
<ctypes.LP_c_long object at 0x...>
```

Calling the pointer type without an argument creates a NULL pointer. NULL pointers have a `False` boolean value:

```python
>>> null_ptr = POINTER(c_int)()
>>> print bool(null_ptr)
False
```

`ctypes` checks for NULL when dereferencing pointers (but dereferencing non-NULL pointers would crash Python):

```python
>>> null_ptr[0]
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
ValueError: NULL pointer access
```
>>> null_ptr[0] = 1234
Traceback (most recent call last):
...
ValueError: NULL pointer access
>>>

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
14.14.1.15 Type conversions

Usually, ctypes does strict type checking. This means, if you have `POINTER(c_int)` in the `argtypes` list of a function or as the type of a member field in a structure definition, only instances of exactly the same type are accepted. There are some exceptions to this rule, where ctypes accepts other objects. For example, you can pass compatible array instances instead of pointer types. So, for `POINTER(c_int)`, ctypes accepts an array of `c_int`:

```python
>>> class Bar(Structure):
...     _fields_ = ["count", c_int], ["values", POINTER(c_int)]
...
>>> bar = Bar()
>>> bar.values = (c_int * 3)(1, 2, 3)
>>> bar.count = 3
>>> for i in range(bar.count):
...     print bar.values[i]
... 1
2
3
```

To set a `POINTER` type field to NULL, you can assign `None`:

```python
>>> bar.values = None
```

XXX list other conversions...

Sometimes you have instances of incompatible types. In C, you can cast one type into another type. ctypes provides a `cast` function which can be used in the same way. The `Bar` structure defined above accepts `POINTER(c_int)` pointers or `c_int` arrays for its `values` field, but not instances of other types:

```python
>>> bar.values = (c_byte * 4)()
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
TypeError: incompatible types, c_byte_Array_4 instance instead of LP
>>>```
For these cases, the `cast` function is handy.

The `cast` function can be used to cast a ctypes instance into a pointer to a different ctypes data type. `cast` takes two parameters, a ctypes object that is or can be converted to a pointer of some kind, and a ctypes pointer type. It returns an instance of the second argument, which references the same memory block as the first argument:

```python
>>> a = (c_byte * 4)()
>>> cast(a, POINTER(c_int))
<ctypes.LP_c_long object at ...>
```

So, `cast` can be used to assign to the `values` field of `Bar` the structure:

```python
>>> bar = Bar()
>>> bar.values = cast((c_byte * 4)(), POINTER(c_int))
>>> print bar.values[0]
0
```
14.14.1.16 Incomplete Types

Incomplete Types are structures, unions or arrays whose members are not yet specified. In C, they are specified by forward declarations, which are defined later:

```c
struct cell; /* forward declaration */

struct {
    char *name;
    struct cell *next;
} cell;
```

The straightforward translation into ctypes code would be this, but it does not work:

```python
>>> class cell(Structure):
...     _fields_ = ["name", c_char_p],
...             ("next", POINTER(cell))]
...
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
  File "<stdin>", line 2, in cell
NameError: name 'cell' is not defined
```

because the new class **cell** is not available in the class statement itself. In ctypes, we can define the **cell** class and set the **_fields_** attribute later, after the class statement:

```python
>>> from ctypes import *
>>> class cell(Structure):
...     pass
...     _fields_ = ["name", c_char_p],
...             ("next", POINTER(cell))]
```

Lets try it. We create two instances of **cell**, and let them point to each other, and finally follow the pointer chain a few times:

```python
>>> c1 = cell()
```
>>> c1.name = "foo"
>>> c2 = cell()
>>> c2.name = "bar"
>>> c1.next = pointer(c2)
>>> c2.next = pointer(c1)
>>> p = c1
>>> for i in range(8):
...    print p.name,
...    p = p.next[0]
...
foo bar foo bar foo bar foo bar

---

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
14.14.17 Callback functions

callable allows to create C callable function pointers from Python callables. These are sometimes called callback functions.

First, you must create a class for the callback function, the class knows the calling convention, the return type, and the number and types of arguments this function will receive.

The CFUNCTYPE factory function creates types for callback functions using the normal cdecl calling convention, and, on Windows, the WINFUNCTYPE factory function creates types for callback functions using the stdcall calling convention.

Both of these factory functions are called with the result type as first argument, and the callback functions expected argument types as the remaining arguments.

I will present an example here which uses the standard C library's qsort function, this is used to sort items with the help of a callback function. qsort will be used to sort an array of integers:

```
>>> IntArray5 = c_int * 5
>>> ia = IntArray5(5, 1, 7, 33, 99)
>>> qsort = libc.qsort
>>> qsort.restype = None
>>> qsort
```

qsort must be called with a pointer to the data to sort, the number of items in the data array, the size of one item, and a pointer to the comparison function, the callback. The callback will then be called with two pointers to items, and it must return a negative integer if the first item is smaller than the second, a zero if they are equal, and a positive integer else.

So our callback function receives pointers to integers, and must return an integer. First we create the type for the callback function:

```
>>> CMPFUNC = CFUNCTYPE(c_int, POINTER(c_int), POINTER(c_int))
>>> CMPFUNC
```
For the first implementation of the callback function, we simply print the arguments we get, and return 0 (incremental development ;-):

```python
>>> def py_cmp_func(a, b):
...     print "py_cmp_func", a, b
...     return 0
... >>>
```

Create the C callable callback:

```python
>>> cmp_func = CMPFUNC(py_cmp_func)
>>> And we're ready to go:

```python
>>> qsort(ia, len(ia), sizeof(c_int), cmp_func) # doctest: +WINDOWS
py_cmp_func <ctypes.LP_c_long object at 0x00...> <ctypes.LP_c_long o
py_cmp_func <ctypes.LP_c_long object at 0x00...> <ctypes.LP_c_long o
py_cmp_func <ctypes.LP_c_long object at 0x00...> <ctypes.LP_c_long o
py_cmp_func <ctypes.LP_c_long object at 0x00...> <ctypes.LP_c_long o
py_cmp_func <ctypes.LP_c_long object at 0x00...> <ctypes.LP_c_long o
py_cmp_func <ctypes.LP_c_long object at 0x00...> <ctypes.LP_c_long o
py_cmp_func <ctypes.LP_c_long object at 0x00...> <ctypes.LP_c_long o
py_cmp_func <ctypes.LP_c_long object at 0x00...> <ctypes.LP_c_long o
py_cmp_func <ctypes.LP_c_long object at 0x00...> <ctypes.LP_c_long o
py_cmp_func <ctypes.LP_c_long object at 0x00...> <ctypes.LP_c_long o
py_cmp_func <ctypes.LP_c_long object at 0x00...> <ctypes.LP_c_long o
py_cmp_func <ctypes.LP_c_long object at 0x00...> <ctypes.LP_c_long o
py_cmp_func <ctypes.LP_c_long object at 0x00...> <ctypes.LP_c_long o
```  

We know how to access the contents of a pointer, so let's redefine our callback:

```python
>>> def py_cmp_func(a, b):
...     print "py_cmp_func", a[0], b[0]
...     return 0
... >>>
```

Here is what we get on Windows:

```python
>>> qsort(ia, len(ia), sizeof(c_int), cmp_func) # doctest: +WINDOWS
py_cmp_func 7 1
py_cmp_func 33 1
py_cmp_func 99 1
py_cmp_func 5 1
py_cmp_func 7 5
py_cmp_func 33 5
py_cmp_func 99 5
py_cmp_func 7 99
```
It is funny to see that on linux the sort function seems to work much more efficient, it is doing less comparisons:

```python
>>> qsort(ia, len(ia), sizeof(c_int), cmp_func) # doctest: +LINUX
py_cmp_func 5 1
py_cmp_func 33 99
py_cmp_func 7 33
py_cmp_func 5 7
py_cmp_func 1 7
```

Ah, we're nearly done! The last step is to actually compare the two items and return a useful result:

```python
>>> def py_cmp_func(a, b):
...     print "py_cmp_func", a[0], b[0]
...     return a[0] - b[0]
... print
```

Final run on Windows:

```python
>>> qsort(ia, len(ia), sizeof(c_int), CMPFUNC(py_cmp_func)) # doctest
py_cmp_func 33 7
py_cmp_func 99 33
py_cmp_func 5 99
py_cmp_func 1 99
py_cmp_func 33 7
py_cmp_func 1 33
py_cmp_func 5 33
py_cmp_func 5 7
py_cmp_func 1 7
py_cmp_func 5 1
```

and on Linux:

```python
>>> qsort(ia, len(ia), sizeof(c_int), CMPFUNC(py_cmp_func)) # doctest
py_cmp_func 5 1
py_cmp_func 33 99
py_cmp_func 7 33
py_cmp_func 1 7
py_cmp_func 5 7
```
It is quite interesting to see that the Windows qsort function needs more comparisons than the linux version!

As we can easily check, our array sorted now:

```python
>>> for i in ia: print i,
... 1 5 7 33 99
>>> 
```

**Important note for callback functions:**

Make sure you keep references to CFUNCTYPE objects as long as they are used from C code. ctypes doesn't, and if you don't, they may be garbage collected, crashing your program when a callback is made.
14.14.1.18 Accessing values exported from dlls

Sometimes, a dll not only exports functions, it also exports variables. An example in the Python library itself is the `Py_OptimizeFlag`, an integer set to 0, 1, or 2, depending on the `-O` or `-OO` flag given on startup.

`ctypes` can access values like this with the `in_dll` class methods of the type. `pythonapi` is a predefined symbol giving access to the Python C api:

```python
>>> opt_flag = c_int.in_dll(pythonapi, "Py_OptimizeFlag")
>>> print opt_flag
c_long(0)
```

If the interpreter would have been started with `-O`, the sample would have printed `c_long(1)`, or `c_long(2)` if `-OO` would have been specified.

An extended example which also demonstrates the use of pointers accesses the `PyImport_FrozenModules` pointer exported by Python.

Quoting the Python docs: *This pointer is initialized to point to an array of \`struct _frozen\` records, terminated by one whose members are all NULL or zero. When a frozen module is imported, it is searched in this table. Third-party code could play tricks with this to provide a dynamically created collection of frozen modules.*

So manipulating this pointer could even prove useful. To restrict the example size, we show only how this table can be read with `ctypes`:

```python
>>> from ctypes import *

>>> class struct_frozen(Structure):
...     _fields_ = [("name", c_char_p),
...          ("code", POINTER(c_ubyte)),
...          ("size", c_int)]
...
```

We have defined the `struct _frozen` data type, so we can get the pointer to
the table:

```python
>>> FrozenTable = POINTER(struct_frozen)
>>> table = FrozenTable.in_dll(pythonapi, "PyImport_FrozenModules")
```

Since `table` is a pointer to the array of `struct_frozen` records, we can iterate over it, but we just have to make sure that our loop terminates, because pointers have no size. Sooner or later it would probably crash with an access violation or whatever, so it's better to break out of the loop when we hit the NULL entry:

```python
>>> for item in table:
...    print item.name, item.size
...    if item.name is None:
...        break
...  __hello__ 104
  __phello__ -104
  __phello__.spam 104
None 0
```

The fact that standard Python has a frozen module and a frozen package (indicated by the negative size member) is not wellknown, it is only used for testing. Try it out with `import __hello__` for example.
14.14.1.19 Surprises

There are some edges in ctypes where you may be expect something else than what actually happens.

Consider the following example:

```python
>>> from ctypes import *
>>> class POINT(Structure):
...    _fields_ = ("x", c_int), ("y", c_int)
...>>> class RECT(Structure):
...    _fields_ = ("a", POINT), ("b", POINT)
...>>> p1 = POINT(1, 2)
>>> p2 = POINT(3, 4)
>>> rc = RECT(p1, p2)
>>> print rc.a.x, rc.a.y, rc.b.x, rc.b.y
1 2 3 4
>>> # now swap the two points
>>> rc.a, rc.b = rc.b, rc.a
>>> print rc.a.x, rc.a.y, rc.b.x, rc.b.y
3 4 3 4
>>>```

Hm. We certainly expected the last statement to print 3 4 1 2. What happened? Here are the steps of the `rc.a, rc.b = rc.b, rc.a` line above:

```python
>>> temp0, temp1 = rc.b, rc.a
>>> rc.a = temp0
>>> rc.b = temp1
```  

Note that `temp0` and `temp1` are objects still using the internal buffer of the `rc` object above. So executing `rc.a = temp0` copies the buffer contents of `temp0` into `rc`'s buffer. This, in turn, changes the contents of `temp1`. So, the last assignment `rc.b = temp1`, doesn't have the expected effect.

Keep in mind that retrieving subobjects from Structure, Unions, and Arrays doesn't copy the subobject, instead it retrieves a wrapper object accessing the
root-object's underlying buffer.

Another example that may behave different from what one would expect is this:

```python
>>> s = c_char_p()
>>> s.value = "abc def ghi"
>>> s.value
'abc def ghi'
>>> s.value is s.value
False
``` 

Why is it printing `False`? ctypes instances are objects containing a memory block plus some descriptors accessing the contents of the memory. Storing a Python object in the memory block does not store the object itself, instead the contents of the object is stored. Accessing the contents again constructs a new Python each time!
14.14.1.20 Variable-sized data types

cypes provides some support for variable-sized arrays and structures (this was added in version 0.9.9.7).

The resize function can be used to resize the memory buffer of an existing ctypes object. The function takes the object as first argument, and the requested size in bytes as the second argument. The memory block cannot be made smaller than the natural memory block specified by the objects type, a ValueError is raised if this is tried:

```python
>>> short_array = (c_short * 4)()
>>> print sizeof(short_array)
8
>>> resize(short_array, 4)
Traceback (most recent call last):
 ... 
ValueError: minimum size is 8
>>> resize(short_array, 32)
>>> sizeof(short_array)
32
>>> sizeof(type(short_array))
8
>>> 
```

This is nice and fine, but how would one access the additional elements contained in this array? Since the type still only knows about 4 elements, we get errors accessing other elements:

```python
>>> short_array[:]
[0, 0, 0, 0]
>>> short_array[7]
Traceback (most recent call last):
 ... 
IndexError: invalid index
>>> 
```

Another way to use variable-sized data types with ctypes is to use the dynamic nature of Python, and (re-)define the data type after the required size is already known, on a case by case basis.
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
14.14.1.21 Bugs, ToDo and non-implemented things

Enumeration types are not implemented. You can do it easily yourself, using c_int as the base class.

long double is not implemented.
14.14.2.1 Finding shared libraries

When programming in a compiled language, shared libraries are accessed when compiling/linking a program, and when the program is run.

The purpose of the `find_library` function is to locate a library in a way similar to what the compiler does (on platforms with several versions of a shared library the most recent should be loaded), while the ctypes library loaders act like when a program is run, and call the runtime loader directly.

The `ctypes.util` module provides a function which can help to determine the library to load.

`find_library(name)`

Try to find a library and return a pathname. `name` is the library name without any prefix like `lib`, suffix like `.so`, `.dylib` or version number (this is the form used for the posix linker option `-l`). If no library can be found, returns `None`.

The exact functionality is system dependend.

On Linux, `find_library` tries to run external programs (/sbin/ldconfig, gcc, and objdump) to find the library file. It returns the filename of the library file. Here are some examples:

```python
>>> from ctypes.util import find_library
>>> find_library("m")
'libm.so.6'
>>> find_library("c")
'libc.so.6'
>>> find_library("bz2")
'libbz2.so.1.0'
```

On OS X, `find_library` tries several predefined naming schemes and paths to locate the library, and returns a full pathname if successful:

```python
>>> from ctypes.util import find_library
```
On Windows, `find_library` searches along the system search path, and returns the full pathname, but since there is no predefined naming scheme a call like `find_library("c")` will fail and return `None`.

If wrapping a shared library with `ctypes`, it *may* be better to determine the shared library name at development type, and hardcode that into the wrapper module instead of using `find_library` to locate the library at runtime.
14.14.2.2 Loading shared libraries

There are several ways to loaded shared libraries into the Python process. One way is to instantiate one of the following classes:

**class CDLL** *(name, mode=DEFAULT_MODE, handle=None)*

Instances of this class represent loaded shared libraries. Functions in these libraries use the standard C calling convention, and are assumed to return int.

**class OleDLL** *(name, mode=DEFAULT_MODE, handle=None)*

Windows only: Instances of this class represent loaded shared libraries, functions in these libraries use the stdcall calling convention, and are assumed to return the windows specific HRESULT code. HRESULT values contain information specifying whether the function call failed or succeeded, together with additional error code. If the return value signals a failure, an WindowsError is automatically raised.

**class WinDLL** *(name, mode=DEFAULT_MODE, handle=None)*

Windows only: Instances of this class represent loaded shared libraries, functions in these libraries use the stdcall calling convention, and are assumed to return int by default.

On Windows CE only the standard calling convention is used, for convenience the WinDLL and OleDLL use the standard calling convention on this platform.

The Python GIL is released before calling any function exported by these libraries, and reaquired afterwards.

**class PyDLL** *(name, mode=DEFAULT_MODE, handle=None)*

Instances of this class behave like CDLL instances, except that the Python GIL is not released during the function call, and after the function execution the Python error flag is checked. If the error flag is set, a Python exception
is raised.

Thus, this is only useful to call Python C api functions directly.

All these classes can be instantiated by calling them with at least one argument, the pathname of the shared library. If you have an existing handle to an already loaded shard library, it can be passed as the handle named parameter, otherwise the underlying platforms dlopen or LoadLibrary function is used to load the library into the process, and to get a handle to it.

The mode parameter can be used to specify how the library is loaded. For details, consult the dlopen(3) manpage, on Windows, mode is ignored.

RTLD_GLOBAL
Flag to use as mode parameter. On platforms where this flag is not available, it is defined as the integer zero.

RTLD_LOCAL
Flag to use as mode parameter. On platforms where this is not available, it is the same as RTLD_GLOBAL.

DEFAULT_MODE
The default mode which is used to load shared libraries. On OSX 10.3, this is RTLD_GLOBAL, otherwise it is the same as RTLD_LOCAL.

Instances of these classes have no public methods, however __getattr__ and __getitem__ have special behaviour: functions exported by the shared library can be accessed as attributes of by index. Please note that both __getattr__ and __getitem__ cache their result, so calling them repeatedly returns the same object each time.

The following public attributes are available, their name starts with an underscore to not clash with exported function names:

_handle
The system handle used to access the library.

_name
The name of the library passed in the contractor.
Shared libraries can also be loaded by using one of the prefabricated objects, which are instances of the `LibraryLoader` class, either by calling the `LoadLibrary` method, or by retrieving the library as attribute of the loader instance.

**class LibraryLoader** *(dlltype)*

Class which loads shared libraries. `dlltype` should be one of the `CDLL`, `PyDLL`, `WinDLL`, or `OleDLL` types.

`__getattr__` has special behaviour: It allows to load a shared library by accessing it as attribute of a library loader instance. The result is cached, so repeated attribute accesses return the same library each time.

**LoadLibrary** *(name)*

Load a shared library into the process and return it. This method always returns a new instance of the library.

These prefabricated library loaders are available:

**cdll**

Creates `CDLL` instances.

**windll**

Windows only: Creates `WinDLL` instances.

**oledll**

Windows only: Creates `OleDLL` instances.

**pydll**

Creates `PyDLL` instances.

For accessing the C Python api directly, a ready-to-use Python shared library object is available:

**pythonapi**

An instance of `PyDLL` that exposes Python C api functions as attributes. Note that all these functions are assumed to return C `int`, which is of course not always the truth, so you have to assign the correct `restype` attribute to use these functions.
14.14.2.3 Foreign functions

As explained in the previous section, foreign functions can be accessed as attributes of loaded shared libraries. The function objects created in this way by default accept any number of arguments, accept any ctypes data instances as arguments, and return the default result type specified by the library loader. They are instances of a private class:

```python
class _FuncPtr
    Base class for C callable foreign functions.
```

Instances of foreign functions are also C compatible data types; they represent C function pointers.

This behaviour can be customized by assigning to special attributes of the foreign function object.

**restype**

Assign a ctypes type to specify the result type of the foreign function. Use `None` for `void` a function not returning anything.

It is possible to assign a callable Python object that is not a ctypes type, in this case the function is assumed to return a `C int`, and the callable will be called with this integer, allowing to do further processing or error checking. Using this is deprecated, for more flexible postprocessing or error checking use a ctypes data type as `restype` and assign a callable to the `errcheck` attribute.

