Welcome! This is the documentation for Python 2.6, last updated Oct 02, 2008.

Parts of the documentation:

What's new in Python 2.6? Changes since previous major release

Tutorial
Start here

Using Python
How to use Python on different platforms

Language Reference
Describes syntax and language elements

Library Reference
Keep this under your pillow

Python HOWTOs
In-depth documents on specific topics

Extending and Embedding
tutorial for C/C++ programmers

Python/C API
Reference for C/C++ programmers

Installing Python Modules
Information for installers & sys-admins

Distributing Python Modules
Sharing modules with others

Documenting Python
Guide for documentation authors

Indices and tables:
## Global Module Index

| A | B | C | D | E | F | G | H | I | J | K | L | M | N | O | P | Q | R | S | T | U | V | W | X | Z |
| __builtin__ | The module that provides the built-in namespace. |
| __future__ | Future statement definitions |
| __main__ | The environment where the top-level script is run. |
| _winreg (Windows) | Routines and objects for manipulating the Windows registry. |

### A

- abc: Abstract base classes according to PEP 3119.
- aepack (Mac): **Deprecated**: Conversion between Python variables and AppleEvent data containers.
- aetools (Mac): **Deprecated**: Basic support for sending Apple Events
- aetypes (Mac): **Deprecated**: Python representation of the Apple Event Object Model.
- aifc: Read and write audio files in AIFF or AIFC format.
- al (IRIX): **Deprecated**: Audio functions on the SGI.
- AL (IRIX): **Deprecated**: Constants used with the al module.
- anydbm: Generic interface to DBM-style database modules.
- applesingle (Mac): **Deprecated**: Rudimentary decoder for AppleSingle format
array
Space efficient arrays of uniformly typed numeric values.

ast
Abstract Syntax Tree classes and manipulation.

asynchat
Support for asynchronous command/response protocols.

asyncore
A base class for developing asynchronous socket handling services.

atexit
Register and execute cleanup functions.

audioop
Manipulate raw audio data.

autoGIL (Mac)
Deprecated: Global Interpreter Lock handling in event loops.

B
base64
RFC 3548: Base16, Base32, Base64 Data Encodings

BaseHTTPServer
Basic HTTP server (base class for SimpleHTTPServer and CGIHTTPServer).

Bastion
Deprecated: Providing restricted access to objects.

bdb
Debugger framework.

binascii
Tools for converting between binary and various ASCII-encoded binary representations.

binhex
Encode and decode files in binhex4 format.

bisect
Array bisection algorithms for binary searching.

bsddb
Interface to Berkeley DB database library
<table>
<thead>
<tr>
<th>buildtools (Mac)</th>
<th>Deprecated: Helper module for BuildApplet, BuildApplication and macfreeze.</th>
</tr>
</thead>
<tbody>
<tr>
<td>bz2</td>
<td>Interface to compression and decompression routines compatible with bzip2.</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>C</th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>calendar</td>
<td>Functions for working with calendars, including some emulation of the Unix cal program.</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Carbon</th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>Carbon.AE (Mac)</td>
<td>Deprecated: Interface to the Apple Events toolbox.</td>
</tr>
<tr>
<td>Carbon.AH (Mac)</td>
<td>Deprecated: Interface to the Apple Help manager.</td>
</tr>
<tr>
<td>Carbon.App (Mac)</td>
<td>Deprecated: Interface to the Appearance Manager.</td>
</tr>
<tr>
<td>Carbon.CF (Mac)</td>
<td>Deprecated: Interface to the Core Foundation.</td>
</tr>
<tr>
<td>Carbon.CG (Mac)</td>
<td>Deprecated: Interface to Core Graphics.</td>
</tr>
<tr>
<td>Carbon.Cm (Mac)</td>
<td>Deprecated: Interface to the Component Manager.</td>
</tr>
<tr>
<td>Carbon.Ctl (Mac)</td>
<td>Deprecated: Interface to the Control Manager.</td>
</tr>
<tr>
<td>CarbonEvt (Mac)</td>
<td>Deprecated: Interface to the classic Event Manager.</td>
</tr>
<tr>
<td>Carbon.Fm (Mac)</td>
<td>Deprecated: Interface to the Font Manager.</td>
</tr>
</tbody>
</table>
Carbon.Folder (Mac)  Deprecated: Interface to the Folder Manager.
Carbon.List (Mac)  Deprecated: Interface to the List Manager.
Carbon.Menu (Mac)  Deprecated: Interface to the Menu Manager.
Carbon.Mlte (Mac)  Deprecated: Interface to the MultiLingual Text Editor.
Carbon.Qd (Mac)  Deprecated: Interface to the QuickDraw toolbox.
Carbon.Qdoffs (Mac)  Deprecated: Interface to the QuickDraw Offscreen APIs.
Carbon.Qt (Mac)  Deprecated: Interface to the QuickTime toolbox.
Carbon.Scrap (Mac)  Deprecated: The Scrap Manager provides basic services for implementing cut & paste and clipboard operations.
Carbon.Snd (Mac)  Deprecated: Interface to the Sound Manager.
Carbon.TE (Mac)  Deprecated: Interface to TextEdit.
Carbon.Win (Mac)  Deprecated: Interface to the Window Manager.
cd (IRIX)  Deprecated: Interface to the CD-ROM on Silicon Graphics systems.
cfmlfile (Mac)  Deprecated: Code Fragment Resource module.
**cgi**

Helpers for running Python scripts via the Common Gateway Interface.

**CGIHTTPServer**

This module provides a request handler for HTTP servers which can run CGI scripts.

**cgitb**

Configurable traceback handler for CGI scripts.

**chunk**

Module to read IFF chunks.

**cmath**

Mathematical functions for complex numbers.

**cmd**

Build line-oriented command interpreters.

**code**

Facilities to implement read-eval-print loops.

**codecs**

Encode and decode data and streams.

**codeop**

Compile (possibly incomplete) Python code.

**collections**

High-performance datatypes

**ColorPicker (Mac)**

Deprecated: Interface to the standard color selection dialog.

**colors**

Conversion functions between RGB and other color systems.

**commands (Unix)**

Utility functions for running external commands.

**compileall**

Tools for byte-compiling all Python source files in a directory tree.

**compiler**

Deprecated: Python code compiler written in Python.

**compiler.ast**

**compiler.visitor**

**ConfigParser**

Configuration file parser.
<table>
<thead>
<tr>
<th>Module</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>contextlib</td>
<td>Utilities for with-statement contexts.</td>
</tr>
<tr>
<td>Cookie</td>
<td>Support for HTTP state management (cookies).</td>
</tr>
<tr>
<td>cookielib</td>
<td>Classes for automatic handling of HTTP cookies.</td>
</tr>
<tr>
<td>copy</td>
<td>Shallow and deep copy operations.</td>
</tr>
<tr>
<td>copy_reg</td>
<td>Register pickle support functions.</td>
</tr>
<tr>
<td>cPickle</td>
<td>Faster version of pickle, but not subclassable.</td>
</tr>
<tr>
<td>cProfile</td>
<td>Python profiler</td>
</tr>
<tr>
<td>crypt (Unix)</td>
<td>The crypt() function used to check Unix passwords.</td>
</tr>
<tr>
<td>cStringIO</td>
<td>Faster version of StringIO, but not subclassable.</td>
</tr>
<tr>
<td>csv</td>
<td>Write and read tabular data to and from delimited files.</td>
</tr>
<tr>
<td>ctypes</td>
<td>A foreign function library for Python.</td>
</tr>
<tr>
<td>curses</td>
<td>An interface to the curses library, providing portable terminal handling.</td>
</tr>
<tr>
<td>curses.ascii</td>
<td>Constants and set-membership functions for ASCII characters.</td>
</tr>
<tr>
<td>curses.panel</td>
<td>A panel stack extension that adds depth to curses windows.</td>
</tr>
<tr>
<td>curses.textpad</td>
<td>Emacs-like input editing in a curses window.</td>
</tr>
<tr>
<td>curses.wrapper</td>
<td>Terminal configuration wrapper for curses programs.</td>
</tr>
</tbody>
</table>
datetime

Basic date and time types.

dbhash

DBM-style interface to the BSD database library.

dbm (Unix)

The standard "database" interface, based on ndbm.

decimal

DEVICE (IRIX)

Deprecated: Constants used with the gl module.

difflib

Helpers for computing differences between objects.

dircache

Deprecated: Return directory listing, with cache mechanism.

dis

Disassembler for Python bytecode.

distutils

Support for building and installing Python modules into an existing Python installation.

distutils.archive_util

Utility functions for creating archive files (tarballs, zip files, ...)

distutils.bcppcompiler

distutils.ccompiler

Abstract CCompiler class

This module provides the abstract base class Command. This class is subclassed by the modules in the distutils.command subpackage.

distutils.command

This subpackage contains one module for each standard Distutils command.

distutils.command.bdist

Build a binary installer for a package

distutils.command.bdist_dumb

Build a "dumb" installer - a
distutils.command.bdist_msi

Build a binary distribution as a Windows MSI file

distutils.command.bdist_packager

Abstract base class for packagers

distutils.command.bdist_rpm

Build a binary distribution as a Redhat RPM and SRPM

Build a Windows installer

distutils.command.bdist_wininst

Build all files of a package

distutils.command.build

Build all files of a package

Build any C libraries in a package

Build any extensions in a package

Build the .py/.pyc files of a package

Build the scripts of a package

distutils.command.build_scripts

Clean a package build area

Perform package configuration

Install a package

Install data files from a package

Install C/C++ header files from a package

Install library files from a package

Install script files from a package

distutils.command.register

Register a module with the Python Package Index

Build a source distribution

The core Distutils functionality

distutils.debug

Provides the debug flag for
<table>
<thead>
<tr>
<th>Module</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>distutils.dep_util</td>
<td>Utility functions for simple dependency checking</td>
</tr>
<tr>
<td>distutils.dir_util</td>
<td>Utility functions for operating on directories and directory trees</td>
</tr>
<tr>
<td>distutils.dist</td>
<td>Provides the Distribution class, which represents the module distribution being built/installed/distributed</td>
</tr>
<tr>
<td>distutils.emxccompiler</td>
<td>OS/2 EMX Compiler support</td>
</tr>
<tr>
<td>distutils.errors</td>
<td>Provides standard distutils exceptions</td>
</tr>
<tr>
<td>distutils.extension</td>
<td>Provides the Extension class, used to describe C/C++ extension modules in setup scripts</td>
</tr>
<tr>
<td>distutils.fancy_getopt</td>
<td>Additional getopt functionality</td>
</tr>
<tr>
<td>distutils.file_util</td>
<td>Utility functions for operating on single files</td>
</tr>
<tr>
<td>distutils.filelist</td>
<td>The FileList class, used for poking about the file system and building lists of files.</td>
</tr>
<tr>
<td>distutils.log</td>
<td>A simple logging mechanism, 282-style</td>
</tr>
<tr>
<td>distutils.msvccompiler</td>
<td>Microsoft Compiler</td>
</tr>
<tr>
<td>distutils.mwerkscompiler</td>
<td>Metrowerks CodeWarrior support</td>
</tr>
<tr>
<td>distutils.spawn</td>
<td>Provides the spawn() function</td>
</tr>
<tr>
<td>distutils.sysconfig</td>
<td>Low-level access to configuration information of the Python interpreter.</td>
</tr>
<tr>
<td>distutils.text_file</td>
<td>provides the TextFile class, a simple interface to text files</td>
</tr>
<tr>
<td>distutils.unixccompiler</td>
<td>UNIX C Compiler</td>
</tr>
<tr>
<td>Module</td>
<td>Description</td>
</tr>
<tr>
<td>---------------------------------------------</td>
<td>-----------------------------------------------------------------------------</td>
</tr>
<tr>
<td><strong>distutils.util</strong></td>
<td>Miscellaneous other utility functions</td>
</tr>
<tr>
<td><strong>distutils.version</strong></td>
<td>implements classes that represent module version numbers.</td>
</tr>
<tr>
<td><strong>dl (Unix)</strong></td>
<td>Deprecated: Call C functions in shared objects.</td>
</tr>
<tr>
<td><strong>doctest</strong></td>
<td>Test pieces of code within docstrings.</td>
</tr>
<tr>
<td><strong>DocXMLRPCServer</strong></td>
<td>Self-documenting XML-RPC server implementation.</td>
</tr>
<tr>
<td><strong>dumbdbm</strong></td>
<td>Portable implementation of the simple DBM interface.</td>
</tr>
<tr>
<td><strong>dummy_thread</strong></td>
<td>Drop-in replacement for the thread module.</td>
</tr>
<tr>
<td><strong>dummy_threading</strong></td>
<td>Drop-in replacement for the threading module.</td>
</tr>
<tr>
<td><strong>E</strong></td>
<td></td>
</tr>
<tr>
<td><strong>EasyDialogs (Mac)</strong></td>
<td>Deprecated: Basic Macintosh dialogs.</td>
</tr>
<tr>
<td><strong>email</strong></td>
<td>Package supporting the parsing, manipulating, and generating email messages, including MIME documents.</td>
</tr>
<tr>
<td><strong>email.charset</strong></td>
<td>Character Sets</td>
</tr>
<tr>
<td><strong>email.encoders</strong></td>
<td>Encoders for email message payloads.</td>
</tr>
<tr>
<td><strong>email.errors</strong></td>
<td>The exception classes used by the email package.</td>
</tr>
<tr>
<td><strong>email.generator</strong></td>
<td>Generate flat text email messages from a message structure.</td>
</tr>
<tr>
<td><strong>email.header</strong></td>
<td>Representing non-ASCII headers</td>
</tr>
</tbody>
</table>
email.iterators
Iterate over a message object tree.

email.message
The base class representing email messages.

email.mime
Build MIME messages.

email.parser
Parse flat text email messages to produce a message object structure.

email.utils
Miscellaneous email package utilities.

encodings

encodings.idna
Internationalized Domain Names implementation

encodings.utf_8_sig
UTF-8 codec with BOM signature

errno
Standard errno system symbols.

exceptions
Standard exception classes.

F

fcntl (Unix)
The fcntl() and ioctl() system calls.

filecmp
Compare files efficiently.

fileinput
Loop over standard input or a list of files.

findertools (Mac)
Wrappers around the finder's Apple Events interface.

FL (IRIX)
Deprecated: Constants used with the fl module.

fl (IRIX)
Deprecated: FORMS library for applications with graphical user interfaces.

flp (IRIX)
Deprecated: Functions for loading stored FORMS designs.
<table>
<thead>
<tr>
<th>Package</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>fm (IRIX)</td>
<td>Deprecated: Font Manager interface for SGI workstations.</td>
</tr>
<tr>
<td>fnmatch</td>
<td>Unix shell style filename pattern matching.</td>
</tr>
<tr>
<td>formatter</td>
<td>Generic output formatter and device interface.</td>
</tr>
<tr>
<td>fpectl (Unix)</td>
<td>Provide control for floating point exception handling.</td>
</tr>
<tr>
<td>fpformat</td>
<td>Deprecated: General floating point formatting functions.</td>
</tr>
<tr>
<td>fractions</td>
<td>Rational numbers.</td>
</tr>
<tr>
<td>FrameWork (Mac)</td>
<td>Deprecated: Interactive application framework.</td>

<tr>
<td><strong>mimetypes</strong></td>
<td><strong>Deprecated:</strong> Tools for parsing MIME-style message bodies.</td>
</tr>
<tr>
<td><strong>mimetypes</strong></td>
<td>Mapping of filename extensions to MIME types.</td>
</tr>
</tbody>
</table>
MimeWriter

**Deprecated:** Write MIME format files.

mimify

**Deprecated:** Mimification and unmimification of mail messages.

MiniAEFrame *(Mac)*

Support to act as an Open Scripting Architecture (OSA) server ("Apple Events").

mmap

Interface to memory-mapped files for Unix and Windows.

modulefinder

Find modules used by a script.

msilib *(Windows)*

Creation of Microsoft Installer files, and CAB files.

msvcrt *(Windows)*

Miscellaneous useful routines from the MS VC++ runtime.

multifile

**Deprecated:** Support for reading files which contain distinct parts, such as some MIME data.

multiprocessing

Process-based "threading" interface.

  multiprocessing.connection

  API for dealing with sockets.

  multiprocessing.dummy

  Dumb wrapper around threading.

  multiprocessing.managers

  Share data between process with shared objects.

  multiprocessing.pool

  Create pools of processes.

  multiprocessing.sharedctypes

  Allocate ctypes objects from shared memory.

mutex

**Deprecated:** Lock and queue for mutual exclusion.

N

**Deprecated:** Interface to Navigation Services.

Nav *(Mac)*
<table>
<thead>
<tr>
<th>Module</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>netrc new</td>
<td>Loading of .netrc files.</td>
</tr>
<tr>
<td>nis (Unix)</td>
<td>Interface to Sun's NIS (Yellow Pages) library.</td>
</tr>
<tr>
<td>nntplib</td>
<td>NNTP protocol client (requires sockets).</td>
</tr>
<tr>
<td>numbers</td>
<td>Numeric abstract base classes (Complex, Real, Integral, etc.).</td>
</tr>
<tr>
<td>operator</td>
<td>Functions corresponding to the standard operators.</td>
</tr>
<tr>
<td>optparse</td>
<td>More convenient, flexible, and powerful command-line parsing library.</td>
</tr>
<tr>
<td>os</td>
<td>Miscellaneous operating system interfaces.</td>
</tr>
<tr>
<td>os.path</td>
<td>Operations on pathnames.</td>
</tr>
<tr>
<td>ossaudiodev</td>
<td>Access to OSS-compatible audio devices.</td>
</tr>
<tr>
<td>parser</td>
<td>Access parse trees for Python source code.</td>
</tr>
<tr>
<td>pdb</td>
<td>The Python debugger for interactive interpreters.</td>
</tr>
<tr>
<td>pickle</td>
<td>Convert Python objects to streams of bytes and back.</td>
</tr>
<tr>
<td>pickletools</td>
<td>Contains extensive comments about the pickle protocols and pickle-machine opcodes, as well as some useful functions.</td>
</tr>
</tbody>
</table>
| pipes (Unix)  | A Python interface to Unix shell.
<table>
<thead>
<tr>
<th><strong>PixMapWrapper (Mac)</strong></th>
<th><strong>Deprecation:</strong> Wrapper for PixMap objects.</th>
</tr>
</thead>
<tbody>

</table>
multiple streams.

**Deprecation:** Implementation of sets of unique elements.

**sgmllib**

 deprecated: Only as much of an SGML parser as needed to parse HTML.

**sha**

 deprecated: NIST’s secure hash algorithm, SHA.

**shelve**

 Python object persistence.

**shlex**

 Simple lexical analysis for Unix shell-like languages.

**shutil**

 High-level file operations, including copying.

**signal**

 Set handlers for asynchronous events.

**SimpleHTTPServer**

 This module provides a basic request handler for HTTP servers.

**SimpleXMLRPCServer**

 Basic XML-RPC server implementation.

**site**

 A standard way to reference site-specific modules.

**smtpd**

 A SMTP server implementation in Python.

**smtplib**

 SMTP protocol client (requires sockets).

**sndhdr**

 Determine type of a sound file.

**socket**

 Low-level networking interface.

**SocketServer**

 A framework for network servers.

**spwd (Unix)**

 The shadow password database (getspnam() and friends).

**sqlite3**

 A DB-API 2.0 implementation using SQLite 3.x.
ssl  SSL wrapper for socket objects
stat  Utilities for interpreting the results of os.stat(), os.lstat() and os.fstat().
statvfs  Deprecated: Constants for interpreting the result of os.statvfs().
string  Common string operations.
StringIO  Read and write strings as if they were files.
stringprep  Deprecated: String preparation, as per RFC 3453
struct  Interpret strings as packed binary data.
subprocess  Subprocess management.
sunau  Provide an interface to the Sun AU sound format.
sunaudiodev (SunOS)  Deprecated: Access to Sun audio hardware.
sunaudiodev (SunOS)  Deprecated: Constants for use with sunaudiodev.
symbol  Constants representing internal nodes of the parse tree.
symtable  Interface to the compiler's internal symbol tables.
sys  Access system-specific parameters and functions.
syslog (Unix)  An interface to the Unix syslog library routines.

T  tabnanny  Tool for detecting white space related problems in Python source files in a directory tree.
tarfile  Read and write tar-format
<table>

warnings

Issue warning messages and control their disposition.

wave

Provide an interface to the WAV sound format.

weakref

Support for weak references and weak dictionaries.

webbrowser

Easy-to-use controller for Web browsers.

whichdb

Guess which DBM-style module created a given database.

winsound (Windows)

Access to the sound-playing machinery for Windows.

wsgiref

WSGI Utilities and Reference Implementation.

wsgiref.handlers

WSGI server/gateway base classes.

wsgiref.headers

WSGI response header tools.

wsgiref.simple_server

A simple WSGI HTTP server.

wsgiref.util

WSGI environment utilities.

wsgiref.validate

WSGI conformance checker.

X

xdr

Encoders and decoders for the External Data Representation (XDR).

xml

Document Object Model API for Python.

xml.dom

Lightweight Document Object Model (DOM) implementation.

xml.dom.minidom

Support for building partial DOM trees from SAX events.

xml.etree.ElementTree

Implementation of the

This article explains the new features in Python 2.6, released on October 1 2008. The release schedule is described in PEP 361.

The major theme of Python 2.6 is preparing the migration path to Python 3.0, a major redesign of the language. Whenever possible, Python 2.6 incorporates new features and syntax from 3.0 while remaining compatible with existing code by not removing older features or syntax. When it's not possible to do that, Python 2.6 tries to do what it can, adding compatibility functions in a future_builtins module and a -3 switch to warn about usages that will become unsupported in 3.0.

Some significant new packages have been added to the standard library, such as the multiprocessing and json modules, but there aren’t many new features that aren’t related to Python 3.0 in some way.

Python 2.6 also sees a number of improvements and bugfixes throughout the source. A search through the change logs finds there were 259 patches applied and 612 bugs fixed between Python 2.5 and 2.6. Both figures are likely to be underestimates.

This article doesn’t attempt to provide a complete specification of the new features, but instead provides a convenient overview. For full details, you should refer to the documentation for Python 2.6. If you want to understand the rationale for the design and implementation, refer to the PEP for a particular new feature. Whenever possible, “What's New in Python” links to the bug/patch item for each change.
The development cycle for Python versions 2.6 and 3.0 was synchronized, with the alpha and beta releases for both versions being made on the same days. The development of 3.0 has influenced many features in 2.6.

Python 3.0 is a far-ranging redesign of Python that breaks compatibility with the 2.x series. This means that existing Python code will need some conversion in order to run on Python 3.0. However, not all the changes in 3.0 necessarily break compatibility. In cases where new features won’t cause existing code to break, they've been backported to 2.6 and are described in this document in the appropriate place. Some of the 3.0-derived features are:

- A `__complex__()` method for converting objects to a complex number.
- Alternate syntax for catching exceptions: `except TypeError as exc`.
- The addition of `functools.reduce()` as a synonym for the built-in `reduce()` function.

Python 3.0 adds several new built-in functions and changes the semantics of some existing built-ins. Functions that are new in 3.0 such as `bin()` have simply been added to Python 2.6, but existing built-ins haven’t been changed; instead, the `future_bultins` module has versions with the new 3.0 semantics. Code written to be compatible with 3.0 can do `from future_bultins import hex, map` as necessary.

A new command-line switch, `-3`, enables warnings about features that will be removed in Python 3.0. You can run code with this switch to see how much work will be necessary to port code to 3.0. The
value of this switch is available to Python code as the boolean variable `sys.py3kwarning`, and to C extension code as `Py_Py3kWarningFlag`.

**See also:** The 3xxx series of PEPs, which contains proposals for Python 3.0. **PEP 3000** describes the development process for Python 3.0. Start with **PEP 3100** that describes the general goals for Python 3.0, and then explore the higher-numbered PEPs that propose specific features.
Changes to the Development Process

While 2.6 was being developed, the Python development process underwent two significant changes: we switched from SourceForge's issue tracker to a customized Roundup installation, and the documentation was converted from LaTeX to reStructuredText.

New Issue Tracker: Roundup

For a long time, the Python developers had been growing increasingly annoyed by SourceForge's bug tracker. SourceForge's hosted solution doesn't permit much customization; for example, it wasn't possible to customize the life cycle of issues.

The infrastructure committee of the Python Software Foundation therefore posted a call for issue trackers, asking volunteers to set up different products and import some of the bugs and patches from SourceForge. Four different trackers were examined: Jira, Launchpad, Roundup, and Trac. The committee eventually settled on Jira and Roundup as the two candidates. Jira is a commercial product that offers no-cost hosted instances to free-software projects; Roundup is an open-source project that requires volunteers to administer it and a server to host it.

After posting a call for volunteers, a new Roundup installation was set up at http://bugs.python.org. One installation of Roundup can host multiple trackers, and this server now also hosts issue trackers for Jython and for the Python web site. It will surely find other uses in the future. Where possible, this edition of “What's New in Python” links to the bug/patch item for each change.

Hosting of the Python bug tracker is kindly provided by Upfront Systems of Stellenbosch, South Africa. Martin von Loewis put a lot of
effort into importing existing bugs and patches from SourceForge; his scripts for this import operation are at http://svn.python.org/view/tracker/importer/ and may be useful to other projects wished to move from SourceForge to Roundup.

New Documentation Format: reStructuredText Using Sphinx

The Python documentation was written using LaTeX since the project started around 1989. In the 1980s and early 1990s, most documentation was printed out for later study, not viewed online. LaTeX was widely used because it provided attractive printed output while remaining straightforward to write once the basic rules of the markup were learned.

Today LaTeX is still used for writing publications destined for printing, but the landscape for programming tools has shifted. We no longer print out reams of documentation; instead, we browse through it online and HTML has become the most important format to support. Unfortunately, converting LaTeX to HTML is fairly complicated and Fred L. Drake Jr., the long-time Python documentation editor, spent
a lot of time maintaining the conversion process. Occasionally people would suggest converting the documentation into SGML and later XML, but performing a good conversion is a major task and no one ever committed the time required to finish the job.

During the 2.6 development cycle, Georg Brandl put a lot of effort into building a new toolchain for processing the documentation. The resulting package is called Sphinx, and is available from http://sphinx.pocoo.org/.

Sphinx concentrates on HTML output, producing attractively styled and modern HTML; printed output is still supported through conversion to LaTeX. The input format is reStructuredText, a markup syntax supporting custom extensions and directives that is commonly used in the Python community.

Sphinx is a standalone package that can be used for writing, and almost two dozen other projects (listed on the Sphinx web site) have adopted Sphinx as their documentation tool.

The underlying reStructuredText parser and toolset.
The previous version, Python 2.5, added the ‘with’ statement as an optional feature, to be enabled by a `from __future__ import with_statement` directive. In 2.6 the statement no longer needs to be specially enabled; this means that `with` is now always a keyword. The rest of this section is a copy of the corresponding section from the “What’s New in Python 2.5” document; if you’re familiar with the ‘with’ statement from Python 2.5, you can skip this section.

The ‘with’ statement clarifies code that previously would use `try...finally` blocks to ensure that clean-up code is executed. In this section, I’ll discuss the statement as it will commonly be used. In the next section, I’ll examine the implementation details and show how to write objects for use with this statement.

The ‘with’ statement is a control-flow structure whose basic structure is:

```python
with expression [as variable]:
    with-block
```

The expression is evaluated, and it should result in an object that supports the context management protocol (that is, has `__enter__()`) and `__exit__()` methods.

The object's `__enter__()` is called before `with-block` is executed and therefore can run set-up code. It also may return a value that is bound to the name `variable`, if given. (Note carefully that `variable` is not assigned the result of `expression`.)

After execution of the `with-block` is finished, the object's `__exit__()` method is called, even if the block raised an exception, and can
therefore run clean-up code.

Some standard Python objects now support the context management protocol and can be used with the 'with' statement. File objects are one example:

```python
with open('/etc/passwd', 'r') as f:
    for line in f:
        print(line)
... more processing code ...
```

After this statement has executed, the file object in f will have been automatically closed, even if the for loop raised an exception part-way through the block.

**Note:** In this case, f is the same object created by `open()`, because `file.__enter__()` returns `self`.

The `threading` module’s locks and condition variables also support the 'with' statement:

```python
lock = threading.Lock()
with lock:
    # Critical section of code
    ...
```

The lock is acquired before the block is executed and always released once the block is complete.