**argtypes**

Assign a tuple of ctypes types to specify the argument types that the function accepts. Functions using the `stdcall` calling convention can only be called with the same number of arguments as the length of this tuple; functions using the C calling convention accept additional, unspecified arguments as well.

When a foreign function is called, each actual argument is passed to the
from_param class method of the items in the argtypes tuple, this method allows to adapt the actual argument to an object that the foreign function accepts. For example, a c_char_p item in the argtypes tuple will convert a unicode string passed as argument into an byte string using ctypes conversion rules.

New: It is now possible to put items in argtypes which are not ctypes types, but each item must have a from_param method which returns a value usable as argument (integer, string, ctypes instance). This allows to define adapters that can adapt custom objects as function parameters.

errcheck
Assign a Python function or another callable to this attribute. The callable will be called with three or more arguments:

callable( result, func, arguments)

result is what the foreign function returns, as specified by the restype attribute.

func is the foreign function object itself, this allows to reuse the same callable object to check or postprocess the results of several functions.

arguments is a tuple containing the parameters originally passed to the function call, this allows to specialize the behaviour on the arguments used.

The object that this function returns will be returned from the foreign function call, but it can also check the result value and raise an exception if the foreign function call failed.

exception ArgumentError()
This exception is raised when a foreign function call cannot convert one of the passed arguments.

Next: 14.14.2.4 Function prototypes

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
14.14.2.4 Function prototypes

Foreign functions can also be created by instantiating function prototypes. Function prototypes are similar to function prototypes in C; they describe a function (return type, argument types, calling convention) without defining an implementation. The factory functions must be called with the desired result type and the argument types of the function.

**CFUNCTYPE( restype, *argtypes)**

The returned function prototype creates functions that use the standard C calling convention. The function will release the GIL during the call.

**WINFUNCTYPE( restype, *argtypes)**

Windows only: The returned function prototype creates functions that use the stdcall calling convention, except on Windows CE where WINFUNCTYPE is the same as CFUNCTYPE. The function will release the GIL during the call.

**PYFUNCTYPE( restype, *argtypes)**

The returned function prototype creates functions that use the Python calling convention. The function will *not* release the GIL during the call.

Function prototypes created by the factory functions can be instantiated in different ways, depending on the type and number of the parameters in the call.

**prototype( address)**

Returns a foreign function at the specified address.

**prototype( callable)**

Create a C callable function (a callback function) from a Python callable.

**prototype( func_spec[, paramflags])**

Returns a foreign function exported by a shared library. **func_spec** must
be a 2-tuple \((name\_or\_ordinal, \ library)\). The first item is the name of the exported function as string, or the ordinal of the exported function as small integer. The second item is the shared library instance.

**prototype**\((vtbl\_index, name[, \ paramflags[, \ iid]])\)

Returns a foreign function that will call a COM method. \(vtbl\_index\) is the index into the virtual function table, a small nonnegative integer. \(name\) is name of the COM method. \(iid\) is an optional pointer to the interface identifier which is used in extended error reporting.

COM methods use a special calling convention: They require a pointer to the COM interface as first argument, in addition to those parameters that are specified in the \texttt{argtypes} tuple.

The optional \texttt{paramflags} parameter creates foreign function wrappers with much more functionality than the features described above.

\texttt{paramflags} must be a tuple of the same length as \texttt{argtypes}.

Each item in this tuple contains further information about a parameter, it must be a tuple containing 1, 2, or 3 items.

The first item is an integer containing flags for the parameter:

1  
Specifies an input parameter to the function.

2  
Output parameter. The foreign function fills in a value.

4  
Input parameter which defaults to the integer zero.

The optional second item is the parameter name as string. If this is specified, the foreign function can be called with named parameters.

The optional third item is the default value for this parameter.

This example demonstrates how to wrap the Windows \texttt{MessageBoxA} function so that it supports default parameters and named arguments. The C declaration
from the windows header file is this:

```c
WINUSERAPI int WINAPI MessageBoxA(
    HWND hWnd,
    LPCSTR lpText,
    LPCSTR lpCaption,
    UINT uType);
```

Here is the wrapping with ctypes:

```python
>>> from ctypes import c_int, WINFUNCTYPE, windll
>>> from ctypes.wintypes import HWND, LPCSTR, UINT
>>> prototype = WINFUNCTYPE(c_int, HWND, LPCSTR, LPCSTR, c_uint)
>>> paramflags = (1, "hwnd", 0),
                (1, "text", "Hi"),
                (1, "caption", None),
                (1, "flags", 0)
>>> MessageBox = prototype(('MessageBoxA', windll.user32), paramflags)

The MessageBox foreign function can now be called in these ways:

```python
>>> MessageBox()
>>> MessageBox(text="Spam, spam, spam")
>>> MessageBox(flags=2, text="foo bar")
```

A second example demonstrates output parameters. The win32 GetWindowRect function retrieves the dimensions of a specified window by copying them into RECT structure that the caller has to supply. Here is the C declaration:

```c
WINUSERAPI BOOL WINAPI GetWindowRect(
    HWND hWnd,
    LPRECT lpRect);
```

Here is the wrapping with ctypes:

```python
>>> from ctypes import POINTER, WINFUNCTYPE, windll
>>> from ctypes.wintypes import BOOL, HWND, RECT
>>> prototype = WINFUNCTYPE(BOOL, HWND, POINTER(RECT))
>>> paramflags = (1, "hwnd"), (2, "lprect")
>>> GetWindowRect = prototype(('GetWindowRect', windll.user32), paramflags)

Functions with output parameters will automatically return the output parameter value if there is a single one, or a tuple containing the output parameter values when there are more than one, so the GetWindowRect function now returns a
RECT instance, when called.

Output parameters can be combined with the errcheck protocol to do further output processing and error checking. The win32 GetWindowRect api function returns a BOOL to signal success or failure, so this function could do the error checking, and raises an exception when the api call failed:

```python
>>> def errcheck(result, func, args):
    ...    if not result:
    ...        raise WinError()
    ...    return args
>>> GetWindowRect.errcheck = errcheck
>>>```

If the errcheck function returns the argument tuple it receives unchanged, ctypes continues the normal processing it does on the output parameters. If you want to return a tuple of window coordinates instead of a RECT instance, you can retrieve the fields in the function and return them instead, the normal processing will no longer take place:

```python
>>> def errcheck(result, func, args):
    ...    if not result:
    ...        raise WinError()
    ...    rc = args[1]
    ...    return rc.left, rc.top, rc.bottom, rc.right
>>> >>>
>>> GetWindowRect.errcheck = errcheck
>>>```
14.14.2.5 Utility functions

**addressof**(obj)

Returns the address of the memory buffer as integer. obj must be an instance of a ctypes type.

**alignment**(obj_or_type)

Returns the alignment requirements of a ctypes type. obj_or_type must be a ctypes type or instance.

**byref**(obj)

Returns a light-weight pointer to obj, which must be an instance of a ctypes type. The returned object can only be used as a foreign function call parameter. It behaves similar to **pointer**(obj), but the construction is a lot faster.

**cast**(obj, type)

This function is similar to the cast operator in C. It returns a new instance of type which points to the same memory block as obj. type must be a pointer type, and obj must be an object that can be interpreted as a pointer.

**create_string_buffer**(init_or_size[, size])

This function creates a mutable character buffer. The returned object is a ctypes array of c_char.

init_or_size must be an integer which specifies the size of the array, or a string which will be used to initialize the array items.

If a string is specified as first argument, the buffer is made one item larger than the length of the string so that the last element in the array is a NUL termination character. An integer can be passed as second argument which allows to specify the size of the array if the length of the string should not be used.
If the first parameter is a unicode string, it is converted into an 8-bit string according to ctypes conversion rules.

**create_unicode_buffer**(init_or_size[, size])
This function creates a mutable unicode character buffer. The returned object is a ctypes array of c_wchar.

init_or_size must be an integer which specifies the size of the array, or a unicode string which will be used to initialize the array items.

If a unicode string is specified as first argument, the buffer is made one item larger than the length of the string so that the last element in the array is a NUL termination character. An integer can be passed as second argument which allows to specify the size of the array if the length of the string should not be used.

If the first parameter is a 8-bit string, it is converted into an unicode string according to ctypes conversion rules.

**DllCanUnloadNow()**
Windows only: This function is a hook which allows to implement inprocess COM servers with ctypes. It is called from the DllCanUnloadNow function that the _ctypes extension dll exports.

**DllGetClassObject()**
Windows only: This function is a hook which allows to implement inprocess COM servers with ctypes. It is called from the DllGetClassObject function that the _ctypes extension dll exports.

**FormatError**(code)
Windows only: Returns a textual description of the error code. If no error code is specified, the last error code is used by calling the Windows api function GetLastError.

**GetLastError()**
Windows only: Returns the last error code set by Windows in the calling thread.
**memmove** *(dst, src, count)*
Same as the standard C memmove library function: copies *count* bytes from *src* to *dst*. *dst* and *src* must be integers or ctypes instances that can be converted to pointers.

**memset** *(dst, c, count)*
Same as the standard C memset library function: fills the memory block at address *dst* with *count* bytes of value *c*. *dst* must be an integer specifying an address, or a ctypes instance.

**POINTER** *(type)*
This factory function creates and returns a new ctypes pointer type. Pointer types are cached and reused internally, so calling this function repeatedly is cheap. *type* must be a ctypes type.

**pointer** *(obj)*
This function creates a new pointer instance, pointing to *obj*. The returned object is of the type `POINTER(type(obj))`.

Note: If you just want to pass a pointer to an object to a foreign function call, you should use `byref(obj)` which is much faster.

**resize** *(obj, size)*
This function resizes the internal memory buffer of *obj*, which must be an instance of a ctypes type. It is not possible to make the buffer smaller than the native size of the objects type, as given by `sizeof(type(obj))`, but it is possible to enlarge the buffer.

**set_conversion_mode** *(encoding, errors)*
This function sets the rules that ctypes objects use when converting between 8-bit strings and unicode strings. *encoding* must be a string specifying an encoding, like 'utf-8' or 'mbcs', *errors* must be a string specifying the error handling on encoding/decoding errors. Examples of possible values are "strict", "replace", or "ignore".

`set_conversion_mode` returns a 2-tuple containing the previous conversion rules. On windows, the initial conversion rules are ('mbcs', 'ignore'), on other systems ('ascii', 'strict').
**sizeof**(obj_or_type)

Returns the size in bytes of a ctypes type or instance memory buffer. Does the same as the C `sizeof()` function.

**string_at**(address[, size])

This function returns the string starting at memory address address. If size is specified, it is used as size, otherwise the string is assumed to be zero-terminated.

**WinError**(code=None, descr=None)

Windows only: this function is probably the worst-named thing in ctypes. It creates an instance of WindowsError. If code is not specified, `GetLastError` is called to determine the error code. If descr is not specified, `FormatError` is called to get a textual description of the error.

**wstring_at**(address)

This function returns the wide character string starting at memory address address as unicode string. If size is specified, it is used as the number of characters of the string, otherwise the string is assumed to be zero-terminated.
14.14.2.6 Data types

class _CData

This non-public class is the common base class of all ctypes data types. Among other things, all ctypes type instances contain a memory block that hold C compatible data; the address of the memory block is returned by the `addressof()` helper function. Another instance variable is exposed as `_objects`; this contains other Python objects that need to be kept alive in case the memory block contains pointers.

Common methods of ctypes data types, these are all class methods (to be exact, they are methods of the metaclass):

`from_address(address)`

This method returns a ctypes type instance using the memory specified by address which must be an integer.

`from_param(obj)`

This method adapts obj to a ctypes type. It is called with the actual object used in a foreign function call, when the type is present in the foreign functions `argtypes` tuple; it must return an object that can be used as function call parameter.

All ctypes data types have a default implementation of this classmethod, normally it returns `obj` if that is an instance of the type. Some types accept other objects as well.

`in_dll(name, library)`

This method returns a ctypes type instance exported by a shared library. `name` is the name of the symbol that exports the data, `library` is the loaded shared library.

Common instance variables of ctypes data types:

`_b_base_`
Sometimes ctypes data instances do not own the memory block they contain, instead they share part of the memory block of a base object. The \_b\_base\_ readonly member is the root ctypes object that owns the memory block.

\_b\_needsfree\_

This readonly variable is true when the ctypes data instance has allocated the memory block itself, false otherwise.

\_objects

This member is either None or a dictionary containing Python objects that need to be kept alive so that the memory block contents is kept valid. This object is only exposed for debugging; never modify the contents of this dictionary.
14.14.2.7 Fundamental data types

class _SimpleCData

This non-public class is the base class of all fundamental ctypes data types. It is mentioned here because it contains the common attributes of the fundamental ctypes data types. _SimpleCData is a subclass of _CData, so it inherits their methods and attributes.

Instances have a single attribute:

value

This attribute contains the actual value of the instance. For integer and pointer types, it is an integer, for character types, it is a single character string, for character pointer types it is a Python string or unicode string.

When the value attribute is retrieved from a ctypes instance, usually a new object is returned each time. ctypes does not implement original object return, always a new object is constructed. The same is true for all other ctypes object instances.

Fundamental data types, when returned as foreign function call results, or, for example, by retrieving structure field members or array items, are transparently converted to native Python types. In other words, if a foreign function has a restype of c_char_p, you will always receive a Python string, not a c_char_p instance.

Subclasses of fundamental data types do not inherit this behaviour. So, if a foreign functions restype is a subclass of c_void_p, you will receive an instance of this subclass from the function call. Of course, you can get the value of the pointer by accessing the value attribute.

These are the fundamental ctypes data types:

class c_byte

Represents the C signed char datatype, and interprets the value as small
integer. The constructor accepts an optional integer initializer; no overflow checking is done.

**class c_char**
Represents the C char datatype, and interprets the value as a single character. The constructor accepts an optional string initializer, the length of the string must be exactly one character.

**class c_char_p**
Represents the C char * datatype, which must be a pointer to a zero-terminated string. The constructor accepts an integer address, or a string.

**class c_double**
Represents the C double datatype. The constructor accepts an optional float initializer.

**class c_float**
Represents the C double datatype. The constructor accepts an optional float initializer.

**class c_int**
Represents the C signed int datatype. The constructor accepts an optional integer initializer; no overflow checking is done. On platforms where `sizeof(int) == sizeof(long)` it is an alias to `c_long`.

**class c_int8**
Represents the C 8-bit signed int datatype. Usually an alias for `c_byte`.

**class c_int16**
Represents the C 16-bit signed int datatype. Usually an alias for `c_short`.

**class c_int32**
Represents the C 32-bit signed int datatype. Usually an alias for `c_int`.

**class c_int64**
Represents the C 64-bit signed int datatype. Usually an alias for `c_longlong`. 
**class c_long**
Represents the C signed long datatype. The constructor accepts an optional integer initializer; no overflow checking is done.

**class c_longlong**
Represents the C signed long long datatype. The constructor accepts an optional integer initializer; no overflow checking is done.

**class c_short**
Represents the C signed short datatype. The constructor accepts an optional integer initializer; no overflow checking is done.

**class c_size_t**
Represents the C size_t datatype.

**class c_ubyte**
Represents the C unsigned char datatype, it interprets the value as small integer. The constructor accepts an optional integer initializer; no overflow checking is done.

**class c_uint**
Represents the C unsigned int datatype. The constructor accepts an optional integer initializer; no overflow checking is done. On platforms where sizeof(int) == sizeof(long) it is an alias for c_ulong.

**class c_uint8**
Represents the C 8-bit unsigned int datatype. Usually an alias for c_ubyte.

**class c_uint16**
Represents the C 16-bit unsigned int datatype. Usually an alias for c_ushort.

**class c_uint32**
Represents the C 32-bit unsigned int datatype. Usually an alias for c_uint.

**class c_uint64**
Represents the C 64-bit unsigned int datatype. Usually an alias for
class c_ulong
Represents the C unsigned long datatype. The constructor accepts an optional integer initializer; no overflow checking is done.

class c_ulonglong
Represents the C unsigned long long datatype. The constructor accepts an optional integer initializer; no overflow checking is done.

class c_ushort
Represents the C unsigned short datatype. The constructor accepts an optional integer initializer; no overflow checking is done.

class c_void_p
Represents the C void * type. The value is represented as integer. The constructor accepts an optional integer initializer.

class c_wchar
Represents the C wchar_t datatype, and interprets the value as a single character unicode string. The constructor accepts an optional string initializer, the length of the string must be exactly one character.

class c_wchar_p
Represents the C wchar_t * datatype, which must be a pointer to a zero-terminated wide character string. The constructor accepts an integer address, or a string.

class HRESULT
Windows only: Represents a HRESULT value, which contains success or error information for a function or method call.

py_object : classdesc*

Represents the C PyObject * datatype. Calling this with an without an argument creates a NULL PyObject * pointer.

The ctypes.wintypes module provides quite some other Windows specific data types, for example HWND, WPARAM, or DWORD. Some useful structures like
MSG or RECT are also defined.
14.14.2.8 Structured data types

class Union(*args, **kw)
    Abstract base class for unions in native byte order.

class BigEndianStructure(*args, **kw)
    Abstract base class for structures in big endian byte order.

class LittleEndianStructure(*args, **kw)
    Abstract base class for structures in little endian byte order.

Structures with non-native byte order cannot contain pointer type fields, or any other data types containing pointer type fields.

class Structure(*args, **kw)
    Abstract base class for structures in native byte order.

Concrete structure and union types must be created by subclassing one of these types, and at least define a _fields_ class variable. ctypes will create descriptors which allow reading and writing the fields by direct attribute accesses. These are the

_fields_
    A sequence defining the structure fields. The items must be 2-tuples or 3-tuples. The first item is the name of the field, the second item specifies the type of the field; it can be any ctypes data type.

    For integer type fields like c_int, a third optional item can be given. It must be a small positive integer defining the bit width of the field.

    Field names must be unique within one structure or union. This is not checked, only one field can be accessed when names are repeated.

    It is possible to define the _fields_ class variable after the class statement that defines the Structure subclass, this allows to create data types
that directly or indirectly reference themselves:

```python
class List(Structure):
    pass
List._fields_ = [('pnext', POINTER(List)),
                 ...
```

The `_fields_` class variable must, however, be defined before the type is first used (an instance is created, `sizeof()` is called on it, and so on). Later assignments to the `_fields_` class variable will raise an AttributeError.

Structure and union subclass constructors accept both positional and named arguments. Positional arguments are used to initialize the fields in the same order as they appear in the `_fields_` definition, named arguments are used to initialize the fields with the corresponding name.

It is possible to defined sub-subclasses of structure types, they inherit the fields of the base class plus the `_fields_` defined in the sub-subclass, if any.

`_pack_`

An optional small integer that allows to override the alignment of structure fields in the instance. `_pack_` must already be defined when `_fields_` is assigned, otherwise it will have no effect.

`_anonymous_`

An optional sequence that lists the names of unnamed (anonymous) fields. `_anonymous_` must be already defined when `_fields_` is assigned, otherwise it will have no effect.

The fields listed in this variable must be structure or union type fields. `ctypes` will create descriptors in the structure type that allows to access the nested fields directly, without the need to create the structure or union field.

Here is an example type (Windows):

```python
class _U(Union):
    _fields_ = [('lptdesc', POINTER(TYPEDESC)),
                ('lpadesc', POINTER(ARRAYDESC)),
                ]
```
class TYPEDESC(Structure):
    _fields_ = ["u", _U],
               ("vt", VARTYPE)]

    _anonymous_ = ("u",)

The TYPEDESC structure describes a COM data type, the vt field specifies which one of the union fields is valid. Since the u field is defined as anonymous field, it is now possible to access the members directly off the TYPEDESC instance. td.lptdesc and td.u.lptdesc are equivalent, but the former is faster since it does not need to create a temporary union instance:

    td = TYPEDESC()
    td.vt = VT_PTR
    td.lptdesc = POINTER(some_type)
    td.u.lptdesc = POINTER(some_type)

It is possible to defined sub-subclasses of structures, they inherit the fields of the base class. If the subclass definition has a separate _fields_ variable, the fields specified in this are appended to the fields of the base class.