The `localcontext()` function in the `decimal` module makes it easy to save and restore the current decimal context, which encapsulates the desired precision and rounding characteristics for computations:

```python
from decimal import Decimal, Context, localcontext

# Displays with default precision of 28 digits
v = Decimal('578')
print(v.sqrt())
```
with localcontext(Context(prec=16)):
    # All code in this block uses a precision of 16 digits.
    # The original context is restored on exiting the block.
    print v.sqrt()

Writing Context Managers

Under the hood, the `with` statement is fairly complicated. Most people will only use `with` in company with existing objects and don’t need to know these details, so you can skip the rest of this section if you like. Authors of new objects will need to understand the details of the underlying implementation and should keep reading.

A high-level explanation of the context management protocol is:

- The expression is evaluated and should result in an object called a “context manager”. The context manager must have `__enter__()` and `__exit__()` methods.
- The context manager’s `__enter__()` method is called. The value returned is assigned to `VAR`. If no `as VAR` clause is present, the value is simply discarded.
- The code in `BLOCK` is executed.
- If `BLOCK` raises an exception, the `__exit__(type, value, traceback)()` is called with the exception details, the same values returned by `sys.exc_info()`. The method’s return value controls whether the exception is re-raised: any false value re-raises the exception, and `True` will result in suppressing it. You’ll only rarely want to suppress the exception, because if you do the author of the code containing the `with` statement will never realize anything went wrong.
- If `BLOCK` didn’t raise an exception, the `__exit__()` method is still called, but `type`, `value`, and `traceback` are all `None`.

Let’s think through an example. I won’t present detailed code but will
only sketch the methods necessary for a database that supports transactions.

(For people unfamiliar with database terminology: a set of changes to the database are grouped into a transaction. Transactions can be either committed, meaning that all the changes are written into the database, or rolled back, meaning that the changes are all discarded and the database is unchanged. See any database textbook for more information.)

Let’s assume there’s an object representing a database connection. Our goal will be to let the user write code like this:

```python
db_connection = DatabaseConnection()
with db_connection as cursor:
    cursor.execute('insert into ...')
    cursor.execute('delete from ...')
    # ... more operations ...
```

The transaction should be committed if the code in the block runs flawlessly or rolled back if there's an exception. Here's the basic interface for `DatabaseConnection` that I'll assume:

```python
class DatabaseConnection:
    # Database interface
    def cursor(self):
        "Returns a cursor object and starts a new transaction"
    def commit(self):
        "Commits current transaction"
    def rollback(self):
        "Rolls back current transaction"
```

The `__enter__()` method is pretty easy, having only to start a new transaction. For this application the resulting cursor object would be a useful result, so the method will return it. The user can then add `as cursor` to their `with` statement to bind the cursor to a variable name.

```python
class DatabaseConnection:
    ...
```
def __enter__(self):
    # Code to start a new transaction
    cursor = self.cursor()
    return cursor

The __exit__() method is the most complicated because it's where most of the work has to be done. The method has to check if an exception occurred. If there was no exception, the transaction is committed. The transaction is rolled back if there was an exception.

In the code below, execution will just fall off the end of the function, returning the default value of None. None is false, so the exception will be re-raised automatically. If you wished, you could be more explicit and add a return statement at the marked location.

class DatabaseConnection:
    ...
    def __exit__(self, type, value, tb):
        if tb is None:
            # No exception, so commit
            self.commit()
        else:
            # Exception occurred, so rollback.
            self.rollback()
            # return False

The contextlib module

The contextlib module provides some functions and a decorator that are useful when writing objects for use with the 'with' statement.

The decorator is called contextmanager(), and lets you write a single generator function instead of defining a new class. The generator should yield exactly one value. The code up to the yield will be executed as the __enter__() method, and the value yielded will be the method’s return value that will get bound to the variable in the 'with' statement’s as clause, if any. The code after the yield will be
executed in the `__exit__()` method. Any exception raised in the block will be raised by the `yield` statement.

Using this decorator, our database example from the previous section could be written as:

```python
from contextlib import contextmanager

@contextmanager
def db_transaction(connection):
    cursor = connection.cursor()
    try:
        yield cursor
    except:
        connection.rollback()
        raise
    else:
        connection.commit()

db = DatabaseConnection()
with db_transaction(db) as cursor:
    ...
```

The `contextlib` module also has a `nested(mgr1, mgr2, ...)()` function that combines a number of context managers so you don't need to write nested 'with' statements. In this example, the single 'with' statement both starts a database transaction and acquires a thread lock:

```python
lock = threading.Lock()
with nested (db_transaction(db), lock) as (cursor, locked):
    ...
```

Finally, the `closing(object)()` function returns `object` so that it can be bound to a variable, and calls `object.close` at the end of the block.

```python
import urllib, sys
from contextlib import closing

with closing(urllib.urlopen('http://www.yahoo.com')) as f:
    ...
```
for line in f:
sys.stdout.write(line)

**PEP 343 - The “with” statement**

PEP written by Guido van Rossum and Nick Coghlan; implemented by Mike Bland, Guido van Rossum, and Neal Norwitz. The PEP shows the code generated for a `with` statement, which can be helpful in learning how the statement works.

The documentation for the `contextlib` module.
PEP 366: Explicit Relative Imports From a Main Module

Python’s -m switch allows running a module as a script. When you ran a module that was located inside a package, relative imports didn’t work correctly.

The fix for Python 2.6 adds a __package__ attribute to modules. When this attribute is present, relative imports will be relative to the value of this attribute instead of the __name__ attribute.

PEP 302-style importers can then set __package__ as necessary. The runpy module that implements the -m switch now does this, so relative imports will now work correctly in scripts running from inside a package.
When you run Python, the module search path `sys.path` usually includes a directory whose path ends in "site-packages". This directory is intended to hold locally-installed packages available to all users using a machine or a particular site installation.

Python 2.6 introduces a convention for user-specific site directories. The directory varies depending on the platform:

- Unix and Mac OS X: `~/.local/`
- Windows: `%APPDATA%/Python`

Within this directory, there will be version-specific subdirectories, such as `lib/python2.6/site-packages` on Unix/Mac OS and `Python26/site-packages` on Windows.

If you don't like the default directory, it can be overridden by an environment variable. `PYTHONUSERBASE` sets the root directory used for all Python versions supporting this feature. On Windows, the directory for application-specific data can be changed by setting the `APPDATA` environment variable. You can also modify the `site.py` file for your Python installation.

The feature can be disabled entirely by running Python with the `-s` option or setting the `PYTHONNOUSERSITE` environment variable.

**See also:**

**PEP 370 - Per-user site-packages Directory**

PEP written and implemented by Christian Heimes.
The new `multiprocessing` package lets Python programs create new processes that will perform a computation and return a result to the parent. The parent and child processes can communicate using queues and pipes, synchronize their operations using locks and semaphores, and can share simple arrays of data.

The `multiprocessing` module started out as an exact emulation of the `threading` module using processes instead of threads. That goal was discarded along the path to Python 2.6, but the general approach of the module is still similar. The fundamental class is the `Process`, which is passed a callable object and a collection of arguments. The `start()` method sets the callable running in a subprocess, after which you can call the `is_alive()` method to check whether the subprocess is still running and the `join()` method to wait for the process to exit.

Here’s a simple example where the subprocess will calculate a factorial. The function doing the calculation is written strangely so that it takes significantly longer when the input argument is a multiple of 4.

```python
import time
from multiprocessing import Process, Queue

def factorial(queue, N):
    "Compute a factorial."
    # If N is a multiple of 4, this function will take much lon
    if (N % 4) == 0:
        time.sleep(.05 * N/4)

    # Calculate the result
    fact = 1L
    for i in range(1, N+1):
        fact = fact * i
```

Here's a simple example where the subprocess will calculate a factorial. The function doing the calculation is written strangely so that it takes significantly longer when the input argument is a multiple of 4.

```python
import time
from multiprocessing import Process, Queue

def factorial(queue, N):
    "Compute a factorial."
    # If N is a multiple of 4, this function will take much lon
    if (N % 4) == 0:
        time.sleep(.05 * N/4)

    # Calculate the result
    fact = 1L
    for i in range(1, N+1):
        fact = fact * i
```
A **Queue** is used to communicate the input parameter \( N \) and the result. The **Queue** object is stored in a global variable. The child process will use the value of the variable when the child was created; because it’s a **Queue**, parent and child can use the object to communicate. (If the parent were to change the value of the global variable, the child’s value would be unaffected, and vice versa.)

Two other classes, **Pool** and **Manager**, provide higher-level interfaces. **Pool** will create a fixed number of worker processes, and requests can then be distributed to the workers by calling **apply()** or **apply_async()** to add a single request, and **map()** or **map_async()** to add a number of requests. The following code uses a **Pool** to spread requests across 5 worker processes and retrieve a list of results:

```python
from multiprocessing import Pool

def factorial(N, dictionary):
    "Compute a factorial."
    ...
    p = Pool(5)
    result = p.map(factorial, range(1, 1000, 10))
    for v in result:
        print v
```
This produces the following output:

```
1
3991680
5109094217170944000
822283865417792281772556288000000
33452526613163807108170062053440751666515200000000
...
```

The other high-level interface, the `Manager` class, creates a separate server process that can hold master copies of Python data structures. Other processes can then access and modify these data structures using proxy objects. The following example creates a shared dictionary by calling the `dict()` method; the worker processes then insert values into the dictionary. (Locking is not done for you automatically, which doesn't matter in this example. `Manager`'s methods also include `Lock()`, `RLock()`, and `Semaphore()` to create shared locks.)

```python
import time
from multiprocessing import Pool, Manager

def factorial(N, dictionary):
    """Compute a factorial."
    # Calculate the result
    fact = 1
    for i in range(1, N+1):
        fact = fact * i

    # Store result in dictionary
    dictionary[N] = fact

if __name__ == '__main__':
    p = Pool(5)
    mgr = Manager()
    d = mgr.dict()  # Create shared dictionary

    # Run tasks using the pool
    for N in range(1, 1000, 10):
        p.apply_async(factorial, (N, d))

    # Mark pool as closed -- no more tasks can be added.
    p.close()
```
```python
# Wait for tasks to exit
p.join()

# Output results
for k, v in sorted(d.items()):
    print(k, v)
```

This will produce the output:

```plaintext
1 1
11 39916800
21 51090942171709440000
31 8222838654177922817725562880000000
41 33452526613163807108170062053440751665152000000000000
51 15511187532873822802242430164693032110632597200169861120000.
```

**See also:** The documentation for the `multiprocessing` module.

**PEP 371 - Addition of the multiprocessing package**

PEP written by Jesse Noller and Richard Oudkerk; implemented by Richard Oudkerk and Jesse Noller.
PEP 3101: Advanced String Formatting

In Python 3.0, the % operator is supplemented by a more powerful string formatting method, \texttt{format()}. Support for the \texttt{str.format()} method has been backported to Python 2.6.

In 2.6, both 8-bit and Unicode strings have a \texttt{.format()} method that treats the string as a template and takes the arguments to be formatted. The formatting template uses curly brackets \{(, )\} as special characters:

```python
# Substitute positional argument 0 into the string.
"User ID: \{0\}".format("root") -> "User ID: root"

# Use the named keyword arguments
'User ID: \{uid\} Last seen: \{last_login\}'.format(
    uid='root',
    last_login = '5 Mar 2008 07:20') ->
'User ID: root Last seen: 5 Mar 2008 07:20'
```

Curly brackets can be escaped by doubling them:

```python
format("Empty dict: \{\}\") -> "Empty dict: {}
```

Field names can be integers indicating positional arguments, such as \{0\}, \{1\}, etc. or names of keyword arguments. You can also supply compound field names that read attributes or access dictionary keys:

```python
import sys
'Platform: \{0.platform\}\nPython version: \{0.version\}'.format(sys)
   [GCC 4.0.1 (Apple Computer, Inc. build 5367)]'

import mimetypes
'Content-type: \{0[.mp4]\}'.format(mimetypes.types_map) ->
   'Content-type: video/mp4'
```
Note that when using dictionary-style notation such as [.mp4], you don’t need to put any quotation marks around the string; it will look up the value using .mp4 as the key. Strings beginning with a number will be converted to an integer. You can’t write more complicated expressions inside a format string.

So far we’ve shown how to specify which field to substitute into the resulting string. The precise formatting used is also controllable by adding a colon followed by a format specifier. For example:

```python
# Field 0: left justify, pad to 15 characters
# Field 1: right justify, pad to 6 characters
fmt = '{0:15} ${1:>6}'

fmt.format('Registration', 35) ->
    'Registration $  35'

fmt.format('Tutorial', 50) ->
    'Tutorial     $  50'

fmt.format('Banquet', 125) ->
    'Banquet       $ 125'
```

Format specifiers can reference other fields through nesting:

```python
fmt = '{0:{1}}'

width = 15
fmt.format('Invoice #1234', width) ->
    'Invoice #1234   '

width = 35
fmt.format('Invoice #1234', width) ->
    'Invoice #1234     '
```

The alignment of a field within the desired width can be specified:

<table>
<thead>
<tr>
<th>Character</th>
<th>Effect</th>
</tr>
</thead>
<tbody>
<tr>
<td>&lt; (default)</td>
<td>Left-align</td>
</tr>
<tr>
<td>&gt;</td>
<td>Right-align</td>
</tr>
</tbody>
</table>
Format specifiers can also include a presentation type, which controls how the value is formatted. For example, floating-point numbers can be formatted as a general number or in exponential notation:

```python
>>> '{0:g}'.format(3.75)
'3.75'
>>> '{0:e}'.format(3.75)
'3.7500000e+00'
```

A variety of presentation types are available. Consult the 2.6 documentation for a complete list; here's a sample:

- `'b'` - Binary. Outputs the number in base 2.
- `'c'` - Character. Converts the integer to the corresponding Unicode character before printing.
- `'d'` - Decimal Integer. Outputs the number in base 10.
- `'o'` - Octal format. Outputs the number in base 8.
- `'x'` - Hex format. Outputs the number in base 16, using lowercase letters for the digits above 9.
- `'e'` - Exponent notation. Prints the number in scientific notation using the letter 'e' to indicate the exponent.
- `'g'` - General format. This prints the number as a fixed-point number, unless the number is too large, in which case it switches to 'e' exponent notation.
- `'n'` - Number. This is the same as 'g' (for floats) or 'd' (for integers), except that it uses the current locale setting to insert the appropriate number separator characters.
- `'%'` - Percentage. Multiplies the number by 100 and displays in fixed ('f') format, followed by a percent sign.

Classes and types can define a `__format__()` method to control how they're formatted. It receives a single argument, the format specifier:

```python
def __format__(self, format_spec):
    if isinstance(format_spec, unicode):
        return unicode(str(self))
```
```python
else:
    return str(self)
```

There's also a `format()` built-in that will format a single value. It calls the type's `__format__() method with the provided specifier:

```python
>>> format(75.6564, '.2f')
'75.66'
```

See also:

* **Format String Syntax**
  The reference documentation for format fields.

* **PEP 3101 - Advanced String Formatting**
  PEP written by Talin. Implemented by Eric Smith.
The `print` statement becomes the `print()` function in Python 3.0. Making `print()` a function makes it possible to replace the function by doing `def print(...)` or importing a new function from somewhere else.

Python 2.6 has a `__future__` import that removes `print` as language syntax, letting you use the functional form instead. For example:

```python
from __future__ import print_function
print('# of entries', len(dictionary), file=sys.stderr)
```

The signature of the new function is:

```python
def print(*args, sep=' ', end='
', file=None)
```

The parameters are:

- `args`: positional arguments whose values will be printed out.
- `sep`: the separator, which will be printed between arguments.
- `end`: the ending text, which will be printed after all of the arguments have been output.
- `file`: the file object to which the output will be sent.

**PEP 3105 - Make print a function**

PEP written by Georg Brandl.
One error that Python programmers occasionally make is writing the following code:

```python
try:
    ...
except TypeError, ValueError:  # Wrong!
    ...
```

The author is probably trying to catch both `TypeError` and `ValueError` exceptions, but this code actually does something different: it will catch `TypeError` and bind the resulting exception object to the local name "ValueError". The `ValueError` exception will not be caught at all. The correct code specifies a tuple of exceptions:

```python
try:
    ...
except (TypeError, ValueError):
    ...
```

This error happens because the use of the comma here is ambiguous: does it indicate two different nodes in the parse tree, or a single node that's a tuple?

Python 3.0 makes this unambiguous by replacing the comma with the word “as”. To catch an exception and store the exception object in the variable `exc`, you must write:

```python
try:
    ...
except TypeError as exc:
    ...
```

Python 3.0 will only support the use of “as”, and therefore interprets the first example as catching two different exceptions. Python 2.6
supports both the comma and “as”, so existing code will continue to work. We therefore suggest using “as” when writing new Python code that will only be executed with 2.6.

See also:

PEP 3110 - Catching Exceptions in Python 3000
PEP written and implemented by Collin Winter.
PEP 3112: Byte Literals

Python 3.0 adopts Unicode as the language’s fundamental string type and denotes 8-bit literals differently, either as `b'string'` or using a `bytes` constructor. For future compatibility, Python 2.6 adds `bytes` as a synonym for the `str` type, and it also supports the `b''` notation.

There’s also a `__future__` import that causes all string literals to become Unicode strings. This means that `\u` escape sequences can be used to include Unicode characters:

```python
from __future__ import unicode_literals

s = ('\u751f\u3080\u304e\u3000\u751f\u3054\n\u3081\u3000\u751f\u305f\u307e\u3054')
print len(s)  # 12 Unicode characters
```

At the C level, Python 3.0 will rename the existing 8-bit string type, called `PyStringObject` in Python 2.x, to `PyBytesObject`. Python 2.6 uses `#define` to support using the names `PyBytesObject`, `PyBytes_Check`, `PyBytes_FromStringAndSize`, and all the other functions and macros used with strings.

Instances of the `bytes` type are immutable just as strings are. A new `bytearray` type stores a mutable sequence of bytes:

```plaintext
>>> bytearray([65, 66, 67])
bytearray(b'ABC')
>>> b = bytearray(u'\u21ef\u3244', 'utf-8')
>>> b
bytearray(b'\xe2\x87\xa1\xe3\x89\x84')
>>> b[0] = '\xe3'
>>> b
bytearray(b'\xe3\x87\xa1\xe3\x89\x84')
>>> unicode(str(b), 'utf-8')
'u'\u31ef \u3244'
```
Byte arrays support most of the methods of string types, such as `startswith()`/`endswith()`, `find()`/`rfind()`, and some of the methods of lists, such as `append()`, `pop()`, and `reverse()`.

```python
>>> b = bytearray('ABC')
>>> b.append('d')
>>> b.append(ord('e'))
>>> b
bytearray(b'ABCde')
```

There's also a corresponding C API, with `PyByteArray_FromObject`, `PyByteArray_FromStringAndSize`, and various other functions.

documentation) — PEP written by Jason Orendorff; backported to 2.6 by Christian Heimes.
PEP 3116: New I/O Library

Python's built-in file objects support a number of methods, but file-like objects don't necessarily support all of them. Objects that imitate files usually support `read()` and `write()`, but they may not support `readline()`, for example. Python 3.0 introduces a layered I/O library in the `io` module that separates buffering and text-handling features from the fundamental read and write operations.

There are three levels of abstract base classes provided by the `io` module:

- **RawIOWrapper** defines raw I/O operations: `read()`, `readinto()`, `write()`, `seek()`, `tell()`, `truncate()`, and `close()`. Most of the methods of this class will often map to a single system call. There are also `readable()`, `writable()`, and `seekable()` methods for determining what operations a given object will allow.

  Python 3.0 has concrete implementations of this class for files and sockets, but Python 2.6 hasn’t restructured its file and socket objects in this way.

- **BufferedIOWrapper** is an abstract base class that buffers data in memory to reduce the number of system calls used, making I/O processing more efficient. It supports all of the methods of `RawIOWrapper`, and adds a `raw` attribute holding the underlying raw object.

  There are five concrete classes implementing this ABC. `BufferedWriter` and `BufferedReader` are for objects that support write-only or read-only usage that have a `seek()` method for random access. `BufferedRandom` objects support read and write
access upon the same underlying stream, and \texttt{BufferedRWPair}
is for objects such as TTYs that have both read and write operations acting upon unconnected streams of data. The \texttt{BytesIO} class supports reading, writing, and seeking over an in-memory buffer.

- \texttt{TextIOBase}: Provides functions for reading and writing strings (remember, strings will be Unicode in Python 3.0), and supporting universal newlines. \texttt{TextIOBase} defines the \texttt{readline()} method and supports iteration upon objects.

There are two concrete implementations. \texttt{TextIOWrapper} wraps a buffered I/O object, supporting all of the methods for text I/O and adding a \texttt{buffer} attribute for access to the underlying object. \texttt{StringIO} simply buffers everything in memory without ever writing anything to disk.

(In Python 2.6, \texttt{io.StringIO} is implemented in pure Python, so it’s pretty slow. You should therefore stick with the existing \texttt{StringIO} module or \texttt{cStringIO} for now. At some point Python 3.0’s \texttt{io} module will be rewritten into C for speed, and perhaps the C implementation will be backported to the 2.x releases.)

In Python 2.6, the underlying implementations haven’t been restructured to build on top of the \texttt{io} module’s classes. The module is being provided to make it easier to write code that’s forward-compatible with 3.0, and to save developers the effort of writing their own implementations of buffering and text I/O.

\textbf{See also:}

\textbf{PEP 3116 - New I/O}

PEP written by Daniel Stutzbach, Mike Verdone, and Guido van Rossum. Code by Guido van Rossum, Georg Brandl, Walter
Doerwald, Jeremy Hylton, Martin von Loewis, Tony Lownds, and others.
The buffer protocol is a C-level API that lets Python types exchange pointers into their internal representations. A memory-mapped file can be viewed as a buffer of characters, for example, and this lets another module such as `re` treat memory-mapped files as a string of characters to be searched.

The primary users of the buffer protocol are numeric-processing packages such as NumPy, which expose the internal representation of arrays so that callers can write data directly into an array instead of going through a slower API. This PEP updates the buffer protocol in light of experience from NumPy development, adding a number of new features such as indicating the shape of an array or locking a memory region.

The most important new C API function is `PyObject_GetBuffer(PyObject *obj, Py_buffer *view, int flags)`, which takes an object and a set of flags, and fills in the `Py_buffer` structure with information about the object’s memory representation. Objects can use this operation to lock memory in place while an external caller could be modifying the contents, so there’s a corresponding `PyBuffer_Release(Py_buffer *view)` to indicate that the external caller is done.

The `flags` argument to `PyObject_GetBuffer` specifies constraints upon the memory returned. Some examples are:

- `PyBUF_WRITABLE` indicates that the memory must be writable.
- `PyBUF_LOCK` requests a read-only or exclusive lock on the memory.
- `PyBUF_C_CONTIGUOUS` and `PyBUF_F_CONTIGUOUS` requests a C-contiguous (last dimension varies the fastest) or Fortran-
contiguous (first dimension varies the fastest) array layout.

Two new argument codes for `PyArg_ParseTuple`, `s*` and `z*`, return locked buffer objects for a parameter.

See also:

**PEP 3118 - Revising the buffer protocol**

PEP written by Travis Oliphant and Carl Banks; implemented by Travis Oliphant.
Some object-oriented languages such as Java support interfaces, declaring that a class has a given set of methods or supports a given access protocol. Abstract Base Classes (or ABCs) are an equivalent feature for Python. The ABC support consists of an `abc` module containing a metaclass called `ABCMeta`, special handling of this metaclass by the `isinstance()` and `issubclass()` built-ins, and a collection of basic ABCs that the Python developers think will be widely useful. Future versions of Python will probably add more ABCs.

Let’s say you have a particular class and wish to know whether it supports dictionary-style access. The phrase “dictionary-style” is vague, however. It probably means that accessing items with `obj[1]` works. Does it imply that setting items with `obj[2] = value` works? Or that the object will have `keys()`, `values()`, and `items()` methods? What about the iterative variants such as `iterkeys()`? `copy()` and `update()`? Iterating over the object with `iter()`?

The Python 2.6 `collections` module includes a number of different ABCs that represent these distinctions. `Iterable` indicates that a class defines `__iter__()`, and `Container` means the class defines a `__contains__()` method and therefore supports `x in y` expressions. The basic dictionary interface of getting items, setting items, and `keys()`, `values()`, and `items()`, is defined by the `MutableMapping` ABC.

You can derive your own classes from a particular ABC to indicate they support that ABC’s interface:

```python
import collections
```
class Storage(collections.MutableMapping):
...

Alternatively, you could write the class without deriving from the desired ABC and instead register the class by calling the ABC's register() method:

```python
import collections
class Storage:
...
collections.MutableMapping.register(Storage)
```

For classes that you write, deriving from the ABC is probably clearer. The `register()` method is useful when you've written a new ABC that can describe an existing type or class, or if you want to declare that some third-party class implements an ABC. For example, if you defined a `PrintableType` ABC, it's legal to do:

```python
# Register Python's types
PrintableType.register(int)
PrintableType.register(float)
PrintableType.register(str)
```

Classes should obey the semantics specified by an ABC, but Python can't check this; it's up to the class author to understand the ABC's requirements and to implement the code accordingly.

To check whether an object supports a particular interface, you can now write:

```python
def func(d):
    if not isinstance(d, collections.MutableMapping):
        raise ValueError("Mapping object expected, not %r" % d)
```

Don't feel that you must now begin writing lots of checks as in the above example. Python has a strong tradition of duck-typing, where
explicit type-checking is never done and code simply calls methods on an object, trusting that those methods will be there and raising an exception if they aren’t. Be judicious in checking for ABCs and only do it where it’s absolutely necessary.

You can write your own ABCs by using `abc.ABCMeta` as the metaclass in a class definition:

```python
from abc import ABCMeta, abstractmethod

class Drawable:
    __metaclass__ = ABCMeta

    @abstractmethod
def draw(self, x, y, scale=1.0):
        pass

    def draw_doubled(self, x, y):
        self.draw(x, y, scale=2.0)

class Square(Drawable):
    def draw(self, x, y, scale):
        ...
```

In the `Drawable` ABC above, the `draw_doubled()` method renders the object at twice its size and can be implemented in terms of other methods described in `Drawable`. Classes implementing this ABC therefore don’t need to provide their own implementation of `draw_doubled()`, though they can do so. An implementation of `draw()` is necessary, though; the ABC can’t provide a useful generic implementation.

You can apply the `@abstractmethod` decorator to methods such as `draw()` that must be implemented; Python will then raise an exception for classes that don’t define the method. Note that the exception is only raised when you actually try to create an instance of a subclass lacking the method:
Abstract data attributes can be declared using the @abstractproperty decorator:

```python
from abc import abstractproperty
...
@abstractproperty
def readonly(self):
    return self._x
```

Subclasses must then define a readonly() property.

See also:

**PEP 3119 - Introducing Abstract Base Classes**
PEP written by Guido van Rossum and Talin. Implemented by Guido van Rossum. Backported to 2.6 by Benjamin Aranguren, with Alex Martelli.
PEP 3127: Integer Literal Support and Syntax

Python 3.0 changes the syntax for octal (base-8) integer literals, prefixing them with “0o” or “0O” instead of a leading zero, and adds support for binary (base-2) integer literals, signalled by a “0b” or “0B” prefix.

Python 2.6 doesn’t drop support for a leading 0 signalling an octal number, but it does add support for “0o” and “0b”:

```
>>> 0o21, 2*8 + 1
(17, 17)
>>> 0b101111
47
```

The `oct()` built-in still returns numbers prefixed with a leading zero, and a new `bin()` built-in returns the binary representation for a number:

```
>>> oct(42)
'o52'
>>> future_builtins.oct(42)
'o052'
>>> bin(173)
'0b10101101'
```

The `int()` and `long()` built-ins will now accept the “0o” and “0b” prefixes when base-8 or base-2 are requested, or when the `base` argument is zero (signalling that the base used should be determined from the string):

```
>>> int ('0o52', 0)
42
>>> int('1101', 2)
13
>>> int('0b1101', 2)
9
```
>>> int('0b1101', 0)
13

See also:

**PEP 3127 - Integer Literal Support and Syntax**

PEP written by Patrick Maupin; backported to 2.6 by Eric Smith.
Decorators have been extended from functions to classes. It’s now legal to write:

```python
@foo
@bar
class A:
    pass
```

This is equivalent to:

```python
class A:
    pass
A = foo(bar(A))
```

See also:

**PEP 3129 - Class Decorators**

PEP written by Collin Winter.
Python 3.0 adds several abstract base classes for numeric types inspired by Scheme’s numeric tower. These classes were backported to 2.6 as the `numbers` module.