Structure and union constructors accept both positional and keyword arguments. Positional arguments are used to initialize member fields in the same order as they are appear in _fields_. Keyword arguments in the constructor are interpreted as attribute assignments, so they will initialize _fields_ with the same name, or create new attributes for names not present in _fields_.

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
14.14.2.9 Arrays and pointers

XXX

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
15.3.4.1 Semaphore Example

Semaphores are often used to guard resources with limited capacity, for example, a database server. In any situation where the size of the resource size is fixed, you should use a bounded semaphore. Before spawning any worker threads, your main thread would initialize the semaphore:

```python
maxconnections = 5
...
pool_sema = BoundedSemaphore(value=maxconnections)
```

Once spawned, worker threads call the semaphore's acquire and release methods when they need to connect to the server:

```python
pool_sema.acquire()
conn = connectdb()
... use connection ...
conn.close()
pool_sema.release()
```

The use of a bounded semaphore reduces the chance that a programming error which causes the semaphore to be released more than it's acquired will go undetected.
17.1.1.1 Convenience Functions

This module also defines two shortcut functions:

**call**(*popenargs, **kwargs*)

Run command with arguments. Wait for command to complete, then return the returncode attribute.

The arguments are the same as for the Popen constructor. Example:

```python
retcode = call(['ls', '-l'])
```

**check_call**(*popenargs, **kwargs*)

Run command with arguments. Wait for command to complete. If the exit code was zero then return, otherwise raise CalledProcessError. The CalledProcessError object will have the return code in the returncode attribute.

The arguments are the same as for the Popen constructor. Example:

```python
check_call(['ls', '-l'])
```
17.1.1.2 Exceptions

Exceptions raised in the child process, before the new program has started to execute, will be re-raised in the parent. Additionally, the exception object will have one extra attribute called child_traceback, which is a string containing traceback information from the childs point of view.

The most common exception raised is OSError. This occurs, for example, when trying to execute a non-existent file. Applications should prepare for OSError exceptions.

A ValueError will be raised if Popen is called with invalid arguments.

check_call() will raise CalledProcessError, if the called process returns a non-zero return code.
17.1.1.3 Security

Unlike some other popen functions, this implementation will never call /bin/sh implicitly. This means that all characters, including shell metacharacters, can safely be passed to child processes.
17.1.3.1 Replacing /bin/sh shell backquote

```python
output=`mycmd myarg`
==> output = Popen(['mycmd', 'myarg'], stdout=PIPE).communicate()[0]
```
17.1.3.2 Replacing shell pipe line

```
output=`dmesg | grep hda`
==> 
p1 = Popen(['dmesg'], stdout=PIPE)
p2 = Popen(['grep', 'hda'], stdin=p1.stdout, stdout=PIPE)
output = p2.communicate()[0]
```
17.1.3.3 Replacing os.system()

```python
sts = os.system("mycmd" + " myarg")
==>  
p = Popen("mycmd" + " myarg", shell=True)  
sts = os.waitpid(p.pid, 0)
```

Notes:

- Calling the program through the shell is usually not required.
- It's easier to look at the `returncode` attribute than the exit status.

A more realistic example would look like this:

```python
try:  
    retcode = call("mycmd" + " myarg", shell=True)  
    if retcode < 0:  
        print >>sys.stderr, "Child was terminated by signal", -retco  
    else:  
        print >>sys.stderr, "Child returned", retcode  
except OSError, e:  
    print >>sys.stderr, "Execution failed:", e
```

---

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
17.1.3.4 Replacing os.spawn*

P_NOWAIT example:

```
    pid = os.spawnlp(os.P_NOWAIT, "/bin/mycmd", "mycmd", "myarg")
    ==> pid = Popen(["/bin/mycmd", "myarg"]).pid
```

P_WAIT example:

```
    retcode = os.spawnlp(os.P_WAIT, "/bin/mycmd", "mycmd", "myarg")
    ==> retcode = call(["/bin/mycmd", "myarg"])
```

Vector example:

```
    os.spawnvp(os.P_NOWAIT, path, args)
    ==> Popen([path] + args[1:])
```

Environment example:

```
    os.spawnlpe(os.P_NOWAIT, "/bin/mycmd", "mycmd", "myarg", env)
    ==> Popen(["/bin/mycmd", "myarg"], env={"PATH": "/usr/bin"})
```
17.1.3.5 Replacing os.popen*

```
pipe = os.popen(cmd, mode='r', bufsize)
==> pipe = Popen(cmd, shell=True, bufsize=bufsize, stdout=PIPE).stdout

pipe = os.popen(cmd, mode='w', bufsize)
==> pipe = Popen(cmd, shell=True, bufsize=bufsize, stdin=PIPE).stdin

(child_stdin, child_stdout) = os.popen2(cmd, mode, bufsize)
==> p = Popen(cmd, shell=True, bufsize=bufsize, stdin=PIPE, stdout=PIPE, close_fds=True)
   (child_stdin, child_stdout) = (p.stdin, p.stdout)

(child_stdin, child_stdout, child_stderr) = os.popen3(cmd, mode, bufsize)
==> p = Popen(cmd, shell=True, bufsize=bufsize, stdin=PIPE, stdout=PIPE, stderr=PIPE, close_fds=True)
   (child_stdin, child_stdout, child_stderr) = (p.stdin, p.stdout, p.stderr)

(child_stdin, child_stdout_and_stderr) = os.popen4(cmd, mode, bufsize)
==> p = Popen(cmd, shell=True, bufsize=bufsize, stdin=PIPE, stdout=PIPE, stderr=STDOUT, close_fds=True)
   (child_stdin, child_stdout_and_stderr) = (p.stdin, p.stdout)
```
17.1.3.6 Replacing popen2.*

Note: If the cmd argument to popen2 functions is a string, the command is executed through /bin/sh. If it is a list, the command is directly executed.

```python
(child_stdout, child_stdin) = popen2.popen2("somestring", bufsize, m
==>
p = Popen(["somestring"], shell=True, bufsize=bufsize,
stdin=PIPE, stdout=PIPE, close_fds=True)
(child_stdout, child_stdin) = (p.stdout, p.stdin)

(child_stdout, child_stdin) = popen2.popen2(["mycmd", "myarg"], bufs
==>
p = Popen(["mycmd", "myarg"], bufsize=bufsize,
stdin=PIPE, stdout=PIPE, close_fds=True)
(child_stdout, child_stdin) = (p.stdout, p.stdin)
```

The popen2.Popen3 and popen2.Popen4 basically works as subprocess.Popen, except that:

- subprocess.Popen raises an exception if the execution fails
- the `capturestderr` argument is replaced with the `stderr` argument.
- `stdin=PIPE` and `stdout=PIPE` must be specified.
- `popen2` closes all file descriptors by default, but you have to specify `close_fds=True` with subprocess.Popen.
20.1.2.1 How To Use This Section

This section is designed in two parts: the first half (roughly) covers background material, while the second half can be taken to the keyboard as a handy reference.

When trying to answer questions of the form ``how do I do blah'', it is often best to find out how to do `blah' in straight Tk, and then convert this back into the corresponding Tkinter call. Python programmers can often guess at the correct Python command by looking at the Tk documentation. This means that in order to use Tkinter, you will have to know a little bit about Tk. This document can't fulfill that role, so the best we can do is point you to the best documentation that exists. Here are some hints:

- The authors strongly suggest getting a copy of the Tk man pages. Specifically, the man pages in the man directory are most useful. The man3 man pages describe the C interface to the Tk library and thus are not especially helpful for script writers.

- Addison-Wesley publishes a book called Tcl and the Tk Toolkit by John Ousterhout (ISBN 0-201-63337-X) which is a good introduction to Tcl and Tk for the novice. The book is not exhaustive, and for many details it defers to the man pages.

- Tkinter.py is a last resort for most, but can be a good place to go when nothing else makes sense.

20.1.2.2 A Simple Hello World Program

from Tkinter import *

class Application(Frame):
    def say_hi(self):
        print "hi there, everyone!"

    def createWidgets(self):
        self.QUIT = Button(self)
        self.QUIT["text"] = "QUIT"
        self.QUIT["fg"] = "red"
        self.QUIT["command"] = self.quit

        self.QUIT.pack({"side": "left"})

        self.hi_there = Button(self)
        self.hi_there["text"] = "Hello",
        self.hi_there["command"] = self.say_hi

        self.hi_there.pack({"side": "left"})

    def __init__(self, master=None):
        Frame.__init__(self, master)
        self.pack()
        self.createWidgets()

root = Tk()
app = Application(master=root)
app.mainloop()
root.destroy()
20.1.6.1 Setting Options

Options control things like the color and border width of a widget. Options can be set in three ways:

At object creation time, using keyword arguments

```
fred = Button(self, fg = "red", bg = "blue")
```

After object creation, treating the option name like a dictionary index

```
fred["fg"] = "red"
fred["bg"] = "blue"
```

Use the config() method to update multiple attrs subsequent to object creation

```
fred.config(fg = "red", bg = "blue")
```

For a complete explanation of a given option and its behavior, see the Tk man pages for the widget in question.

Note that the man pages list "STANDARD OPTIONS" and "WIDGET SPECIFIC OPTIONS" for each widget. The former is a list of options that are common to many widgets, the latter are the options that are idiosyncratic to that particular widget. The Standard Options are documented on the options(3) man page.

No distinction between standard and widget-specific options is made in this document. Some options don't apply to some kinds of widgets. Whether a given widget responds to a particular option depends on the class of the widget; buttons have a command option, labels do not.

The options supported by a given widget are listed in that widget's man page, or can be queried at runtime by calling the config() method without arguments,
or by calling the `keys()` method on that widget. The return value of these calls is a dictionary whose key is the name of the option as a string (for example, 'relief') and whose values are 5-tuples.

Some options, like bg are synonyms for common options with long names (bg is shorthand for "background"). Passing the `config()` method the name of a shorthand option will return a 2-tuple, not 5-tuple. The 2-tuple passed back will contain the name of the synonym and the "real" option (such as ('bg', 'background')).

<table>
<thead>
<tr>
<th>Index</th>
<th>Meaning</th>
<th>Example</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>option name</td>
<td>'relief'</td>
</tr>
<tr>
<td>1</td>
<td>option name for database lookup</td>
<td>'relief'</td>
</tr>
<tr>
<td>2</td>
<td>option class for database lookup</td>
<td>'Relief'</td>
</tr>
<tr>
<td>3</td>
<td>default value</td>
<td>'raised'</td>
</tr>
<tr>
<td>4</td>
<td>current value</td>
<td>'groove'</td>
</tr>
</tbody>
</table>

Example:

```python
>>> print fred.config()
{'relief': ('relief', 'relief', 'Relief', 'raised', 'groove')}
```

Of course, the dictionary printed will include all the options available and their values. This is meant only as an example.
20.1.6.2 The Packer

The packer is one of Tk's geometry-management mechanisms.

Geometry managers are used to specify the relative positioning of the positioning of widgets within their container - their mutual master. In contrast to the more cumbersome placer (which is used less commonly, and we do not cover here), the packer takes qualitative relationship specification - above, to the left of, filling, etc - and works everything out to determine the exact placement coordinates for you.

The size of any master widget is determined by the size of the "slave widgets" inside. The packer is used to control where slave widgets appear inside the master into which they are packed. You can pack widgets into frames, and frames into other frames, in order to achieve the kind of layout you desire. Additionally, the arrangement is dynamically adjusted to accommodate incremental changes to the configuration, once it is packed.

Note that widgets do not appear until they have had their geometry specified with a geometry manager. It's a common early mistake to leave out the geometry specification, and then be surprised when the widget is created but nothing appears. A widget will appear only after it has had, for example, the packer's pack() method applied to it.

The pack() method can be called with keyword-option/value pairs that control where the widget is to appear within its container, and how it is to behave when the main application window is resized. Here are some examples:

```python
fred.pack() # defaults to side = "top"
fred.pack(side = "left")
fred.pack(expand = 1)
```
20.1.6.3 Packer Options

For more extensive information on the packer and the options that it can take, see the man pages and page 183 of John Ousterhout's book.

anchor
Anchor type. Denotes where the packer is to place each slave in its parcel.

expand
Boolean, 0 or 1.

fill
Legal values: 'x', 'y', 'both', 'none'.

ipadx and ipady
A distance - designating internal padding on each side of the slave widget.

padx and pady
A distance - designating external padding on each side of the slave widget.

side
Legal values are: 'left', 'right', 'top', 'bottom'.

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
The current-value setting of some widgets (like text entry widgets) can be connected directly to application variables by using special options. These options are variable, textvariable, onvalue, offvalue, and value. This connection works both ways: if the variable changes for any reason, the widget it's connected to will be updated to reflect the new value.

Unfortunately, in the current implementation of Tkinter it is not possible to hand over an arbitrary Python variable to a widget through a variable or textvariable option. The only kinds of variables for which this works are variables that are subclassed from a class called Variable, defined in the Tkinter module.

There are many useful subclasses of Variable already defined: StringVar, IntVar, DoubleVar, and BooleanVar. To read the current value of such a variable, call the get() method on it, and to change its value you call the set() method. If you follow this protocol, the widget will always track the value of the variable, with no further intervention on your part.

For example:

```python
class App(Frame):
    def __init__(self, master=None):
        Frame.__init__(self, master)
        self.pack()

        self.entrythingy = Entry()
        self.entrythingy.pack()

        # here is the application variable
        self.contents = StringVar()
        # set it to some value
        self.contents.set("this is a variable")
        # tell the entry widget to watch this variable
        self.entrythingy["textvariable"] = self.contents

        # and here we get a callback when the user hits return.
        # we will have the program print out the value of the
        # application variable when the user hits return
```
self.entrythingy.bind('<Key-Return>',
    self.print_contents)

def print_contents(self, event):
    print "hi. contents of entry is now ---->", \
    self.contents.get()
20.1.6.5 The Window Manager

In Tk, there is a utility command, `wm`, for interacting with the window manager. Options to the `wm` command allow you to control things like titles, placement, icon bitmaps, and the like. In Tkinter, these commands have been implemented as methods on the `Wm` class. Toplevel widgets are subclassed from the `Wm` class, and so can call the `Wm` methods directly.

To get at the toplevel window that contains a given widget, you can often just refer to the widget's master. Of course if the widget has been packed inside of a frame, the master won't represent a toplevel window. To get at the toplevel window that contains an arbitrary widget, you can call the `_root()` method. This method begins with an underscore to denote the fact that this function is part of the implementation, and not an interface to Tk functionality.

Here are some examples of typical usage:

```python
from Tkinter import *
class App(Frame):
    def __init__(self, master=None):
        Frame.__init__(self, master)
        self.pack()

    # create the application
    myapp = App()

    # # here are method calls to the window manager class
    # #
    # myapp.master.title("My Do-Nothing Application")
    # myapp.master.maxsize(1000, 400)

    # start the program
    myapp.mainloop()
```
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
20.1.6.6 Tk Option Data Types

anchor
Legal values are points of the compass: "n", "ne", "e", "se", "s", "sw", "w", "nw", and also "center".

bitmap
There are eight built-in, named bitmaps: 'error', 'gray25', 'gray50', 'hourglass', 'info', 'questhead', 'question', 'warning'. To specify an X bitmap filename, give the full path to the file, preceded with an @, as in "@/usr/contrib(bitmap/gumby.bit".

boolean
You can pass integers 0 or 1 or the strings "yes" or "no".

callback
This is any Python function that takes no arguments. For example:

```python
def print_it():
    print "hi there"
fred["command"] = print_it
```

color
Colors can be given as the names of X colors in the rgb.txt file, or as strings representing RGB values in 4 bit: "#RGB", 8 bit: "#RRGGBB", 12 bit "#RRGGBBB", or 16 bit "#RRRGGGGBBBB" ranges, where R,G,B here represent any legal hex digit. See page 160 of Ousterhout's book for details.

cursor
The standard X cursor names from cursorfont.h can be used, without the XC_ prefix. For example to get a hand cursor (XC_hand2), use the string "hand2". You can also specify a bitmap and mask file of your own. See page 179 of Ousterhout's book.
distance
Screen distances can be specified in either pixels or absolute distances. Pixels are given as numbers and absolute distances as strings, with the trailing character denoting units: c for centimetres, i for inches, m for millimetres, p for printer's points. For example, 3.5 inches is expressed as "3.5i".

font
Tk uses a list font name format, such as {courier 10 bold}. Font sizes with positive numbers are measured in points; sizes with negative numbers are measured in pixels.

gemoetry
This is a string of the form "widthxheight", where width and height are measured in pixels for most widgets (in characters for widgets displaying text). For example: fred["geometry"] = "200x100".

justify
Legal values are the strings: "left", "center", "right", and "fill".

region
This is a string with four space-delimited elements, each of which is a legal distance (see above). For example: "2 3 4 5" and "3i 2i 4.5i 2i" and "3c 2c 4c 10.43c" are all legal regions.

relief
Determines what the border style of a widget will be. Legal values are: "raised", "sunken", "flat", "groove", and "ridge".

scrollcommand
This is almost always the set() method of some scrollbar widget, but can be any widget method that takes a single argument. Refer to the file Demo/tkinter/matt/canvas-with-scrollbars.py in the Python source distribution for an example.

wrap:
Must be one of: "none", "char", or "word".
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
20.1.6.7 Bindings and Events

The bind method from the widget command allows you to watch for certain events and to have a callback function trigger when that event type occurs. The form of the bind method is:

\[
def bind(self, sequence, func, add=''):\]

where:

- **sequence**
  is a string that denotes the target kind of event. (See the bind man page and page 201 of John Ousterhout's book for details).

- **func**
  is a Python function, taking one argument, to be invoked when the event occurs. An Event instance will be passed as the argument. (Functions deployed this way are commonly known as *callbacks*.)

- **add**
  is optional, either "" or "+". Passing an empty string denotes that this binding is to replace any other bindings that this event is associated with. Preceeding with a "+" means that this function is to be added to the list of functions bound to this event type.

For example:

\[
def turnRed(self, event):
    event.widget["activeforeground"] = "red"
    self.button.bind("<Enter>", self.turnRed)
\]

Notice how the widget field of the event is being accessed in the \texttt{turnRed()} callback. This field contains the widget that caught the X event. The following table lists the other event fields you can access, and how they are denoted in Tk, which can be useful when referring to the Tk man pages.
The index Parameter

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
20.1.6.8 The index Parameter

A number of widgets require ```index``` parameters to be passed. These are used to point at a specific place in a Text widget, or to particular characters in an Entry widget, or to particular menu items in a Menu widget.

**Entry widget indexes (index, view index, etc.)**
Entry widgets have options that refer to character positions in the text being displayed. You can use these `Tkinter` functions to access these special points in text widgets:

- **AtEnd()**
  refers to the last position in the text

- **AtInsert()**
  refers to the point where the text cursor is

- **AtSelFirst()**
  indicates the beginning point of the selected text

- **AtSelLast()**
  denotes the last point of the selected text and finally

- **At(x, y)**
  refers to the character at pixel location x, y (with y not used in the case of a text entry widget, which contains a single line of text).

**Text widget indexes**
The index notation for Text widgets is very rich and is best described in the Tk man pages.

**Menu indexes (menu.invoke(), menu.entryconfig(), etc.)**
Some options and methods for menus manipulate specific menu entries. Anytime a menu index is needed for an option or a parameter, you may pass in:
• an integer which refers to the numeric position of the entry in the widget, counted from the top, starting with 0;
• the string 'active', which refers to the menu position that is currently under the cursor;
• the string "last" which refers to the last menu item;
• An integer preceded by @, as in @6, where the integer is interpreted as a y pixel coordinate in the menu's coordinate system;
• the string "none", which indicates no menu entry at all, most often used with menu.activate() to deactivate all entries, and finally,
• a text string that is pattern matched against the label of the menu entry, as scanned from the top of the menu to the bottom. Note that this index type is considered after all the others, which means that matches for menu items labelled last, active, or none may be interpreted as the above literals, instead.
20.1.6.9 Images

Bitmap/Pixelmap images can be created through the subclasses of Tkinter.Image:

- **BitmapImage** can be used for X11 bitmap data.
- **PhotoImage** can be used for GIF and PPM/PGM color bitmaps.

Either type of image is created through either the **file** or the **data** option (other options are available as well).

The image object can then be used wherever an image option is supported by some widget (e.g. labels, buttons, menus). In these cases, Tk will not keep a reference to the image. When the last Python reference to the image object is deleted, the image data is deleted as well, and Tk will display an empty box wherever the image was used.
20.2.2.1 Basic Widgets

class Balloon()

A Balloon that pops up over a widget to provide help. When the user moves the cursor inside a widget to which a Balloon widget has been bound, a small pop-up window with a descriptive message will be shown on the screen.

class ButtonBox()

The ButtonBox widget creates a box of buttons, such as is commonly used for Ok Cancel.

class ComboBox()

The ComboBox widget is similar to the combo box control in MS Windows. The user can select a choice by either typing in the entry subwidget or selecting from the listbox subwidget.

class Control()

The Control widget is also known as the SpinBox widget. The user can adjust the value by pressing the two arrow buttons or by entering the value directly into the entry. The new value will be checked against the user-defined upper and lower limits.

class LabelEntry()

The LabelEntry widget packages an entry widget and a label into one mega widget. It can be used to simplify the creation of `entry-form` type of interface.

class LabelFrame()

The LabelFrame widget packages a frame widget and a label into one mega widget. To create widgets inside a LabelFrame widget, one creates the new widgets relative to the frame subwidget and manage them inside the frame subwidget.
class Meter()
    The Meter widget can be used to show the progress of a background job which may take a long time to execute.

class OptionMenu()
    The OptionMenu creates a menu button of options.

class PopupMenu()
    The PopupMenu widget can be used as a replacement of the tk_popup command. The advantage of the Tix PopupMenu widget is it requires less application code to manipulate.

class Select()
    The Select widget is a container of button subwidgets. It can be used to provide radio-box or check-box style of selection options for the user.

class StdButtonBox()
    The StdButtonBox widget is a group of standard buttons for Motif-like dialog boxes.
20.2.2.2 File Selectors

class DirList()

The DirList widget displays a list view of a directory, its previous directories and its sub-directories. The user can choose one of the directories displayed in the list or change to another directory.

class DirTree()

The DirTree widget displays a tree view of a directory, its previous directories and its sub-directories. The user can choose one of the directories displayed in the list or change to another directory.

class DirSelectDialog()

The DirSelectDialog widget presents the directories in the file system in a dialog window. The user can use this dialog window to navigate through the file system to select the desired directory.

class DirSelectBox()

The DirSelectBox is similar to the standard Motif(TM) directory-selection box. It is generally used for the user to choose a directory. DirSelectBox stores the directories mostly recently selected into a ComboBox widget so that they can be quickly selected again.

class ExFileSelectBox()

The ExFileSelectBox widget is usually embedded in a tixExFileSelectDialog widget. It provides a convenient method for the user to select files. The style of the ExFileSelectBox widget is very similar to the standard file dialog on MS Windows 3.1.

class FileSelectBox()

The FileSelectBox is similar to the standard Motif(TM) file-selection box. It is generally used for the user to choose a file. FileSelectBox stores the files mostly recently selected into a ComboBox widget so that they can be quickly selected again.
class FileEntry()

The FileEntry widget can be used to input a filename. The user can type in the filename manually. Alternatively, the user can press the button widget that sits next to the entry, which will bring up a file selection dialog.

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
20.2.2.3 Hierarchical ListBox

**class HList()**

The `HList` widget can be used to display any data that have a hierarchical structure, for example, file system directory trees. The list entries are indented and connected by branch lines according to their places in the hierarchy.

**class CheckList()**

The `CheckList` widget displays a list of items to be selected by the user. CheckList acts similarly to the Tk checkbutton or radiobutton widgets, except it is capable of handling many more items than checkbuttons or radiobuttons.

**class Tree()**

The `Tree` widget can be used to display hierarchical data in a tree form. The user can adjust the view of the tree by opening or closing parts of the tree.
20.2.2.4 Tabular ListBox

class TList()

The TList widget can be used to display data in a tabular format. The list entries of a TList widget are similar to the entries in the Tk listbox widget. The main differences are (1) the TList widget can display the list entries in a two dimensional format and (2) you can use graphical images as well as multiple colors and fonts for the list entries.
20.2.2.5 Manager Widgets

class PanedWindow()

The PanedWindow widget allows the user to interactively manipulate the sizes of several panes. The panes can be arranged either vertically or horizontally. The user changes the sizes of the panes by dragging the resize handle between two panes.

class ListNoteBook()

The ListNoteBook widget is very similar to the TixNoteBook widget: it can be used to display many windows in a limited space using a notebook metaphor. The notebook is divided into a stack of pages (windows). At one time only one of these pages can be shown. The user can navigate through these pages by choosing the name of the desired page in the hlist subwidget.

class NoteBook()

The NoteBook widget can be used to display many windows in a limited space using a notebook metaphor. The notebook is divided into a stack of pages. At one time only one of these pages can be shown. The user can navigate through these pages by choosing the visual `tabs'' at the top of the NoteBook widget.
20.2.2.6 Image Types

The Tix module adds:

- **Pixmap** capabilities to all Tix and Tkinter widgets to create color images from XPM files.

- **Compound** image types can be used to create images that consists of multiple horizontal lines; each line is composed of a series of items (texts, bitmaps, images or spaces) arranged from left to right. For example, a compound image can be used to display a bitmap and a text string simultaneously in a Tk Button widget.
20.2.2.7 Miscellaneous Widgets

class InputOnly()

    The InputOnly widgets are to accept inputs from the user, which can be done with the bind command (UNIX only).
20.2.2.8 Form Geometry Manager

In addition, `Tix` augments `Tkinter` by providing:

```
class Form():
    The `Form` geometry manager based on attachment rules for all Tk widgets.
```

Python Library Reference

Previous: 20.2.2.7 Miscellaneous Widgets Up: 20.2.2 Tix Widgets Next: 20.2.3 Tix Commands

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
20.5.1.1 File menu

New window
create a new editing window

Open...
open an existing file

Open module...
open an existing module (searches sys.path)

Class browser
show classes and methods in current file

Path browser
show sys.path directories, modules, classes and methods

Save
save current window to the associated file (unsaved windows have a * before and after the window title)

Save As...
save current window to new file, which becomes the associated file

Save Copy As...
save current window to different file without changing the associated file

Close
close current window (asks to save if unsaved)

Exit
close all windows and quit IDLE (asks to save if unsaved)
20.5.1.2 Edit menu

**Undo**
Undo last change to current window (max 1000 changes)

**Redo**
Redo last undone change to current window

**Cut**
Copy selection into system-wide clipboard; then delete selection

**Copy**
Copy selection into system-wide clipboard

**Paste**
Insert system-wide clipboard into window

**Select All**
Select the entire contents of the edit buffer

**Find...**
Open a search dialog box with many options

**Find again**
Repeat last search

**Find selection**
Search for the string in the selection

**Find in Files...**
Open a search dialog box for searching files

**Replace...**
Open a search-and-replace dialog box

**Go to line**
Ask for a line number and show that line

**Indent region**
Shift selected lines right 4 spaces

**Dedent region**
Shift selected lines left 4 spaces

**Comment out region**
Insert ## in front of selected lines

**Uncomment region**
Remove leading # or ## from selected lines

**Tabify region**
Turn *leading* stretches of spaces into tabs

**Untabify region**
Turn *all* tabs into the right number of spaces

**Expand word**
Expand the word you have typed to match another word in the same buffer; repeat to get a different expansion

**Format Paragraph**
Reformat the current blank-line-separated paragraph

**Import module**
Import or reload the current module

**Run script**
Execute the current file in the __main__ namespace
20.5.1.3 Windows menu

**Zoom Height**

toggles the window between normal size (24x80) and maximum height.

The rest of this menu lists the names of all open windows; select one to bring it to the foreground (deiconifying it if necessary).
20.5.1.4 Debug menu (in the Python Shell window only)

Go to file/line
look around the insert point for a filename and linenumber, open the file, and show the line.

Open stack viewer
show the stack traceback of the last exception

Debugger toggle
Run commands in the shell under the debugger

JIT Stack viewer toggle
Open stack viewer on traceback
20.5.2.1 Automatic indentation

After a block-opening statement, the next line is indented by 4 spaces (in the Python Shell window by one tab). After certain keywords (break, return etc.) the next line is dedented. In leading indentation, Backspace deletes up to 4 spaces if they are there. Tab inserts 1-4 spaces (in the Python Shell window one tab). See also the indent/dedent region commands in the edit menu.
20.5.2.2 Python Shell window

- `c-c` interrupts executing command
- `c-d` sends end-of-file; closes window if typed at a ">>>>" prompt

- `Alt-p` retrieves previous command matching what you have typed
- `Alt-n` retrieves next
- `Return` while on any previous command retrieves that command
- `Alt-/` (Expand word) is also useful here
20.5.3.1 Command line usage

idle.py [-c command] [-d] [-e] [-s] [-t title] [arg] ...

- `c command` run this command
- `-d` enable debugger
- `-e` edit mode; arguments are files to be edited
- `-s` run $IDLESTARTUP or $PYTHONSTARTUP first
- `-t title` set title of shell window

If there are arguments:

1. If `-e` is used, arguments are files opened for editing and `sys.argv` reflects the arguments passed to IDLE itself.

2. Otherwise, if `-c` is used, all arguments are placed in `sys.argv[1:]`, with `sys.argv[0]` set to '-c'.

3. Otherwise, if neither `-e` nor `-c` is used, the first argument is a script which is executed with the remaining arguments in `sys.argv[1:]` and `sys.argv[0]` set to the script name. If the script name is '-', no script is executed but an interactive Python session is started; the arguments are still available in `sys.argv`. 
21.1.2.1 The NullTranslations class

Translation classes are what actually implement the translation of original source file message strings to translated message strings. The base class used by all translation classes is NullTranslations; this provides the basic interface you can use to write your own specialized translation classes. Here are the methods of NullTranslations:

__init__(fp)

Takes an optional file object fp, which is ignored by the base class. Initializes "protected" instance variables __info and __charset which are set by derived classes, as well as __fallback, which is set through add_fallback. It then calls self.__parse(fp) if fp is not None.

__parse(fp)

No-op'd in the base class, this method takes file object fp, and reads the data from the file, initializing its message catalog. If you have an unsupported message catalog file format, you should override this method to parse your format.

add_fallback(fallback)

Add fallback as the fallback object for the current translation object. A translation object should consult the fallback if it cannot provide a translation for a given message.

gettext(message)

If a fallback has been set, forward gettext() to the fallback. Otherwise, return the translated message. Overridden in derived classes.

lgettext(message)

If a fallback has been set, forward lgettext() to the fallback. Otherwise, return the translated message. Overridden in derived classes.

New in version 2.4.
**uggettext**(message)

If a fallback has been set, forward `uggettext()` to the fallback. Otherwise, return the translated message as a Unicode string. Overridden in derived classes.

**ngettext**(singular, plural, n)

If a fallback has been set, forward `ngettext()` to the fallback. Otherwise, return the translated message. Overridden in derived classes.

New in version 2.3.

**lngettext**(singular, plural, n)

If a fallback has been set, forward `ngettext()` to the fallback. Otherwise, return the translated message. Overridden in derived classes.

New in version 2.4.

**ungettext**(singular, plural, n)

If a fallback has been set, forward `ungettext()` to the fallback. Otherwise, return the translated message as a Unicode string. Overridden in derived classes.

New in version 2.3.

**info()**

Return the ``protected`` `_info` variable.

**charset()**

Return the ``protected`` `_charset` variable.

**output_charset()**

Return the ``protected`` `_output_charset` variable, which defines the encoding used to return translated messages.

New in version 2.4.

**set_output_charset**(charset)
Change the ``protected'' _output_charset variable, which defines the encoding used to return translated messages.

New in version 2.4.

install([unicode [, names]])

If the unicode flag is false, this method installs self.gettext() into the built-in namespace, binding it to "_". If unicode is true, it binds self.ugettext() instead. By default, unicode is false.

If the names parameter is given, it must be a sequence containing the names of functions you want to install in the builtin namespace in addition to _(). Supported names are 'gettext' (bound to self.gettext() or self.ugettext() according to the unicode flag), 'ngettext' (bound to self.ngettext() or self.ungettext() according to the unicode flag), 'lgettext' and 'lngettext'.

Note that this is only one way, albeit the most convenient way, to make the _ function available to your application. Because it affects the entire application globally, and specifically the built-in namespace, localized modules should never install _. Instead, they should use this code to make _ available to their module:

```python
import gettext
t = gettext.translation('mymodule', ...)
_ = t.gettext
```

This puts _ only in the module's global namespace and so only affects calls within this module.

Changed in version 2.5: Added the names parameter.
21.1.2.2 The GNUTranslations class

The gettext module provides one additional class derived from NullTranslations: GNUTranslations. This class overrides _parse() to enable reading GNU gettext format .mo files in both big-endian and little-endian format. It also coerces both message ids and message strings to Unicode.

GNUTranslations parses optional meta-data out of the translation catalog. It is convention with GNU gettext to include meta-data as the translation for the empty string. This meta-data is in RFC 822-style key: value pairs, and should contain the Project-Id-Version key. If the key Content-Type is found, then the charset property is used to initialize the "protected" _charset instance variable, defaulting to None if not found. If the charset encoding is specified, then all message ids and message strings read from the catalog are converted to Unicode using this encoding. The ugettext() method always returns a Unicode, while the gettext() returns an encoded 8-bit string. For the message id arguments of both methods, either Unicode strings or 8-bit strings containing only US-ASCII characters are acceptable. Note that the Unicode version of the methods (i.e. ugettext() and ungettext()) are the recommended interface to use for internationalized Python programs.

The entire set of key/value pairs are placed into a dictionary and set as the "protected" _info instance variable.

If the .mo file's magic number is invalid, or if other problems occur while reading the file, instantiating a GNUTranslations class can raise IOError.

The following methods are overridden from the base class implementation:

gettext( message)
Look up the message id in the catalog and return the corresponding message string, as an 8-bit string encoded with the catalog's charset encoding, if known. If there is no entry in the catalog for the message id, and a fallback has been set, the look up is forwarded to the fallback's
gettext() method. Otherwise, the message id is returned.

lgettext(message)
Equivalent to gettext(), but the translation is returned in the preferred system encoding, if no other encoding was explicitly set with set_output_charset().

New in version 2.4.

ugettext(message)
Look up the message id in the catalog and return the corresponding message string, as a Unicode string. If there is no entry in the catalog for the message id, and a fallback has been set, the look up is forwarded to the fallback's ugettext() method. Otherwise, the message id is returned.

ngettext(singular, plural, n)
Do a plural-forms lookup of a message id. singular is used as the message id for purposes of lookup in the catalog, while n is used to determine which plural form to use. The returned message string is an 8-bit string encoded with the catalog's charset encoding, if known.

If the message id is not found in the catalog, and a fallback is specified, the request is forwarded to the fallback's ngettext() method. Otherwise, when n is 1 singular is returned, and plural is returned in all other cases.

New in version 2.3.

lngettext(singular, plural, n)
Equivalent to gettext(), but the translation is returned in the preferred system encoding, if no other encoding was explicitly set with set_output_charset().

New in version 2.4.

ungettext(singular, plural, n)
Do a plural-forms lookup of a message id. singular is used as the message id for purposes of lookup in the catalog, while n is used to determine which plural form to use. The returned message string is a Unicode string.
If the message id is not found in the catalog, and a fallback is specified, the request is forwarded to the fallback's `ungettext()` method. Otherwise, when \(n\) is 1 *singular* is returned, and *plural* is returned in all other cases.

Here is an example:

```python
n = len(os.listdir('.'))
cat = GNUTranslations(somefile)
message = cat.ungettext(
    'There is %(num)d file in this directory',
    'There are %(num)d files in this directory',
    n) % {'num': n}
```

New in version 2.3.
21.1.2.3 Solaris message catalog support

The Solaris operating system defines its own binary .mo file format, but since no documentation can be found on this format, it is not supported at this time.
21.1.2.4 The Catalog constructor

GNOME uses a version of the gettext module by James Henstridge, but this version has a slightly different API. Its documented usage was:

```python
import gettext
cat = gettextCatalog(domain, localedir)
_ = cat.gettext
print _('hello world')
```

For compatibility with this older module, the function Catalog() is an alias for the translation() function described above.

One difference between this module and Henstridge's: his catalog objects supported access through a mapping API, but this appears to be unused and so is not currently supported.
21.1.3.1 Localizing your module

If you are localizing your module, you must take care not to make global changes, e.g. to the built-in namespace. You should not use the GNU gettext API but instead the class-based API.

Let's say your module is called ``spam'' and the module's various natural language translation .mo files reside in /usr/share/locale in GNU gettext format. Here's what you would put at the top of your module:

```python
import gettext
t = gettext.translation('spam', '/usr/share/locale')
_ = t.lgettext
```

If your translators were providing you with Unicode strings in their .po files, you'd instead do:

```python
import gettext
t = gettext.translation('spam', '/usr/share/locale')
_ = t.ugettext
```

---

Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
21.1.3.2 Localizing your application

If you are localizing your application, you can install the \_( )\ function globally into the built-in namespace, usually in the main driver file of your application. This will let all your application-specific files just use \_( ' . . ' )\ without having to explicitly install it in each file.

In the simple case then, you need only add the following bit of code to the main driver file of your application:

```python
import gettext
gettext.install('myapplication')
```

If you need to set the locale directory or the `unicode` flag, you can pass these into the `install()` function:

```python
import gettext
gettext.install('myapplication', '/usr/share/locale', unicode=1)
```
21.1.3.3 Changing languages on the fly

If your program needs to support many languages at the same time, you may want to create multiple translation instances and then switch between them explicitly, like so:

```python
import gettext

lang1 = gettext.translation('myapplication', languages=['en'])
lang2 = gettext.translation('myapplication', languages=['fr'])
lang3 = gettext.translation('myapplication', languages=['de'])

# start by using language1
lang1.install()

# ... time goes by, user selects language 2
lang2.install()

# ... more time goes by, user selects language 3
lang3.install()
```
In most coding situations, strings are translated where they are coded. Occasionally however, you need to mark strings for translation, but defer actual translation until later. A classic example is:

```python
animals = ['mollusk',
           'albatross',
           'rat',
           'penguin',
           'python',
]
#
for a in animals:
    print a
```

Here, you want to mark the strings in the `animals` list as being translatable, but you don’t actually want to translate them until they are printed.

Here is one way you can handle this situation:

```python
def _(message): return message
animals = [_(m) for m in
           'mollusk',
           'albatross',
           'rat',
           'penguin',
           'python',
          ]
del _
#
for a in animals:
    print _(a)
```

This works because the dummy definition of `_` simply returns the string unchanged. And this dummy definition will temporarily override any definition of `_` in the built-in namespace (until the `del` command). Take care, though if you have a previous definition of `_` in the local namespace.
Note that the second use of \_( )\ will not identify ``a'' as being translatable to the \texttt{pygettext} program, since it is not a string.

Another way to handle this is with the following example:

\begin{verbatim}
    def N_(message): return message

    animals = [N_('mollusk'),
               N_('albatross'),
               N_('rat'),
               N_('penguin'),
               N_('python'),
               ]

    # ...
    for a in animals:
        print \_(a)
\end{verbatim}

In this case, you are marking translatable strings with the function \texttt{N\_()},\footnote{21.5} which won't conflict with any definition of \_( ). However, you will need to teach your message extraction program to look for translatable strings marked with \texttt{N\_()}. \texttt{pygettext} and \texttt{xpot} both support this through the use of command line switches.

---

**Footnotes**

\footnote{21.5} The choice of \texttt{N\_()} here is totally arbitrary; it could have just as easily been \texttt{MarkThisStringForTranslation()}.
21.1.3.5 gettext() vs. lgettext()

In Python 2.4 the lgettext() family of functions were introduced. The intention of these functions is to provide an alternative which is more compliant with the current implementation of GNU gettext. Unlike gettext(), which returns strings encoded with the same codeset used in the translation file, lgettext() will return strings encoded with the preferred system encoding, as returned by locale.getpreferredencoding(). Also notice that Python 2.4 introduces new functions to explicitly choose the codeset used in translated strings. If a codeset is explicitly set, even lgettext() will return translated strings in the requested codeset, as would be expected in the GNU gettext implementation.
23.2.3.1 Which Docstrings Are Examined?

The module docstring, and all function, class and method docstrings are searched. Objects imported into the module are not searched.