The most general ABC is `Number`. It defines no operations at all, and only exists to allow checking if an object is a number by doing `isinstance(obj, Number)`.

`Complex` is a subclass of `Number`. Complex numbers can undergo the basic operations of addition, subtraction, multiplication, division, and exponentiation, and you can retrieve the real and imaginary parts and obtain a number’s conjugate. Python’s built-in complex type is an implementation of `Complex`.

`Real` further derives from `Complex`, and adds operations that only work on real numbers: `floor()`, `trunc()`, rounding, taking the remainder mod N, floor division, and comparisons.

`Rational` numbers derive from `Real`, have `numerator` and `denominator` properties, and can be converted to floats. Python 2.6 adds a simple rational-number class, `Fraction`, in the `fractions` module. (It's called `Fraction` instead of `Rational` to avoid a name clash with `numbers.Rational`.)

`Integral` numbers derive from `Rational`, and can be shifted left and right with `<<` and `>>`, combined using bitwise operations such as `&` and `|`, and can be used as array indexes and slice boundaries.

In Python 3.0, the PEP slightly redefines the existing built-ins `round()`, `math.floor()`, `math.ceil()`, and adds a new one,
math.trunc(), that's been backported to Python 2.6. math.trunc() rounds toward zero, returning the closest Integral that's between the function's argument and zero.

See also:

PEP 3141 - A Type Hierarchy for Numbers
PEP written by Jeffrey Yasskin.

Scheme's numerical tower, from the Guile manual. Scheme's number datatypes from the R5RS Scheme specification.

The fractions Module

To fill out the hierarchy of numeric types, the fractions module provides a rational-number class. Rational numbers store their values as a numerator and denominator forming a fraction, and can exactly represent numbers such as \( \frac{2}{3} \) that floating-point numbers can only approximate.

The Fraction constructor takes two Integral values that will be the numerator and denominator of the resulting fraction.

```python
>>> from fractions import Fraction
>>> a = Fraction(2, 3)
>>> b = Fraction(2, 5)
>>> float(a), float(b)
(0.6666666666666666, 0.40000000000000006)
>>> a+b
Fraction(16, 15)
>>> a/b
Fraction(5, 3)
```

For converting floating-point numbers to rationals, the float type now has an as_integer_ratio() method that returns the numerator and denominator for a fraction that evaluates to the same floating-point value:
Note that values that can only be approximated by floating-point numbers, such as 1./3, are not simplified to the number being approximated; the fraction attempts to match the floating-point value exactly.

The \texttt{fractions} module is based upon an implementation by Sjoerd Mullender that was in Python's \texttt{Demo/classes/} directory for a long time. This implementation was significantly updated by Jeffrey Yasskin.
Other Language Changes

Some smaller changes made to the core Python language are:

- The `hasattr()` function was catching and ignoring all errors, under the assumption that they meant a `__getattr__()` method was failing somehow and the return value of `hasattr()` would therefore be `False`. This logic shouldn’t be applied to `KeyboardInterrupt` and `SystemExit`, however; Python 2.6 will no longer discard such exceptions when `hasattr()` encounters them. (Fixed by Benjamin Peterson; issue 2196.)

- When calling a function using the `**` syntax to provide keyword arguments, you are no longer required to use a Python dictionary; any mapping will now work:

  ```python
  >>> def f(**kw):
  ...     print sorted(kw)
  ...
  >>> ud=UserDict.UserDict()
  >>> ud['a'] = 1
  >>> ud['b'] = 'string'
  >>> f(**ud)
  ['a', 'b']
  ```

  (Contributed by Alexander Belopolsky; issue 1686487.)

  It’s also become legal to provide keyword arguments after a `*args` argument to a function call.

  ```python
  >>> def f(*args, **kw):
  ...     print args, kw
  ...
  ```
Previously this would have been a syntax error. (Contributed by Amaury Forgeot d'Arc; issue 3473.)

- A new built-in, `next(iterator, [default])` returns the next item from the specified iterator. If the `default` argument is supplied, it will be returned if `iterator` has been exhausted; otherwise, the `StopIteration` exception will be raised. (Backported in issue 2719.)

- Tuples now have `index()` and `count()` methods matching the list type's `index()` and `count()` methods:

```python
>>> t = (0, 1, 2, 3, 4, 0, 1, 2)
>>> t.index(3)
3
>>> t.count(0)
2
```

(Contributed by Raymond Hettinger)

- The built-in types now have improved support for extended slicing syntax, accepting various combinations of `(start, stop, step)`. Previously, the support was partial and certain corner cases wouldn't work. (Implemented by Thomas Wouters.)

- Properties now have three attributes, `getter`, `setter` and `deleter`, that are decorators providing useful shortcuts for adding a getter, setter or deleter function to an existing property. You would use them like this:

```python
class C(object):
```
@property
def x(self):
    return self._x

@x.setter
def x(self, value):
    self._x = value

@x.deleter
def x(self):
    del self._x

class D(C):
    @C.x.getter
def x(self):
        return self._x * 2

    @x.setter
def x(self, value):
        self._x = value / 2

- Several methods of the built-in set types now accept multiple iterables: `intersection()`, `intersection_update()`, `union()`, `update()`, `difference()` and `difference_update()`.

```python
>>> s=set('1234567890')
>>> s.intersection('abc123', 'cdf246')  # Intersection between all inputs
set(['2'])
>>> s.difference('246', '789')
set(['1', '0', '3', '5'])
```

(Contributed by Raymond Hettinger.)

- Many floating-point features were added. The `float()` function
will now turn the string `nan` into an IEEE 754 Not A Number value, and `+inf` and `-inf` into positive or negative infinity. This works on any platform with IEEE 754 semantics. (Contributed by Christian Heimes; issue 1635.)

Other functions in the `math` module, `isinf()` and `isnan()`, return true if their floating-point argument is infinite or Not A Number. (issue 1640)

Conversion functions were added to convert floating-point numbers into hexadecimal strings (issue 3008). These functions convert floats to and from a string representation without introducing rounding errors from the conversion between decimal and binary. Floats have a `hex()` method that returns a string representation, and the `float.fromhex()` method converts a string back into a number:

```python
>>> a = 3.75
>>> a.hex()
'0x1.e0000000000000p+1'
>>> float.fromhex('0x1.e0000000000000p+1')
3.75
>>> b=1./3
>>> b.hex()
'0x1.5555555555555p-2'
```

- A numerical nicety: when creating a complex number from two floats on systems that support signed zeros (-0 and +0), the `complex()` constructor will now preserve the sign of the zero. (Fixed by Mark T. Dickinson; issue 1507.)

- Classes that inherit a `__hash__()` method from a parent class can set `__hash__ = None` to indicate that the class isn’t hashable. This will make `hash(obj)` raise a `TypeError` and the class will not
be indicated as implementing the **Hashable** ABC.

You should do this when you've defined a `__cmp__()` or `__eq__()` method that compares objects by their value rather than by identity. All objects have a default hash method that uses `id(obj)` as the hash value. There's no tidy way to remove the `__hash__()` method inherited from a parent class, so assigning `None` was implemented as an override. At the C level, extensions can set `tp_hash` to `PyObject_HashNotImplemented`. (Fixed by Nick Coghlan and Amaury Forgeot d'Arc; issue 2235.)

- Changes to the **Exception** interface as dictated by **PEP 352** continue to be made. For 2.6, the `message` attribute is being deprecated in favor of the `args` attribute.

- The **GeneratorExit** exception now subclasses **BaseException** instead of **Exception**. This means that an exception handler that does `except Exception:` will not inadvertently catch **GeneratorExit**. (Contributed by Chad Austin; issue 1537.)

- Generator objects now have a `gi_code` attribute that refers to the original code object backing the generator. (Contributed by Collin Winter; issue 1473257.)

- The `compile()` built-in function now accepts keyword arguments as well as positional parameters. (Contributed by Thomas Wouters; issue 1444529.)

- The `complex()` constructor now accepts strings containing parenthesized complex numbers, meaning that `complex(repr(cplx))` will now round-trip values. For example, `complex('(3+4j)')` now returns the value `(3+4j)`. (issue 1491866)
• The string `translate()` method now accepts `None` as the translation table parameter, which is treated as the identity transformation. This makes it easier to carry out operations that only delete characters. (Contributed by Bengt Richter and implemented by Raymond Hettinger; issue 1193128.)

• The built-in `dir()` function now checks for a `__dir__()` method on the objects it receives. This method must return a list of strings containing the names of valid attributes for the object, and lets the object control the value that `dir()` produces. Objects that have `__getattr__()` or `__getattribute__()` methods can use this to advertise pseudo-attributes they will honor. (issue 1591665)

• Instance method objects have new attributes for the object and function comprising the method; the new synonym for `im_self` is `__self__`, and `im_func` is also available as `__func__`. The old names are still supported in Python 2.6, but are gone in 3.0.

• An obscure change: when you use the the `locals()` function inside a `class` statement, the resulting dictionary no longer returns free variables. (Free variables, in this case, are variables referenced in the `class` statement that aren't attributes of the class.)

**Optimizations**

• The `warnings` module has been rewritten in C. This makes it possible to invoke warnings from the parser, and may also make the interpreter’s startup faster. (Contributed by Neal Norwitz and Brett Cannon; issue 1631171.)

• Type objects now have a cache of methods that can reduce the work required to find the correct method implementation for a
particular class; once cached, the interpreter doesn’t need to traverse base classes to figure out the right method to call. The cache is cleared if a base class or the class itself is modified, so the cache should remain correct even in the face of Python’s dynamic nature. (Original optimization implemented by Armin Rigo, updated for Python 2.6 by Kevin Jacobs; issue 1700288.)

By default, this change is only applied to types that are included with the Python core. Extension modules may not necessarily be compatible with this cache, so they must explicitly add `Py_TPFLAGS_HAVE_VERSION_TAG` to the module’s `tp_flags` field to enable the method cache. (To be compatible with the method cache, the extension module’s code must not directly access and modify the `tp_dict` member of any of the types it implements. Most modules don’t do this, but it’s impossible for the Python interpreter to determine that. See issue 1878 for some discussion.)

- Function calls that use keyword arguments are significantly faster by doing a quick pointer comparison, usually saving the time of a full string comparison. (Contributed by Raymond Hettinger, after an initial implementation by Antoine Pitrou; issue 1819.)

- All of the functions in the `struct` module have been rewritten in C, thanks to work at the Need For Speed sprint. (Contributed by Raymond Hettinger.)

- Some of the standard built-in types now set a bit in their type objects. This speeds up checking whether an object is a subclass of one of these types. (Contributed by Neal Norwitz.)

- Unicode strings now use faster code for detecting whitespace and line breaks; this speeds up the `split()` method by about 25% and `splitlines()` by 35%. (Contributed by Antoine Pitrou.)
Memory usage is reduced by using pymalloc for the Unicode string's data.

- The `with` statement now stores the `__exit__()` method on the stack, producing a small speedup. (Implemented by Jeffrey Yasskin.)

- To reduce memory usage, the garbage collector will now clear internal free lists when garbage-collecting the highest generation of objects. This may return memory to the operating system sooner.

### Interpreter Changes

Two command-line options have been reserved for use by other Python implementations. The `-J` switch has been reserved for use by Jython for Jython-specific options, such as switches that are passed to the underlying JVM. `-X` has been reserved for options specific to a particular implementation of Python such as CPython, Jython, or IronPython. If either option is used with Python 2.6, the interpreter will report that the option isn’t currently used.

Python can now be prevented from writing `.pyc` or `.pyo` files by supplying the `-B` switch to the Python interpreter, or by setting the `PYTHONONDDONTWRITEBYTECODE` environment variable before running the interpreter. This setting is available to Python programs as the `sys.dont_write_bytecode` variable, and Python code can change the value to modify the interpreter’s behaviour. (Contributed by Neal Norwitz and Georg Brandl.)

The encoding used for standard input, output, and standard error can be specified by setting the `PYTHONIOENCODING` environment variable before running the interpreter. The value should be a string in the form `<encoding>` or `<encoding>:<errorhandler>`. The `encoding`
part specifies the encoding’s name, e.g. utf-8 or latin-1; the optional errorhandler part specifies what to do with characters that can’t be handled by the encoding, and should be one of “error”, “ignore”, or “replace”. (Contributed by Martin von Loewis.)
New, Improved, and Deprecated Modules

As in every release, Python's standard library received a number of enhancements and bug fixes. Here's a partial list of the most notable changes, sorted alphabetically by module name. Consult the Misc/NEWS file in the source tree for a more complete list of changes, or look through the Subversion logs for all the details.

- (3.0-warning mode) Python 3.0 will feature a reorganized standard library that will drop many outdated modules and rename others. Python 2.6 running in 3.0-warning mode will warn about these modules when they are imported.

  The list of deprecated modules is: audiodev, bgenlocations, buildtools, bundlebuilder, Canvas, compiler, dircache, dl, fpformat, gensuitemodule, ihooks, imageop, imgfile, linuxaudiodev, mhlib, mimetools, multifile, new, pure, statvfs, sunaudiodev, test.testall, andtoaiff.

- The asyncore and asynchat modules are being actively maintained again, and a number of patches and bugfixes were applied. (Maintained by Josiah Carlson; see issue 1736190 for one patch.)

- The bsddb module also has a new maintainer, Jesús Cea, and the package is now available as a standalone package. The web page for the package is www.jcea.es/programacion/pybsddb.htm. The plan is to remove the package from the standard library in Python 3.0, because its pace of releases is much more frequent than Python's.

  The bsddb.dbshelve module now uses the highest pickling protocol available, instead of restricting itself to protocol 1.
(Contributed by W. Barnes; issue 1551443.)

- The `cgi` module will now read variables from the query string of an HTTP POST request. This makes it possible to use form actions with URLs that include query strings such as “/cgi-bin/add.py?category=1”. (Contributed by Alexandre Fiori and Nubis; issue 1817.)

  The `parse_qs()` and `parse_qsl()` functions have been relocated from the `cgi` module to the `urlparse` module. The versions still available in the `cgi` module will trigger `PendingDeprecationWarning` messages in 2.6 (issue 600362).

- The `cmath` module underwent extensive revision, contributed by Mark Dickinson and Christian Heimes. Five new functions were added:
  
  - `polar()` converts a complex number to polar form, returning the modulus and argument of the complex number.
  - `rect()` does the opposite, turning a modulus, argument pair back into the corresponding complex number.
  - `phase()` returns the argument (also called the angle) of a complex number.
  - `isnan()` returns `True` if either the real or imaginary part of its argument is a NaN.
  - `isinf()` returns `True` if either the real or imaginary part of its argument is infinite.

  The revisions also improved the numerical soundness of the `cmath` module. For all functions, the real and imaginary parts of the results are accurate to within a few units of least precision (ulps) whenever possible. See issue 1381 for the details. The branch cuts for `asinh()`, `atanh()` and `atan()` have also been corrected.
The tests for the module have been greatly expanded; nearly 2000 new test cases exercise the algebraic functions.

On IEEE 754 platforms, the \texttt{cmath} module now handles IEEE 754 special values and floating-point exceptions in a manner consistent with Annex ‘G’ of the C99 standard.

- A new data type in the \texttt{collections} module: \texttt{namedtuple(typename, fieldnames)} is a factory function that creates subclasses of the standard tuple whose fields are accessible by name as well as index. For example:

```python
>>> var_type = collections.namedtuple('variable', ...
   'id name type size')
# Names are separated by spaces or commas.
# 'id, name, type, size' would also work.
>>> var_type._fields
('id', 'name', 'type', 'size')

>>> var = var_type(1, 'frequency', 'int', 4)
>>> print var[0], var.id      # Equivalent
1 1
>>> print var[2], var.type    # Equivalent
int int
>>> var._asdict()
{'size': 4, 'type': 'int', 'id': 1, 'name': 'frequency'}
>>> v2 = var._replace(name='amplitude')
>>> v2
variable(id=1, name='amplitude', type='int', size=4)
```

Several places in the standard library that returned tuples have been modified to return \texttt{namedtuple} instances. For example, the \texttt{Decimal.as_tuple()} method now returns a named tuple with \texttt{sign}, \texttt{digits}, and \texttt{exponent} fields.
Another change to the `collections` module is that the `deque` type now supports an optional `maxlen` parameter; if supplied, the deque's size will be restricted to no more than `maxlen` items. Adding more items to a full deque causes old items to be discarded.

```
>>> from collections import deque
>>> dq=deque(maxlen=3)
>>> dq
deque([], maxlen=3)
>>> dq.append(1) ; dq.append(2) ; dq.append(3)
>>> dq
deque([1, 2, 3], maxlen=3)
>>> dq.append(4)
>>> dq
deque([2, 3, 4], maxlen=3)
```

The `Cookie` module's `Morsel` objects now support an `httponly` attribute. In some browsers, cookies with this attribute set cannot be accessed or manipulated by JavaScript code. (Contributed by Arvin Schnell; issue 1638033.)

A new window method in the `curses` module, `chgat()`, changes the display attributes for a certain number of characters on a single line. (Contributed by Fabian Kreutz.)

```
# Boldface text starting at y=0, x=21
# and affecting the rest of the line.
stdscr.chgat(0, 21, curses.A_BOLD)
```
The `Textbox` class in the `curses.textpad` module now supports editing in insert mode as well as overwrite mode. Insert mode is enabled by supplying a true value for the `insert_mode` parameter when creating the `Textbox` instance.

- The `datetime` module’s `strftime()` methods now support a `%f` format code that expands to the number of microseconds in the object, zero-padded on the left to six places. (Contributed by Skip Montanaro; issue 1158.)

- The `decimal` module was updated to version 1.66 of the General Decimal Specification. New features include some methods for some basic mathematical functions such as `exp()` and `log10()`:

  ```
  >>> Decimal(1).exp()
  Decimal("2.718281828459045235360287471")
  >>> Decimal("2.7182818").ln()
  Decimal("0.9999999895305022877376682436")
  >>> Decimal(1000).log10()
  Decimal("3")
  ```

  The `as_tuple()` method of `Decimal` objects now returns a named tuple with `sign`, `digits`, and `exponent` fields.

  (Implemented by Facundo Batista and Mark Dickinson. Named tuple support added by Raymond Hettinger.)

- The `difflib` module’s `SequenceMatcher` class now returns named tuples representing matches, with `a`, `b`, and `size` attributes. (Contributed by Raymond Hettinger.)

- An optional `timeout` parameter, specifying a timeout measured in seconds, was added to the `ftplib.FTP` class constructor as well as the `connect()` method. (Added by Facundo Batista.)
Also, the FTP class’s `storbinary()` and `storlines()` now take an optional `callback` parameter that will be called with each block of data after the data has been sent. (Contributed by Phil Schwartz; issue 1221598.)

- The `reduce()` built-in function is also available in the `functools` module. In Python 3.0, the built-in has been dropped and `reduce()` is only available from `functools`; currently there are no plans to drop the built-in in the 2.x series. (Patched by Christian Heimes; issue 1739906.)

- When possible, the `getpass` module will now use `/dev/tty` to print a prompt message and read the password, falling back to standard error and standard input. If the password may be echoed to the terminal, a warning is printed before the prompt is displayed. (Contributed by Gregory P. Smith.)

- The `glob.glob()` function can now return Unicode filenames if a Unicode path was used and Unicode filenames are matched within the directory. (issue 1001604)

- The `gopherlib` module has been removed.

- A new function in the `heapq` module, `merge(iter1, iter2, ...)`, takes any number of iterables returning data in sorted order, and returns a new generator that returns the contents of all the iterators, also in sorted order. For example:

```python
heapq.merge([1, 3, 5, 9], [2, 8, 16]) ->
[1, 2, 3, 5, 8, 9, 16]
```

Another new function, `heappushpop(heap, item)`, pushes `item` onto `heap`, then pops off and returns the smallest item. This is more efficient than making a call to `heappush()` and then
heappop().

heapq is now implemented to only use less-than comparison, instead of the less-than-or-equal comparison it previously used. This makes heapq's usage of a type match the list.sort() method. (Contributed by Raymond Hettinger.)

- An optional timeout parameter, specifying a timeout measured in seconds, was added to the httplib.HTTPConnection and HTTPSConnection class constructors. (Added by Facundo Batista.)

- Most of the inspect module's functions, such as getmoduleinfo() and getargs(), now return named tuples. In addition to behaving like tuples, the elements of the return value can also be accessed as attributes. (Contributed by Raymond Hettinger.)

Some new functions in the module include isgenerator(), isgeneratorfunction(), and isabstract().

- The itertools module gained several new functions.

izip_longest(iter1, iter2, ...[, fillvalue]) makes tuples from each of the elements; if some of the iterables are shorter than others, the missing values are set to fillvalue. For example:

```python
itertools.izip_longest([1,2,3], [1,2,3,4,5]) ->
    (1, 1), (2, 2), (3, 3), (None, 4), (None, 5)
```

product(iter1, iter2, ..., [repeat=N]) returns the Cartesian product of the supplied iterables, a set of tuples containing every possible combination of the elements returned from each iterable.
The optional *repeat* keyword argument is used for taking the product of an iterable or a set of iterables with themselves, repeated *N* times. With a single iterable argument, *N*-tuples are returned:

```
itertools.product([1,2], repeat=3) ->
    (1, 1, 1), (1, 1, 2), (1, 2, 1), (1, 2, 2),
    (2, 1, 1), (2, 1, 2), (2, 2, 1), (2, 2, 2)
```

With two iterables, $2N$-tuples are returned.

```
itertools.product([1,2], [3,4], repeat=2) ->
    (1, 3, 1, 3), (1, 3, 1, 4), (1, 3, 2, 3), (1, 3, 2, 4),
    (1, 4, 1, 3), (1, 4, 1, 4), (1, 4, 2, 3), (1, 4, 2, 4),
    (2, 3, 1, 3), (2, 3, 1, 4), (2, 3, 2, 3), (2, 3, 2, 4),
    (2, 4, 1, 3), (2, 4, 1, 4), (2, 4, 2, 3), (2, 4, 2, 4)
```

combinations(iterable, r) returns sub-sequences of length *r* from the elements of *iterable*.

```
itertools.combinations('123', 2) ->
    ('1', '2'), ('1', '3'), ('2', '3')

itertools.combinations('123', 3) ->
    ('1', '2', '3')

itertools.combinations('1234', 3) ->
    ('1', '2', '3'), ('1', '2', '4'), ('1', '3', '4'),
    ('2', '3', '4')
```
permutations(iter[, r]) returns all the permutations of length \( r \) of the iterable's elements. If \( r \) is not specified, it will default to the number of elements produced by the iterable.

\[
\text{itertools.permutations([1,2,3,4], 2) ->}
(1, 2), (1, 3), (1, 4),
(2, 1), (2, 3), (2, 4),
(3, 1), (3, 2), (3, 4),
(4, 1), (4, 2), (4, 3)
\]

\[
\text{itertools.chain(*iterables) is an existing function in itertools that gained a new constructor in Python 2.6. itertools.chain.from_iterable(iterable) takes a single iterable that should return other iterables. chain() will then return all the elements of the first iterable, then all the elements of the second, and so on.}
\]

\[
\text{chain.from_iterable([[1,2,3], [4,5,6]]) ->}
1, 2, 3, 4, 5, 6
\]

(All contributed by Raymond Hettinger.)

- The **logging** module's **FileHandler** class and its subclasses **WatchedFileHandler**, **RotatingFileHandler**, and **TimedRotatingFileHandler** now have an optional \( \text{delay} \) parameter to their constructors. If \( \text{delay} \) is true, opening of the log file is deferred until the first \( \text{emit()} \) call is made. (Contributed by Vinay Sajip.)

**TimedRotatingFileHandler** also has a \( \text{utc} \) constructor parameter. If the argument is true, UTC time will be used in determining when midnight occurs and in generating filenames; otherwise local time will be used.
Several new functions were added to the math module:

- `isinf()` and `isnan()` determine whether a given float is a (positive or negative) infinity or a NaN (Not a Number), respectively.
- `copysign()` copies the sign bit of an IEEE 754 number, returning the absolute value of $x$ combined with the sign bit of $y$. For example, `math.copysign(1, -0.0)` returns `-1.0`. (Contributed by Christian Heimes.)
- `factorial()` computes the factorial of a number. (Contributed by Raymond Hettinger; issue 2138.)
- `fsum()` adds up the stream of numbers from an iterable, and is careful to avoid loss of precision through using partial sums. (Contributed by Jean Brouwers, Raymond Hettinger, and Mark Dickinson; issue 2819.)
- `acosh()`, `asinh()` and `atanh()` compute the inverse hyperbolic functions.
- `log1p()` returns the natural logarithm of $1+x$ (base $e$).
- `trunc()` rounds a number toward zero, returning the closest `Integral` that's between the function's argument and zero. Added as part of the backport of PEP 3141's type hierarchy for numbers.

The math module has been improved to give more consistent behaviour across platforms, especially with respect to handling of floating-point exceptions and IEEE 754 special values.

Whenever possible, the module follows the recommendations of the C99 standard about 754's special values. For example, `sqrt(-1.)` should now give a `ValueError` across almost all platforms, while `sqrt(float('NaN'))` should return a NaN on all IEEE 754 platforms. Where Annex ‘F’ of the C99 standard recommends signaling ‘divide-by-zero’ or ‘invalid’, Python will raise `ValueError`. Where Annex ‘F’ of the C99 standard
recommends signaling ‘overflow’, Python will raise `OverflowError`. (See issue 711019 and issue 1640.)

(Contributed by Christian Heimes and Mark Dickinson.)

- The `MimeWriter` module and `mimify` module have been deprecated; use the `email` package instead.

- The `md5` module has been deprecated; use the `hashlib` module instead.

- `mmap` objects now have a `rfind()` method that searches for a substring beginning at the end of the string and searching backwards. The `find()` method also gained an `end` parameter giving an index at which to stop searching. (Contributed by John Lenton.)

- The `operator` module gained a `methodcaller()` function that takes a name and an optional set of arguments, returning a callable that will call the named function on any arguments passed to it. For example:

  ```python
  >>> # Equivalent to lambda s: s.replace('old', 'new')
  >>> replacer = operator.methodcaller('replace', 'old', 'new')
  >>> replacer('old wine in old bottles')
  'new wine in new bottles'
  ```

  (Contributed by Georg Brandl, after a suggestion by Gregory Petrosyan.)

The `attrgetter()` function now accepts dotted names and performs the corresponding attribute lookups:

```python
>>> inst_name = operator.attrgetter(
```
(Contributed by Georg Brandl, after a suggestion by Barry Warsaw.)

- The `os` module now wraps several new system calls. `fchmod(fd, mode)` and `fchown(fd, uid, gid)` change the mode and ownership of an opened file, and `lchmod(path, mode)` changes the mode of a symlink. (Contributed by Georg Brandl and Christian Heimes.)

  `chflags()` and `lchflags()` are wrappers for the corresponding system calls (where they're available), changing the flags set on a file. Constants for the flag values are defined in the `stat` module; some possible values include `UF_IMMUTABLE` to signal the file may not be changed and `UF_APPEND` to indicate that data can only be appended to the file. (Contributed by M. Levinson.)

  `os.closerange(low, high)` efficiently closes all file descriptors from `low` to `high`, ignoring any errors and not including `high` itself. This function is now used by the `subprocess` module to make starting processes faster. (Contributed by Georg Brandl; issue 1663329.)

- The `os.environ` object's `clear()` method will now unset the environment variables using `os.unsetenv()` in addition to clearing the object's keys. (Contributed by Martin Horcicka; issue 1181.)

- The `os.walk()` function now has a `followlinks` parameter. If set
to True, it will follow symlinks pointing to directories and visit the
directory’s contents. For backward compatibility, the parameter’s
default value is false. Note that the function can fall into an
infinite recursion if there’s a symlink that points to a parent
directory. (issue 1273829)

- In the os.path module, the splitext() function has been
  changed to not split on leading period characters. This produces
  better results when operating on Unix’s dot-files. For example,
  os.path.splitext('.ipython') now returns ('.ipython', '')
  instead of ('', '.ipython'). (issue 115886)

  A new function, os.path.relpath(path, start='.'), returns a
  relative path from the start path, if it's supplied, or from the
current working directory to the destination path. (Contributed
  by Richard Barran; issue 1339796.)