In addition, if M.__test__ exists and "is true", it must be a dict, and each entry maps a (string) name to a function object, class object, or string. Function and class object docstrings found from M.__test__ are searched, and strings are treated as if they were docstrings. In output, a key K in M.__test__ appears with name

\[<\text{name of M}>.__\text{test__}.K\]

Any classes found are recursively searched similarly, to test docstrings in their contained methods and nested classes.

Changed in version 2.4: A "private name" concept is deprecated and no longer documented.
23.2.3.2 How are Docstring Examples Recognized?

In most cases a copy-and-paste of an interactive console session works fine, but doctest isn't trying to do an exact emulation of any specific Python shell. All hard tab characters are expanded to spaces, using 8-column tab stops. If you don't believe tabs should mean that, too bad: don't use hard tabs, or write your own DocTestParser class.

Changed in version 2.4: Expanding tabs to spaces is new; previous versions tried to preserve hard tabs, with confusing results.

```python
>>> # comments are ignored
>>> x = 12
>>> x
12
>>> if x == 13:
...    print "yes"
... else:
...    print "no"
...    print "NO"
...    print "NO!!"
...
no
NO
NO!!
>>>```

Any expected output must immediately follow the final '>>> ' or '...
line containing the code, and the expected output (if any) extends to the next '>>> ' or all-whitespace line.

The fine print:

- Expected output cannot contain an all-whitespace line, since such a line is taken to signal the end of expected output. If expected output does contain a blank line, put `<BLANKLINE>` in your doctest example each place a blank line is expected. Changed in version 2.4: `<BLANKLINE>` was added; there was no way to use expected output containing empty lines in previous versions.
• Output to stdout is captured, but not output to stderr (exception tracebacks are captured via a different means).

• If you continue a line via backslashing in an interactive session, or for any other reason use a backslash, you should use a raw docstring, which will preserve your backslashes exactly as you type them:

```python
>>> def f(x):
    ...   r'''Backslashes in a raw docstring: m\n'''
>>> print f.__doc__
Backslashes in a raw docstring: m
```

Otherwise, the backslash will be interpreted as part of the string. For example, the "\" above would be interpreted as a newline character. Alternatively, you can double each backslash in the doctest version (and not use a raw string):

```python
>>> def f(x):
    ...   ''Backslashes in a raw docstring: m\n''
>>> print f.__doc__
Backslashes in a raw docstring: m
```

• The starting column doesn't matter:

```python
>>> assert "Easy!"
>>> import math
    >>> math.floor(1.9)
1.0
```

and as many leading whitespace characters are stripped from the expected output as appeared in the initial '>>> ' line that started the example.
23.2.3.3 What's the Execution Context?

By default, each time `doctest` finds a docstring to test, it uses a shallow copy of M's globals, so that running tests doesn't change the module's real globals, and so that one test in M can't leave behind crumbs that accidentally allow another test to work. This means examples can freely use any names defined at top-level in M, and names defined earlier in the docstring being run. Examples cannot see names defined in other docstrings.

You can force use of your own own dict as the execution context by passing `globs=your_dict` to `testmod()` or `testfile()` instead.
23.2.3.4 What About Exceptions?

No problem, provided that the traceback is the only output produced by the example: just paste in the traceback. Since tracebacks contain details that are likely to change rapidly (for example, exact file paths and line numbers), this is one case where doctest works hard to be flexible in what it accepts.

Simple example:

```python
>>> [1, 2, 3].remove(42)
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
ValueError: list.remove(x): x not in list
```

That doctest succeeds if `ValueError` is raised, with the "list.remove(x): x not in list" detail as shown.

The expected output for an exception must start with a traceback header, which may be either of the following two lines, indented the same as the first line of the example:

```plaintext
Traceback (most recent call last):
Traceback (innermost last):
```

The traceback header is followed by an optional traceback stack, whose contents are ignored by doctest. The traceback stack is typically omitted, or copied verbatim from an interactive session.

The traceback stack is followed by the most interesting part: the line(s) containing the exception type and detail. This is usually the last line of a traceback, but can extend across multiple lines if the exception has a multi-line detail:

```python
>>> raise ValueError('multi
				line
detail')
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
ValueError: multi
  line
detail
```
The last three lines (starting with `ValueError`) are compared against the exception's type and detail, and the rest are ignored.

Best practice is to omit the traceback stack, unless it adds significant documentation value to the example. So the last example is probably better as:

```python
>>> raise ValueError('multi
	line
detail')
Traceback (most recent call last):
...
ValueError: multi
line
detail
```

Note that tracebacks are treated very specially. In particular, in the rewritten example, the use of "..." is independent of doctest's ELLIPSIS option. The ellipsis in that example could be left out, or could just as well be three (or three hundred) commas or digits, or an indented transcript of a Monty Python skit.

Some details you should read once, but won't need to remember:

- Doctest can't guess whether your expected output came from an exception traceback or from ordinary printing. So, e.g., an example that expects "ValueError: 42 is prime" will pass whether `ValueError` is actually raised or if the example merely prints that traceback text. In practice, ordinary output rarely begins with a traceback header line, so this doesn't create real problems.

- Each line of the traceback stack (if present) must be indented further than the first line of the example, or start with a non-alphanumeric character. The first line following the traceback header indented the same and starting with an alphanumeric is taken to be the start of the exception detail. Of course this does the right thing for genuine tracebacks.

- When the `IGNORE_EXCEPTION_DETAIL` doctest option is is specified, everything following the leftmost colon is ignored.

- The interactive shell omits the traceback header line for some `SyntaxErrors`. But doctest uses the traceback header line to distinguish exceptions from non-exceptions. So in the rare case where you need to test a `SyntaxError` that omits the traceback header, you will need to manually add the traceback header line to your test example.
For some SyntaxErrors, Python displays the character position of the syntax error, using a ^ marker:

```python
>>> 1 1
  File "<stdin>", line 1
  1 1
  ^
  SyntaxError: invalid syntax
```

Since the lines showing the position of the error come before the exception type and detail, they are not checked by doctest. For example, the following test would pass, even though it puts the ^ marker in the wrong location:

```python
>>> 1 1
  Traceback (most recent call last):
  File "<stdin>", line 1
  1 1
  ^
  SyntaxError: invalid syntax
```

Changed in version 2.4: The ability to handle a multi-line exception detail, and the IGNORE_EXCEPTION_DETAIL doctest option, were added.

---

Footnotes

... traceback.\(^{23.1}\)

Examples containing both expected output and an exception are not supported. Trying to guess where one ends and the other begins is too error-prone, and that also makes for a confusing test.
23.2.3.5 Option Flags and Directives

A number of option flags control various aspects of doctest's behavior. Symbolic names for the flags are supplied as module constants, which can be or'ed together and passed to various functions. The names can also be used in doctest directives (see below).

The first group of options define test semantics, controlling aspects of how doctest decides whether actual output matches an example's expected output:

**DONT_ACCEPT_TRUE_FOR_1**
By default, if an expected output block contains just 1, an actual output block containing just 1 or just True is considered to be a match, and similarly for 0 versus False. When DONT_ACCEPT_TRUE_FOR_1 is specified, neither substitution is allowed. The default behavior caters to that Python changed the return type of many functions from integer to boolean; doctests expecting "little integer" output still work in these cases. This option will probably go away, but not for several years.

**DONT_ACCEPT_BLANKLINE**
By default, if an expected output block contains a line containing only the string `<BLANKLINE>`, then that line will match a blank line in the actual output. Because a genuinely blank line delimits the expected output, this is the only way to communicate that a blank line is expected. When DONT_ACCEPT_BLANKLINE is specified, this substitution is not allowed.

**NORMALIZE_WHITESPACE**
When specified, all sequences of whitespace (blanks and newlines) are treated as equal. Any sequence of whitespace within the expected output will match any sequence of whitespace within the actual output. By default, whitespace must match exactly. NORMALIZE_WHITESPACE is especially useful when a line of expected output is very long, and you want to wrap it across multiple lines in your source.

**ELLIPSIS**
When specified, an ellipsis marker (\ldots) in the expected output can match any substring in the actual output. This includes substrings that span line boundaries, and empty substrings, so it's best to keep usage of this simple. Complicated uses can lead to the same kinds of "oops, it matched too much!" surprises that .* is prone to in regular expressions.

**IGNORE_EXCEPTION_DETAIL**

When specified, an example that expects an exception passes if an exception of the expected type is raised, even if the exception detail does not match. For example, an example expecting "ValueError: 42" will pass if the actual exception raised is "ValueError: 3*14", but will fail, e.g., if TypeError is raised.

Note that a similar effect can be obtained using ELLIPSIS, and IGNORE_EXCEPTION_DETAIL may go away when Python releases prior to 2.4 become uninteresting. Until then, IGNORE_EXCEPTION_DETAIL is the only clear way to write a doctest that doesn't care about the exception detail yet continues to pass under Python releases prior to 2.4 (doctest directives appear to be comments to them). For example,

```
>>> (1, 2)[3] = 'moo' #doctest: +IGNORE_EXCEPTION_DETAIL
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
TypeError: object doesn't support item assignment
```

passes under Python 2.4 and Python 2.3. The detail changed in 2.4, to say "does not" instead of "doesn't".

**SKIP**

When specified, do not run the example at all. This can be useful in contexts where doctest examples serve as both documentation and test cases, and an example should be included for documentation purposes, but should not be checked. E.g., the example's output might be random; or the example might depend on resources which would be unavailable to the test driver.

The SKIP flag can also be used for temporarily "commenting out" examples.
COMPARISON_FLAGS
   A bitmask or’ing together all the comparison flags above.

The second group of options controls how test failures are reported:

REPORT_UDIFF
   When specified, failures that involve multi-line expected and actual outputs are displayed using a unified diff.

REPORT_CDIFF
   When specified, failures that involve multi-line expected and actual outputs will be displayed using a context diff.

REPORT_NDIFF
   When specified, differences are computed by difflib.Differ, using the same algorithm as the popular ndiff.py utility. This is the only method that marks differences within lines as well as across lines. For example, if a line of expected output contains digit 1 where actual output contains letter l, a line is inserted with a caret marking the mismatching column positions.

REPORT_ONLY_FIRST_FAILURE
   When specified, display the first failing example in each doctest, but suppress output for all remaining examples. This will prevent doctest from reporting correct examples that break because of earlier failures; but it might also hide incorrect examples that fail independently of the first failure. When REPORT_ONLY_FIRST_FAILURE is specified, the remaining examples are still run, and still count towards the total number of failures reported; only the output is suppressed.

REPORTING_FLAGS
   A bitmask or’ing together all the reporting flags above.

"Doctest directives" may be used to modify the option flags for individual examples. Doctest directives are expressed as a special Python comment following an example's source code:

```python
directive ::= "#" "doctest:"
            directive_options

directive_options ::= directive_option (",")
```

Whitespace is not allowed between the + or - and the directive option name. The directive option name can be any of the option flag names explained above.

An example's doctest directives modify doctest's behavior for that single example. Use + to enable the named behavior, or - to disable it.

For example, this test passes:

```python
>>> print range(20) # doctest: +NORMALIZE_WHITESPACE
[0, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19]
```

Without the directive it would fail, both because the actual output doesn't have two blanks before the single-digit list elements, and because the actual output is on a single line. This test also passes, and also requires a directive to do so:

```python
>>> print range(20) # doctest:+ELLIPSIS
[0, 1, ..., 18, 19]
```

Multiple directives can be used on a single physical line, separated by commas:

```python
>>> print range(20) # doctest: +ELLIPSIS, +NORMALIZE_WHITESPACE
[0, 1, ..., 18, 19]
```

If multiple directive comments are used for a single example, then they are combined:

```python
>>> print range(20) # doctest: +ELLIPSIS...
... # doctest: +NORMALIZE_WHITESPACE
[0, 1, ..., 18, 19]
```

As the previous example shows, you can add "..." lines to your example
containing only directives. This can be useful when an example is too long for a directive to comfortably fit on the same line:

```python
>>> print range(5) + range(10,20) + range(30,40) + range(50,60)
... # doctest: +ELLIPSIS
[0, ..., 4, 10, ..., 19, 30, ..., 39, 50, ..., 59]
```

Note that since all options are disabled by default, and directives apply only to the example they appear in, enabling options (via + in a directive) is usually the only meaningful choice. However, option flags can also be passed to functions that run doctests, establishing different defaults. In such cases, disabling an option via - in a directive can be useful.

Changed in version 2.4: Constants `DONT_ACCEPT_BLANKLINE`, `NORMALIZE_WHITESPACE`, `ELLIPSIS`, `IGNORE_EXCEPTION_DETAIL`, `REPORT_UDIFF`, `REPORT_CDIFF`, `REPORT_NDIFF`, `REPORT_ONLY_FIRST_FAILURE`, `COMPARISON_FLAGS` and `REPORTING_FLAGS` were added; by default `<BLANKLINE>` in expected output matches an empty line in actual output; and doctest directives were added. Changed in version 2.5: Constant `SKIP` was added.

There's also a way to register new option flag names, although this isn't useful unless you intend to extend `doctest` internals via subclassing:

```python
register_optionflag(name)
```

Create a new option flag with a given name, and return the new flag's integer value. `register_optionflag()` can be used when subclassing `OutputChecker` or `DocTestRunner` to create new options that are supported by your subclasses. `register_optionflag` should always be called using the following idiom:

```python
MY_FLAG = register_optionflag('MY_FLAG')
```

New in version 2.4.
Release 2.5, documentation updated on 19th September, 2006. See About this document... for information on suggesting changes.
23.2.3.6 Warnings

doctest is serious about requiring exact matches in expected output. If even a single character doesn't match, the test fails. This will probably surprise you a few times, as you learn exactly what Python does and doesn't guarantee about output. For example, when printing a dict, Python doesn't guarantee that the key-value pairs will be printed in any particular order, so a test like

```python
>>> foo()
{'Hermione': 'hippogryph', 'Harry': 'broomstick'}
```

is vulnerable! One workaround is to do

```python
>>> foo() == {'Hermione': 'hippogryph', 'Harry': 'broomstick'}
True
```

instead. Another is to do

```python
>>> d = foo().items()
>>> d.sort()
>>> d
[('Harry', 'broomstick'), ('Hermione', 'hippogryph')]
```

There are others, but you get the idea.

Another bad idea is to print things that embed an object address, like

```python
>>> id(1.0) # certain to fail some of the time
7948648
>>> class C: pass
>>> C() # the default repr() for instances embeds an address
<__main__.C instance at 0x00AC18F0>
```

The ELLIPSIS directive gives a nice approach for the last example:

```python
>>> C() # doctest: +ELLIPSIS
<__main__.C instance at 0x...>
```

Floating-point numbers are also subject to small output variations across platforms, because Python defers to the platform C library for float formatting,
and C libraries vary widely in quality here.

```python
>>> 1./7  # risky
0.14285714285714285
>>> print 1./7 # safer
0.142857142857
>>> print round(1./7, 6) # much safer
0.142857
```

Numbers of the form $I/2^J$ are safe across all platforms, and I often contrive doctest examples to produce numbers of that form:

```python
>>> 3./4  # utterly safe
0.75
```

Simple fractions are also easier for people to understand, and that makes for better documentation.
23.2.6.1 DocTest Objects

class DocTest( examples, globs, name, filename, lineno, docstring)

A collection of doctest examples that should be run in a single namespace. The constructor arguments are used to initialize the member variables of the same names. New in version 2.4.

DocTest defines the following member variables. They are initialized by the constructor, and should not be modified directly.

examples
A list of Example objects encoding the individual interactive Python examples that should be run by this test.

globs
The namespace (aka globals) that the examples should be run in. This is a dictionary mapping names to values. Any changes to the namespace made by the examples (such as binding new variables) will be reflected in globs after the test is run.

name
A string name identifying the DocTest. Typically, this is the name of the object or file that the test was extracted from.

filename
The name of the file that this DocTest was extracted from; or None if the filename is unknown, or if the DocTest was not extracted from a file.

lineno
The line number within filename where this DocTest begins, or None if the line number is unavailable. This line number is zero-based with respect to the beginning of the file.

docstring
The string that the test was extracted from, or `None` if the string is
unavailable, or if the test was not extracted from a string.
23.2.6.2 Example Objects

class Example( source, want[, exc_msg][, lineno][, indent][, options])

A single interactive example, consisting of a Python statement and its expected output. The constructor arguments are used to initialize the member variables of the same names. New in version 2.4.

Example defines the following member variables. They are initialized by the constructor, and should not be modified directly.

**source**
A string containing the example's source code. This source code consists of a single Python statement, and always ends with a newline; the constructor adds a newline when necessary.

**want**
The expected output from running the example's source code (either from stdout, or a traceback in case of exception). **want** ends with a newline unless no output is expected, in which case it's an empty string. The constructor adds a newline when necessary.

**exc_msg**
The exception message generated by the example, if the example is expected to generate an exception; or None if it is not expected to generate an exception. This exception message is compared against the return value of traceback.format_exception_only(). **exc_msg** ends with a newline unless it's None. The constructor adds a newline if needed.

**lineno**
The line number within the string containing this example where the example begins. This line number is zero-based with respect to the beginning of the containing string.

**indent**
The example's indentation in the containing string, i.e., the number of space
characters that precede the example's first prompt.

**options**

A dictionary mapping from option flags to `True` or `False`, which is used to override default options for this example. Any option flags not contained in this dictionary are left at their default value (as specified by the `DocTestRunner`'s `optionflags`). By default, no options are set.
23.2.6.3 DocTestFinder objects

class DocTestFinder([verbose][, parser][, recurse][, exclude_empty])

A processing class used to extract the DocTests that are relevant to a
given object, from its docstring and the docstrings of its contained objects.
DocTests can currently be extracted from the following object types:
modules, functions, classes, methods, staticmethods, classmethods, and
properties.

The optional argument verbose can be used to display the objects searched
by the finder. It defaults to False (no output).

The optional argument parser specifies the DocTestParser object (or a
drop-in replacement) that is used to extract doctests from docstrings.

If the optional argument recurse is false, then DocTestFinder.find() will only examine the given object, and not any contained objects.

If the optional argument exclude_empty is false, then DocTestFinder.find() will include tests for objects with empty
docstrings.

New in version 2.4.

DocTestFinder defines the following method:

find( obj[, name][, module][, globs][, extraglobs])

Return a list of the DocTests that are defined by obj's docstring, or by any
of its contained objects' docstrings.

The optional argument name specifies the object's name; this name will be
used to construct names for the returned DocTests. If name is not
specified, then obj.__name__ is used.

The optional parameter module is the module that contains the given object.
If the module is not specified or is None, then the test finder will attempt to automatically determine the correct module. The object's module is used:

- As a default namespace, if `globs` is not specified.
- To prevent the DocTestFinder from extracting DocTests from objects that are imported from other modules. (Contained objects with modules other than `module` are ignored.)
- To find the name of the file containing the object.
- To help find the line number of the object within its file.

If `module` is `False`, no attempt to find the module will be made. This is obscure, of use mostly in testing doctest itself: if `module` is `False`, or is `None` but cannot be found automatically, then all objects are considered to belong to the (non-existent) module, so all contained objects will (recursively) be searched for doctests.

The globals for each `DocTest` is formed by combining `globs` and `extraglobs` (bindings in `extraglobs` override bindings in `globs`). A new shallow copy of the globals dictionary is created for each `DocTest`. If `globs` is not specified, then it defaults to the module's `__dict__`, if specified, or `{}` otherwise. If `extraglobs` is not specified, then it defaults to `{}`.
23.2.6.4 DocTestParser objects

class DocTestParser()

A processing class used to extract interactive examples from a string, and use them to create a DocTest object. New in version 2.4.

DocTestParser defines the following methods:

get_doctest( string, globs, name, filename, lineno)

Extract all doctest examples from the given string, and collect them into a DocTest object.

globs, name, filename, and lineno are attributes for the new DocTest object. See the documentation for DocTest for more information.

get_examples( string[, name])

Extract all doctest examples from the given string, and return them as a list of Example objects. Line numbers are 0-based. The optional argument name is a name identifying this string, and is only used for error messages.

parse( string[, name])

Divide the given string into examples and intervening text, and return them as a list of alternating Examples and strings. Line numbers for the Examples are 0-based. The optional argument name is a name identifying this string, and is only used for error messages.
23.2.6.5 DocTestRunner objects

class DocTestRunner( [checker][, verbose][, optionflags])

A processing class used to execute and verify the interactive examples in a DocTest.

The comparison between expected outputs and actual outputs is done by an OutputChecker. This comparison may be customized with a number of option flags; see section 23.2.3 for more information. If the option flags are insufficient, then the comparison may also be customized by passing a subclass of OutputChecker to the constructor.

The test runner's display output can be controlled in two ways. First, an output function can be passed to TestRunner.run(); this function will be called with strings that should be displayed. It defaults to sys.stdout.write. If capturing the output is not sufficient, then the display output can be also customized by subclassing DocTestRunner, and overriding the methods report_start, report_success, report_unexpected_exception, and report_failure.

The optional keyword argument checker specifies the OutputChecker object (or drop-in replacement) that should be used to compare the expected outputs to the actual outputs of doctest examples.

The optional keyword argument verbose controls the DocTestRunner's verbosity. If verbose is True, then information is printed about each example, as it is run. If verbose is False, then only failures are printed. If verbose is unspecified, or None, then verbose output is used iff the command-line switch -v is used.

The optional keyword argument optionflags can be used to control how the test runner compares expected output to actual output, and how it displays failures. For more information, see section 23.2.3.

New in version 2.4.
DocTestParser defines the following methods:

\textbf{report\_start}(\texttt{out, test, example})

Report that the test runner is about to process the given example. This method is provided to allow subclasses of \texttt{DocTestRunner} to customize their output; it should not be called directly.

\textit{example} is the example about to be processed. \textit{test} is the test containing \textit{example}. \textit{out} is the output function that was passed to \texttt{DocTestRunner.run()}. 

\textbf{report\_success}(\texttt{out, test, example, got})

Report that the given example ran successfully. This method is provided to allow subclasses of \texttt{DocTestRunner} to customize their output; it should not be called directly.

\textit{example} is the example about to be processed. \textit{got} is the actual output from the example. \textit{test} is the test containing \textit{example}. \textit{out} is the output function that was passed to \texttt{DocTestRunner.run()}. 

\textbf{report\_failure}(\texttt{out, test, example, got})

Report that the given example failed. This method is provided to allow subclasses of \texttt{DocTestRunner} to customize their output; it should not be called directly.

\textit{example} is the example about to be processed. \textit{got} is the actual output from the example. \textit{test} is the test containing \textit{example}. \textit{out} is the output function that was passed to \texttt{DocTestRunner.run()}. 

\textbf{report\_unexpected\_exception}(\texttt{out, test, example, exc\_info})

Report that the given example raised an unexpected exception. This method is provided to allow subclasses of \texttt{DocTestRunner} to customize their output; it should not be called directly.

\textit{example} is the example about to be processed. \textit{exc\_info} is a tuple containing information about the unexpected exception (as returned by \texttt{sys.exc\_info()}). \textit{test} is the test containing \textit{example}. \textit{out} is the output function that was passed to \texttt{DocTestRunner.run()}. 
**run**(*test[, compileflags][, out][, clear_globs]*)

Run the examples in *test* (a DocTest object), and display the results using the writer function *out*.

The examples are run in the namespace *test.globs*. If *clear_globs* is true (the default), then this namespace will be cleared after the test runs, to help with garbage collection. If you would like to examine the namespace after the test completes, then use *clear_globs=False*.

*compileflags* gives the set of flags that should be used by the Python compiler when running the examples. If not specified, then it will default to the set of future-import flags that apply to *globs*.

The output of each example is checked using the DocTestRunner's output checker, and the results are formatted by the DocTestRunner.report_* methods.

**summarize**(*[verbose]*)

Print a summary of all the test cases that have been run by this DocTestRunner, and return a tuple "(*failure_count*,  *test_count*)".

The optional *verbose* argument controls how detailed the summary is. If the verbosity is not specified, then the DocTestRunner's verbosity is used.
23.2.6.6 OutputChecker objects

class OutputChecker()

A class used to check the whether the actual output from a doctest example matches the expected output. OutputChecker defines two methods: check_output, which compares a given pair of outputs, and returns true if they match; and output_difference, which returns a string describing the differences between two outputs. New in version 2.4.

OutputChecker defines the following methods:

check_output( want, got, optionflags)

Return True iff the actual output from an example (got) matches the expected output (want). These strings are always considered to match if they are identical; but depending on what option flags the test runner is using, several non-exact match types are also possible. See section 23.2.3 for more information about option flags.

output_difference( example, got, optionflags)

Return a string describing the differences between the expected output for a given example (example) and the actual output (got). optionflags is the set of option flags used to compare want and got.
30.1.6.1 Emulation of compile()

While many useful operations may take place between parsing and bytecode generation, the simplest operation is to do nothing. For this purpose, using the parser module to produce an intermediate data structure is equivalent to the code