  On Windows, os.path.expandvars() will now expand
  environment variables given in the form “%var%”, and “~user”
  will be expanded into the user’s home directory path.
  (Contributed by Josiah Carlson; issue 957650.)

- The Python debugger provided by the pdb module gained a new
  command: “run” restarts the Python program being debugged
  and can optionally take new command-line arguments for the
  program. (Contributed by Rocky Bernstein; issue 1393667.)

- The posixfile module has been deprecated; fcntl.lockf()
  provides better locking.

  The post_mortem() function, used to begin debugging a
  traceback, will now use the traceback returned by
  sys.exc_info() if no traceback is supplied. (Contributed by
  Facundo Batista; issue 1106316.)
• The pickletools module now has an optimize() function that takes a string containing a pickle and removes some unused opcodes, returning a shorter pickle that contains the same data structure. (Contributed by Raymond Hettinger.)

• The popen2 module has been deprecated; use the subprocess module.

• A get_data() function was added to the pkgutil module that returns the contents of resource files included with an installed Python package. For example:

```python
>>> import pkgutil
>>> pkgutil.get_data('test', 'exception_hierarchy.txt')
'BaseException
   +- SystemExit
   +- KeyboardInterrupt
   +- GeneratorExit
   +- Exception
      +- StopIteration
      +- StandardError
   ...'
>>> 
```

(Contributed by Paul Moore; issue 2439.)

• The pyexpat module’s Parser objects now allow setting their buffer_size attribute to change the size of the buffer used to hold character data. (Contributed by Achim Gaedke; issue 1137.)

• The Queue module now provides queue variants that retrieve entries in different orders. The PriorityQueue class stores queued items in a heap and retrieves them in priority order, and
**LifoQueue** retrieves the most recently added entries first, meaning that it behaves like a stack. (Contributed by Raymond Hettinger.)

- The **random** module's **Random** objects can now be pickled on a 32-bit system and unpickled on a 64-bit system, and vice versa. Unfortunately, this change also means that Python 2.6’s **Random** objects can’t be unpickled correctly on earlier versions of Python. (Contributed by Shawn Ligocki; issue 1727780.)

The new **triangular**(low, high, mode) function returns random numbers following a triangular distribution. The returned values are between low and high, not including high itself, and with mode as the most frequently occurring value in the distribution. (Contributed by Wladmir van der Laan and Raymond Hettinger; issue 1681432.)

- Long regular expression searches carried out by the **re** module will check for signals being delivered, so time-consuming searches can now be interrupted. (Contributed by Josh Hoyt and Ralf Schmitt; issue 846388.)

The regular expression module is implemented by compiling bytecodes for a tiny regex-specific virtual machine. Untrusted code could create malicious strings of bytecode directly and cause crashes, so Python 2.6 includes a verifier for the regex bytecode. (Contributed by Guido van Rossum from work for Google App Engine; issue 3487.)

- The **rgbimg** module has been removed.

- The **rlcompleter** module's **Completer.complete()** method will now ignore exceptions triggered while evaluating a name. (Fixed by Lorenz Quack; issue 2250.)
The `sched` module's `scheduler` instances now have a read-only `queue` attribute that returns the contents of the scheduler's queue, represented as a list of named tuples with the fields `(time, priority, action, argument)`. (Contributed by Raymond Hettinger; issue 1861.)

The `select` module now has wrapper functions for the Linux `epoll` and BSD `kqueue` system calls. `modify()` method was added to the existing `poll` objects; `pollobj.modify(fd, eventmask)` takes a file descriptor or file object and an event mask, modifying the recorded event mask for that file. (Contributed by Christian Heimes; issue 1657.)

The `sets` module has been deprecated; it's better to use the built-in `set` and `frozenset` types.

The `sha` module has been deprecated; use the `hashlib` module instead.

The `shutil.copytree()` function now has an optional `ignore` argument that takes a callable object. This callable will receive each directory path and a list of the directory's contents, and returns a list of names that will be ignored, not copied.

The `shutil` module also provides an `ignore_patterns()` function for use with this new parameter. `ignore_patterns()` takes an arbitrary number of glob-style patterns and returns a callable that will ignore any files and directories that match any of these patterns. The following example copies a directory tree, but skips both `.svn` directories and Emacs backup files, which have names ending with `~`:

```python
shutil.copytree('Doc/library', '/tmp/library',
               ignore=shutil.ignore_patterns('*~', '.svn'))
```
Integrating signal handling with GUI handling event loops like those used by Tkinter or GTK+ has long been a problem; most software ends up polling, waking up every fraction of a second to check if any GUI events have occurred. The `signal` module can now make this more efficient. Calling `signal.set_wakeup_fd(fd)` sets a file descriptor to be used; when a signal is received, a byte is written to that file descriptor. There's also a C-level function, `PySignal_SetWakeupFd`, for setting the descriptor.

Event loops will use this by opening a pipe to create two descriptors, one for reading and one for writing. The writable descriptor will be passed to `set_wakeup_fd()`, and the readable descriptor will be added to the list of descriptors monitored by the event loop via `select` or `poll`. On receiving a signal, a byte will be written and the main event loop will be woken up, avoiding the need to poll.

The `siginterrupt()` function is now available from Python code, and allows changing whether signals can interrupt system calls or not. (Contributed by Ralf Schmitt.)

The `setitimer()` and `getitimer()` functions have also been added (where they're available). `setitimer()` allows setting interval timers that will cause a signal to be delivered to the process after a specified time, measured in wall-clock time, consumed process time, or combined process+system time. (Contributed by Guilherme Polo; issue 2240.)
• The `smtplib` module now supports SMTP over SSL thanks to the addition of the `SMTP_SSL` class. This class supports an interface identical to the existing `SMTP` class. (Contributed by Monty Taylor.) Both class constructors also have an optional `timeout` parameter that specifies a timeout for the initial connection attempt, measured in seconds. (Contributed by Facundo Batista.)

An implementation of the LMTP protocol (RFC 2033) was also added to the module. LMTP is used in place of SMTP when transferring e-mail between agents that don’t manage a mail queue. (LMTP implemented by Leif Hedstrom; issue 957003.)

SMTP.starttls() now complies with RFC 3207 and forgets any knowledge obtained from the server not obtained from the TLS negotiation itself. (Patch contributed by Bill Fenner; issue 829951.)

• The `socket` module now supports TIPC (http://tipc.sf.net), a high-performance non-IP-based protocol designed for use in clustered environments. TIPC addresses are 4- or 5-tuples. (Contributed by Alberto Bertogli; issue 1646.)

A new function, create_connection(), takes an address and connects to it using an optional timeout value, returning the connected socket object.

• The base classes in the `SocketServer` module now support calling a `handle_timeout()` method after a span of inactivity specified by the server’s `timeout` attribute. (Contributed by Michael Pomraning.) The `serve_forever()` method now takes an optional poll interval measured in seconds, controlling how often the server will check for a shutdown request. (Contributed by Pedro Werneck and Jeffrey Yasskin; issue 742598, issue
The sqlite3 module, maintained by Gerhard Haering, has been updated from version 2.3.2 in Python 2.5 to version 2.4.1.

The struct module now supports the C99 _Bool type, using the format character `?`. (Contributed by David Remahl.)

The Popen objects provided by the subprocess module now have terminate(), kill(), and send_signal() methods. On Windows, send_signal() only supports the SIGTERM signal, and all these methods are aliases for the Win32 API function TerminateProcess. (Contributed by Christian Heimes.)

A new variable in the sys module, float_info, is an object containing information derived from the float.h file about the platform's floating-point support. Attributes of this object include mant_dig (number of digits in the mantissa), epsilon (smallest difference between 1.0 and the next largest value representable), and several others. (Contributed by Christian Heimes; issue 1534.)

Another new variable, dont_write_bytecode, controls whether Python writes any .pyc or .pyo files on importing a module. If this variable is true, the compiled files are not written. The variable is initially set on start-up by supplying the -B switch to the Python interpreter, or by setting the PYTHONDONTWRITEBYTECODE environment variable before running the interpreter. Python code can subsequently change the value of this variable to control whether bytecode files are written or not. (Contributed by Neal Norwitz and Georg Brandl.)

Information about the command-line arguments supplied to the Python interpreter is available by reading attributes of a named
tuple available as `sys.flags`. For example, the `verbose` attribute is true if Python was executed in verbose mode, `debug` is true in debugging mode, etc. These attributes are all read-only. (Contributed by Christian Heimes.)

A new function, `getsizeof()`, takes a Python object and returns the amount of memory used by the object, measured in bytes. Built-in objects return correct results; third-party extensions may not, but can define a `__sizeof__()` method to return the object's size. (Contributed by Robert Schuppenies; issue 2898.)

It's now possible to determine the current profiler and tracer functions by calling `sys.getprofile()` and `sys.gettrace()`. (Contributed by Georg Brandl; issue 1648.)

- The `tarfile` module now supports POSIX.1-2001 (pax) tarfiles in addition to the POSIX.1-1988 (ustar) and GNU tar formats that were already supported. The default format is GNU tar; specify the `format` parameter to open a file using a different format:

  ```python
  tar = tarfile.open("output.tar", "w",
                      format=tarfile.PAX_FORMAT)
  ```

  The new `encoding` and `errors` parameters specify an encoding and an error handling scheme for character conversions. `strict`, `ignore`, and `replace` are the three standard ways Python can handle errors; `utf-8` is a special value that replaces bad characters with their UTF-8 representation. (Character conversions occur because the PAX format supports Unicode filenames, defaulting to UTF-8 encoding.)

  The `TarFile.add()` method now accepts an `exclude` argument that's a function that can be used to exclude certain filenames
from an archive. The function must take a filename and return 
true if the file should be excluded or false if it should be 
archived. The function is applied to both the name initially 
passed to add() and to the names of files in recursively-added 
directories.

(All changes contributed by Lars Gustäbel).

- An optional timeout parameter was added to the 
telnetlib.Telnet class constructor, specifying a timeout 
measured in seconds. (Added by Facundo Batista.)

- The tempfile.NamedTemporaryFile class usually deletes the 
temporary file it created when the file is closed. This behaviour 
can now be changed by passing delete=False to the 
constructor. (Contributed by Damien Miller; issue 1537850.)

A new class, SpooledTemporaryFile, behaves like a temporary 
file but stores its data in memory until a maximum size is 
exceeded. On reaching that limit, the contents will be written to 
an on-disk temporary file. (Contributed by Dustin J. Mitchell.)

The NamedTemporaryFile and SpooledTemporaryFile classes both 
work as context managers, so you can write with 
tempfile.NamedTemporaryFile() as tmp: .... (Contributed by 
Alexander Belopolsky; issue 2021.)

- The test.test_support module gained a number of context 
managers useful for writing tests. EnvironmentVarGuard() is a 
context manager that temporarily changes environment 
variables and automatically restores them to their old values.

Another context manager, TransientResource, can surround 
calls to resources that may or may not be available; it will catch
and ignore a specified list of exceptions. For example, a network test may ignore certain failures when connecting to an external web site:

```python
with test_support.TransientResource(IOError,
        errno=errno.ETIMEDOUT):
    f = urllib.urlopen('https://sf.net')
...
```

Finally, `check_warnings()` resets the `warning` module’s warning filters and returns an object that will record all warning messages triggered (issue 3781):  

```python
with test_support.check_warnings() as wrec:
    warnings.simplefilter("always")
    ... code that triggers a warning ...
    assert str(wrec.message) == "function is outdated"
    assert len(wrec.warnings) == 1, "Multiple warnings raised"
```

(Contributed by Brett Cannon.)

- The `textwrap` module can now preserve existing whitespace at the beginnings and ends of the newly-created lines by specifying `drop_whitespace=False` as an argument:

```python
>>> S = """This sentence has a bunch of ... extra whitespace."""
>>> print textwrap.fill(S, width=15)
This sentence
has a bunch
of extra
whitespace.
>>> print textwrap.fill(S, drop_whitespace=False, width=15)
```
This sentence has a bunch of extra whitespace.

>>> (Contributed by Dwayne Bailey; issue 1581073.)

- The `threading` module API is being changed to use properties such as `daemon` instead of `setDaemon()` and `isDaemon()` methods, and some methods have been renamed to use underscores instead of camel-case; for example, the `activeCount()` method is renamed to `active_count()`. Both the 2.6 and 3.0 versions of the module support the same properties and renamed methods, but don’t remove the old methods. No date has been set for the deprecation of the old APIs in Python 3.x; the old APIs won’t be removed in any 2.x version. (Carried out by several people, most notably Benjamin Peterson.)

  The `threading` module’s `Thread` objects gained an `ident` property that returns the thread’s identifier, a nonzero integer. (Contributed by Gregory P. Smith; issue 2871.)

- The `timeit` module now accepts callables as well as strings for the statement being timed and for the setup code. Two convenience functions were added for creating `Timer` instances: `repeat(stmt, setup, time, repeat, number)` and `timeit(stmt, setup, time, number)` create an instance and call the corresponding method. (Contributed by Erik Demaine; issue 1533909.)

- The `Tkinter` module now accepts lists and tuples for options, separating the elements by spaces before passing the resulting
value to Tcl/Tk. (Contributed by Guilherme Polo; issue 2906.)

- The **turtle** module for turtle graphics was greatly enhanced by Gregor Lingl. New features in the module include:
  - Better animation of turtle movement and rotation.
  - Control over turtle movement using the new `delay()`, `tracer()`, and `speed()` methods.
  - The ability to set new shapes for the turtle, and to define a new coordinate system.
  - Turtles now have an `undo()` method that can roll back actions.
  - Simple support for reacting to input events such as mouse and keyboard activity, making it possible to write simple games.
  - A `turtle.cfg` file can be used to customize the starting appearance of the turtle's screen.
  - The module's docstrings can be replaced by new docstrings that have been translated into another language.

(issue 1513695)

- An optional `timeout` parameter was added to the `urllib.urlopen()` function and the `urllib.ftpwrapper` class constructor, as well as the `urllib2.urlopen()` function. The parameter specifies a timeout measured in seconds. For example:

```python
>>> u = urllib2.urlopen("http://slow.example.com",
                      timeout=3)
Traceback (most recent call last):
...
urllib2.URLError: <urlopen error timed out>
>>>```
The Unicode database provided by the `unicodedata` module has been updated to version 5.1.0. (Updated by Martin von Loewis; issue 3811.)

The `warnings` module’s `formatwarning()` and `showwarning()` gained an optional `line` argument that can be used to supply the line of source code. (Added as part of issue 1631171, which re-implemented part of the `warnings` module in C code.)

A new function, `catch_warnings()`, is a context manager intended for testing purposes that lets you temporarily modify the warning filters and then restore their original values (issue 3781).

The XML-RPC `SimpleXMLRPCServer` and `DocXMLRPCServer` classes can now be prevented from immediately opening and binding to their socket by passing `True` as the `bind_and_activate` constructor parameter. This can be used to modify the instance’s `allow_reuse_address` attribute before calling the `server_bind()` and `server_activate()` methods to open the socket and begin listening for connections. (Contributed by Peter Parente; issue 1599845.)

`SimpleXMLRPCServer` also has a `_send_traceback_header` attribute; if true, the exception and formatted traceback are returned as HTTP headers “X-Exception” and “X-Traceback”. This feature is for debugging purposes only and should not be used on production servers because the tracebacks might reveal passwords or other sensitive information. (Contributed by Alan McIntyre as part of his project for Google’s Summer of Code 2007.)
The xmlrpclib module no longer automatically converts \texttt{datetime.date} and \texttt{datetime.time} to the xmlrpclib\texttt{.DateTime} type; the conversion semantics were not necessarily correct for all applications. Code using xmlrpclib should convert \texttt{date} and \texttt{time} instances. (issue 1330538) The code can also handle dates before 1900 (contributed by Ralf Schmitt; issue 2014) and 64-bit integers represented by using \texttt{<i8>} in XML-RPC responses (contributed by Riku Lindblad; issue 2985).

The zipfile module’s \texttt{ZipFile} class now has \texttt{extract()} and \texttt{extractall()} methods that will unpack a single file or all the files in the archive to the current directory, or to a specified directory:

\begin{verbatim}
z = zipfile.ZipFile('python-251.zip')

# Unpack a single file, writing it relative
# to the /tmp directory.
z.extract('Python/sysmodule.c', '/tmp')

# Unpack all the files in the archive.
z.extractall()
\end{verbatim}

(Contributed by Alan McIntyre; issue 467924.)

The \texttt{open()}, \texttt{read()} and \texttt{extract()} methods can now take either a filename or a \texttt{ZipInfo} object. This is useful when an archive accidentally contains a duplicated filename. (Contributed by Graham Horler; issue 1775025.)

Finally, zipfile now supports using Unicode filenames for archived files. (Contributed by Alexey Borzenkov; issue 1734346.)
The \texttt{ast} module provides an Abstract Syntax Tree representation of Python code, and Armin Ronacher contributed a set of helper functions that perform a variety of common tasks. These will be useful for HTML templating packages, code analyzers, and similar tools that process Python code.

The \texttt{parse()} function takes an expression and returns an AST. The \texttt{dump()} function outputs a representation of a tree, suitable for debugging:

```python
import ast
t = ast.parse('"
  d = {}
  for i in 'abcdefgijklm':
    d[i + i] = ord(i) - ord('a') + 1
  print d
  
print ast.dump(t)
```

This outputs a deeply nested tree:

```
Module(body=[
  Assign(targets=[
    Name(id='d', ctx=Store())
  ], value=Dict(keys=[], values=[]))
  For(target=Name(id='i', ctx=Store()),
    iter=Str(s='abcdefgijklm'), body=[
      Assign(targets=[
        Subscript(value=
          Name(id='d', ctx=Load()),
          slice=Index(value=
            BinOp(left=Name(id='i', ctx=Load()),
              op=Add(),
              right=Name(id='i', ctx=Load()))),
          ctx=Store())
      ], value=
        BinOp(left=BinOp(left=Call(func=Name(id='ord', ctx=Load()), args=[
```

```python
])
```

```python
])
```

```python
])
```

```python
])
```
The `literal_eval()` method takes a string or an AST representing a literal expression, parses and evaluates it, and returns the resulting value. A literal expression is a Python expression containing only strings, numbers, dictionaries, etc. but no statements or function calls. If you need to evaluate an expression but accept the security risk of using an `eval()` call, `literal_eval()` will handle it safely:

```python
>>> literal = 'a', 'b', {2:4, 3:8, 1:2}
>>> print ast.literal_eval(literal)
('a', 'b', {1: 2, 2: 4, 3: 8})
>>> print ast.literal_eval('a + b')
Traceback (most recent call last):
 ...  
ValueError: malformed string
```

The module also includes `NodeVisitor` and `NodeTransformer` classes for traversing and modifying an AST, and functions for common transformations such as changing line numbers.

The `future_builtins` module

Python 3.0 makes many changes to the repertoire of built-in functions, and most of the changes can’t be introduced in the Python 2.x series because they would break compatibility. The `future_builtins` module provides versions of these built-in functions that can be imported when writing 3.0-compatible code.
The functions in this module currently include:

- `ascii(obj)`: equivalent to `repr()`. In Python 3.0, `repr()` will return a Unicode string, while `ascii()` will return a pure ASCII bytestring.
- `filter(predicate, iterable), map(func, iterable1, ...)`: the 3.0 versions return iterators, unlike the 2.x built-ins which return lists.
- `hex(value), oct(value)`: instead of calling the `__hex__()` or `__oct__()` methods, these versions will call the `__index__()` method and convert the result to hexadecimal or octal. `oct()` will use the new `0o` notation for its result.

### The json module: JavaScript Object Notation

The new `json` module supports the encoding and decoding of Python types in JSON (Javascript Object Notation). JSON is a lightweight interchange format often used in web applications. For more information about JSON, see [http://www.json.org](http://www.json.org).

`json` comes with support for decoding and encoding most built-in Python types. The following example encodes and decodes a dictionary:

```python
>>> import json
>>> data = {"spam" : "foo", "parrot" : 42}
>>> in_json = json.dumps(data) # Encode the data
>>> in_json
'{"parrot": 42, "spam": "foo"}'
>>> json.loads(in_json) # Decode into a Python object
{"spam" : "foo", "parrot" : 42}
```

It’s also possible to write your own decoders and encoders to support more types. Pretty-printing of the JSON strings is also supported.
json (originally called simplejson) was written by Bob Ippolito.

The `plistlib` module: A Property-List Parser

The `.plist` format is commonly used on Mac OS X to store basic data types (numbers, strings, lists, and dictionaries) by serializing them into an XML-based format. It resembles the XML-RPC serialization of data types.

Despite being primarily used on Mac OS X, the format has nothing Mac-specific about it and the Python implementation works on any platform that Python supports, so the `plistlib` module has been promoted to the standard library.

Using the module is simple:

```python
import sys
import plistlib
import datetime

# Create data structure
data_struct = dict(lastAccessed=datetime.datetime.now(),
                   version=1,
                   categories=('Personal','Shared','Private'))

# Create string containing XML.
pplist_str = plistlib.writePlistToString(data_struct)
new_struct = plistlib.readPlistFromString(pplist_str)
print data_struct
print new_struct

# Write data structure to a file and read it back.
pplistlib.writePlist(data_struct, '/tmp/customizations.plist')
new_struct = plistlib.readPlist('/tmp/customizations.plist')