```python
>>> code = compile('a + 5', 'file.py', 'eval')
>>> a = 5
>>> eval(code)
10
```

The equivalent operation using the parser module is somewhat longer, and allows the intermediate internal parse tree to be retained as an AST object:

```python
>>> import parser
>>> ast = parser.expr('a + 5')
>>> code = ast.compile('file.py')
>>> a = 5
>>> eval(code)
10
```

An application which needs both AST and code objects can package this code into readily available functions:

```python
import parser

def load_suite(source_string):
    ast = parser.suite(source_string)
    return ast, ast.compile()

def load_expression(source_string):
    ast = parser.expr(source_string)
    return ast, ast.compile()
```
Release 2.5, documentation updated on 19th September, 2006.
See About this document... for information on suggesting changes.
30.1.6.2 Information Discovery

Some applications benefit from direct access to the parse tree. The remainder of this section demonstrates how the parse tree provides access to module documentation defined in docstrings without requiring that the code being examined be loaded into a running interpreter via `import`. This can be very useful for performing analyses of untrusted code.

Generally, the example will demonstrate how the parse tree may be traversed to distill interesting information. Two functions and a set of classes are developed which provide programmatic access to high level function and class definitions provided by a module. The classes extract information from the parse tree and provide access to the information at a useful semantic level, one function provides a simple low-level pattern matching capability, and the other function defines a high-level interface to the classes by handling file operations on behalf of the caller. All source files mentioned here which are not part of the Python installation are located in the `Demo/parser/` directory of the distribution.

The dynamic nature of Python allows the programmer a great deal of flexibility, but most modules need only a limited measure of this when defining classes, functions, and methods. In this example, the only definitions that will be considered are those which are defined in the top level of their context, e.g., a function defined by a `def` statement at column zero of a module, but not a function defined within a branch of an `if ... else` construct, though there are some good reasons for doing so in some situations. Nesting of definitions will be handled by the code developed in the example.

To construct the upper-level extraction methods, we need to know what the parse tree structure looks like and how much of it we actually need to be concerned about. Python uses a moderately deep parse tree so there are a large number of intermediate nodes. It is important to read and understand the formal grammar used by Python. This is specified in the file `Grammar/Grammar` in the distribution. Consider the simplest case of interest when searching for docstrings: a module consisting of a docstring and nothing else. (See file `docstring.py`.)
Using the interpreter to take a look at the parse tree, we find a bewildering mass of numbers and parentheses, with the documentation buried deep in nested tuples.

```python
>>> import parser
>>> import pprint
>>> ast = parser.suite(open('docstring.py').read())
>>> tup = ast.totuple()
>>> pprint.pprint(tup)
(257,
 (264,
  (265,
   (266,
    (267,
     (307,
      (287,
       (288,
        (289,
         (290,
          (292,
           (293,
            (294,
             (295,
              (296,
               (297,
                (298,
                 (299,
                  (300, (3, """Some documentation.""
                 )))))))))))))))),
  (4, '.replaceAll
  ))),
 (4, 'println
 (0, 'println

The numbers at the first element of each node in the tree are the node types; they map directly to terminal and non-terminal symbols in the grammar. Unfortunately, they are represented as integers in the internal representation, and the Python structures generated do not change that. However, the `symbol` and `token` modules provide symbolic names for the node types and dictionaries which map from the integers to the symbolic names for the node types.

In the output presented above, the outermost tuple contains four elements: the integer 257 and three additional tuples. Node type 257 has the symbolic name `file_input`. Each of these inner tuples contains an integer as the first element; these integers, 264, 4, and 0, represent the node types `stmt`,
NEWLINE, and ENDMARKER, respectively. Note that these values may change depending on the version of Python you are using; consult symbol.py and token.py for details of the mapping. It should be fairly clear that the outermost node is related primarily to the input source rather than the contents of the file, and may be disregarded for the moment. The stmt node is much more interesting. In particular, all docstrings are found in subtrees which are formed exactly as this node is formed, with the only difference being the string itself. The association between the docstring in a similar tree and the defined entity (class, function, or module) which it describes is given by the position of the docstring subtree within the tree defining the described structure.

By replacing the actual docstring with something to signify a variable component of the tree, we allow a simple pattern matching approach to check any given subtree for equivalence to the general pattern for docstrings. Since the example demonstrates information extraction, we can safely require that the tree be in tuple form rather than list form, allowing a simple variable representation to be ['variable_name']. A simple recursive function can implement the pattern matching, returning a Boolean and a dictionary of variable name to value mappings. (See file example.py.)

```python
from types import ListType, TupleType

def match(pattern, data, vars=None):
    if vars is None:
        vars = {}
    if type(pattern) is ListType:
        vars[pattern[0]] = data
        return 1, vars
    if type(pattern) is not TupleType:
        return (pattern == data), vars
    if len(data) != len(pattern):
        return 0, vars
    for pattern, data in map(None, pattern, data):
        same, vars = match(pattern, data, vars)
        if not same:
            break
    return same, vars
```

Using this simple representation for syntactic variables and the symbolic node types, the pattern for the candidate docstring subtrees becomes fairly readable. (See file example.py.)

```python
import symbol
import token
```
DOCSTRING_STMT_PATTERN = (
    symbol.stmt,
    (symbol.simple_stmt,
    (symbol.small_stmt,
      (symbol.expr_stmt,
        (symbol.testlist,
          (symbol.test,
            (symbol.and_test,
              (symbol.not_test,
                (symbol.comparison,
                  (symbol.expr,
                    (symbol.xor_expr,
                      (symbol.and_expr,
                        (symbol.shift_expr,
                          (symbol.arith_expr,
                            (symbol.term,
                              (symbol.factor,
                                (symbol.power,
                                  (symbol.atom,
                                    (token.STRING, ['docstring'])))
                  ))))))))))
        ))))))
    (token.NEWLINE, '')
))

Using the \texttt{match()} function with this pattern, extracting the module docstring from the parse tree created previously is easy:

```python
>>> found, vars = match(DOCSTRING_STMT_PATTERN, tup[1])
>>> found
1
>>> vars
{'docstring': '\"\"\"Some documentation.\n\"\"\"'}
```

Once specific data can be extracted from a location where it is expected, the question of where information can be expected needs to be answered. When dealing with docstrings, the answer is fairly simple: the docstring is the first \texttt{stmt} node in a code block (\texttt{file_input} or \texttt{suite} node types). A module consists of a single \texttt{file_input} node, and class and function definitions each contain exactly one \texttt{suite} node. Classes and functions are readily identified as subtrees of code block nodes which start with \texttt{(stmt, (compound_stmt, (classdef, ... or (stmt, (compound_stmt, (funcdef, ....}

Note that these subtrees cannot be matched by \texttt{match()} since it does not support multiple sibling nodes to match without regard to number. A more elaborate matching function could be used to overcome this limitation, but this is sufficient for the example.
Given the ability to determine whether a statement might be a docstring and extract the actual string from the statement, some work needs to be performed to walk the parse tree for an entire module and extract information about the names defined in each context of the module and associate any docstrings with the names. The code to perform this work is not complicated, but bears some explanation.

The public interface to the classes is straightforward and should probably be somewhat more flexible. Each "major" block of the module is described by an object providing several methods for inquiry and a constructor which accepts at least the subtree of the complete parse tree which it represents. The ModuleInfo constructor accepts an optional name parameter since it cannot otherwise determine the name of the module.

The public classes include ClassInfo, FunctionInfo, and ModuleInfo. All objects provide the methods get_name(), get_docstring(), get_class_names(), and get_class_info(). The ClassInfo objects support get_method_names() and get_method_info() while the other classes provide get_function_names() and get_function_info().

Within each of the forms of code block that the public classes represent, most of the required information is in the same form and is accessed in the same way, with classes having the distinction that functions defined at the top level are referred to as "methods." Since the difference in nomenclature reflects a real semantic distinction from functions defined outside of a class, the implementation needs to maintain the distinction. Hence, most of the functionality of the public classes can be implemented in a common base class, SuiteInfoBase, with the accessors for function and method information provided elsewhere. Note that there is only one class which represents function and method information; this parallels the use of the def statement to define both types of elements.

Most of the accessor functions are declared in SuiteInfoBase and do not need to be overridden by subclasses. More importantly, the extraction of most information from a parse tree is handled through a method called by the SuiteInfoBase constructor. The example code for most of the classes is clear when read alongside the formal grammar, but the method which recursively creates new information objects requires further examination. Here is the
relevant part of the `SuiteInfoBase` definition from example.py:

```python
class SuiteInfoBase:
    _docstring = ''
    _name = ''

def __init__(self, tree = None):
    self._class_info = {}
    self._function_info = {}  
    if tree:
        self._extract_info(tree)

def _extract_info(self, tree):
    # extract docstring
    if len(tree) == 2:
        found, vars = match(DOCSTRING_STMT_PATTERN[1], tree[1])
    else:
        found, vars = match(DOCSTRING_STMT_PATTERN, tree[3])
    if found:
        self._docstring = eval(vars['docstring'])
    # discover inner definitions
    for node in tree[1:]:  
        found, vars = match(COMPOUND_STMT_PATTERN, node)
        if found:
            cstmt = vars['compound']
            if cstmt[0] == symbol.funcdef:
                name = cstmt[2][1]
                self._function_info[name] = FunctionInfo(cstmt)
            elif cstmt[0] == symbol.classdef:
                name = cstmt[2][1]
                self._class_info[name] = ClassInfo(cstmt)
```

After initializing some internal state, the constructor calls the `_extract_info()` method. This method performs the bulk of the information extraction which takes place in the entire example. The extraction has two distinct phases: the location of the docstring for the parse tree passed in, and the discovery of additional definitions within the code block represented by the parse tree.

The initial if test determines whether the nested suite is of the ``short form'' or the ``long form." The short form is used when the code block is on the same line as the definition of the code block, as in

```python
    def square(x): "Square an argument."; return x ** 2
```  

while the long form uses an indented block and allows nested definitions:
def make_power(exp):
    "Make a function that raises an argument to the exponent `exp'."
    def raiser(x, y=exp):
        return x ** y
    return raiser

When the short form is used, the code block may contain a docstring as the first, and possibly only, small_stmt element. The extraction of such a docstring is slightly different and requires only a portion of the complete pattern used in the more common case. As implemented, the docstring will only be found if there is only one small_stmt node in the simple_stmt node. Since most functions and methods which use the short form do not provide a docstring, this may be considered sufficient. The extraction of the docstring proceeds using the match() function as described above, and the value of the docstring is stored as an attribute of the SuiteInfoBase object.

After docstring extraction, a simple definition discovery algorithm operates on the stmt nodes of the suite node. The special case of the short form is not tested; since there are no stmt nodes in the short form, the algorithm will silently skip the single simple_stmt node and correctly not discover any nested definitions.

Each statement in the code block is categorized as a class definition, function or method definition, or something else. For the definition statements, the name of the element defined is extracted and a representation object appropriate to the definition is created with the defining subtree passed as an argument to the constructor. The representation objects are stored in instance variables and may be retrieved by name using the appropriate accessor methods.

The public classes provide any accessors required which are more specific than those provided by the SuiteInfoBase class, but the real extraction algorithm remains common to all forms of code blocks. A high-level function can be used to extract the complete set of information from a source file. (See file example.py.)

def get_docs(fileName):
    import os
    import parser

    source = open(fileName).read()
    basename = os.path.basename(os.path.splitext(fileName)[0])
    ast = parser.suite(source)
This provides an easy-to-use interface to the documentation of a module. If information is required which is not extracted by the code of this example, the code may be extended at clearly defined points to provide additional capabilities.
Abstract:

Python is an interpreted, object-oriented, high-level programming language with dynamic semantics. Its high-level built in data structures, combined with dynamic typing and dynamic binding, make it very attractive for rapid application development, as well as for use as a scripting or glue language to connect existing components together. Python's simple, easy to learn syntax emphasizes readability and therefore reduces the cost of program maintenance. Python supports modules and packages, which encourages program modularity and code reuse. The Python interpreter and the extensive standard library are available in source or binary form without charge for all major platforms, and can be freely distributed.

This reference manual describes the syntax and ``core semantics'' of the language. It is terse, but attempts to be exact and complete. The semantics of non-essential built-in object types and of the built-in functions and modules are described in the Python Library Reference. For an informal introduction to the language, see the Python Tutorial. For C or C++ programmers, two additional manuals exist: Extending and Embedding the Python Interpreter describes the high-level picture of how to write a Python extension module, and the Python/C API Reference Manual describes the interfaces available to C/C++ programmers in detail.
Release 2.5, documentation updated on 19th September, 2006.

The application of \LaTeX2HTML to the Python documentation has been heavily tailored by Fred L. Drake, Jr. Original navigation icons were contributed by Christopher Petrilli.
Comments and Questions

General comments and questions regarding this document should be sent by email to docs@python.org. If you find specific errors in this document, either in the content or the presentation, please report the bug at the Python Bug Tracker at SourceForge. If you are able to provide suggested text, either to replace existing incorrect or unclear material, or additional text to supplement what's already available, we'd appreciate the contribution. There's no need to worry about text markup; our documentation team will gladly take care of that.

Questions regarding how to use the information in this document should be sent to the Python news group, comp.lang.python, or the Python mailing list (which is gated to the newsgroup and carries the same content).

For any of these channels, please be sure not to send HTML email. Thanks.
3.4.2.1 More attribute access for new-style classes

The following methods only apply to new-style classes.

__getattribute__(self, name)

Called unconditionally to implement attribute accesses for instances of the class. If the class also defines __getattr__(), the latter will not be called unless __getattribute__() either calls it explicitly or raises an AttributeError. This method should return the (computed) attribute value or raise an AttributeError exception. In order to avoid infinite recursion in this method, its implementation should always call the base class method with the same name to access any attributes it needs, for example, "object.__getattribute__(self, name)".
3.4.2.2 Implementing Descriptors

The following methods only apply when an instance of the class containing the method (a so-called descriptor class) appears in the class dictionary of another new-style class, known as the owner class. In the examples below, ``the attribute'' refers to the attribute whose name is the key of the property in the owner class' `__dict__'. Descriptors can only be implemented as new-style classes themselves.

```python
__get__( self, instance, owner)
```

Called to get the attribute of the owner class (class attribute access) or of an instance of that class (instance attribute access). `owner` is always the owner class, while `instance` is the instance that the attribute was accessed through, or `None` when the attribute is accessed through the `owner`. This method should return the (computed) attribute value or raise an `AttributeError` exception.

```python
__set__( self, instance, value)
```

Called to set the attribute on an instance `instance` of the owner class to a new value, `value`.

```python
__delete__( self, instance)
```

Called to delete the attribute on an instance `instance` of the owner class.
3.4.2.3 Invoking Descriptors

In general, a descriptor is an object attribute with "binding behavior", one whose attribute access has been overridden by methods in the descriptor protocol: __get__(), __set__(), and __delete__(). If any of those methods are defined for an object, it is said to be a descriptor.

The default behavior for attribute access is to get, set, or delete the attribute from an object's dictionary. For instance, a.x has a lookup chain starting with a.__dict__['x'], then type(a).__dict__['x'], and continuing through the base classes of type(a) excluding metaclasses.

However, if the looked-up value is an object defining one of the descriptor methods, then Python may override the default behavior and invoke the descriptor method instead. Where this occurs in the precedence chain depends on which descriptor methods were defined and how they were called. Note that descriptors are only invoked for new style objects or classes (ones that subclass object() or type()).

The starting point for descriptor invocation is a binding, a.x. How the arguments are assembled depends on a:

Direct Call
The simplest and least common call is when user code directly invokes a descriptor method: x.__get__(a).