# read/writePlist accepts file-like objects as well as paths.
pplistlib.writePlist(data_struct, sys.stdout)
```

cotypes Enhancements
Thomas Heller continued to maintain and enhance the ctypes module.

ctypes now supports a c_bool datatype that represents the C99 bool type. (Contributed by David Remahl; issue 1649190.)

The ctypes string, buffer and array types have improved support for extended slicing syntax, where various combinations of (start, stop, step) are supplied. (Implemented by Thomas Wouters.)

All ctypes data types now support from_buffer() and from_buffer_copy() methods that create a ctypes instance based on a provided buffer object. from_buffer_copy() copies the contents of the object, while from_buffer() will share the same memory area.

A new calling convention tells ctypes to clear the errno or Win32 LastError variables at the outset of each wrapped call. (Implemented by Thomas Heller; issue 1798.)

You can now retrieve the Unix errno variable after a function call. When creating a wrapped function, you can supply use_errno=True as a keyword parameter to the DLL() function and then call the module-level methods set_errno() and get_errno() to set and retrieve the error value.

The Win32 LastError variable is similarly supported by the DLL(), OleDLL(), and WinDLL() functions. You supply use_last_error=True as a keyword parameter and then call the module-level methods set_last_error() and get_last_error().

The byref() function, used to retrieve a pointer to a ctypes instance, now has an optional offset parameter that is a byte count that will be added to the returned pointer.
Improved SSL Support

Bill Janssen made extensive improvements to Python 2.6’s support for the Secure Sockets Layer by adding a new module, `ssl`, that's built atop the OpenSSL library. This new module provides more control over the protocol negotiated, the X.509 certificates used, and has better support for writing SSL servers (as opposed to clients) in Python. The existing SSL support in the `socket` module hasn’t been removed and continues to work, though it will be removed in Python 3.0.

To use the new module, you must first create a TCP connection in the usual way and then pass it to the `ssl.wrap_socket()` function. It's possible to specify whether a certificate is required, and to obtain certificate info by calling the `getpeercert()` method.

**See also:** The documentation for the `ssl` module.
Changes to Python's build process and to the C API include:

- Python now must be compiled with C89 compilers (after 19 years!). This means that the Python source tree has dropped its own implementations of `memmove` and `strerror`, which are in the C89 standard library.

- Python 2.6 can be built with Microsoft Visual Studio 2008 (version 9.0), and this is the new default compiler. See the `PCbuild` directory for the build files. (Implemented by Christian Heimes.)

- On Mac OS X, Python 2.6 can be compiled as a 4-way universal build. The `configure` script can take a `--with-universal-archs= [32-bit|64-bit|all]` switch, controlling whether the binaries are built for 32-bit architectures (x86, PowerPC), 64-bit (x86-64 and PPC-64), or both. (Contributed by Ronald Oussoren.)

- The BerkeleyDB module now has a C API object, available as `bsddb.db.api`. This object can be used by other C extensions that wish to use the `bsddb` module for their own purposes. (Contributed by Duncan Grisby; issue 1551895.)

- The new buffer interface, previously described in the PEP 3118 section, adds `PyObject_GetBuffer` and `PyBuffer_Release`, as well as a few other functions.

- Python's use of the C stdio library is now thread-safe, or at least as thread-safe as the underlying library is. A long-standing potential bug occurred if one thread closed a file object while another thread was reading from or writing to the object. In 2.6 file objects have a reference count, manipulated by the
PyFile_IncUseCount and PyFile_DecUseCount functions. File objects can’t be closed unless the reference count is zero. PyFile_IncUseCount should be called while the GIL is still held, before carrying out an I/O operation using the FILE * pointer, and PyFile_DecUseCount should be called immediately after the GIL is re-acquired. (Contributed by Antoine Pitrou and Gregory P. Smith.)

- Importing modules simultaneously in two different threads no longer deadlocks; it will now raise an ImportError. A new API function, PyImport_ImportModuleNoBlock, will look for a module in sys.modules first, then try to import it after acquiring an import lock. If the import lock is held by another thread, an ImportError is raised. (Contributed by Christian Heimes.)

- Several functions return information about the platform’s floating-point support. PyFloat_GetMax returns the maximum representable floating point value, and PyFloat_GetMin returns the minimum positive value. PyFloat_GetInfo returns an object containing more information from the float.h file, such as "mant_dig" (number of digits in the mantissa), "epsilon" (smallest difference between 1.0 and the next largest value representable), and several others. (Contributed by Christian Heimes; issue 1534.)

- C functions and methods that use PyComplex_AsCComplex will now accept arguments that have a __complex__() method. In particular, the functions in the cmath module will now accept objects with this method. This is a backport of a Python 3.0 change. (Contributed by Mark Dickinson; issue 1675423.)

- Python’s C API now includes two functions for case-insensitive string comparisons, PyOS_stricmp(char*, char*) and
Many C extensions define their own little macro for adding integers and strings to the module’s dictionary in the \texttt{init*} function. Python 2.6 finally defines standard macros for adding values to a module, \texttt{PyModule_AddStringMacro} and \texttt{PyModule_AddIntMacro()}. (Contributed by Christian Heimes.)

Some macros were renamed in both 3.0 and 2.6 to make it clearer that they are macros, not functions. \texttt{Py\_Size()} became \texttt{Py\_SIZE()}, \texttt{Py\_Type()} became \texttt{Py\_TYPE()}, and \texttt{Py\_Refcnt()} became \texttt{Py\_REFCNT()}. The mixed-case macros are still available in Python 2.6 for backward compatibility. (issue 1629)

Distutils now places C extensions it builds in a different directory when running on a debug version of Python. (Contributed by Collin Winter; issue 1530959.)

Several basic data types, such as integers and strings, maintain internal free lists of objects that can be re-used. The data structures for these free lists now follow a naming convention: the variable is always named \texttt{free\_list}, the counter is always named \texttt{numfree}, and a macro \texttt{Py\_typename\_MAXFREELIST} is always defined.

A new Makefile target, “make check”, prepares the Python source tree for making a patch: it fixes trailing whitespace in all modified \texttt{.py} files, checks whether the documentation has been changed, and reports whether the \texttt{Misc/ACKS} and \texttt{Misc/NEWS} files have been updated. (Contributed by Brett Cannon.)

Another new target, “make profile-opt”, compiles a Python binary using GCC’s profile-guided optimization. It compiles
Python with profiling enabled, runs the test suite to obtain a set of profiling results, and then compiles using these results for optimization. (Contributed by Gregory P. Smith.)

Port-Specific Changes: Windows

- The support for Windows 95, 98, ME and NT4 has been dropped. Python 2.6 requires at least Windows 2000 SP4.

- The new default compiler on Windows is Visual Studio 2008 (version 9.0). The build directories for Visual Studio 2003 (version 7.1) and 2005 (version 8.0) were moved into the PC directory. The new PCbuild directory supports cross compilation for X64, debug builds and Profile Guided Optimization (PGO). PGO builds are roughly 10% faster than normal builds. (Contributed by Christian Heimes with help from Amaury Forgeot d'Arc and Martin von Loewis.)

- The msvcrt module now supports both the normal and wide char variants of the console I/O API. The getwch() function reads a keypress and returns a Unicode value, as does the getwche() function. The putwch() function takes a Unicode character and writes it to the console. (Contributed by Christian Heimes.)

- os.path.expandvars() will now expand environment variables in the form “%var%”, and “~user” will be expanded into the user's home directory path. (Contributed by Josiah Carlson; issue 957650.)

- The socket module's socket objects now have an ioctl() method that provides a limited interface to the WSAIoctl system interface.

- The _winreg module now has a function,
ExpandEnvironmentStrings(), that expands environment variable references such as `%NAME%` in an input string. The handle objects provided by this module now support the context protocol, so they can be used in `with` statements. (Contributed by Christian Heimes.)

__winreg also has better support for x64 systems, exposing the DisableReflectionKey(), EnableReflectionKey(), and QueryReflectionKey() functions, which enable and disable registry reflection for 32-bit processes running on 64-bit systems. (issue 1753245)

- The _msilib module's Record object gained GetInteger() and GetString() methods that return field values as an integer or a string. (Contributed by Floris Bruynooghe; issue 2125.)

### Port-Specific Changes: Mac OS X

- When compiling a framework build of Python, you can now specify the framework name to be used by providing the `--with-framework-name=` option to the configure script.
- The macfs module has been removed. This in turn required the macostools.touched() function to be removed because it depended on the macfs module. (issue 1490190)
- Many other Mac OS modules have been deprecated and will removed in Python 3.0: _builtinSuites, aepack, aetools, aetypes, applesingle, appletrawmain, appletrunner, argvemulator, Audio_mac, autoGIL, Carbon, cfmfile, CodeWarrior, ColorPicker, EasyDialogs, Explorer, Finder, FrameWork, findertools, ic, icglue, icopen, macerrors, MacOS, macfs, macostools, macresource, MiniAEFrame, Nav, Netscape, OSATerminology, pimp, PixMapWrapper, StdSuites, SystemEvents,
Terminal, and terminalcommand.

**Port-Specific Changes: IRIX**

A number of old IRIX-specific modules were deprecated and will be removed in Python 3.0: al and AL, cd, cddb, cdplayer, CL and cl, DEVICE, ERRNO, FILE, FL and f1, flp, fm, GET, GLWS, GL and gl, IN, IOCTL, jpeg, panelparser, readcd, SV and sv, torgb, videoreader, and WAIT.
This section lists previously described changes and other bugfixes that may require changes to your code:

- Classes that aren’t supposed to be hashable should set `__hash__ = None` in their definitions to indicate the fact.

- The `__init__()` method of `collections.deque` now clears any existing contents of the deque before adding elements from the iterable. This change makes the behavior match `list.__init__()`. object.__init__() previously accepted arbitrary arguments and keyword arguments, ignoring them. In Python 2.6, this is no longer allowed and will result in a `TypeError`. This will affect `__init__()` methods that end up calling the corresponding method on `object` (perhaps through using `super()`). See issue 1683368 for discussion.

- The `Decimal` constructor now accepts leading and trailing whitespace when passed a string. Previously it would raise an `InvalidOperation` exception. On the other hand, the `create_decimal()` method of `Context` objects now explicitly disallows extra whitespace, raising a `ConversionSyntax` exception.

- Due to an implementation accident, if you passed a file path to the built-in `__import__()` function, it would actually import the specified file. This was never intended to work, however, and the implementation now explicitly checks for this case and raises an `ImportError`. 
• C API: the `PyImport_Import` and `PyImport_ImportModule` functions now default to absolute imports, not relative imports. This will affect C extensions that import other modules.

• C API: extension data types that shouldn't be hashable should define their `tp_hash` slot to `PyObject_HashNotImplemented`.

• The `socket` module exception `socket.error` now inherits from `IOError`. Previously it wasn't a subclass of `StandardError` but now it is, through `IOError`. (Implemented by Gregory P. Smith; issue 1706815.)

• The `xmlrpclib` module no longer automatically converts `datetime.date` and `datetime.time` to the `xmlrpclib.DateTime` type; the conversion semantics were not necessarily correct for all applications. Code using `xmlrpclib` should convert `date` and `time` instances. (issue 1330538)

• (3.0-warning mode) The `Exception` class now warns when accessed using slicing or index access; having `Exception` behave like a tuple is being phased out.

• (3.0-warning mode) Inequality comparisons between two dictionaries or two objects that don't implement comparison methods are reported as warnings. `dict1 == dict2` still works, but `dict1 < dict2` is being phased out.

Comparisons between cells, which are an implementation detail of Python's scoping rules, also cause warnings because such comparisons are forbidden entirely in 3.0.
Acknowledgements

The author would like to thank the following people for offering suggestions, corrections and assistance with various drafts of this article: Georg Brandl, Steve Brown, Nick Coghan, Jim Jewett, Kent Johnson, Chris Lambacher, Antoine Pitrou.
If you do much work on computers, eventually you find that there’s some task you’d like to automate. For example, you may wish to perform a search-and-replace over a large number of text files, or rename and rearrange a bunch of photo files in a complicated way. Perhaps you’d like to write a small custom database, or a specialized GUI application, or a simple game.

If you’re a professional software developer, you may have to work with several C/C++/Java libraries but find the usual write/compile/test/re-compile cycle is too slow. Perhaps you’re writing a test suite for such a library and find writing the testing code a tedious task. Or maybe you’ve written a program that could use an extension language, and you don’t want to design and implement a whole new language for your application.

Python is just the language for you.

You could write a Unix shell script or Windows batch files for some of these tasks, but shell scripts are best at moving around files and changing text data, not well-suited for GUI applications or games. You could write a C/C++/Java program, but it can take a lot of development time to get even a first-draft program. Python is simpler to use, available on Windows, Mac OS X, and Unix operating systems, and will help you get the job done more quickly.

Python is simple to use, but it is a real programming language, offering much more structure and support for large programs than shell scripts or batch files can offer. On the other hand, Python also offers much more error checking than C, and, being a very-high-level language, it has high-level data types built in, such as flexible arrays and dictionaries. Because of its more general data types Python is applicable to a much larger problem domain than Awk or even Perl,
yet many things are at least as easy in Python as in those languages.

Python allows you to split your program into modules that can be reused in other Python programs. It comes with a large collection of standard modules that you can use as the basis of your programs — or as examples to start learning to program in Python. Some of these modules provide things like file I/O, system calls, sockets, and even interfaces to graphical user interface toolkits like Tk.

Python is an interpreted language, which can save you considerable time during program development because no compilation and linking is necessary. The interpreter can be used interactively, which makes it easy to experiment with features of the language, to write throw-away programs, or to test functions during bottom-up program development. It is also a handy desk calculator.

Python enables programs to be written compactly and readably. Programs written in Python are typically much shorter than equivalent C, C++, or Java programs, for several reasons:

- the high-level data types allow you to express complex operations in a single statement;
- statement grouping is done by indentation instead of beginning and ending brackets;
- no variable or argument declarations are necessary.

Python is extensible: if you know how to program in C it is easy to add a new built-in function or module to the interpreter, either to perform critical operations at maximum speed, or to link Python programs to libraries that may only be available in binary form (such as a vendor-specific graphics library). Once you are really hooked, you can link the Python interpreter into an application written in C and use it as an extension or command language for that application.
By the way, the language is named after the BBC show “Monty Python’s Flying Circus” and has nothing to do with reptiles. Making references to Monty Python skits in documentation is not only allowed, it is encouraged!

Now that you are all excited about Python, you’ll want to examine it in some more detail. Since the best way to learn a language is to use it, the tutorial invites you to play with the Python interpreter as you read.

In the next chapter, the mechanics of using the interpreter are explained. This is rather mundane information, but essential for trying out the examples shown later.

The rest of the tutorial introduces various features of the Python language and system through examples, beginning with simple expressions, statements and data types, through functions and modules, and finally touching upon advanced concepts like exceptions and user-defined classes.
Using the Python Interpreter
Invoking the Interpreter

The Python interpreter is usually installed as `/usr/local/bin/python` on those machines where it is available; putting `/usr/local/bin` in your Unix shell's search path makes it possible to start it by typing the command

```
python
```

to the shell. Since the choice of the directory where the interpreter lives is an installation option, other places are possible; check with your local Python guru or system administrator. (E.g., `/usr/local/python` is a popular alternative location.)

On Windows machines, the Python installation is usually placed in `C:\Python26`, though you can change this when you're running the installer. To add this directory to your path, you can type the following command into the command prompt in a DOS box:

```
set path=%path%;C:\python26
```

Typing an end-of-file character (Control-D on Unix, Control-Z on Windows) at the primary prompt causes the interpreter to exit with a zero exit status. If that doesn't work, you can exit the interpreter by typing the following commands: `import sys; sys.exit()`.

The interpreter's line-editing features usually aren't very sophisticated. On Unix, whoever installed the interpreter may have enabled support for the GNU readline library, which adds more elaborate interactive editing and history features. Perhaps the quickest check to see whether command line editing is supported is typing Control-P to the first Python prompt you get. If it beeps, you have command line editing; see Appendix _Interactive Input Editing_.
and History Substitution for an introduction to the keys. If nothing appears to happen, or if \(^{\text{AP}}\) is echoed, command line editing isn't available; you'll only be able to use backspace to remove characters from the current line.

The interpreter operates somewhat like the Unix shell: when called with standard input connected to a tty device, it reads and executes commands interactively; when called with a file name argument or with a file as standard input, it reads and executes a script from that file.

A second way of starting the interpreter is `python -c command [arg] ...`, which executes the statement(s) in `command`, analogous to the shell's `-c` option. Since Python statements often contain spaces or other characters that are special to the shell, it is usually advised to quote `command` in its entirety with single quotes.

Some Python modules are also useful as scripts. These can be invoked using `python -m module [arg] ...`, which executes the source file for `module` as if you had spelled out its full name on the command line.

Note that there is a difference between `python file` and `python <file`. In the latter case, input requests from the program, such as calls to `input()` and `raw_input()`, are satisfied from `file`. Since this file has already been read until the end by the parser before the program starts executing, the program will encounter end-of-file immediately. In the former case (which is usually what you want) they are satisfied from whatever file or device is connected to standard input of the Python interpreter.

When a script file is used, it is sometimes useful to be able to run the script and enter interactive mode afterwards. This can be done by passing `-i` before the script. (This does not work if the script is read
from standard input, for the same reason as explained in the previous paragraph.)

**Argument Passing**

When known to the interpreter, the script name and additional arguments thereafter are passed to the script in the variable `sys.argv`, which is a list of strings. Its length is at least one; when no script and no arguments are given, `sys.argv[0]` is an empty string. When the script name is given as `-` (meaning standard input), `sys.argv[0]` is set to `-`. When `-c command` is used, `sys.argv[0]` is set to `-c`. When `-m module` is used, `sys.argv[0]` is set to the full name of the located module. Options found after `-c command or -m module` are not consumed by the Python interpreter’s option processing but left in `sys.argv` for the command or module to handle.

**Interactive Mode**

When commands are read from a tty, the interpreter is said to be in *interactive mode*. In this mode it prompts for the next command with the *primary prompt*, usually three greater-than signs (`>>>`); for continuation lines it prompts with the *secondary prompt*, by default three dots (`...`). The interpreter prints a welcome message stating its version number and a copyright notice before printing the first prompt:

```
python
Python 2.6 (#1, Feb 28 2007, 00:02:06)
Type "help", "copyright", "credits" or "license" for more information.
>>> 
```

Continuation lines are needed when entering a multi-line construct. As an example, take a look at this *if* statement:
the_world_is_flat = 1

if the_world_is_flat:
    print "Be careful not to fall off!"

Be careful not to fall off!
The Interpreter and Its Environment

Error Handling

When an error occurs, the interpreter prints an error message and a stack trace. In interactive mode, it then returns to the primary prompt; when input came from a file, it exits with a nonzero exit status after printing the stack trace. (Exceptions handled by an except clause in a try statement are not errors in this context.) Some errors are unconditionally fatal and cause an exit with a nonzero exit; this applies to internal inconsistencies and some cases of running out of memory. All error messages are written to the standard error stream; normal output from executed commands is written to standard output.

Typing the interrupt character (usually Control-C or DEL) to the primary or secondary prompt cancels the input and returns to the primary prompt. [1] Typing an interrupt while a command is executing raises the KeyboardInterrupt exception, which may be handled by a try statement.

Executable Python Scripts

On BSD’ish Unix systems, Python scripts can be made directly executable, like shell scripts, by putting the line

```
#!/usr/bin/env python
```

(assuming that the interpreter is on the user’s PATH) at the beginning of the script and giving the file an executable mode. The #! must be the first two characters of the file. On some platforms, this first line must end with a Unix-style line ending ("\n"), not a
Windows (\r\n) line ending. Note that the hash, or pound, character, ' # ', is used to start a comment in Python.

The script can be given an executable mode, or permission, using the **chmod** command:

```
$ chmod +x myscript.py
```

On Windows systems, there is no notion of an “executable mode”. The Python installer automatically associates .py files with **python.exe** so that a double-click on a Python file will run it as a script. The extension can also be .pyw, in that case, the console window that normally appears is suppressed.

### Source Code Encoding

It is possible to use encodings different than ASCII in Python source files. The best way to do it is to put one more special comment line right after the `#!` line to define the source file encoding:

```
# -*- coding: encoding -*-
```

With that declaration, all characters in the source file will be treated as having the encoding **encoding**, and it will be possible to directly write Unicode string literals in the selected encoding. The list of possible encodings can be found in the Python Library Reference, in the section on **codecs**.

For example, to write Unicode literals including the Euro currency symbol, the ISO-8859-15 encoding can be used, with the Euro symbol having the ordinal value 164. This script will print the value 8364 (the Unicode codepoint corresponding to the Euro symbol) and then exit:

```
# -*- coding: iso-8859-15 -*-
```
currency = u"€"

\textbf{print} \textbf{ord}(\textbf{currency})

If your editor supports saving files as \texttt{UTF-8} with a UTF-8 \textit{byte order mark} (aka BOM), you can use that instead of an encoding declaration. IDLE supports this capability if \texttt{Options/General/Default Source Encoding/UTF-8} is set. Notice that this signature is not understood in older Python releases (2.2 and earlier), and also not understood by the operating system for script files with \texttt{#!} lines (only used on Unix systems).

By using UTF-8 (either through the signature or an encoding declaration), characters of most languages in the world can be used simultaneously in string literals and comments. Using non-ASCII characters in identifiers is not supported. To display all these characters properly, your editor must recognize that the file is UTF-8, and it must use a font that supports all the characters in the file.

\section*{The Interactive Startup File}

When you use Python interactively, it is frequently handy to have some standard commands executed every time the interpreter is started. You can do this by setting an environment variable named \texttt{PYTHONSTARTUP} to the name of a file containing your start-up commands. This is similar to the \texttt{.profile} feature of the Unix shells.

This file is only read in interactive sessions, not when Python reads commands from a script, and not when \texttt{/dev/tty} is given as the explicit source of commands (which otherwise behaves like an interactive session). It is executed in the same namespace where interactive commands are executed, so that objects that it defines or imports can be used without qualification in the interactive session. You can also change the prompts \texttt{sys.ps1} and \texttt{sys.ps2} in this file.
If you want to read an additional start-up file from the current directory, you can program this in the global start-up file using code like

```python
if os.path.isfile('.pythonrc.py'):
    execfile('.pythonrc.py')
```

If you want to use the startup file in a script, you must do this explicitly in the script:

```python
import os
filename = os.environ.get('PYTHONSTARTUP')
if filename and os.path.isfile(filename):
    execfile(filename)
```

Footnotes

[1] A problem with the GNU Readline package may prevent this.
In the following examples, input and output are distinguished by the presence or absence of prompts (``` and ```): to repeat the example, you must type everything after the prompt, when the prompt appears; lines that do not begin with a prompt are output from the interpreter. Note that a secondary prompt on a line by itself in an example means you must type a blank line; this is used to end a multi-line command.

Many of the examples in this manual, even those entered at the interactive prompt, include comments. Comments in Python start with the hash character, `#`, and extend to the end of the physical line. A comment may appear at the start of a line or following whitespace or code, but not within a string literal. A hash character within a string literal is just a hash character. Since comments are to clarify code and are not interpreted by Python, they may be omitted when typing in examples.

Some examples:

```python
# this is the first comment
SPAM = 1  # and this is the second comment
# ... and now a third!
STRING = "# This is not a comment."
```
Using Python as a Calculator

Let’s try some simple Python commands. Start the interpreter and wait for the primary prompt, `>>>`. (It shouldn’t take long.)

Numbers

The interpreter acts as a simple calculator: you can type an expression at it and it will write the value. Expression syntax is straightforward: the operators `+`, `-`, `*` and `/` work just like in most other languages (for example, Pascal or C); parentheses can be used for grouping. For example:

```python
>>> 2+2
4
>>> # This is a comment
... 2+2
4
>>> 2+2  # and a comment on the same line as code
4
>>> (50-5*6)/4
5
>>> # Integer division returns the floor:
... 7/3
2
>>> 7/-3
-3
```

The equal sign (`=`) is used to assign a value to a variable. Afterwards, no result is displayed before the next interactive prompt:

```python
>>> width = 20
>>> height = 5*9
>>> width * height
900
```

A value can be assigned to several variables simultaneously:
```
>>> x = y = z = 0  # Zero x, y and z
>>> x
0
>>> y
0
>>> z
0
```

Variables must be “defined” (assigned a value) before they can be used, or an error will occur:

```
>>> # try to access an undefined variable
... n
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
NameError: name 'n' is not defined
```

There is full support for floating point; operators with mixed type operands convert the integer operand to floating point:

```
>>> 3 * 3.75 / 1.5
7.5
>>> 7.0 / 2
3.5
```

Complex numbers are also supported; imaginary numbers are written with a suffix of j or J. Complex numbers with a nonzero real component are written as \((\text{real+imag}j)\), or can be created with the \texttt{complex}(\text{real, imag}) function.

```
>>> 1j * 1j
(-1+0j)
>>> 1j * complex(0,1)
(-1+0j)
>>> 3+1j*3
(3+3j)
>>> (3+1j)**3
(9+3j)
>>> (1+2j)/(1+1j)
(1.5+0.5j)
```

Complex numbers are always represented as two floating point
numbers, the real and imaginary part. To extract these parts from a complex number \( z \), use \( \texttt{z.real} \) and \( \texttt{z.imag} \).

```python
>>> a = 1.5 + 0.5j
>>> a.real
1.5
>>> a.imag
0.5
```

The conversion functions to floating point and integer (\texttt{float()}, \texttt{int()} and \texttt{long()}) don’t work for complex numbers — there is no one correct way to convert a complex number to a real number. Use \( \texttt{abs(z)} \) to get its magnitude (as a float) or \( \texttt{z.real} \) to get its real part.

```python
>>> a = 3.0 + 4.0j
>>> float(a)
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
TypeError: can't convert complex to float; use abs(z)
>>> a.real
3.0
>>> a.imag
4.0
>>> abs(a)  # \( \sqrt{a.real^2 + a.imag^2} \)
5.0
```

In interactive mode, the last printed expression is assigned to the variable \( _{} \). This means that when you are using Python as a desk calculator, it is somewhat easier to continue calculations, for example:

```python
>>> tax = 12.5 / 100
>>> price = 100.50
>>> price * tax
12.5625
>>> price + _
113.0625
>>> round(_ , 2)
113.06
```
This variable should be treated as read-only by the user. Don’t explicitly assign a value to it — you would create an independent local variable with the same name masking the built-in variable with its magic behavior.

**Strings**

Besides numbers, Python can also manipulate strings, which can be expressed in several ways. They can be enclosed in single quotes or double quotes:

```python
>>> 'spam eggs'
'spam eggs'
>>> 'doesn\'t'
'doesn\'t'
>>> "doesn't"
"doesn't"
>>> "'Yes,\" he said."
"'Yes,\" he said."
>>> ""Yes,\" he said."
"Yes,\" he said."
>>> "'Isn\'t,\" she said."
"'Isn\'t,\" she said."
```

String literals can span multiple lines in several ways. Continuation lines can be used, with a backslash as the last character on the line indicating that the next line is a logical continuation of the line:

```python
hello = "This is a rather long string containing\nseveral lines of text just as you would do in C.\n    Note that whitespace at the beginning of the line is\nsignificant."

print hello
```

Note that newlines still need to be embedded in the string using \n; the newline following the trailing backslash is discarded. This example would print the following:

```python
This is a rather long string containing
```
If we make the string literal a “raw” string, however, the \n sequences are not converted to newlines, but the backslash at the end of the line, and the newline character in the source, are both included in the string as data. Thus, the example:

```python
hello = r"This is a rather long string containing\n\nseveral lines of text much as you would do in C."
```

```python
print hello
```

would print:

```
This is a rather long string containing\n\nseveral lines of text much as you would do in C.
```

Or, strings can be surrounded in a pair of matching triple-quotes: """" or ''''. End of lines do not need to be escaped when using triple-quotes, but they will be included in the string.

```python
print """
Usage: thingy [OPTIONS]
   -h                         Display this usage message
   -H hostname               Hostname to connect to
"""
```

produces the following output:

```
Usage: thingy [OPTIONS]
   -h                         Display this usage message
   -H hostname               Hostname to connect to
```

The interpreter prints the result of string operations in the same way as they are typed for input: inside quotes, and with quotes and other funny characters escaped by backslashes, to show the precise value. The string is enclosed in double quotes if the string contains a
single quote and no double quotes, else it's enclosed in single quotes. (The \texttt{print} statement, described later, can be used to write strings without quotes or escapes.)

Strings can be concatenated (glued together) with the \texttt{+} operator, and repeated with \texttt{*}:

```python
>>> word = 'Help' + 'A'
>>> word
'HelpA'
>>> '<' + word*5 + '>
'<HelpAHelpAHelpAHelpAHelpA>'
```

Two string literals next to each other are automatically concatenated; the first line above could also have been written \texttt{word = 'Help' 'A'}; this only works with two literals, not with arbitrary string expressions:

```python
>>> 'str' 'ing'
'string'
>>> 'str'.strip() + 'ing'
'string'
>>> 'str'.strip()'ing'
^ File "<stdin>", line 1, in ?
  'str'.strip()'ing'
SyntaxError: invalid syntax
```

Strings can be subscripted (indexed); like in C, the first character of a string has subscript (index) 0. There is no separate character type; a character is simply a string of size one. Like in Icon, substrings can be specified with the \textit{slice notation}: two indices separated by a colon.

```python
>>> word[4]
'A'
>>> word[0:2]
'He'
>>> word[2:4]
'lp'
```

Slice indices have useful defaults; an omitted first index defaults to
zero, an omitted second index defaults to the size of the string being sliced.

```python
>>> word[:2]  # The first two characters
'He'
>>> word[2:]  # Everything except the first two characters
'lpA'
```

Unlike a C string, Python strings cannot be changed. Assigning to an indexed position in the string results in an error:

```python
>>> word[0] = 'x'
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
TypeError: object doesn't support item assignment
>>> word[1] = 'Splat'
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
TypeError: object doesn't support slice assignment
```

However, creating a new string with the combined content is easy and efficient:

```python
>>> 'x' + word[1:]
'xelpA'
>>> 'Splat' + word[4]
'SplatA'
```

Here’s a useful invariant of slice operations: `s[:i] + s[i:]` equals `s`.

```python
>>> word[2:] + word[2:]
'HelpA'
>>> word[3:] + word[3:]
'HelpA'
```

Degenerate slice indices are handled gracefully: an index that is too large is replaced by the string size, an upper bound smaller than the lower bound returns an empty string.

```python
>>> word[1:100]
'elpA'
```
Indices may be negative numbers, to start counting from the right. For example:

```python
>>> word[-1]  # The last character
'A'
>>> word[-2]  # The last-but-one character
'p'
>>> word[-2:] # The last two characters
'pA'
>>> word[:2]  # Everything except the last two characters
'Hel'
```

But note that -0 is really the same as 0, so it does not count from the right!

```python
>>> word[-0]  # (since -0 equals 0)
'H'
```

Out-of-range negative slice indices are truncated, but don’t try this for single-element (non-slice) indices:

```python
>>> word[-100:]  # HelpA'
>>> word[-10]    # error
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
IndexError: string index out of range
```

One way to remember how slices work is to think of the indices as pointing *between* characters, with the left edge of the first character numbered 0. Then the right edge of the last character of a string of *n* characters has index *n*, for example:

```
+--------+--------+--------+--------+--------+--------+
| H | e | l | p | A |
+--------+--------+--------+--------+--------+
0 1 2 3 4 5
```
The first row of numbers gives the position of the indices 0...5 in the string; the second row gives the corresponding negative indices. The slice from $i$ to $j$ consists of all characters between the edges labeled $i$ and $j$, respectively.

For non-negative indices, the length of a slice is the difference of the indices, if both are within bounds. For example, the length of `word[1:3]` is 2.

The built-in function `len()` returns the length of a string:

```python
g>>> s = 'supercalifragilisticexpialidocious'
g>>> len(s)
34
```

**Sequence Types** — `str, unicode, list, tuple, buffer, xrange`

Strings, and the Unicode strings described in the next section, are examples of *sequence types*, and support the common operations supported by such types.

**String Methods**

Both strings and Unicode strings support a large number of methods for basic transformations and searching.

**String Formatting**

Information about string formatting with `str.format()` is described here.

**String Formatting Operations**

The old formatting operations invoked when strings and Unicode strings are the left operand of the `%` operator are described in more detail here.
Starting with Python 2.0 a new data type for storing text data is available to the programmer: the Unicode object. It can be used to store and manipulate Unicode data (see http://www.unicode.org/) and integrates well with the existing string objects, providing auto-conversions where necessary.

Unicode has the advantage of providing one ordinal for every character in every script used in modern and ancient texts. Previously, there were only 256 possible ordinals for script characters. Texts were typically bound to a code page which mapped the ordinals to script characters. This lead to very much confusion especially with respect to internationalization (usually written as `i18n` — 'i' + 18 characters + 'n') of software. Unicode solves these problems by defining one code page for all scripts.

Creating Unicode strings in Python is just as simple as creating normal strings:

```python
>>> u'Hello World !'
'u'Hello World !'
```

The small `u` in front of the quote indicates that a Unicode string is supposed to be created. If you want to include special characters in the string, you can do so by using the Python Unicode-Escape encoding. The following example shows how:

```python
>>> u'Hello\u0020World !'
'u'Hello World !'
```

The escape sequence `\u0020` indicates to insert the Unicode character with the ordinal value 0x0020 (the space character) at the given position.
Other characters are interpreted by using their respective ordinal values directly as Unicode ordinals. If you have literal strings in the standard Latin-1 encoding that is used in many Western countries, you will find it convenient that the lower 256 characters of Unicode are the same as the 256 characters of Latin-1.

For experts, there is also a raw mode just like the one for normal strings. You have to prefix the opening quote with ‘ur’ to have Python use the Raw-Unicode-Escape encoding. It will only apply the above conversion if there is an uneven number of backslashes in front of the small ‘u’.

```python
>>> ur'Hello\u0020World !'
u'Hello World !'
>>> ur'Hello\\u0020World !'
u'Hello\\\u0020World !'
```

The raw mode is most useful when you have to enter lots of backslashes, as can be necessary in regular expressions.

Apart from these standard encodings, Python provides a whole set of other ways of creating Unicode strings on the basis of a known encoding.

The built-in function `unicode()` provides access to all registered Unicode codecs (COders and DECoderS). Some of the more well known encodings which these codecs can convert are Latin-1, ASCII, UTF-8, and UTF-16. The latter two are variable-length encodings that store each Unicode character in one or more bytes. The default encoding is normally set to ASCII, which passes through characters in the range 0 to 127 and rejects any other characters with an error. When a Unicode string is printed, written to a file, or converted with `str()`, conversion takes place using this default encoding.

```python
>>> u"abc"
```
u'abc'
>>> str(u"abc")
'abc'
>>> u"äöü"
u'\xe4\xf6\xfc'
>>> str(u"äöü")
Traceback (most recent call last):
File "<stdin>", line 1, in ?
UnicodeEncodeError: 'ascii' codec can't encode characters in position 0-2

To convert a Unicode string into an 8-bit string using a specific
encoding, Unicode objects provide an encode() method that takes
one argument, the name of the encoding. Lowercase names for
encodings are preferred.
>>> u"äöü".encode('utf-8')
'\xc3\xa4\xc3\xb6\xc3\xbc'

If you have data in a specific encoding and want to produce a
corresponding Unicode string from it, you can use the unicode()
function with the encoding name as the second argument.
>>> unicode('\xc3\xa4\xc3\xb6\xc3\xbc', 'utf-8')
u'\xe4\xf6\xfc'

Lists
Python knows a number of compound data types, used to group
together other values. The most versatile is the list, which can be
written as a list of comma-separated values (items) between square
brackets. List items need not all have the same type.
>>> a = ['spam', 'eggs', 100, 1234]
>>> a
['spam', 'eggs', 100, 1234]

Like string indices, list indices start at 0, and lists can be sliced,
concatenated and so on:


Unlike strings, which are *immutable*, it is possible to change individual elements of a list:

```python
>>> a = ['spam', 'eggs', 100, 1234]
>>> a
['spam', 'eggs', 123, 1234]
```

Assignment to slices is also possible, and this can even change the size of the list or clear it entirely:

```python
>>> # Replace some items:
... a[0:2] = [1, 12]
>>> a
[1, 12, 123, 1234]
>>> # Remove some:
... a[0:2] = []
>>> a
[123, 1234]
>>> # Insert some:
... a[1:1] = ['bletch', 'xyzzy']
>>> a
[123, 'bletch', 'xyzzy', 1234]
>>> # Insert (a copy of) itself at the beginning
>>> a[:0] = a
>>> a
[123, 'bletch', 'xyzzy', 1234, 123, 'bletch', 'xyzzy', 1234]
>>> # Clear the list: replace all items with an empty list
>>> a[:0] = []
>>> a
[]
```
The built-in function `len()` also applies to lists:

```python
>>> a = ['a', 'b', 'c', 'd']
>>> len(a)
4
```

It is possible to nest lists (create lists containing other lists), for example:

```python
>>> q = [2, 3]
>>> p = [1, q, 4]
>>> len(p)
3
>>> p[1]
[2, 3]
>>> p[1][0]
2
>>> p[1].append('xtra')  # See section 5.1
>>> p
[1, [2, 3, 'xtra'], 4]
>>> q
[2, 3, 'xtra']
```

Note that in the last example, `p[1]` and `q` really refer to the same object! We'll come back to object semantics later.
First Steps Towards Programming

Of course, we can use Python for more complicated tasks than adding two and two together. For instance, we can write an initial sub-sequence of the Fibonacci series as follows:

```python
>>> # Fibonacci series:
... # the sum of two elements defines the next
... a, b = 0, 1
>>> while b < 10:
...     print b
...     a, b = b, a+b
... 1
  2
  3
  5
  8
```

This example introduces several new features.

- The first line contains a *multiple assignment*: the variables `a` and `b` simultaneously get the new values 0 and 1. On the last line this is used again, demonstrating that the expressions on the right-hand side are all evaluated first before any of the assignments take place. The right-hand side expressions are evaluated from the left to the right.

- The `while` loop executes as long as the condition (here: `b < 10`) remains true. In Python, like in C, any non-zero integer value is true; zero is false. The condition may also be a string or list value, in fact any sequence; anything with a non-zero length is true, empty sequences are false. The test used in the example is a simple comparison. The standard comparison operators are written the same as in C: `<` (less than), `>` (greater than), `==` (equal to), `<=` (less than or equal to), `>=` (greater than or equal
to) and \(!=\) (not equal to).

- The *body* of the loop is *indented*: indentation is Python’s way of grouping statements. Python does not (yet!) provide an intelligent input line editing facility, so you have to type a tab or space(s) for each indented line. In practice you will prepare more complicated input for Python with a text editor; most text editors have an auto-indent facility. When a compound statement is entered interactively, it must be followed by a blank line to indicate completion (since the parser cannot guess when you have typed the last line). Note that each line within a basic block must be indented by the same amount.

- The *print* statement writes the value of the expression(s) it is given. It differs from just writing the expression you want to write (as we did earlier in the calculator examples) in the way it handles multiple expressions and strings. Strings are printed without quotes, and a space is inserted between items, so you can format things nicely, like this:

```
>>> i = 256 * 256
>>> print 'The value of i is', i
The value of i is 65536
```

A trailing comma avoids the newline after the output:

```
>>> a, b = 0, 1
>>> while b < 1000:
...     print b,
...     a, b = b, a+b
...
1 1 2 3 5 8 13 21 34 55 89 144 233 377 610 987
```

Note that the interpreter inserts a newline before it prints the
next prompt if the last line was not completed.
Besides the `while` statement just introduced, Python knows the usual control flow statements known from other languages, with some twists.
if Statements

Perhaps the most well-known statement type is the if statement. For example:

```python
>>> x = int(raw_input("Please enter an integer: "))
Please enter an integer: 42
>>> if x < 0:
...     x = 0
...     print 'Negative changed to zero'
... elif x == 0:
...     print 'Zero'
... elif x == 1:
...     print 'Single'
... else:
...     print 'More'
More
```

There can be zero or more elif parts, and the else part is optional. The keyword `elif` is short for ‘else if’, and is useful to avoid excessive indentation. An if ... elif ... elif ... sequence is a substitute for the switch or case statements found in other languages.
for Statements

The for statement in Python differs a bit from what you may be used to in C or Pascal. Rather than always iterating over an arithmetic progression of numbers (like in Pascal), or giving the user the ability to define both the iteration step and halting condition (as C), Python's for statement iterates over the items of any sequence (a list or a string), in the order that they appear in the sequence. For example (no pun intended):

```python
>>> # Measure some strings:
... a = ['cat', 'window', 'defenestrate']
>>> for x in a:
...     print x, len(x)
...
cat 3
window 6
defenestrate 12
```

It is not safe to modify the sequence being iterated over in the loop (this can only happen for mutable sequence types, such as lists). If you need to modify the list you are iterating over (for example, to duplicate selected items) you must iterate over a copy. The slice notation makes this particularly convenient:

```python
>>> for x in a[:]: # make a slice copy of the entire list
...     if len(x) > 6: a.insert(0, x)
...
>>> a
['defenestrate', 'cat', 'window', 'defenestrate']
```
The \texttt{range()} Function

If you do need to iterate over a sequence of numbers, the built-in function \texttt{range()} comes in handy. It generates lists containing arithmetic progressions:

\[
\begin{array}{l}
\texttt{range(10)}
\end{array}
\]
\[
[0, 1, 2, 3, 4, 5, 6, 7, 8, 9]
\]

The given end point is never part of the generated list; \texttt{range(10)} generates a list of 10 values, the legal indices for items of a sequence of length 10. It is possible to let the range start at another number, or to specify a different increment (even negative; sometimes this is called the ‘step’):

\[
\begin{array}{l}
\texttt{range(5, 10)}
\end{array}
\]
\[
[5, 6, 7, 8, 9]
\]

\[
\begin{array}{l}
\texttt{range(0, 10, 3)}
\end{array}
\]
\[
[0, 3, 6, 9]
\]

\[
\begin{array}{l}
\texttt{range(-10, -100, -30)}
\end{array}
\]
\[
[-10, -40, -70]
\]

To iterate over the indices of a sequence, combine \texttt{range()} and \texttt{len()} as follows:

\[
\begin{array}{l}
\texttt{a = ['Mary', 'had', 'a', 'little', 'lamb']}
\texttt{for i in range(len(a)):
  ... \texttt{print i, a[i]}
  ...}
\end{array}
\]
\[
0 Mary
1 had
2 a
3 little
4 lamb
\]
break and continue Statements, and else Clauses on Loops

The **break** statement, like in C, breaks out of the smallest enclosing **for** or **while** loop.

The **continue** statement, also borrowed from C, continues with the next iteration of the loop.

Loop statements may have an **else** clause; it is executed when the loop terminates through exhaustion of the list (with **for**) or when the condition becomes false (with **while**), but not when the loop is terminated by a **break** statement. This is exemplified by the following loop, which searches for prime numbers:

```python
>>> for n in range(2, 10):
...     for x in range(2, n):
...         if n % x == 0:
...             print n, 'equals', x, '*', n/x
...             break
...     else:
...         # loop fell through without finding a factor
...         print n, 'is a prime number'
...
2 is a prime number
3 is a prime number
4 equals 2 * 2
5 is a prime number
6 equals 2 * 3
7 is a prime number
8 equals 2 * 4
9 equals 3 * 3
```
The `pass` statement does nothing. It can be used when a statement is required syntactically but the program requires no action. For example:

```python
>>> while True:
...   pass  # Busy-wait for keyboard interrupt (Ctrl+C)
...```
Defining Functions

We can create a function that writes the Fibonacci series to an arbitrary boundary:

```python
>>> def fib(n):    # write Fibonacci series up to n
...     """Print a Fibonacci series up to n."""
...     a, b = 0, 1
...     while b < n:
...         print b,
...         a, b = b, a+b
...     >>> # Now call the function we just defined:
...     ... fib(2000)
... 1 1 2 3 5 8 13 21 34 55 89 144 233 377 610 987 1597
```

The keyword `def` introduces a function definition. It must be followed by the function name and the parenthesized list of formal parameters. The statements that form the body of the function start at the next line, and must be indented.

The first statement of the function body can optionally be a string literal; this string literal is the function’s documentation string, or docstring. (More about docstrings can be found in the section Documentation Strings.) There are tools which use docstrings to automatically produce online or printed documentation, or to let the user interactively browse through code; it’s good practice to include docstrings in code that you write, so make a habit of it.

The execution of a function introduces a new symbol table used for the local variables of the function. More precisely, all variable assignments in a function store the value in the local symbol table; whereas variable references first look in the local symbol table, then in the local symbol tables of enclosing functions, then in the global symbol table, and finally in the table of built-in names. Thus, global variables cannot be directly assigned a value within a function.
(unless named in a `global` statement), although they may be referenced.

The actual parameters (arguments) to a function call are introduced in the local symbol table of the called function when it is called; thus, arguments are passed using *call by value* (where the *value* is always an object *reference*, not the value of the object). [1] When a function calls another function, a new local symbol table is created for that call.

A function definition introduces the function name in the current symbol table. The value of the function name has a type that is recognized by the interpreter as a user-defined function. This value can be assigned to another name which can then also be used as a function. This serves as a general renaming mechanism:

```python
>>> fib
<function fib at 10042ed0>
>>> f = fib
>>> f(100)
1 1 2 3 5 8 13 21 34 55 89
```

Coming from other languages, you might object that `fib` is not a function but a procedure since it doesn’t return a value. In fact, even functions without a `return` statement do return a value, albeit a rather boring one. This value is called `None` (it’s a built-in name). Writing the value `None` is normally suppressed by the interpreter if it would be the only value written. You can see it if you really want to using `print`:

```python
>>> fib(0)
>>> print fib(0)
None
```

It is simple to write a function that returns a list of the numbers of the Fibonacci series, instead of printing it:
```python
def fib2(n):  
    """Return a list containing the Fibonacci series up to n."
    result = []
    a, b = 0, 1
    while b < n:
        result.append(b)  # see below
        a, b = b, a+b
    return result

>>> f100 = fib2(100)  # call it
>>> f100  # write the result
[1, 1, 2, 3, 5, 8, 13, 21, 34, 55, 89]
```

This example, as usual, demonstrates some new Python features:

- The `return` statement returns with a value from a function. `return` without an expression argument returns `None`. Falling off the end of a function also returns `None`.

- The statement `result.append(b)` calls a `method` of the list object `result`. A method is a function that ‘belongs’ to an object and is named `obj.methodname`, where `obj` is some object (this may be an expression), and `methodname` is the name of a method that is defined by the object’s type. Different types define different methods. Methods of different types may have the same name without causing ambiguity. (It is possible to define your own object types and methods, using `classes`, as discussed later in this tutorial.) The method `append()` shown in the example is defined for list objects; it adds a new element at the end of the list. In this example it is equivalent to `result = result + [b]`, but more efficient.
More on Defining Functions

It is also possible to define functions with a variable number of arguments. There are three forms, which can be combined.

Default Argument Values

The most useful form is to specify a default value for one or more arguments. This creates a function that can be called with fewer arguments than it is defined to allow. For example:

```python
def ask_ok(prompt, retries=4, complaint='Yes or no, please!'):
    while True:
        ok = raw_input(prompt)
        if ok in ('y', 'ye', 'yes'): return True
        if ok in ('n', 'no', 'nop', 'nope'): return False
        retries = retries - 1
        if retries < 0: raise IOError, 'refusenik user'
        print complaint
```

This function can be called either like this: `ask_ok('Do you really want to quit?')` or like this: `ask_ok('OK to overwrite the file?', 2).

This example also introduces the `in` keyword. This tests whether or not a sequence contains a certain value.

The default values are evaluated at the point of function definition in the `defining` scope, so that

```python
i = 5
def f(arg=i):
    print arg
i = 6
f()
```
will print 5.

**Important warning:** The default value is evaluated only once. This makes a difference when the default is a mutable object such as a list, dictionary, or instances of most classes. For example, the following function accumulates the arguments passed to it on subsequent calls:

```python
def f(a, L=[]):
    L.append(a)
    return L

print f(1)
print f(2)
print f(3)
```

This will print:

```
[1]
[1, 2]
[1, 2, 3]
```

If you don’t want the default to be shared between subsequent calls, you can write the function like this instead:

```python
def f(a, L=None):
    if L is None:
        L = []
    L.append(a)
    return L
```

### Keyword Arguments

Functions can also be called using keyword arguments of the form `keyword = value`. For instance, the following function:

```python
def parrot(voltage, state='a stiff', action='voom', type='Norwegian Blue',
            print "-- This parrot wouldn't", action,
            print "if you put", voltage, "volts through it."
            print "-- Lovely plumage, the", type
```

```python
def parrot(voltage, state='a stiff', action='voom', type='Norwegian Blue',
            print "-- This parrot wouldn't", action,
            print "if you put", voltage, "volts through it."
            print "-- Lovely plumage, the", type
```
could be called in any of the following ways:

```python
parrot(1000)
parrot(action = 'V000000M', voltage = 1000000)
parrot('a thousand', state = 'pushing up the daisies')
parrot('a million', 'bereft of life', 'jump')
```

but the following calls would all be invalid:

```python
parrot()                       # required argument missing
parrot(voltage=5.0, 'dead')   # non-keyword argument following k
parrot(110, voltage=220)      # duplicate value for argument
parrot(actor='John Cleese')   # unknown keyword
```

In general, an argument list must have any positional arguments followed by any keyword arguments, where the keywords must be chosen from the formal parameter names. It’s not important whether a formal parameter has a default value or not. No argument may receive a value more than once — formal parameter names corresponding to positional arguments cannot be used as keywords in the same calls. Here’s an example that fails due to this restriction:

```python
>>> def function(a):
...     pass
... >>> function(0, a=0)
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
TypeError: function() got multiple values for keyword argument
```

When a final formal parameter of the form `**name` is present, it receives a dictionary (see *Mapping Types — dict*) containing all keyword arguments except for those corresponding to a formal parameter. This may be combined with a formal parameter of the form `*name` (described in the next subsection) which receives a tuple
containing the positional arguments beyond the formal parameter list. (*name must occur before **name.) For example, if we define a function like this:

```python
def cheeseshop(kind, *arguments, **keywords):
    print "-- Do you have any", kind, "?"
    print "-- I'm sorry, we're all out of", kind
    for arg in arguments: print arg
    print "-" * 40
    keys = keywords.keys()
    keys.sort()
    for kw in keys: print kw, ":", keywords[kw]
```

It could be called like this:

```python
cheeseshop("Limburger", "It's very runny, sir.", "It's really very, VERY runny, sir.", shopkeeper='Michael Palin', client="John Cleese", sketch="Cheese Shop Sketch")
```

and of course it would print:

```
-- Do you have any Limburger ?
-- I'm sorry, we're all out of Limburger
It's very runny, sir.
It's really very, VERY runny, sir.
----------------------------------------
client : John Cleese
shopkeeper : Michael Palin
sketch : Cheese Shop Sketch
```

Note that the sort() method of the list of keyword argument names is called before printing the contents of the keywords dictionary; if this is not done, the order in which the arguments are printed is undefined.

**Arbitrary Argument Lists**

Finally, the least frequently used option is to specify that a function
can be called with an arbitrary number of arguments. These arguments will be wrapped up in a tuple (see *Tuples and Sequences*). Before the variable number of arguments, zero or more normal arguments may occur.

```python
def write_multiple_items(file, separator, *args):
    file.write(separator.join(args))
```

### Unpacking Argument Lists

The reverse situation occurs when the arguments are already in a list or tuple but need to be unpacked for a function call requiring separate positional arguments. For instance, the built-in *range()* function expects separate *start* and *stop* arguments. If they are not available separately, write the function call with the `*`-operator to unpack the arguments out of a list or tuple:

```
>>> range(3, 6)  # normal call with separate arguments
[3, 4, 5]
>>> args = [3, 6]
>>> range(*args)  # call with arguments unpacked from a list
[3, 4, 5]
```

In the same fashion, dictionaries can deliver keyword arguments with the `**`-operator:

```
>>> def parrot(voltage, state='a stiff', action='voom'):
...    print '-- This parrot wouldn''t', action, 'if you put', voltage, 'volts through it.','
...    print 'E''s', state, '!',
...
>>> d = {'voltage': 'four million', 'state': 'bleedin'' demised'}
>>> parrot(**d)
-- This parrot wouldn't VOOM if you put four million volts through it.
E's bleedin' demised!
```

### Lambda Forms
By popular demand, a few features commonly found in functional programming languages like Lisp have been added to Python. With the `lambda` keyword, small anonymous functions can be created. Here’s a function that returns the sum of its two arguments: `lambda a, b: a+b`. Lambda forms can be used wherever function objects are required. They are syntactically restricted to a single expression. Semantically, they are just syntactic sugar for a normal function definition. Like nested function definitions, lambda forms can reference variables from the containing scope:

```python
>>> def make_incrementor(n):
...     return lambda x: x + n
... >>> f = make_incrementor(42)
>>> f(0)
42
>>> f(1)
43
```

**Documentation Strings**

There are emerging conventions about the content and formatting of documentation strings.

The first line should always be a short, concise summary of the object's purpose. For brevity, it should not explicitly state the object's name or type, since these are available by other means (except if the name happens to be a verb describing a function’s operation). This line should begin with a capital letter and end with a period.

If there are more lines in the documentation string, the second line should be blank, visually separating the summary from the rest of the description. The following lines should be one or more paragraphs describing the object's calling conventions, its side effects, etc.

The Python parser does not strip indentation from multi-line string literals in Python, so tools that process documentation have to strip
indentation if desired. This is done using the following convention. The first non-blank line after the first line of the string determines the amount of indentation for the entire documentation string. (We can’t use the first line since it is generally adjacent to the string’s opening quotes so its indentation is not apparent in the string literal.) Whitespace “equivalent” to this indentation is then stripped from the start of all lines of the string. Lines that are indented less should not occur, but if they occur all their leading whitespace should be stripped. Equivalence of whitespace should be tested after expansion of tabs (to 8 spaces, normally).

Here is an example of a multi-line docstring:

```python
>>> def my_function():
...     """Do nothing, but document it.
...     No, really, it doesn't do anything.
...     """
...     pass
...
>>> print my_function.__doc__
Do nothing, but document it.
    No, really, it doesn't do anything.
```
Intermezzo: Coding Style

Now that you are about to write longer, more complex pieces of Python, it is a good time to talk about coding style. Most languages can be written (or more concise, formatted) in different styles; some are more readable than others. Making it easy for others to read your code is always a good idea, and adopting a nice coding style helps tremendously for that.

For Python, PEP 8 has emerged as the style guide that most projects adhere to; it promotes a very readable and eye-pleasing coding style. Every Python developer should read it at some point; here are the most important points extracted for you:

- Use 4-space indentation, and no tabs.
  
  4 spaces are a good compromise between small indentation (allows greater nesting depth) and large indentation (easier to read). Tabs introduce confusion, and are best left out.

- Wrap lines so that they don’t exceed 79 characters.
  
  This helps users with small displays and makes it possible to have several code files side-by-side on larger displays.

- Use blank lines to separate functions and classes, and larger blocks of code inside functions.

- When possible, put comments on a line of their own.

- Use docstrings.

- Use spaces around operators and after commas, but not directly inside bracketing constructs: 
  
  a = f(1, 2) + g(3, 4).
• Name your classes and functions consistently; the convention is to use \texttt{CamelCase} for classes and \texttt{lower_case_with_underscores} for functions and methods. Always use \texttt{self} as the name for the first method argument (see \textit{A First Look at Classes} for more on classes and methods).

• Don’t use fancy encodings if your code is meant to be used in international environments. Plain ASCII works best in any case.

\textbf{Footnotes}

Actually, \textit{call by object reference} would be a better description, \footnote{Actually, \textit{call by object reference} would be a better description, since if a mutable object is passed, the caller will see any changes the callee makes to it (items inserted into a list).}
Data Structures

This chapter describes some things you’ve learned about already in more detail, and adds some new things as well.
More on Lists

The list data type has some more methods. Here are all of the methods of list objects:

**list.** **append** (**x**)  
Add an item to the end of the list; equivalent to `a[len(a):] = [x]`. 

**list.** **extend** (**L**)  
Extend the list by appending all the items in the given list; equivalent to `a[len(a):] = L`. 

**list.** **insert** (**i**, **x**)  
Insert an item at a given position. The first argument is the index of the element before which to insert, so `a.insert(0, x)` inserts at the front of the list, and `a.insert(len(a), x)` is equivalent to `a.append(x)`. 

**list.** **remove** (**x**)  
Remove the first item from the list whose value is `x`. It is an error if there is no such item. 

**list.** **pop** ([**i**])  
Remove the item at the given position in the list, and return it. If no index is specified, `a.pop()` removes and returns the last item in the list. (The square brackets around the `i` in the method signature denote that the parameter is optional, not that you should type square brackets at that position. You will see this notation frequently in the Python Library Reference.) 

**list.** **index** (**x**)  
Return the index in the list of the first item whose value is `x`. It is
an error if there is no such item.

```python
list.count(x)
```
Return the number of times $x$ appears in the list.

```python
list.sort()
```
Sort the items of the list, in place.

```python
list.reverse()
```
Reverse the elements of the list, in place.

An example that uses most of the list methods:

```python
>>> a = [66.25, 333, 333, 1, 1234.5]
>>> print a.count(333), a.count(66.25), a.count('x')
2 1 0
>>> a.insert(2, -1)
>>> a.append(333)
>>> a
[66.25, 333, -1, 333, 1, 1234.5, 333]
>>> a.index(333)
1
>>> a.remove(333)
>>> a
[66.25, -1, 333, 1, 1234.5, 333]
>>> a.reverse()
>>> a
[333, 1234.5, 1, 333, -1, 66.25]
>>> a.sort()
>>> a
[-1, 1, 66.25, 333, 333, 1234.5]
```

Using Lists as Stacks

The list methods make it very easy to use a list as a stack, where the last element added is the first element retrieved (“last-in, first-out”). To add an item to the top of the stack, use `append()`. To retrieve an item from the top of the stack, use `pop()` without an explicit index. For example:
Using Lists as Queues

You can also use a list conveniently as a queue, where the first element added is the first element retrieved (“first-in, first-out”). To add an item to the back of the queue, use `append()`. To retrieve an item from the front of the queue, use `pop()` with 0 as the index. For example:

```python
>>> queue = ['Eric', 'John', 'Michael']
>>> queue.append("Terry")          # Terry arrives
>>> queue.append("Graham")         # Graham arrives
>>> queue.pop(0)                   # 'Eric'
'Eric'
>>> queue.pop(0)                   # 'John'
'John'
>>> queue                       
['Michael', 'Terry', 'Graham']
```

Functional Programming Tools

There are three built-in functions that are very useful when used with lists: `filter()`, `map()`, and `reduce()`.

`filter(function, sequence)` returns a sequence consisting of those
items from the sequence for which \texttt{function(item)} is true. If \textit{sequence} is a \texttt{string} or \texttt{tuple}, the result will be of the same type; otherwise, it is always a \texttt{list}. For example, to compute some primes:

\begin{verbatim}
>>> def f(x): return x % 2 != 0 and x % 3 != 0
... >>> filter(f, range(2, 25))
[5, 7, 11, 13, 17, 19, 23]
\end{verbatim}

\texttt{map(function, sequence)} calls \texttt{function(item)} for each of the sequence's items and returns a list of the return values. For example, to compute some cubes:

\begin{verbatim}
>>> def cube(x): return x**x**x
... >>> map(cube, range(1, 11))
[1, 8, 27, 64, 125, 216, 343, 512, 729, 1000]
\end{verbatim}

More than one sequence may be passed; the function must then have as many arguments as there are sequences and is called with the corresponding item from each sequence (or \texttt{None} if some sequence is shorter than another). For example:

\begin{verbatim}
>>> seq = range(8)
>>> def add(x, y): return x+y
... >>> map(add, seq, seq)
[0, 2, 4, 6, 8, 10, 12, 14]
\end{verbatim}

\texttt{reduce(function, sequence)} returns a single value constructed by calling the binary function \texttt{function} on the first two items of the sequence, then on the result and the next item, and so on. For example, to compute the sum of the numbers 1 through 10:

\begin{verbatim}
>>> def add(x,y): return x+y
... >>> reduce(add, range(1, 11))
55
\end{verbatim}
If there’s only one item in the sequence, its value is returned; if the sequence is empty, an exception is raised.

A third argument can be passed to indicate the starting value. In this case the starting value is returned for an empty sequence, and the function is first applied to the starting value and the first sequence item, then to the result and the next item, and so on. For example,

```python
>>> def sum(seq):
...     def add(x, y): return x+y
...     return reduce(add, seq, 0)
...  
>>> sum(range(1, 11))
55
>>> sum([])
0
```

Don’t use this example’s definition of `sum()`: since summing numbers is such a common need, a built-in function `sum(sequence)` is already provided, and works exactly like this.

*New in version 2.3.*

### List Comprehensions

List comprehensions provide a concise way to create lists without resorting to use of `map()`, `filter()` and/or `lambda`. The resulting list definition tends often to be clearer than lists built using those constructs. Each list comprehension consists of an expression followed by a `for` clause, then zero or more `for` or `if` clauses. The result will be a list resulting from evaluating the expression in the context of the `for` and `if` clauses which follow it. If the expression would evaluate to a tuple, it must be parenthesized.

```python
>>> freshfruit = ['banana', 'loganberry', 'passion fruit
>>> [weapon.strip() for weapon in freshfruit]
```
List comprehensions are much more flexible than `map()` and can be applied to complex expressions and nested functions:

```python
>>> [str(round(355/113.0, i)) for i in range(1, 6)]
['3.1', '3.14', '3.142', '3.1416', '3.14159']
```

**Nested List Comprehensions**

If you’ve got the stomach for it, list comprehensions can be nested. They are a powerful tool but – like all powerful tools – they need to be used carefully, if at all.

Consider the following example of a 3x3 matrix held as a list containing three lists, one list per row:

```python
>>> mat = [ ]
```
Now, if you wanted to swap rows and columns, you could use a list comprehension:

```python
>>> print ([[row[i] for row in mat] for i in [0, 1, 2]]
[[[1, 4, 7], [2, 5, 8], [3, 6, 9]]
```

Special care has to be taken for the *nested* list comprehension:

To avoid apprehension when nesting list comprehensions, read from right to left.

A more verbose version of this snippet shows the flow explicitly:

```python
for i in [0, 1, 2]:
    for row in mat:
        print row[i],
    print
```

In real world, you should prefer builtin functions to complex flow statements. The `zip()` function would do a great job for this use case:

```python
>>> zip(*mat)
[(1, 4, 7), (2, 5, 8), (3, 6, 9)]
```

See *Unpacking Argument Lists* for details on the asterisk in this line.
The `del` statement

There is a way to remove an item from a list given its index instead of its value: the `del` statement. This differs from the `pop()` method which returns a value. The `del` statement can also be used to remove slices from a list or clear the entire list (which we did earlier by assignment of an empty list to the slice). For example:

```python
>>> a = [-1, 1, 66.25, 333, 333, 1234.5]
>>> del a[0]
>>> a
[1, 66.25, 333, 333, 1234.5]
>>> del a[2:4]
>>> a
[1, 66.25, 1234.5]
>>> del a[:]
>>> a
[]
```

`del` can also be used to delete entire variables:

```python
>>> del a
```

Referencing the name `a` hereafter is an error (at least until another value is assigned to it). We'll find other uses for `del` later.
Tuples and Sequences

We saw that lists and strings have many common properties, such as indexing and slicing operations. They are two examples of sequence data types (see Sequence Types — str, unicode, list, tuple, buffer, xrange). Since Python is an evolving language, other sequence data types may be added. There is also another standard sequence data type: the tuple.