Instance Binding
If binding to a new-style object instance, a.x is transformed into the call: type(a).__dict__['x'].__get__(a, type(a)).

Class Binding
If binding to a new-style class, A.x is transformed into the call: A.__dict__['x'].__get__(None, A).

Super Binding
If `a` is an instance of `super`, then the binding `super(B, obj).m()` searches `obj.__class__.__mro__` for the base class `A` immediately preceding `B` and then invokes the descriptor with the call: `A.__dict__['m'].__get__(obj, A)`.

For instance bindings, the precedence of descriptor invocation depends on the which descriptor methods are defined. Data descriptors define both `__get__()` and `__set__()`. Non-data descriptors have just the `__get__()` method. Data descriptors always override a redefinition in an instance dictionary. In contrast, non-data descriptors can be overridden by instances.

Python methods (including `staticmethod()` and `classmethod()`)) are implemented as non-data descriptors. Accordingly, instances can redefine and override methods. This allows individual instances to acquire behaviors that differ from other instances of the same class.

The `property()` function is implemented as a data descriptor. Accordingly, instances cannot override the behavior of a property.
3.4.2.4 __slots__

By default, instances of both old and new-style classes have a dictionary for attribute storage. This wastes space for objects having very few instance variables. The space consumption can become acute when creating large numbers of instances.

The default can be overridden by defining __slots__ in a new-style class definition. The __slots__ declaration takes a sequence of instance variables and reserves just enough space in each instance to hold a value for each variable. Space is saved because __dict__ is not created for each instance.

__slots__

This class variable can be assigned a string, iterable, or sequence of strings with variable names used by instances. If defined in a new-style class, __slots__ reserves space for the declared variables and prevents the automatic creation of __dict__ and __weakref__ for each instance. New in version 2.2.

Notes on using __slots__

- Without a __dict__ variable, instances cannot be assigned new variables not listed in the __slots__ definition. Attempts to assign to an unlisted variable name raises AttributeError. If dynamic assignment of new variables is desired, then add '__dict__' to the sequence of strings in the __slots__ declaration. Changed in version 2.3: Previously, adding '__dict__' to the __slots__ declaration would not enable the assignment of new attributes not specifically listed in the sequence of instance variable names.

- Without a __weakref__ variable for each instance, classes defining __slots__ do not support weak references to its instances. If weak reference support is needed, then add '__weakref__' to the sequence of strings in the __slots__ declaration. Changed in version 2.3: Previously, adding '__weakref__' to the __slots__ declaration would not enable support
for weak references.

- **__slots__** are implemented at the class level by creating descriptors (3.4.2) for each variable name. As a result, class attributes cannot be used to set default values for instance variables defined by **__slots__**: otherwise, the class attribute would overwrite the descriptor assignment.

- If a class defines a slot also defined in a base class, the instance variable defined by the base class slot is inaccessible (except by retrieving its descriptor directly from the base class). This renders the meaning of the program undefined. In the future, a check may be added to prevent this.

- The action of a **__slots__** declaration is limited to the class where it is defined. As a result, subclasses will have a **__dict__** unless they also define **__slots__**.

- **__slots__** do not work for classes derived from ``variable-length'' built-in types such as long, str and tuple.

- Any non-string iterable may be assigned to **__slots__**. Mappings may also be used; however, in the future, special meaning may be assigned to the values corresponding to each key.

Abstract:

This library reference manual documents Python’s extensions for the Macintosh. It should be used in conjunction with the Python Library Reference, which documents the standard library and built-in types.

This manual assumes basic knowledge about the Python language. For an informal introduction to Python, see the Python Tutorial; the Python Reference Manual remains the highest authority on syntactic and semantic questions. Finally, the manual entitled Extending and Embedding the Python Interpreter describes how to add new extensions to Python and how to embed it in other applications.
Contents

- 1. Using Python on a Macintosh
  - 1.1 Getting and Installing MacPython
    - 1.1.1 How to run a Python script
    - 1.1.2 Running scripts with a GUI
    - 1.1.3 configuration
  - 1.2 The IDE
    - 1.2.1 Using the "Python Interactive" window
    - 1.2.2 Writing a Python Script
    - 1.2.3 Executing a script from within the IDE
    - 1.2.4 "Save as" versus "Save as Applet"
  - 1.3 The Package Manager
- 2. MacPython Modules
  - 2.1 macpath -- MacOS path manipulation functions
  - 2.2 macfs -- Various file system services
    - 2.2.1 FSSpec Objects
    - 2.2.2 Alias Objects
    - 2.2.3 FInfo Objects
  - 2.3 ic -- Access to Internet Config
    - 2.3.1 IC Objects
  - 2.4 MacOS -- Access to Mac OS interpreter features
  - 2.5 macostools -- Convenience routines for file manipulation
  - 2.6 findertools -- The finder's Apple Events interface
  - 2.7 EasyDialogs -- Basic Macintosh dialogs
    - 2.7.1 ProgressBar Objects
  - 2.8 FrameWork -- Interactive application framework
    - 2.8.1 Application Objects
    - 2.8.2 Window Objects
    - 2.8.3 ControlsWindow Object
    - 2.8.4 ScrolledWindow Object
    - 2.8.5 DialogWindow Objects
  - 2.9 autoGIL -- Global Interpreter Lock handling in event loops
- 3. MacPython OSA Modules
  - 3.1 gensuitemodule -- Generate OSA stub packages
  - 3.2 aetools -- OSA client support
  - 3.3 aepack -- Conversion between Python variables and AppleEvent
data containers

- 3.4 aetypes -- AppleEvent objects
- 3.5 MiniAEFrame -- Open Scripting Architecture server support
  - 3.5.1 AEServer Objects

4. MacOS Toolbox Modules
- 4.1 Carbon.AE -- Apple Events
- 4.2 Carbon.AH -- Apple Help
- 4.3 Carbon.App -- Appearance Manager
- 4.4 Carbon.CF -- Core Foundation
- 4.5 Carbon.CG -- Core Graphics
- 4.6 Carbon.CarbonEvt -- Carbon Event Manager
- 4.7 Carbon.Cm -- Component Manager
- 4.8 Carbon.Ctl -- Control Manager
- 4.9 Carbon.Dlg -- Dialog Manager
- 4.10 Carbon.Evt -- Event Manager
- 4.11 Carbon.Fm -- Font Manager
- 4.12 Carbon.Folder -- Folder Manager
- 4.13 Carbon.Help -- Help Manager
- 4.14 Carbon.List -- List Manager
- 4.15 Carbon.Menu -- Menu Manager
- 4.16 Carbon.Mlte -- MultiLingual Text Editor
- 4.17 Carbon.Qd -- QuickDraw
- 4.18 Carbon.Qdoffs -- QuickDraw Offscreen
- 4.19 Carbon.Qt -- QuickTime
- 4.20 Carbon.Res -- Resource Manager and Handles
- 4.21 Carbon.Scrap -- Scrap Manager
- 4.22 Carbon.Snd -- Sound Manager
- 4.23 Carbon.TE -- TextEdit
- 4.24 Carbon.Win -- Window Manager
- 4.25 ColorPicker -- Color selection dialog

5. Undocumented Modules
- 5.1 applesingle -- AppleSingle decoder
- 5.2 buildtools -- Helper module for BuildApplet and Friends
- 5.3 cfmfile -- Code Fragment Resource module
- 5.4 icopen -- Internet Config replacement for open()
- 5.5 macerrors -- Mac OS Errors
- 5.6 macresource -- Locate script resources
- 5.7 Nav -- NavServices calls
- 5.8 PixMapWrapper -- Wrapper for PixMap objects
5.9 videoreader -- Read QuickTime movies
5.10 W -- Widgets built on FrameWork

About this document ...

Macintosh Library Modules, 19th September, 2006, Release 2.5

This document was generated using the LaTeX2HTML translator.

The application of LaTeX2HTML to the Python documentation has been heavily tailored by Fred L. Drake, Jr. Original navigation icons were contributed by Christopher Petrilli.
Comments and Questions

General comments and questions regarding this document should be sent by email to docs@python.org. If you find specific errors in this document, either in the content or the presentation, please report the bug at the Python Bug Tracker at SourceForge. If you are able to provide suggested text, either to replace existing incorrect or unclear material, or additional text to supplement what's already available, we'd appreciate the contribution. There's no need to worry about text markup; our documentation team will gladly take care of that.

Questions regarding how to use the information in this document should be sent to the Python news group, comp.lang.python, or the Python mailing list (which is gated to the newsgroup and carries the same content).

For any of these channels, please be sure not to send HTML email. Thanks.
Front Matter

Abstract:

Python is an interpreted, object-oriented programming language. This document describes how to write modules in C or C++ to extend the Python interpreter with new modules. Those modules can define new functions but also new object types and their methods. The document also describes how to embed the Python interpreter in another application, for use as an extension language. Finally, it shows how to compile and link extension modules so that they can be loaded dynamically (at run time) into the interpreter, if the underlying operating system supports this feature.

This document assumes basic knowledge about Python. For an informal introduction to the language, see the Python Tutorial. The Python Reference Manual gives a more formal definition of the language. The Python Library Reference documents the existing object types, functions and modules (both built-in and written in Python) that give the language its wide application range.

For a detailed description of the whole Python/C API, see the separate Python/C API Reference Manual.

Extending and Embedding the Python Interpreter

2.2.3.1 Generic Attribute Management

New in version 2.2.

Most extension types only use simple attributes. So, what makes the attributes simple? There are only a couple of conditions that must be met:

1. The name of the attributes must be known when PyType_Ready() is called.

2. No special processing is needed to record that an attribute was looked up or set, nor do actions need to be taken based on the value.

Note that this list does not place any restrictions on the values of the attributes, when the values are computed, or how relevant data is stored.

When PyType_Ready() is called, it uses three tables referenced by the type object to create descriptors which are placed in the dictionary of the type object. Each descriptor controls access to one attribute of the instance object. Each of the tables is optional; if all three are NULL, instances of the type will only have attributes that are inherited from their base type, and should leave the tp_getattro and tp_setattro fields NULL as well, allowing the base type to handle attributes.

The tables are declared as three fields of the type object:

```c
struct PyMethodDef *tp_methods;
struct PyMemberDef *tp_members;
struct PyGetSetDef *tp_getset;
```

If tp_methods is not NULL, it must refer to an array of PyMethodDef structures. Each entry in the table is an instance of this structure:

```c
typedef struct PyMethodDef {
    char    *ml_name;    /* method name */
    PyCFunction ml_meth;    /* implementation function */
    int      ml_flags;    /* flags */
    char    *ml_doc;    /* docstring */
} PyMethodDef;
```
One entry should be defined for each method provided by the type; no entries are needed for methods inherited from a base type. One additional entry is needed at the end; it is a sentinel that marks the end of the array. The \texttt{ml\_name} field of the sentinel must be \texttt{NULL}.

XXX Need to refer to some unified discussion of the structure fields, shared with the next section.

The second table is used to define attributes which map directly to data stored in the instance. A variety of primitive C types are supported, and access may be read-only or read-write. The structures in the table are defined as:

```c
typedef struct PyMemberDef {
    char *name;
    int type;
    int offset;
    int flags;
    char *doc;
} PyMemberDef;
```

For each entry in the table, a descriptor will be constructed and added to the type which will be able to extract a value from the instance structure. The \texttt{type} field should contain one of the type codes defined in the \texttt{structmember.h} header; the value will be used to determine how to convert Python values to and from C values. The \texttt{flags} field is used to store flags which control how the attribute can be accessed.

XXX Need to move some of this to a shared section!

The following flag constants are defined in \texttt{structmember.h}; they may be combined using bitwise-OR.

<table>
<thead>
<tr>
<th>Constant</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>READONLY</td>
<td>Never writable.</td>
</tr>
<tr>
<td>R0</td>
<td>Shorthand for \texttt{READONLY}.</td>
</tr>
<tr>
<td>READ_RESTRICTED</td>
<td>Not readable in restricted mode.</td>
</tr>
<tr>
<td>WRITE_RESTRICTED</td>
<td>Not writable in restricted mode.</td>
</tr>
<tr>
<td>RESTRICTED</td>
<td>Not readable or writable in restricted mode.</td>
</tr>
</tbody>
</table>
An interesting advantage of using the `tp_members` table to build descriptors that are used at runtime is that any attribute defined this way can have an associated doc string simply by providing the text in the table. An application can use the introspection API to retrieve the descriptor from the class object, and get the doc string using its `__doc__` attribute.

As with the `tp_methods` table, a sentinel entry with a name value of NULL is required.
2.2.3.2 Type-specific Attribute Management

For simplicity, only the char* version will be demonstrated here; the type of the name parameter is the only difference between the char* and PyObject* flavors of the interface. This example effectively does the same thing as the generic example above, but does not use the generic support added in Python 2.2. The value in showing this is two-fold: it demonstrates how basic attribute management can be done in a way that is portable to older versions of Python, and explains how the handler functions are called, so that if you do need to extend their functionality, you'll understand what needs to be done.

The tp_getattr handler is called when the object requires an attribute lookup. It is called in the same situations where the __getattr__() method of a class would be called.

A likely way to handle this is (1) to implement a set of functions (such as newdatatype_getSize() and newdatatype_setSize() in the example below), (2) provide a method table listing these functions, and (3) provide a getattr function that returns the result of a lookup in that table. The method table uses the same structure as the tp_methods field of the type object.

Here is an example:

```c
static PyMethodDef newdatatype_methods[] = {
    {"getSize", (PyCFunction)newdatatype_getSize, METH_VARARGS,
       "Return the current size."},
    {"setSize", (PyCFunction)newdatatype_setSize, METH_VARARGS,
       "Set the size."},
    {NULL, NULL, 0, NULL} /* sentinel */
};

static PyObject *
newdatatype_getattr(newdatatypeobject *obj, char *name)
{
    return Py_FindMethod(newdatatype_methods, (PyObject *)obj, name)
}
```

The tp_setattr handler is called when the __setattr__() or
__delattr__() method of a class instance would be called. When an attribute should be deleted, the third parameter will be NULL. Here is an example that simply raises an exception; if this were really all you wanted, the tp_setattr handler should be set to NULL.

```c
static int
newdatatype_setattr(newdatatypeobject *obj, char *name, PyObject *v)
{
    (void)PyErr_Format(PyExc_RuntimeError, "Read-only attribute: \%s",
                       name);
    return -1;
}
```

Extending and Embedding the Python Interpreter

Previous: 2.2.3.1 Generic Attribute Management Up: 2.2.3 Attribute Management Next: 2.2.4 Object Comparison

Release 2.5, documentation updated on 19th September, 2006.

Abstract:

This manual documents the API used by C and C++ programmers who want to write extension modules or embed Python. It is a companion to Extending and Embedding the Python Interpreter, which describes the general principles of extension writing but does not document the API functions in detail.

Warning: The current version of this document is incomplete. I hope that it is nevertheless useful. I will continue to work on it, and release new versions from time to time, independent from Python source code releases.

Questions regarding how to use the information in this document should be sent to the Python news group, comp.lang.python, or the Python mailing list (which is gated to the newsgroup and carries the same content).

For any of these channels, please be sure not to send HTML email. Thanks.
1.2.1.1 Reference Count Details

The reference count behavior of functions in the Python/C API is best explained in terms of *ownership of references*. Ownership pertains to references, never to objects (objects are not owned: they are always shared). "Owning a reference" means being responsible for calling Py_Decref on it when the reference is no longer needed. Ownership can also be transferred, meaning that the code that receives ownership of the reference then becomes responsible for eventually decref'ing it by calling Py_Decref() or Py_XDecref() when it's no longer needed--or passing on this responsibility (usually to its caller). When a function passes ownership of a reference on to its caller, the caller is said to receive a new reference. When no ownership is transferred, the caller is said to borrow the reference. Nothing needs to be done for a borrowed reference.

Conversely, when a calling function passes it a reference to an object, there are two possibilities: the function steals a reference to the object, or it does not. *Stealing a reference* means that when you pass a reference to a function, that function assumes that it now owns that reference, and you are not responsible for it any longer.

Few functions steal references; the two notable exceptions are PyTuple_SetItem() and PyTuple_SetItem(), which steal a reference to the item (but not to the tuple or list into which the item is put!). These functions were designed to steal a reference because of a common idiom for populating a tuple or list with newly created objects; for example, the code to create the tuple (1, 2, "three") could look like this (forgetting about error handling for the moment; a better way to code this is shown below):

```c
PyObject *t;
    t = PyTuple_New(3);
    PyTuple_SetItem(t, 0, PyInt_FromLong(1L));
    PyTuple_SetItem(t, 1, PyInt_FromLong(2L));
    PyTuple_SetItem(t, 2, PyString_FromString("three"));
```

Here, PyInt_FromLong() returns a new reference which is immediately stolen by PyTuple_SetItem(). When you want to keep using an object
although the reference to it will be stolen, use Py_INCREF() to grab another reference before calling the reference-stealing function.

Incidentally, PyTuple_SetItem() is the only way to set tuple items; PySequence_SetItem() and PyObject_SetItem() refuse to do this since tuples are an immutable data type. You should only use PyTuple_SetItem() for tuples that you are creating yourself.

Equivalent code for populating a list can be written using PyList_New() and PyList_SetItem().

However, in practice, you will rarely use these ways of creating and populating a tuple or list. There's a generic function, Py_BuildValue(), that can create most common objects from C values, directed by a format string. For example, the above two blocks of code could be replaced by the following (which also takes care of the error checking):

```c
PyObject *tuple, *list;

tuple = Py_BuildValue("(iis)", 1, 2, "three");
list = Py_BuildValue("[iis]", 1, 2, "three");
```

It is much more common to use PyObject_SetItem() and friends with items whose references you are only borrowing, like arguments that were passed in to the function you are writing. In that case, their behaviour regarding reference counts is much saner, since you don't have to increment a reference count so you can give a reference away (``have it be stolen''). For example, this function sets all items of a list (actually, any mutable sequence) to a given item:

```c
int
set_all(PyObject *target, PyObject *item)
{
    int i, n;

    n = PyObject_Length(target);
    if (n < 0)
        return -1;
    for (i = 0; i < n; i++) {
        PyObject *index = PyInt_FromLong(i);
        if (!index)
            return -1;
        if (PyObject_SetItem(target, index, item) < 0)
            return -1;
        Py_DECREF(index);
    }
```
The situation is slightly different for function return values. While passing a reference to most functions does not change your ownership responsibilities for that reference, many functions that return a reference to an object give you ownership of the reference. The reason is simple: in many cases, the returned object is created on the fly, and the reference you get is the only reference to the object. Therefore, the generic functions that return object references, like PyObject_GetItem() and PySequence_GetItem(), always return a new reference (the caller becomes the owner of the reference).

It is important to realize that whether you own a reference returned by a function depends on which function you call only -- the plumage (the type of the object passed as an argument to the function) doesn't enter into it! Thus, if you extract an item from a list using PyList_GetItem(), you don't own the reference -- but if you obtain the same item from the same list using PySequence_GetItem() (which happens to take exactly the same arguments), you do own a reference to the returned object.

Here is an example of how you could write a function that computes the sum of the items in a list of integers; once using PyList_GetItem(), and once using PySequence_GetItem().

```c
long
sum_list(PyObject *list)
{
    int i, n;
    long total = 0;
    PyObject *item;

    n = PyList_Size(list);
    if (n < 0)
        return -1; /* Not a list */
    for (i = 0; i < n; i++) {
        item = PyList_GetItem(list, i); /* Can't fail */
        if (!PyInt_Check(item)) continue; /* Skip non-integers */
        total += PyInt_AsLong(item);
    }
    return total;
}

long
sum_sequence(PyObject *sequence)
```
{  
    int i, n;
    long total = 0;
    PyObject *item;
    n = PySequence_Length(sequence);
    if (n < 0)  
        return -1; /* Has no length */
    for (i = 0; i < n; i++) {  
        item = PySequence_GetItem(sequence, i);
        if (item == NULL)  
            return -1; /* Not a sequence, or other failure */
        if (PyInt_Check(item))
            total += PyInt_AsLong(item);
        Py_DECREF(item); /* Discard reference ownership */
    }
    return total;
}
7.2.5.1 Complex Numbers as C Structures

Note that the functions which accept these structures as parameters and return them as results do so by value rather than dereferencing them through pointers. This is consistent throughout the API.