A tuple consists of a number of values separated by commas, for instance:

```plaintext
>>> t = 12345, 54321, 'hello!' >>> t[0] 12345 >>> t (12345, 54321, 'hello!') >>> # Tuples may be nested: ... u = t, (1, 2, 3, 4, 5) >>> u ((12345, 54321, 'hello!'), (1, 2, 3, 4, 5))
```

As you see, on output tuples are always enclosed in parentheses, so that nested tuples are interpreted correctly; they may be input with or without surrounding parentheses, although often parentheses are necessary anyway (if the tuple is part of a larger expression).

Tuples have many uses. For example: (x, y) coordinate pairs, employee records from a database, etc. Tuples, like strings, are immutable: it is not possible to assign to the individual items of a tuple (you can simulate much of the same effect with slicing and concatenation, though). It is also possible to create tuples which contain mutable objects, such as lists.

A special problem is the construction of tuples containing 0 or 1 items: the syntax has some extra quirks to accommodate these.
Empty tuples are constructed by an empty pair of parentheses; a tuple with one item is constructed by following a value with a comma (it is not sufficient to enclose a single value in parentheses). Ugly, but effective. For example:

```python
>>> empty = ()
>>> singleton = 'hello',  # <-- note trailing comma
>>> len(empty)
0
>>> len(singleton)
1
>>> singleton
('hello',)
```

The statement `t = 12345, 54321, 'hello!'` is an example of *tuple packing*: the values `12345`, `54321` and `'hello!'` are packed together in a tuple. The reverse operation is also possible:

```python
>>> x, y, z = t
```

This is called, appropriately enough, *sequence unpacking*. Sequence unpacking requires the list of variables on the left to have the same number of elements as the length of the sequence. Note that multiple assignment is really just a combination of tuple packing and sequence unpacking!

There is a small bit of asymmetry here: packing multiple values always creates a tuple, and unpacking works for any sequence.
Sets

Python also includes a data type for sets. A set is an unordered collection with no duplicate elements. Basic uses include membership testing and eliminating duplicate entries. Set objects also support mathematical operations like union, intersection, difference, and symmetric difference.

Here is a brief demonstration:

```python
>>> basket = ['apple', 'orange', 'apple', 'pear', 'orange', 'banana']
>>> fruit = set(basket)  # create a set without duplicates
set(['orange', 'pear', 'apple', 'banana'])
>>> 'orange' in fruit  # fast membership testing
True
>>> 'crabgrass' in fruit
False

>>> # Demonstrate set operations on unique letters from two words...
...  
>>> a = set('abracadabra')
>>> b = set('alacazam')

>>> a  # unique letters in a
set(['a', 'r', 'b', 'c', 'd'])

>>> a - b  # letters in a but not in b
set(['r', 'd', 'b'])

>>> a | b  # letters in either a or b
set(['a', 'c', 'r', 'd', 'b', 'm', 'z', 'l'])

>>> a & b  # letters in both a and b
set(['a', 'c'])

>>> a ^ b  # letters in a or b but not both
set(['r', 'd', 'b', 'm', 'z', 'l'])
```
Dictionaries

Another useful data type built into Python is the *dictionary* (see *Mapping Types — dict*). Dictionaries are sometimes found in other languages as “associative memories” or “associative arrays”. Unlike sequences, which are indexed by a range of numbers, dictionaries are indexed by *keys*, which can be any immutable type; strings and numbers can always be keys. Tuples can be used as keys if they contain only strings, numbers, or tuples; if a tuple contains any mutable object either directly or indirectly, it cannot be used as a key. You can’t use lists as keys, since lists can be modified in place using index assignments, slice assignments, or methods like `append()` and `extend()`.

It is best to think of a dictionary as an unordered set of *key: value* pairs, with the requirement that the keys are unique (within one dictionary). A pair of braces creates an empty dictionary: `{}`. Placing a comma-separated list of key:value pairs within the braces adds initial key:value pairs to the dictionary; this is also the way dictionaries are written on output.

The main operations on a dictionary are storing a value with some key and extracting the value given the key. It is also possible to delete a key:value pair with `del`. If you store using a key that is already in use, the old value associated with that key is forgotten. It is an error to extract a value using a non-existent key.

The `keys()` method of a dictionary object returns a list of all the keys used in the dictionary, in arbitrary order (if you want it sorted, just apply the `sort()` method to the list of keys). To check whether a single key is in the dictionary, use the `in` keyword.

Here is a small example using a dictionary:
The \texttt{dict()} constructor builds dictionaries directly from lists of key-value pairs stored as tuples. When the pairs form a pattern, list comprehensions can compactly specify the key-value list.

Later in the tutorial, we will learn about Generator Expressions which are even better suited for the task of supplying key-values pairs to the \texttt{dict()} constructor.

When the keys are simple strings, it is sometimes easier to specify pairs using keyword arguments:
Looping Techniques

When looping through dictionaries, the key and corresponding value can be retrieved at the same time using the `iteritems()` method.

```python
>>> knights = {'gallahad': 'the pure', 'robin': 'the brave'}
>>> for k, v in knights.items():
...    print k, v
... gallahad the pure
robin the brave
```

When looping through a sequence, the position index and corresponding value can be retrieved at the same time using the `enumerate()` function.

```python
>>> for i, v in enumerate(['tic', 'tac', 'toe']):
...    print i, v
... 0 tic
1 tac
2 toe
```

To loop over two or more sequences at the same time, the entries can be paired with the `zip()` function.

```python
>>> questions = ['name', 'quest', 'favorite color']
>>> answers = ['lancelot', 'the holy grail', 'blue']
>>> for q, a in zip(questions, answers):
...    print 'What is your {0}?  It is {1}.' .format(q, a)
... What is your name?  It is lancelot.
What is your quest?  It is the holy grail.
What is your favorite color?  It is blue.
```

To loop over a sequence in reverse, first specify the sequence in a forward direction and then call the `reversed()` function.

```python
>>> for i in reversed(xrange(1,10,2)):
...```
To loop over a sequence in sorted order, use the `sorted()` function which returns a new sorted list while leaving the source unaltered.

```python
>>> basket = ['apple', 'orange', 'apple', 'pear', 'orange', 'banana']
>>> for f in sorted(set(basket)):
...     print f
...
apple
banana
orange
pear
```
The conditions used in `while` and `if` statements can contain any operators, not just comparisons.

The comparison operators `in` and `not in` check whether a value occurs (does not occur) in a sequence. The operators `is` and `is not` compare whether two objects are really the same object; this only matters for mutable objects like lists. All comparison operators have the same priority, which is lower than that of all numerical operators.

Comparisons can be chained. For example, `a < b == c` tests whether `a` is less than `b` and moreover `b` equals `c`.

Comparisons may be combined using the Boolean operators `and` and `or`, and the outcome of a comparison (or of any other Boolean expression) may be negated with `not`. These have lower priorities than comparison operators; between them, `not` has the highest priority and `or` the lowest, so that `A and not B or C` is equivalent to `(A and (not B)) or C`. As always, parentheses can be used to express the desired composition.

The Boolean operators `and` and `or` are so-called *short-circuit* operators: their arguments are evaluated from left to right, and evaluation stops as soon as the outcome is determined. For example, if `A` and `C` are true but `B` is false, `A and B and C` does not evaluate the expression `C`. When used as a general value and not as a Boolean, the return value of a short-circuit operator is the last evaluated argument.

It is possible to assign the result of a comparison or other Boolean expression to a variable. For example,
Note that in Python, unlike C, assignment cannot occur inside expressions. C programmers may grumble about this, but it avoids a common class of problems encountered in C programs: typing `=` in an expression when `==` was intended.
Comparing Sequences and Other Types

Sequence objects may be compared to other objects with the same sequence type. The comparison uses \textit{lexicographical} ordering: first the first two items are compared, and if they differ this determines the outcome of the comparison; if they are equal, the next two items are compared, and so on, until either sequence is exhausted. If two items to be compared are themselves sequences of the same type, the lexicographical comparison is carried out recursively. If all items of two sequences compare equal, the sequences are considered equal. If one sequence is an initial sub-sequence of the other, the shorter sequence is the smaller (lesser) one. Lexicographical ordering for strings uses the ASCII ordering for individual characters. Some examples of comparisons between sequences of the same type:

\[
\begin{align*}
(1, 2, 3) & \ < \ (1, 2, 4) \\
[1, 2, 3] & \ < \ [1, 2, 4] \\
'ABC' & \ < \ 'C' \ < \ 'Pascal' \ < \ 'Python' \\
(1, 2, 3, 4) & \ < \ (1, 2, 4) \\
(1, 2) & \ < \ (1, 2, -1) \\
(1, 2, 3) & \ == \ (1.0, 2.0, 3.0) \\
(1, 2, ('aa', 'ab')) & \ < \ (1, 2, ('abc', 'a'), 4)
\end{align*}
\]

Note that comparing objects of different types is legal. The outcome is deterministic but arbitrary: the types are ordered by their name. Thus, a list is always smaller than a string, a string is always smaller than a tuple, etc. [1] Mixed numeric types are compared according to their numeric value, so 0 equals 0.0, etc.

Footnotes

[1] The rules for comparing objects of different types should not be relied upon; they may change in a future version of the language.
Modules

If you quit from the Python interpreter and enter it again, the definitions you have made (functions and variables) are lost. Therefore, if you want to write a somewhat longer program, you are better off using a text editor to prepare the input for the interpreter and running it with that file as input instead. This is known as creating a script. As your program gets longer, you may want to split it into several files for easier maintenance. You may also want to use a handy function that you’ve written in several programs without copying its definition into each program.

To support this, Python has a way to put definitions in a file and use them in a script or in an interactive instance of the interpreter. Such a file is called a module; definitions from a module can be imported into other modules or into the main module (the collection of variables that you have access to in a script executed at the top level and in calculator mode).

A module is a file containing Python definitions and statements. The file name is the module name with the suffix .py appended. Within a module, the module’s name (as a string) is available as the value of the global variable __name__. For instance, use your favorite text editor to create a file called fibo.py in the current directory with the following contents:

```python
# Fibonacci numbers module

def fib(n):   # write Fibonacci series up to n
    a, b = 0, 1
    while b < n:
        print b,
        a, b = b, a+b

def fib2(n):  # return Fibonacci series up to n
    result = []
    a, b = 0, 1
```
```python
while b < n:
    result.append(b)
    a, b = b, a+b
return result
```

Now enter the Python interpreter and import this module with the following command:

```python
>>> import fibo
```

This does not enter the names of the functions defined in `fibo` directly in the current symbol table; it only enters the module name `fibo` there. Using the module name you can access the functions:

```python
>>> fibo.fib(1000)
1 1 2 3 5 8 13 21 34 55 89 144 233 377 610 987
>>> fibo.fib2(100)
[1, 1, 2, 3, 5, 8, 13, 21, 34, 55, 89]
>>> fibo.__name__
'fibo'
```

If you intend to use a function often you can assign it to a local name:

```python
>>> fib = fibo.fib
>>> fib(500)
1 1 2 3 5 8 13 21 34 55 89 144 233 377
```
More on Modules

A module can contain executable statements as well as function definitions. These statements are intended to initialize the module. They are executed only the first time the module is imported somewhere. [1]

Each module has its own private symbol table, which is used as the global symbol table by all functions defined in the module. Thus, the author of a module can use global variables in the module without worrying about accidental clashes with a user’s global variables. On the other hand, if you know what you are doing you can touch a module’s global variables with the same notation used to refer to its functions, `modname.itemname`.

Modules can import other modules. It is customary but not required to place all `import` statements at the beginning of a module (or script, for that matter). The imported module names are placed in the importing module’s global symbol table.

There is a variant of the `import` statement that imports names from a module directly into the importing module’s symbol table. For example:

```python
>>> from fibo import fib, fib2
>>> fib(500)
1 1 2 3 5 8 13 21 34 55 89 144 233 377
```

This does not introduce the module name from which the imports are taken in the local symbol table (so in the example, `fibo` is not defined).

There is even a variant to import all names that a module defines:

```python
>>> from fibo import *
```
This imports all names except those beginning with an underscore (_).

**Note:** For efficiency reasons, each module is only imported once per interpreter session. Therefore, if you change your modules, you must restart the interpreter – or, if it's just one module you want to test interactively, use `reload()`, e.g. `reload(modulename)`.  

---

**Executing modules as scripts**

When you run a Python module with

```
python fibo.py <arguments>
```

the code in the module will be executed, just as if you imported it, but with the `__name__` set to `"__main__"`. That means that by adding this code at the end of your module:

```python
if __name__ == "__main__":
    import sys
    fib(int(sys.argv[1]))
```

you can make the file usable as a script as well as an importable module, because the code that parses the command line only runs if the module is executed as the “main” file:

```
$ python fibo.py 50
1 1 2 3 5 8 13 21 34
```

If the module is imported, the code is not run:

```
>>> import fibo
>>> 
```
This is often used either to provide a convenient user interface to a module, or for testing purposes (running the module as a script executes a test suite).

**The Module Search Path**

When a module named `spam` is imported, the interpreter searches for a file named `spam.py` in the current directory, and then in the list of directories specified by the environment variable `PYTHONPATH`. This has the same syntax as the shell variable `PATH`, that is, a list of directory names. When `PYTHONPATH` is not set, or when the file is not found there, the search continues in an installation-dependent default path; on Unix, this is usually `:/usr/local/lib/python`.

Actually, modules are searched in the list of directories given by the variable `sys.path` which is initialized from the directory containing the input script (or the current directory), `PYTHONPATH` and the installation-dependent default. This allows Python programs that know what they’re doing to modify or replace the module search path. Note that because the directory containing the script being run is on the search path, it is important that the script not have the same name as a standard module, or Python will attempt to load the script as a module when that module is imported. This will generally be an error. See section *Standard Modules* for more information.

**“Compiled” Python files**

As an important speed-up of the start-up time for short programs that use a lot of standard modules, if a file called `spam.pyc` exists in the directory where `spam.py` is found, this is assumed to contain an already-“byte-compiled” version of the module `spam`. The modification time of the version of `spam.py` used to create `spam.pyc` is recorded in `spam.pyc`, and the `.pyc` file is ignored if these don't
match.

Normally, you don’t need to do anything to create the spam.pyc file. Whenever spam.py is successfully compiled, an attempt is made to write the compiled version to spam.pyc. It is not an error if this attempt fails; if for any reason the file is not written completely, the resulting spam.pyc file will be recognized as invalid and thus ignored later. The contents of the spam.pyc file are platform independent, so a Python module directory can be shared by machines of different architectures.

Some tips for experts:

- When the Python interpreter is invoked with the -O flag, optimized code is generated and stored in .pyo files. The optimizer currently doesn’t help much; it only removes assert statements. When -O is used, all bytecode is optimized; .pyc files are ignored and .py files are compiled to optimized bytecode.

- Passing two -O flags to the Python interpreter (-OO) will cause the bytecode compiler to perform optimizations that could in some rare cases result in malfunctioning programs. Currently only __doc__ strings are removed from the bytecode, resulting in more compact .pyo files. Since some programs may rely on having these available, you should only use this option if you know what you’re doing.

- A program doesn’t run any faster when it is read from a .pyc or .pyo file than when it is read from a .py file; the only thing that’s faster about .pyc or .pyo files is the speed with which they are loaded.

- When a script is run by giving its name on the command line,
the bytecode for the script is never written to a .pyc or .pyo file. Thus, the startup time of a script may be reduced by moving most of its code to a module and having a small bootstrap script that imports that module. It is also possible to name a .pyc or .pyo file directly on the command line.

- It is possible to have a file called spam.pyc (or spam.pyo when -O is used) without a file spam.py for the same module. This can be used to distribute a library of Python code in a form that is moderately hard to reverse engineer.

- The module compileall can create .pyc files (or .pyo files when -O is used) for all modules in a directory.
Standard Modules

Python comes with a library of standard modules, described in a separate document, the Python Library Reference (“Library Reference” hereafter). Some modules are built into the interpreter; these provide access to operations that are not part of the core of the language but are nevertheless built in, either for efficiency or to provide access to operating system primitives such as system calls. The set of such modules is a configuration option which also depends on the underlying platform For example, the winreg module is only provided on Windows systems. One particular module deserves some attention: sys, which is built into every Python interpreter. The variables sys.ps1 and sys.ps2 define the strings used as primary and secondary prompts:

```python
>>> import sys
>>> sys.ps1
'>>>
>>> sys.ps2
'...
>>> sys.ps1 = 'C> '
C> print 'Yuck!'
Yuck!
C>
```

These two variables are only defined if the interpreter is in interactive mode.

The variable sys.path is a list of strings that determines the interpreter’s search path for modules. It is initialized to a default path taken from the environment variable PYTHONPATH, or from a built-in default if PYTHONPATH is not set. You can modify it using standard list operations:

```python
>>> import sys
>>> sys.path.append('/ufs/guido/lib/python')
```
The **dir()** Function

The built-in function **dir()** is used to find out which names a module defines. It returns a sorted list of strings:

```python
>>> import fibo, sys
>>> dir(fibo)
['__name__', 'fib', 'fib2']
>>> dir(sys)
```

Without arguments, **dir()** lists the names you have defined currently:

```python
>>> a = [1, 2, 3, 4, 5]
>>> import fibo
>>> fib = fibo.fib
>>> dir()
['__builtins__', '__doc__', '__file__', '__name__', 'a', 'fib',
```

Note that it lists all types of names: variables, modules, functions, etc.

**dir()** does not list the names of built-in functions and variables. If you want a list of those, they are defined in the standard module **__builtin__**:

```python
>>> import __builtin__
>>> dir(__builtin__)
```
Packages

Packages are a way of structuring Python’s module namespace by using “dotted module names”. For example, the module name `A.B` designates a submodule named `B` in a package named `A`. Just like the use of modules saves the authors of different modules from having to worry about each other's global variable names, the use of dotted module names saves the authors of multi-module packages like NumPy or the Python Imaging Library from having to worry about each other’s module names.

Suppose you want to design a collection of modules (a “package”) for the uniform handling of sound files and sound data. There are many different sound file formats (usually recognized by their extension, for example: `.wav`, `.aiff`, `.au`), so you may need to create and maintain a growing collection of modules for the conversion between the various file formats. There are also many different operations you might want to perform on sound data (such as mixing, adding echo, applying an equalizer function, creating an artificial stereo effect), so in addition you will be writing a never-ending stream of modules to perform these operations. Here’s a possible structure for your package (expressed in terms of a hierarchical filesystem):

```
sound/
   __init__.py
   formats/
      __init__.py
      wavread.py
      wavwrite.py
      aiffread.py
      aiffwrite.py
      auread.py
      afwritee.py
      ...
   effects/
      __init__.py
```

- **Top-level package**
  - Initialize the sound package
- **Subpackage for file format conversions**
  - Subpackage for sound effects
When importing the package, Python searches through the directories on `sys.path` looking for the package subdirectory.

The `__init__.py` files are required to make Python treat the directories as containing packages; this is done to prevent directories with a common name, such as `string`, from unintentionally hiding valid modules that occur later on the module search path. In the simplest case, `__init__.py` can just be an empty file, but it can also execute initialization code for the package or set the `__all__` variable, described later.

Users of the package can import individual modules from the package, for example:

```python
import sound.effects.echo
```

This loads the submodule `sound.effects.echo`. It must be referenced with its full name.

```python
sound.effects.echo.echofilter(input, output, delay=0.7, atten=4
```

An alternative way of importing the submodule is:

```python
from sound.effects import echo
```

This also loads the submodule `echo`, and makes it available without
its package prefix, so it can be used as follows:

```python
echo.echofilter(input, output, delay=0.7, atten=4)
```

Yet another variation is to import the desired function or variable directly:

```python
from sound.effects.echo import echofilter
```

Again, this loads the submodule `echo`, but this makes its function `echofilter()` directly available:

```python
echofilter(input, output, delay=0.7, atten=4)
```

Note that when using `from package import item`, the item can be either a submodule (or subpackage) of the package, or some other name defined in the package, like a function, class or variable. The `import` statement first tests whether the item is defined in the package; if not, it assumes it is a module and attempts to load it. If it fails to find it, an `ImportError` exception is raised.

Contrarily, when using syntax like `import item.subitem.subsubitem`, each item except for the last must be a package; the last item can be a module or a package but can’t be a class or function or variable defined in the previous item.

### Importing * From a Package

Now what happens when the user writes `from sound.effects import *`? Ideally, one would hope that this somehow goes out to the filesystem, finds which submodules are present in the package, and imports them all. Unfortunately, this operation does not work very well on Windows platforms, where the filesystem does not always have accurate information about the case of a filename! On these
platforms, there is no guaranteed way to know whether a file ECHO.PY should be imported as a module echo, Echo or ECHO. (For example, Windows 95 has the annoying practice of showing all file names with a capitalized first letter.) The DOS 8+3 filename restriction adds another interesting problem for long module names.

The only solution is for the package author to provide an explicit index of the package. The import statement uses the following convention: if a package's __init__.py code defines a list named __all__, it is taken to be the list of module names that should be imported when from package import * is encountered. It is up to the package author to keep this list up-to-date when a new version of the package is released. Package authors may also decide not to support it, if they don't see a use for importing * from their package. For example, the file sounds/effects/__init__.py could contain the following code:

```python
__all__ = ['echo', 'surround', 'reverse']
```

This would mean that from sound.effects import * would import the three named submodules of the sound package.

If __all__ is not defined, the statement from sound.effects import * does not import all submodules from the package sound.effects into the current namespace; it only ensures that the package sound.effects has been imported (possibly running any initialization code in __init__.py) and then imports whatever names are defined in the package. This includes any names defined (and submodules explicitly loaded) by __init__.py. It also includes any submodules of the package that were explicitly loaded by previous import statements. Consider this code:

```python
import sound.effects.echo
import sound.effects.surround
```
In this example, the echo and surround modules are imported in the current namespace because they are defined in the `sound.effects` package when the `from...import` statement is executed. (This also works when `__all__` is defined.)

Note that in general the practice of importing `*` from a module or package is frowned upon, since it often causes poorly readable code. However, it is okay to use it to save typing in interactive sessions, and certain modules are designed to export only names that follow certain patterns.

Remember, there is nothing wrong with using `from Package import specific_submodule`! In fact, this is the recommended notation unless the importing module needs to use submodules with the same name from different packages.

### Intra-package References

The submodules often need to refer to each other. For example, the `surround` module might use the `echo` module. In fact, such references are so common that the `import` statement first looks in the containing package before looking in the standard module search path. Thus, the `surround` module can simply use `import echo` or `from echo import echofilter`. If the imported module is not found in the current package (the package of which the current module is a submodule), the `import` statement looks for a top-level module with the given name.

When packages are structured into subpackages (as with the `sound` package in the example), you can use absolute imports to refer to submodules of siblings packages. For example, if the module `sound.filters.vocoder` needs to use the `echo` module in the
sound.effects package, it can use `from sound.effects import echo`.

Starting with Python 2.5, in addition to the implicit relative imports described above, you can write explicit relative imports with the `from module import name` form of import statement. These explicit relative imports use leading dots to indicate the current and parent packages involved in the relative import. From the `surround` module for example, you might use:

```python
from . import echo
from .. import formats
from ..filters import equalizer
```

Note that both explicit and implicit relative imports are based on the name of the current module. Since the name of the main module is always `__main__`, modules intended for use as the main module of a Python application should always use absolute imports.

### Packages in Multiple Directories

Packages support one more special attribute, `__path__`. This is initialized to be a list containing the name of the directory holding the package’s `__init__.py` before the code in that file is executed. This variable can be modified; doing so affects future searches for modules and subpackages contained in the package.

While this feature is not often needed, it can be used to extend the set of modules found in a package.

### Footnotes

[1] In fact function definitions are also ‘statements’ that are 'executed'; the execution enters the function name in the module’s global symbol table.
There are several ways to present the output of a program; data can be printed in a human-readable form, or written to a file for future use. This chapter will discuss some of the possibilities.
Fancier Output Formatting

So far we've encountered two ways of writing values: expression statements and the `print` statement. (A third way is using the `write()` method of file objects; the standard output file can be referenced as `sys.stdout`. See the Library Reference for more information on this.)

Often you'll want more control over the formatting of your output than simply printing space-separated values. There are two ways to format your output; the first way is to do all the string handling yourself; using string slicing and concatenation operations you can create any layout you can imagine. The standard module `string` contains some useful operations for padding strings to a given column width; these will be discussed shortly. The second way is to use the `str.format()` method.

One question remains, of course: how do you convert values to strings? Luckily, Python has ways to convert any value to a string: pass it to the `repr()` or `str()` functions.

The `str()` function is meant to return representations of values which are fairly human-readable, while `repr()` is meant to generate representations which can be read by the interpreter (or will force a `SyntaxError` if there is not equivalent syntax). For objects which don't have a particular representation for human consumption, `str()` will return the same value as `repr()`. Many values, such as numbers or structures like lists and dictionaries, have the same representation using either function. Strings and floating point numbers, in particular, have two distinct representations.

Some examples:
Here are two ways to write a table of squares and cubes:

```python
>>> for x in range(1, 11):
...     print '{0:2d} {1:3d} {2:4d}'.format(x, x*x, x*x*x)
... # Note trailing comma on previous line

1  1  1
2  4  8
3  9 27
4 16  64
5 25 125
6 36 216
7 49 343
8 64 512
9 81 729
10 100 1000
```
<p>| | | |</p>
<table>
<thead>
<tr>
<th></th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>4</td>
<td>16</td>
<td>64</td>
</tr>
<tr>
<td>5</td>
<td>25</td>
<td>125</td>
</tr>
<tr>
<td>6</td>
<td>36</td>
<td>216</td>
</tr>
<tr>
<td>7</td>
<td>49</td>
<td>343</td>
</tr>
<tr>
<td>8</td>
<td>64</td>
<td>512</td>
</tr>
<tr>
<td>9</td>
<td>81</td>
<td>729</td>
</tr>
<tr>
<td>10</td>
<td>100</td>
<td>1000</td>
</tr>
</tbody>
</table>

(Note that in the first example, one space between each column was added by the way `print` works: it always adds spaces between its arguments.)

This example demonstrates the `rjust()` method of string objects, which right-justifies a string in a field of a given width by padding it with spaces on the left. There are similar methods `ljust()` and `center()`. These methods do not write anything, they just return a new string. If the input string is too long, they don’t truncate it, but return it unchanged; this will mess up your column lay-out but that’s usually better than the alternative, which would be lying about a value. (If you really want truncation you can always add a slice operation, as in `x.ljust(n)[:n].`)

There is another method, `zfill()`, which pads a numeric string on the left with zeros. It understands about plus and minus signs:

```
>>> '12'.zfill(5)
'00012'
>>> '-3.14'.zfill(7)
'-003.14'
>>> '3.14159265359'.zfill(5)
'3.14159265359'
```

Basic usage of the `str.format()` method looks like this:

```
>>> print 'We are the {0} who say "{1}"'.format('knights', 'Ni')
We are the knights who say "Ni!"
```

The brackets and characters within them (called format fields) are
replaced with the objects passed into the format method. The number in the brackets refers to the position of the object passed into the format method.

```python
>>> print '{0} and {1}'.format('spam', 'eggs')
spam and eggs
>>> print '{1} and {0}'.format('spam', 'eggs')
eggs and spam
```

If keyword arguments are used in the format method, their values are referred to by using the name of the argument.

```python
>>> print 'This {food} is {adjective}.'.format(food='spam', adjective='absolutely horrible')
This spam is absolutely horrible.
```

Positional and keyword arguments can be arbitrarily combined:

```python
>>> print 'The story of {0}, {1}, and {other}.' .format('Bill', 'Manfred', other='Georg')
The story of Bill, Manfred, and Georg.
```

An optional ':` and format specifier can follow the field name. This also greater control over how the value is formatted. The following example truncates the Pi to three places after the decimal.

```python
>>> import math
>>> print 'The value of PI is approximately {0:.3f}'.format(math.pi)
The value of PI is approximately 3.142.
```

Passing an integer after the `:` will cause that field to be a minimum number of characters wide. This is useful for making tables pretty:

```python
>>> table = {'Sjoerd': 4127, 'Jack': 4098, 'Dcab': 7678}
>>> for name, phone in table.items():
...     print '{0:10} ==> {1:10d}'.format(name, phone)
...         Jack  ==>  4098
Dcab  ==>  7678
```
If you have a really long format string that you don’t want to split up, it would be nice if you could reference the variables to be formatted by name instead of by position. This can be done by simply passing the dict and using square brackets `[]` to access the keys.