**Py_complex**

The C structure which corresponds to the value portion of a Python complex number object. Most of the functions for dealing with complex number objects use structures of this type as input or output values, as appropriate. It is defined as:

```c
typedef struct {
    double real;
    double imag;
} Py_complex;
```

**Py_complex **_Py_c_sum**( Py_complex left, Py_complex right)

Return the sum of two complex numbers, using the C Py_complex representation.

**Py_complex **_Py_c_diff**( Py_complex left, Py_complex right)

Return the difference between two complex numbers, using the C Py_complex representation.

**Py_complex **_Py_c_neg**( Py_complex complex)

Return the negation of the complex number complex, using the C Py_complex representation.

**Py_complex **_Py_c_prod**( Py_complex left, Py_complex right)

Return the product of two complex numbers, using the C Py_complex representation.

**Py_complex **_Py_c_quot**( Py_complex dividend, Py_complex divisor)

Return the quotient of two complex numbers, using the C Py_complex representation.
representation.

Py_complex \_Py\_c\_pow(Py_complex num, Py_complex exp)

Return the exponentiation of num by exp, using the C Py_complex representation.
7.2.5.2 Complex Numbers as Python Objects

**PyComplexObject**
This subtype of PyObject represents a Python complex number object.

PyTypeObject **PyComplex_Type**
This instance of PyTypeObject represents the Python complex number type. It is the same object as complex and types.ComplexType.

int **PyComplex_Check**( PyObject *p)
Return true if its argument is a PyComplexObject or a subtype of PyComplexObject. Changed in version 2.2: Allowed subtypes to be accepted.

int **PyComplex_CheckExact**( PyObject *p)
Return true if its argument is a PyComplexObject, but not a subtype of PyComplexObject. New in version 2.2.

PyObject* **PyComplex_FromCComplex**( Py_complex v)
*Return value: New reference.*
Create a new Python complex number object from a C Py_complex value.

PyObject* **PyComplex_FromDoubles**( double real, double imag)
*Return value: New reference.*
Return a new PyComplexObject object from real and imag.

double **PyComplex_RealAsDouble**( PyObject *op)
Return the real part of op as a C double.

double **PyComplex_ImagAsDouble**( PyObject *op)
Return the imaginary part of op as a C double.
Py_complex  \texttt{PyComplex\_AsCComplex}( \texttt{PyObject \, *op} )

Return the Py\_complex value of the complex number \textit{op}.
7.3.2.1 Built-in Codecs

Python provides a set of builtin codecs which are written in C for speed. All of these codecs are directly usable via the following functions.

Many of the following APIs take two arguments encoding and errors. These parameters encoding and errors have the same semantics as the ones of the builtin unicode() Unicode object constructor.

Setting encoding to NULL causes the default encoding to be used which is ASCII. The file system calls should use `Py_FileSystemDefaultEncoding` as the encoding for file names. This variable should be treated as read-only: On some systems, it will be a pointer to a static string, on others, it will change at run-time (such as when the application invokes setlocale).

Error handling is set by errors which may also be set to NULL meaning to use the default handling defined for the codec. Default error handling for all builtin codecs is ``strict'' (`ValueError` is raised).

The codecs all use a similar interface. Only deviation from the following generic ones are documented for simplicity.

These are the generic codec APIs:

```c
PyObject* PyUnicode_Decode( const char *s, Py_ssize_t size, const char *encoding, const char *errors)
```

Create a Unicode object by decoding size bytes of the encoded string s. 
*encoding* and *errors* have the same meaning as the parameters of the same name in the `unicode()` builtin function. The codec to be used is looked up using the Python codec registry. Return NULL if an exception was raised by the codec.

```c
const Py_UNICODE *s, Py_ssize_t size,
```
PyObject* **PyUnicode_Encode**( const char *encoding, const char *errors)

*Return value: New reference.*
Encode the Py_UNICODE buffer of the given size and return a Python string object. *encoding* and *errors* have the same meaning as the parameters of the same name in the Unicode *encode()* method. The codec to be used is looked up using the Python codec registry. Return NULL if an exception was raised by the codec.

PyObject* **PyUnicode_AsEncodedString**( PyObject *unicode, char *encoding, const char *errors)

*Return value: New reference.*
Encode a Unicode object and return the result as Python string object. *encoding* and *errors* have the same meaning as the parameters of the same name in the Unicode *encode()* method. The codec to be used is looked up using the Python codec registry. Return NULL if an exception was raised by the codec.

These are the UTF-8 codec APIs:

PyObject* **PyUnicode_DecodeUTF8**( const char *s, Py_ssize_t size, const char *errors)

*Return value: New reference.*
Create a Unicode object by decoding *size* bytes of the UTF-8 encoded string *s*. Return NULL if an exception was raised by the codec.

PyObject* **PyUnicode_DecodeUTF8Stateful**( size, const char *errors, Py_ssize_t *consumed)

*Return value: New reference.*
If consumed is NULL, behave like PyUnicode_DecodeUTF8(). If consumed is not NULL, trailing incomplete UTF-8 byte sequences will not be treated as an error. Those bytes will not be decoded and the number of bytes that have been decoded will be stored in consumed. New in version 2.4.
PyObject* **PyUnicode_EncodeUTF8**( size, const char *errors)

*Return value:* New reference.
Encode the Py_UNICODE buffer of the given size using UTF-8 and return a Python string object. Return NULL if an exception was raised by the codec.

PyObject* **PyUnicode_AsUTF8String**( PyObject *unicode)

*Return value:* New reference.
Encode a Unicode objects using UTF-8 and return the result as Python string object. Error handling is ``strict``. Return NULL if an exception was raised by the codec.

These are the UTF-16 codec APIs:

PyObject* **PyUnicode_DecodeUTF16**( const char *s, Py_ssize_t size, const char *errors, int *byteorder)

*Return value:* New reference.
Decode length bytes from a UTF-16 encoded buffer string and return the corresponding Unicode object. errors (if non-NULL) defines the error handling. It defaults to ``strict``.

If byteorder is non-NULL, the decoder starts decoding using the given byte order:

*byteorder == -1: little endian
*byteorder == 0: native order
*byteorder == 1: big endian

and then switches according to all byte order marks (BOM) it finds in the input data. BOMs are not copied into the resulting Unicode string. After completion, *byteorder is set to the current byte order at the end of input data.

If byteorder is NULL, the codec starts in native order mode.

Return NULL if an exception was raised by the codec.

const char *s,
Py_ssize_t size, const
PyObject* **PyUnicode_DecodeUTF16Stateful** (char *errors, int *byteorder, Py_ssize_t *consumed)

*Return value: New reference.*

If `consumed` is NULL, behave like `PyUnicode_DecodeUTF16()`. If `consumed` is not NULL, `PyUnicode_DecodeUTF16Stateful()` will not treat trailing incomplete UTF-16 byte sequences (such as an odd number of bytes or a split surrogate pair) as an error. Those bytes will not be decoded and the number of bytes that have been decoded will be stored in `consumed`. New in version 2.4.

```c
PyObject* PyUnicode_EncodeUTF16 (const Py_UNICODE* s, Py_ssize_t size, const char* errors, int byteorder)
```

*Return value: New reference.*

Return a Python string object holding the UTF-16 encoded value of the Unicode data in `s`. If `byteorder` is not 0, output is written according to the following byte order:

- `byteorder == -1`: little endian
- `byteorder == 0`: native byte order (writes a BOM mark)
- `byteorder == 1`: big endian

If byteorder is 0, the output string will always start with the Unicode BOM mark (U+FEFF). In the other two modes, no BOM mark is prepended.

If `Py_UNICODE_WIDE` is defined, a single `Py_UNICODE` value may get represented as a surrogate pair. If it is not defined, each `Py_UNICODE` values is interpreted as an UCS-2 character.

Return NULL if an exception was raised by the codec.

PyObject* **PyUnicode_AsUTF16String** (PyObject *`unicode`)  

*Return value: New reference.*

Return a Python string using the UTF-16 encoding in native byte order. The string always starts with a BOM mark. Error handling is ``strict''. Return NULL if an exception was raised by the codec.

These are the ``Unicode Escape'' codec APIs:
PyObject* **PyUnicode_DecodeUnicodeEscape**( Py_ssize_t size, const char *errors)

*Return value: New reference.*
Create a Unicode object by decoding *size* bytes of the Unicode-Escape encoded string *s*. Return NULL if an exception was raised by the codec.

PyObject* **PyUnicode_EncodeUnicodeEscape**( const Py_UNICODE *s, Py_ssize_t size)

*Return value: New reference.*
Encode the Py_UNICODE buffer of the given size using Unicode-Escape and return a Python string object. Return NULL if an exception was raised by the codec.

PyObject* **PyUnicode_AsUnicodeEscapeString**( PyObject *unicode)

*Return value: New reference.*
Encode a Unicode objects using Unicode-Escape and return the result as Python string object. Error handling is ``strict``. Return NULL if an exception was raised by the codec.

These are the ``Raw Unicode Escape`` codec APIs:

PyObject* **PyUnicode_DecodeRawUnicodeEscape**( Py_ssize_t size, const char *errors)

*Return value: New reference.*
Create a Unicode object by decoding *size* bytes of the Raw-Unicode-Escape encoded string *s*. Return NULL if an exception was raised by the codec.

PyObject* **PyUnicode_EncodeRawUnicodeEscape**( const Py_UNICODE *s, Py_ssize_t size, const char *errors)

*Return value: New reference.*
Encode the Py_UNICODE buffer of the given size using Raw-Unicode-Escape and return a Python string object. Return NULL if an exception was raised by the codec.
PyObject* `PyUnicode_AsRawUnicodeEscapeString`(PyObject* `unicode`)

*Return value: New reference.*
Encode a Unicode objects using Raw-Unicode-Escape and return the result as Python string object. Error handling is ``strict``. Return NULL if an exception was raised by the codec.

These are the Latin-1 codec APIs: Latin-1 corresponds to the first 256 Unicode ordinals and only these are accepted by the codecs during encoding.

PyObject* `PyUnicode_DecodeLatin1`(const char* `s`, Py_ssize_t `size`, const char* `errors`)

*Return value: New reference.*
Create a Unicode object by decoding size bytes of the Latin-1 encoded string s. Return NULL if an exception was raised by the codec.

PyObject* `PyUnicode_EncodeLatin1`(Py_ssize_t `size`, const char* `errors`)

*Return value: New reference.*
Encode the Py_UNICODE buffer of the given size using Latin-1 and return a Python string object. Return NULL if an exception was raised by the codec.

PyObject* `PyUnicode_AsLatin1String`(PyObject* `unicode`)

*Return value: New reference.*
Encode a Unicode objects using Latin-1 and return the result as Python string object. Error handling is ``strict``. Return NULL if an exception was raised by the codec.

These are the ASCII codec APIs. Only 7-bit ASCII data is accepted. All other codes generate errors.

PyObject* `PyUnicode_DecodeASCII`(const char* `s`, Py_ssize_t `size`, const char* `errors`)

*Return value: New reference.*
Create a Unicode object by decoding size bytes of the ASCII encoded string s. Return NULL if an exception was raised by the codec.
PyObject* PyUnicode_EncodeASCII(const Py_UNICODE *s, Py_ssize_t size, const char *errors)

*Return value: New reference.*
Encode the Py_UNICODE buffer of the given size using ASCII and return a Python string object. Return NULL if an exception was raised by the codec.

PyObject* PyUnicode_AsASCIIString( PyObject *unicode)

*Return value: New reference.*
Encode a Unicode objects using ASCII and return the result as Python string object. Error handling is ``strict''. Return NULL if an exception was raised by the codec.

These are the mapping codec APIs:

This codec is special in that it can be used to implement many different codecs (and this is in fact what was done to obtain most of the standard codecs included in the encodings package). The codec uses mapping to encode and decode characters.

Decoding mappings must map single string characters to single Unicode characters, integers (which are then interpreted as Unicode ordinals) or None (meaning "undefined mapping" and causing an error).

Encoding mappings must map single Unicode characters to single string characters, integers (which are then interpreted as Latin-1 ordinals) or None (meaning "undefined mapping" and causing an error).

The mapping objects provided must only support the __getitem__ mapping interface.

If a character lookup fails with a LookupError, the character is copied as-is meaning that its ordinal value will be interpreted as Unicode or Latin-1 ordinal resp. Because of this, mappings only need to contain those mappings which map characters to different code points.

PyObject* PyUnicode_DecodeCharmap( PyObject *mapping, const char *errors)
Create a Unicode object by decoding size bytes of the encoded string s using the given mapping object. Return NULL if an exception was raised by the codec. If mapping is NULL latin-1 decoding will be done. Else it can be a dictionary mapping byte or a unicode string, which is treated as a lookup table. Byte values greater that the length of the string and U+FFFE "characters" are treated as "undefined mapping". Changed in version 2.4: Allowed unicode string as mapping argument.

PyObject* PyUnicode_EncodeCharmap( const Py_UNICODE* s, Py_ssize_t size, PyObject* mapping, const char* errors)

Encode the Py_UNICODE buffer of the given size using the given mapping object and return a Python string object. Return NULL if an exception was raised by the codec.

PyObject* PyUnicode_AsCharmapString( PyObject* unicode, PyObject* mapping)

Encode a Unicode objects using the given mapping object and return the result as Python string object. Error handling is ``strict''. Return NULL if an exception was raised by the codec.

The following codec API is special in that maps Unicode to Unicode.

PyObject* PyUnicode_TranslateCharmap( const Py_UNICODE* s, Py_ssize_t size, PyObject* table, const char* errors)

Translate a Py_UNICODE buffer of the given length by applying a character mapping table to it and return the resulting Unicode object. Return NULL when an exception was raised by the codec.

The mapping table must map Unicode ordinal integers to Unicode ordinal integers or None (causing deletion of the character).

Mapping tables need only provide the __getitem__() interface;
dictionaries and sequences work well. Unmapped character ordinals (ones which cause a LookupError) are left untouched and are copied as-is.

These are the MBCS codec APIs. They are currently only available on Windows and use the Win32 MBCS converters to implement the conversions. Note that MBCS (or DBCS) is a class of encodings, not just one. The target encoding is defined by the user settings on the machine running the codec.

*PyObject* **PyUnicode_DecodeMBCS**( const char *s, Py_ssize_t size, const char *errors)

*Return value:* New reference.
Create a Unicode object by decoding size bytes of the MBCS encoded string s. Return NULL if an exception was raised by the codec.

*PyObject* **PyUnicode_DecodeMBCSStateful**( const char *errors, int *consumed)

If consumed is NULL, behave like PyUnicode_DecodeMBCS(). If consumed is not NULL, PyUnicode_DecodeMBCSStateful() will not decode trailing lead byte and the number of bytes that have been decoded will be stored in consumed. New in version 2.5.

*PyObject* **PyUnicode_EncodeMBCS**( const Py_UNICODE *s, Py_ssize_t size, const char *errors)

*Return value:* New reference.
Encode the Py_UNICODE buffer of the given size using MBCS and return a Python string object. Return NULL if an exception was raised by the codec.

*PyObject* **PyUnicode_AsMBCSString**( PyObject *unicode)

*Return value:* New reference.
Encode a Unicode objects using MBCS and return the result as Python string object. Error handling is `strict`. Return NULL if an exception was raised by the codec.
Methods and Slot

Release 2.5, documentation updated on 19th September, 2006. 
See About this document... for information on suggesting changes.
7.3.2.2 Methods and Slot Functions

The following APIs are capable of handling Unicode objects and strings on input (we refer to them as strings in the descriptions) and return Unicode objects or integers as appropriate.

They all return `NULL` or `-1` if an exception occurs.

**PyObject* **`PyUnicode_Concat`**( PyObject *left, PyObject *right)**

*Return value: New reference.*
Concat two strings giving a new Unicode string.

**PyObject* **`PyUnicode_Split`**( PyObject *s, PyObject *sep, Py_ssize_t maxsplit)**

*Return value: New reference.*
Split a string giving a list of Unicode strings. If `sep` is `NULL`, splitting will be done at all whitespace substrings. Otherwise, splits occur at the given separator. At most `maxsplit` splits will be done. If negative, no limit is set. Separators are not included in the resulting list.

**PyObject* **`PyUnicode_Splitlines`**( PyObject *s, int keepend)**

*Return value: New reference.*
Split a Unicode string at line breaks, returning a list of Unicode strings. CRLF is considered to be one line break. If `keepend` is 0, the Line break characters are not included in the resulting strings.

**PyObject* **`PyUnicode_Translate`**( PyObject *str, PyObject *table, const char *errors)**

*Return value: New reference.*
Translate a string by applying a character mapping table to it and return the resulting Unicode object.

The mapping table must map Unicode ordinal integers to Unicode ordinal integers or None (causing deletion of the character).
Mapping tables need only provide the `__getitem__()` interface; dictionaries and sequences work well. Unmapped character ordinals (ones which cause a `LookupError`) are left untouched and are copied as-is.

`errors` has the usual meaning for codecs. It may be `NULL` which indicates to use the default error handling.

```python
PyObject* PyUnicode_Join( PyObject *separator, PyObject *seq)
```

*Return value: New reference.*
Join a sequence of strings using the given separator and return the resulting Unicode string.

```python
int PyUnicode_Tailmatch( PyObject *str, PyObject *substr, Py_ssize_t start, Py_ssize_t end, int direction)
```

*Return value: New reference.*
Return 1 if `substr` matches `str[start:end]` at the given tail end (`direction` == -1 means to do a prefix match, `direction` == 1 a suffix match), 0 otherwise. Return -1 if an error occurred.

```python
Py_ssize_t PyUnicode_Find( PyObject *str, PyObject *substr, Py_ssize_t start, Py_ssize_t end, int direction)
```

*Return value:* Index of the first ```match```. A value of -1 indicates that no match was found, and -2 indicates that an error occurred and an exception has been set.

```python
Py_ssize_t PyUnicode_Count( PyObject *str, PyObject *substr, Py_ssize_t start, Py_ssize_t end)
```

*Return value:* Number of non-overlapping occurrences of `substr` in ```str[start:end]```. Return -1 if an error occurred.

```python
PyObject* PyUnicode_Replace( PyObject *str, PyObject *substr, PyObject *replstr, Py_ssize_t maxcount)
```

*Return value: New reference.*
Replace at most `maxcount` occurrences of `substr` in `str` with `replstr` and return the resulting Unicode object. `maxcount` == -1 means replace all occurrences.
int PyUnicode_Compare( PyObject *left, PyObject *right)

Compare two strings and return -1, 0, 1 for less than, equal, and greater than, respectively.

int PyUnicode_RichCompare( PyObject *left, PyObject *right, int op)

Rich compare two unicode strings and return one of the following:

- NULL in case an exception was raised
- Py_True or Py_False for successful comparisons
- Py_NotImplemented in case the type combination is unknown

Note that Py_EQ and Py_NE comparisons can cause a UnicodeWarning in case the conversion of the arguments to Unicode fails with a UnicodeDecodeError.

Possible values for op are Py_GT, Py_GE, Py_EQ, Py_NE, Py_LT, and Py_LE.

PyObject* PyUnicode_Format( PyObject *format, PyObject *args)

Return a new string object from format and args; this is analogous to format % args. The args argument must be a tuple.

int PyUnicode_Contains( PyObject *container, PyObject *element)

Check whether element is contained in container and return true or false accordingly.

element has to coerce to a one element Unicode string. -1 is returned if there was an error.

About this document ...

Documenting Python, 19th September, 2006, Release 2.5

This document was generated using the LaTeX2HTML translator.

The application of LaTeX2HTML to the Python documentation has been heavily tailored by Fred L. Drake, Jr. Original navigation icons were contributed by Christopher Petrilli.
Comments and Questions

General comments and questions regarding this document should be sent by email to docs@python.org. If you find specific errors in this document, either in the content or the presentation, please report the bug at the Python Bug Tracker at SourceForge. If you are able to provide suggested text, either to replace existing incorrect or unclear material, or additional text to supplement what's already available, we'd appreciate the contribution. There's no need to worry about text markup; our documentation team will gladly take care of that.

Questions regarding how to use the information in this document should be sent to the Python news group, comp.lang.python, or the Python mailing list (which is gated to the newsgroup and carries the same content).

For any of these channels, please be sure not to send HTML email. Thanks.