```python
>>> table = {'Sjoerd': 4127, 'Jack': 4098, 'Dcab': 8637678}
>>> print ('Jack: {0[Jack]:d}; Sjoerd: {0[Sjoerd]:d}; '
...    'Dcab: {0[Dcab]:d}'.format(table))
Jack: 4098; Sjoerd: 4127; Dcab: 8637678
```

This could also be done by passing the table as keyword arguments with the ```**``` notation:

```python
>>> table = {'Sjoerd': 4127, 'Jack': 4098, 'Dcab': 8637678}
Jack: 4098; Sjoerd: 4127; Dcab: 8637678
```

This is particularly useful in combination with the new built-in `vars()` function, which returns a dictionary containing all local variables.

For a complete overview of string formatting with `str.format()`, see [Format String Syntax](#).

## Old string formatting

The `%` operator can also be used for string formatting. It interprets the left argument much like a `printf`-style format string to be applied to the right argument, and returns the string resulting from this formatting operation. For example:

```python
>>> import math
>>> print 'The value of PI is approximately %5.3f.' % math.pi
The value of PI is approximately 3.142.
```
Since `str.format()` is quite new, a lot of Python code still uses the `%` operator. However, because this old style of formatting will eventually be removed from the language, `str.format()` should generally be used.

More information can be found in the *String Formatting Operations* section.
Reading and Writing Files

`open()` returns a file object, and is most commonly used with two arguments: `open(filename, mode)`.

```python
g>>> f = open('/tmp/workfile', 'w')
g>>> print f
<open file '/tmp/workfile', mode 'w' at 80a0960>
```

The first argument is a string containing the filename. The second argument is another string containing a few characters describing the way in which the file will be used. `mode` can be 'r' when the file will only be read, 'w' for only writing (an existing file with the same name will be erased), and 'a' opens the file for appending; any data written to the file is automatically added to the end. 'r+' opens the file for both reading and writing. The `mode` argument is optional; 'r' will be assumed if it's omitted.

On Windows, 'b' appended to the mode opens the file in binary mode, so there are also modes like 'rb', 'wb', and 'r+b'. Windows makes a distinction between text and binary files; the end-of-line characters in text files are automatically altered slightly when data is read or written. This behind-the-scenes modification to file data is fine for ASCII text files, but it'll corrupt binary data like that in JPEG or EXE files. Be very careful to use binary mode when reading and writing such files. On Unix, it doesn’t hurt to append a 'b' to the mode, so you can use it platform-independently for all binary files.

Methods of File Objects

The rest of the examples in this section will assume that a file object called `f` has already been created.
To read a file's contents, call `f.read(size)`, which reads some quantity of data and returns it as a string. `size` is an optional numeric argument. When `size` is omitted or negative, the entire contents of the file will be read and returned; it's your problem if the file is twice as large as your machine's memory. Otherwise, at most `size` bytes are read and returned. If the end of the file has been reached, `f.read()` will return an empty string ("").

```python
>>> f.read()
'This is the entire file.
' >>> f.read()
''
```

`f.readline()` reads a single line from the file; a newline character (`\n`) is left at the end of the string, and is only omitted on the last line of the file if the file doesn't end in a newline. This makes the return value unambiguous; if `f.readline()` returns an empty string, the end of the file has been reached, while a blank line is represented by `'
'`, a string containing only a single newline.

```python
>>> f.readline()
'This is the first line of the file.
' >>> f.readline()
'Second line of the file
' >>> f.readline()
''
```

`f.readlines()` returns a list containing all the lines of data in the file. If given an optional parameter `sizehint`, it reads that many bytes from the file and enough more to complete a line, and returns the lines from that. This is often used to allow efficient reading of a large file by lines, but without having to load the entire file in memory. Only complete lines will be returned.

```python
>>> f.readlines()
['This is the first line of the file.
', 'Second line of the file
']
```
An alternative approach to reading lines is to loop over the file object. This is memory efficient, fast, and leads to simpler code:

```python
>>> for line in f:
    print line,
This is the first line of the file.
Second line of the file
```

The alternative approach is simpler but does not provide as fine-grained control. Since the two approaches manage line buffering differently, they should not be mixed.

`f.write(string)` writes the contents of `string` to the file, returning `None`.

```python
>>> f.write('This is a test\n')
```

To write something other than a string, it needs to be converted to a string first:

```python
>>> value = ('the answer', 42)
>>> s = str(value)
>>> f.write(s)
```

`f.tell()` returns an integer giving the file object's current position in the file, measured in bytes from the beginning of the file. To change the file object's position, use `f.seek(offset, from_what)`. The position is computed from adding `offset` to a reference point; the reference point is selected by the `from_what` argument. A `from_what` value of 0 measures from the beginning of the file, 1 uses the current file position, and 2 uses the end of the file as the reference point. `from_what` can be omitted and defaults to 0, using the beginning of the file as the reference point.

```python
>>> f = open('/tmp/workfile', 'r+')
>>> f.write('0123456789abcdef')
>>> f.seek(5)  # Go to the 6th byte in the file
```
When you’re done with a file, call \texttt{f.close()} to close it and free up any system resources taken up by the open file. After calling \texttt{f.close()}, attempts to use the file object will automatically fail.

It is good practice to use the \texttt{with} keyword when dealing with file objects. This has the advantage that the file is properly closed after its suite finishes, even if an exception is raised on the way. It is also much shorter than writing equivalent \texttt{try-finally} blocks:

File objects have some additional methods, such as \texttt{isatty()} and \texttt{truncate()} which are less frequently used; consult the Library Reference for a complete guide to file objects.

\textbf{The pickle Module}

Strings can easily be written to and read from a file. Numbers take a bit more effort, since the \texttt{read()} method only returns strings, which will have to be passed to a function like \texttt{int()}, which takes a string like '123' and returns its numeric value 123. However, when you want to save more complex data types like lists, dictionaries, or class
instances, things get a lot more complicated.

Rather than have users be constantly writing and debugging code to save complicated data types, Python provides a standard module called pickle. This is an amazing module that can take almost any Python object (even some forms of Python code!), and convert it to a string representation; this process is called pickling. Reconstructing the object from the string representation is called unpickling. Between pickling and unpickling, the string representing the object may have been stored in a file or data, or sent over a network connection to some distant machine.

If you have an object \( x \), and a file object \( f \) that’s been opened for writing, the simplest way to pickle the object takes only one line of code:

\[
\text{pickle.dump}(x, f)
\]

To unpickle the object again, if \( f \) is a file object which has been opened for reading:

\[
x = \text{pickle.load}(f)
\]

(There are other variants of this, used when pickling many objects or when you don’t want to write the pickled data to a file; consult the complete documentation for pickle in the Python Library Reference.)

pickle is the standard way to make Python objects which can be stored and reused by other programs or by a future invocation of the same program; the technical term for this is a persistent object. Because pickle is so widely used, many authors who write Python extensions take care to ensure that new data types such as matrices can be properly pickled and unpickled.
Errors and Exceptions

Until now error messages haven't been more than mentioned, but if you have tried out the examples you have probably seen some. There are (at least) two distinguishable kinds of errors: syntax errors and exceptions.
Syntax Errors

Syntax errors, also known as parsing errors, are perhaps the most common kind of complaint you get while you are still learning Python:

```python
>>> while True print 'Hello world'
  File "<stdin>", line 1, in ?
    while True print 'Hello world'
      ^
SyntaxError: invalid syntax
```

The parser repeats the offending line and displays a little ‘arrow’ pointing at the earliest point in the line where the error was detected. The error is caused by (or at least detected at) the token preceding the arrow: in the example, the error is detected at the keyword `print`, since a colon (':' ) is missing before it. File name and line number are printed so you know where to look in case the input came from a script.
Exceptions

Even if a statement or expression is syntactically correct, it may cause an error when an attempt is made to execute it. Errors detected during execution are called exceptions and are not unconditionally fatal: you will soon learn how to handle them in Python programs. Most exceptions are not handled by programs, however, and result in error messages as shown here:

```python
>>> 10 * (1/0)
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
ZeroDivisionError: integer division or modulo by zero
```  
```python
>>> 4 + spam*3
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
NameError: name 'spam' is not defined
```  
```python
>>> '2' + 2
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
TypeError: cannot concatenate 'str' and 'int' objects
```  

The last line of the error message indicates what happened. Exceptions come in different types, and the type is printed as part of the message: the types in the example are ZeroDivisionError, NameError and TypeError. The string printed as the exception type is the name of the built-in exception that occurred. This is true for all built-in exceptions, but need not be true for user-defined exceptions (although it is a useful convention). Standard exception names are built-in identifiers (not reserved keywords).

The rest of the line provides detail based on the type of exception and what caused it.

The preceding part of the error message shows the context where the exception happened, in the form of a stack traceback. In general it contains a stack traceback listing source lines; however, it will not
display lines read from standard input.

*Built-in Exceptions* lists the built-in exceptions and their meanings.
Handling Exceptions

It is possible to write programs that handle selected exceptions. Look at the following example, which asks the user for input until a valid integer has been entered, but allows the user to interrupt the program (using Control-C or whatever the operating system supports); note that a user-generated interruption is signalled by raising the `KeyboardInterrupt` exception.

```python
>>> while True:
...     try:
...         x = int(raw_input("Please enter a number: "))
...         break
...     except ValueError:
...         print "Oops! That was no valid number. Try again."
...```

The `try` statement works as follows.

- First, the `try clause` (the statement(s) between the `try` and `except` keywords) is executed.
- If no exception occurs, the `except clause` is skipped and execution of the `try` statement is finished.
- If an exception occurs during execution of the `try` clause, the rest of the clause is skipped. Then if its type matches the exception named after the `except` keyword, the `except` clause is executed, and then execution continues after the `try` statement.
- If an exception occurs which does not match the exception named in the `except` clause, it is passed on to outer `try` statements; if no handler is found, it is an `unhandled exception` and execution stops with a message as shown above.

A `try` statement may have more than one `except` clause, to specify handlers for different exceptions. At most one handler will be
executed. Handlers only handle exceptions that occur in the corresponding try clause, not in other handlers of the same try statement. An except clause may name multiple exceptions as a parenthesized tuple, for example:

```python
... except (RuntimeError, TypeError, NameError):
...     pass
```

The last except clause may omit the exception name(s), to serve as a wildcard. Use this with extreme caution, since it is easy to mask a real programming error in this way! It can also be used to print an error message and then re-raise the exception (allowing a caller to handle the exception as well):

```python
import sys

try:
    f = open('myfile.txt')
    s = f.readline()
    i = int(s.strip())
except IOError as (errno, strerror):
    print "I/O error({0}):	{1}".format(errno, strerror)
except ValueError:
    print "Could not convert data to an integer."
except:
    print "Unexpected error:", sys.exc_info()[0]
raise
```

The `try ... except` statement has an optional *else clause*, which, when present, must follow all except clauses. It is useful for code that must be executed if the try clause does not raise an exception. For example:

```python
for arg in sys.argv[1:]:
    try:
        f = open(arg, 'r')
    except IOError:
        print 'cannot open', arg
    else:
        print arg, 'has', len(f.readlines()), 'lines'
    f.close()
```
The use of the `else` clause is better than adding additional code to the `try` clause because it avoids accidentally catching an exception that wasn't raised by the code being protected by the `try ... except` statement.

When an exception occurs, it may have an associated value, also known as the exception’s `argument`. The presence and type of the argument depend on the exception type.

The except clause may specify a variable after the exception name (or tuple). The variable is bound to an exception instance with the arguments stored in `instance.args`. For convenience, the exception instance defines `__getitem__()` and `__str__()` so the arguments can be accessed or printed directly without having to reference `.args`.

But use of `.args` is discouraged. Instead, the preferred use is to pass a single argument to an exception (which can be a tuple if multiple arguments are needed) and have it bound to the `message` attribute. One may also instantiate an exception first before raising it and add any attributes to it as desired.

```python
>>> try:
...     raise Exception('spam', 'eggs')
... except Exception as inst:
...     print type(inst)    # the exception instance
...     print inst.args    # arguments stored in .args
...     print inst         # __str__ allows args to printed directly
...     x, y = inst        # __getitem__ allows args to be unpacked directly
...     print 'x=', x
...     print 'y=', y
...
<type 'exceptions.Exception'>
('spam', 'eggs')
('spam', 'eggs')
x = spam
y = eggs
```

If an exception has an argument, it is printed as the last part (‘detail’).
of the message for unhandled exceptions.

Exception handlers don’t just handle exceptions if they occur immediately in the try clause, but also if they occur inside functions that are called (even indirectly) in the try clause. For example:

```python
>>> def this_fails():
...     x = 1/0
...
>>> try:
...     this_fails()
... except ZeroDivisionError as detail:
...     print 'Handling run-time error:', detail
...
Handling run-time error: integer division or modulo by zero
Raising Exceptions

The `raise` statement allows the programmer to force a specified exception to occur. For example:

```python
>>> raise NameError, 'HiThere'
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
NameError: HiThere
```

The first argument to `raise` names the exception to be raised. The optional second argument specifies the exception's argument. Alternatively, the above could be written as `raise NameError('HiThere')`. Either form works fine, but there seems to be a growing stylistic preference for the latter.

If you need to determine whether an exception was raised but don’t intend to handle it, a simpler form of the `raise` statement allows you to re-raise the exception:

```python
>>> try:
...     raise NameError, 'HiThere'
... except NameError:
...     print 'An exception flew by!'
...     raise
...
An exception flew by!
Traceback (most recent call last):
  File "<stdin>", line 2, in ?
NameError: HiThere
```
User-defined Exceptions

Programs may name their own exceptions by creating a new exception class. Exceptions should typically be derived from the `Exception` class, either directly or indirectly. For example:

```python
>>> class MyError(Exception):
...     def __init__(self, value):
...         self.value = value
...     def __str__(self):
...         return repr(self.value)
...
>>> try:
...     raise MyError(2*2)
... except MyError as e:
...     print 'My exception occurred, value:', e.value
...
My exception occurred, value: 4
>>> raise MyError, 'oops!'
Traceback (most recent call last):
  File "<stdin>", line 1, in 
__main__.MyError: 'oops!'
```

In this example, the default `__init__()` of `Exception` has been overridden. The new behavior simply creates the `value` attribute. This replaces the default behavior of creating the `args` attribute.

Exception classes can be defined which do anything any other class can do, but are usually kept simple, often only offering a number of attributes that allow information about the error to be extracted by handlers for the exception. When creating a module that can raise several distinct errors, a common practice is to create a base class for exceptions defined by that module, and subclass that to create specific exception classes for different error conditions:

```python
class Error(Exception):
    """Base class for exceptions in this module.""
    pass
```
class InputError(Error):
    """Exception raised for errors in the input.

    Attributes:
    expression -- input expression in which the error occurred
    message -- explanation of the error
    ""

    def __init__(self, expression, message):
        self.expression = expression
        self.message = message

class TransitionError(Error):
    """Raised when an operation attempts a state transition that is not allowed.

    Attributes:
    previous -- state at beginning of transition
    next -- attempted new state
    message -- explanation of why the specific transition is not allowed
    ""

    def __init__(self, previous, next, message):
        self.previous = previous
        self.next = next
        self.message = message

Most exceptions are defined with names that end in “Error,” similar to the naming of the standard exceptions.

Many standard modules define their own exceptions to report errors that may occur in functions they define. More information on classes is presented in chapter Classes.
Defining Clean-up Actions

The `try` statement has another optional clause which is intended to define clean-up actions that must be executed under all circumstances. For example:

```python
>>> try:
...     raise KeyboardInterrupt
... finally:
...     print 'Goodbye, world!'
...
Goodbye, world!
Traceback (most recent call last):

```

A `finally` clause is always executed before leaving the `try` statement, whether an exception has occurred or not. When an exception has occurred in the `try` clause and has not been handled by an `except` clause (or it has occurred in a `except` or `else` clause), it is re-raised after the `finally` clause has been executed. The `finally` clause is also executed “on the way out” when any other clause of the `try` statement is left via a `break`, `continue` or `return` statement. A more complicated example (having `except` and `finally` clauses in the same `try` statement works as of Python 2.5):

```python
>>> def divide(x, y):
...     try:
...         result = x / y
...     except ZeroDivisionError:
...         print "division by zero!"
...     else:
...         print "result is", result
... finally:
...     print "executing finally clause"

>>> divide(2, 1)
result is 2
executing finally clause
```
As you can see, the `finally` clause is executed in any event. The `TypeError` raised by dividing two strings is not handled by the `except` clause and therefore re-raised after the `finally` clause has been executed.

In real world applications, the `finally` clause is useful for releasing external resources (such as files or network connections), regardless of whether the use of the resource was successful.
Predefined Clean-up Actions

Some objects define standard clean-up actions to be undertaken when the object is no longer needed, regardless of whether or not the operation using the object succeeded or failed. Look at the following example, which tries to open a file and print its contents to the screen.

```python
for line in open("myfile.txt"):
    print line
```

The problem with this code is that it leaves the file open for an indeterminate amount of time after the code has finished executing. This is not an issue in simple scripts, but can be a problem for larger applications. The `with` statement allows objects like files to be used in a way that ensures they are always cleaned up promptly and correctly.

```python
with open("myfile.txt") as f:
    for line in f:
        print line
```

After the statement is executed, the file `f` is always closed, even if a problem was encountered while processing the lines. Other objects which provide predefined clean-up actions will indicate this in their documentation.
Classes

Python’s class mechanism adds classes to the language with a minimum of new syntax and semantics. It is a mixture of the class mechanisms found in C++ and Modula-3. As is true for modules, classes in Python do not put an absolute barrier between definition and user, but rather rely on the politeness of the user not to “break into the definition.” The most important features of classes are retained with full power, however: the class inheritance mechanism allows multiple base classes, a derived class can override any methods of its base class or classes, and a method can call the method of a base class with the same name. Objects can contain an arbitrary amount of private data.

In C++ terminology, all class members (including the data members) are public, and all member functions are virtual. There are no special constructors or destructors. As in Modula-3, there are no shorthands for referencing the object’s members from its methods: the method function is declared with an explicit first argument representing the object, which is provided implicitly by the call. As in Smalltalk, classes themselves are objects, albeit in the wider sense of the word: in Python, all data types are objects. This provides semantics for importing and renaming. Unlike C++ and Modula-3, built-in types can be used as base classes for extension by the user. Also, like in C++ but unlike in Modula-3, most built-in operators with special syntax (arithmetic operators, subscripting etc.) can be redefined for class instances.
A Word About Terminology

Lacking universally accepted terminology to talk about classes, I will make occasional use of Smalltalk and C++ terms. (I would use Modula-3 terms, since its object-oriented semantics are closer to those of Python than C++, but I expect that few readers have heard of it.)

Objects have individuality, and multiple names (in multiple scopes) can be bound to the same object. This is known as aliasing in other languages. This is usually not appreciated on a first glance at Python, and can be safely ignored when dealing with immutable basic types (numbers, strings, tuples). However, aliasing has an (intended!) effect on the semantics of Python code involving mutable objects such as lists, dictionaries, and most types representing entities outside the program (files, windows, etc.). This is usually used to the benefit of the program, since aliases behave like pointers in some respects. For example, passing an object is cheap since only a pointer is passed by the implementation; and if a function modifies an object passed as an argument, the caller will see the change — this eliminates the need for two different argument passing mechanisms as in Pascal.
Before introducing classes, I first have to tell you something about Python's scope rules. Class definitions play some neat tricks with namespaces, and you need to know how scopes and namespaces work to fully understand what's going on. Incidentally, knowledge about this subject is useful for any advanced Python programmer.

Let's begin with some definitions.

A *namespace* is a mapping from names to objects. Most namespaces are currently implemented as Python dictionaries, but that's normally not noticeable in any way (except for performance), and it may change in the future. Examples of namespaces are: the set of built-in names (functions such as `abs()`, and built-in exception names); the global names in a module; and the local names in a function invocation. In a sense the set of attributes of an object also form a namespace. The important thing to know about namespaces is that there is absolutely no relation between names in different namespaces; for instance, two different modules may both define a function “maximize” without confusion — users of the modules must prefix it with the module name.

By the way, I use the word *attribute* for any name following a dot — for example, in the expression `z.real`, `real` is an attribute of the object `z`. Strictly speaking, references to names in modules are attribute references: in the expression `modname.funcname`, `modname` is a module object and `funcname` is an attribute of it. In this case there happens to be a straightforward mapping between the module's attributes and the global names defined in the module: they share the same namespace! [1]

Attributes may be read-only or writable. In the latter case,
assignment to attributes is possible. Module attributes are writable: you can write `modname.the_answer = 42`. Writable attributes may also be deleted with the `del` statement. For example, `del modname.the_answer` will remove the attribute `the_answer` from the object named by `modname`.

Name spaces are created at different moments and have different lifetimes. The namespace containing the built-in names is created when the Python interpreter starts up, and is never deleted. The global namespace for a module is created when the module definition is read in; normally, module namespaces also last until the interpreter quits. The statements executed by the top-level invocation of the interpreter, either read from a script file or interactively, are considered part of a module called `__main__`, so they have their own global namespace. (The built-in names actually also live in a module; this is called `__builtin__`.)

The local namespace for a function is created when the function is called, and deleted when the function returns or raises an exception that is not handled within the function. (Actually, forgetting would be a better way to describe what actually happens.) Of course, recursive invocations each have their own local namespace.

A scope is a textual region of a Python program where a namespace is directly accessible. “Directly accessible” here means that an unqualified reference to a name attempts to find the name in the namespace.

Although scopes are determined statically, they are used dynamically. At any time during execution, there are at least three nested scopes whose namespaces are directly accessible: the innermost scope, which is searched first, contains the local names; the namespaces of any enclosing functions, which are searched starting with the nearest enclosing scope; the middle scope,
searched next, contains the current module's global names; and the outermost scope (searched last) is the namespace containing built-in names.

If a name is declared global, then all references and assignments go directly to the middle scope containing the module's global names. Otherwise, all variables found outside of the innermost scope are read-only (an attempt to write to such a variable will simply create a new local variable in the innermost scope, leaving the identically named outer variable unchanged).

Usually, the local scope references the local names of the (textually) current function. Outside functions, the local scope references the same namespace as the global scope: the module's namespace. Class definitions place yet another namespace in the local scope.

It is important to realize that scopes are determined textually: the global scope of a function defined in a module is that module's namespace, no matter from where or by what alias the function is called. On the other hand, the actual search for names is done dynamically, at run time — however, the language definition is evolving towards static name resolution, at “compile” time, so don’t rely on dynamic name resolution! (In fact, local variables are already determined statically.)

A special quirk of Python is that – if no `global` statement is in effect – assignments to names always go into the innermost scope. Assignments do not copy data — they just bind names to objects. The same is true for deletions: the statement `del x` removes the binding of `x` from the namespace referenced by the local scope. In fact, all operations that introduce new names use the local scope: in particular, import statements and function definitions bind the module or function name in the local scope. (The `global` statement can be used to indicate that particular variables live in the global scope.)
A First Look at Classes

Classes introduce a little bit of new syntax, three new object types, and some new semantics.

Class Definition Syntax

The simplest form of class definition looks like this:

```
class ClassName:
    <statement-1>
    ...
    ...
    <statement-N>
```

Class definitions, like function definitions (``def`` statements) must be executed before they have any effect. (You could conceivably place a class definition in a branch of an `if` statement, or inside a function.)

In practice, the statements inside a class definition will usually be function definitions, but other statements are allowed, and sometimes useful — we'll come back to this later. The function definitions inside a class normally have a peculiar form of argument list, dictated by the calling conventions for methods — again, this is explained later.

When a class definition is entered, a new namespace is created, and used as the local scope — thus, all assignments to local variables go into this new namespace. In particular, function definitions bind the name of the new function here.

When a class definition is left normally (via the end), a *class object* is created. This is basically a wrapper around the contents of the
namespace created by the class definition; we'll learn more about class objects in the next section. The original local scope (the one in effect just before the class definition was entered) is reinstated, and the class object is bound here to the class name given in the class definition header (ClassName in the example).

Class Objects

Class objects support two kinds of operations: attribute references and instantiation.

*Attribute references* use the standard syntax used for all attribute references in Python: `obj.name`. Valid attribute names are all the names that were in the class's namespace when the class object was created. So, if the class definition looked like this:

```python
class MyClass:
    '''A simple example class'''
    i = 12345
    def f(self):
        return 'hello world'
```

then `MyClass.i` and `MyClass.f` are valid attribute references, returning an integer and a function object, respectively. Class attributes can also be assigned to, so you can change the value of `MyClass.i` by assignment. `__doc__` is also a valid attribute, returning the docstring belonging to the class: "A simple example class".

Class *instantiation* uses function notation. Just pretend that the class object is a parameterless function that returns a new instance of the class. For example (assuming the above class):

```python
x = MyClass()
```

creates a new *instance* of the class and assigns this object to the local variable `x`. 
The instantiation operation (“calling” a class object) creates an empty object. Many classes like to create objects with instances customized to a specific initial state. Therefore a class may define a special method named `__init__()` , like this:

```python
def __init__(self):
    self.data = []
```

When a class defines an `__init__()` method, class instantiation automatically invokes `__init__()` for the newly-created class instance. So in this example, a new, initialized instance can be obtained by:

```python
x = MyClass()
```

Of course, the `__init__()` method may have arguments for greater flexibility. In that case, arguments given to the class instantiation operator are passed on to `__init__()`. For example,

```python
>>> class Complex:
...     def __init__(self, realpart, imagpart):
...         self.r = realpart
...         self.i = imagpart
... >>> x = Complex(3.0, -4.5)
>>> x.r, x.i
(3.0, -4.5)
```

**Instance Objects**

Now what can we do with instance objects? The only operations understood by instance objects are attribute references. There are two kinds of valid attribute names, data attributes and methods.

`data attributes` correspond to “instance variables” in Smalltalk, and to “data members” in C++. Data attributes need not be declared; like local variables, they spring into existence when they are first
assigned to. For example, if $x$ is the instance of `MyClass` created above, the following piece of code will print the value 16, without leaving a trace:

```python
x.counter = 1
while x.counter < 10:
    x.counter = x.counter * 2
print x.counter
del x.counter
```

The other kind of instance attribute reference is a *method*. A method is a function that “belongs to” an object. (In Python, the term method is not unique to class instances: other object types can have methods as well. For example, list objects have methods called `append`, `insert`, `remove`, `sort`, and so on. However, in the following discussion, we'll use the term method exclusively to mean methods of class instance objects, unless explicitly stated otherwise.)

Valid method names of an instance object depend on its class. By definition, all attributes of a class that are function objects define corresponding methods of its instances. So in our example, $x.f$ is a valid method reference, since `MyClass.f` is a function, but $x.i$ is not, since `MyClass.i` is not. But $x.f$ is not the same thing as `MyClass.f` — it is a *method object*, not a function object.

### Method Objects

Usually, a method is called right after it is bound:

```python
x.f()
```

In the `MyClass` example, this will return the string `'hello world'`. However, it is not necessary to call a method right away: $x.f$ is a method object, and can be stored away and called at a later time. For example:
will continue to print `hello world` until the end of time.

What exactly happens when a method is called? You may have noticed that `x.f()` was called without an argument above, even though the function definition for `f()` specified an argument. What happened to the argument? Surely Python raises an exception when a function that requires an argument is called without any — even if the argument isn’t actually used...

Actually, you may have guessed the answer: the special thing about methods is that the object is passed as the first argument of the function. In our example, the call `x.f()` is exactly equivalent to `MyClass.f(x)`. In general, calling a method with a list of `n` arguments is equivalent to calling the corresponding function with an argument list that is created by inserting the method’s object before the first argument.

If you still don’t understand how methods work, a look at the implementation can perhaps clarify matters. When an instance attribute is referenced that isn’t a data attribute, its class is searched. If the name denotes a valid class attribute that is a function object, a method object is created by packing (pointers to) the instance object and the function object just found together in an abstract object: this is the method object. When the method object is called with an argument list, it is unpacked again, a new argument list is constructed from the instance object and the original argument list, and the function object is called with this new argument list.
Data attributes override method attributes with the same name; to avoid accidental name conflicts, which may cause hard-to-find bugs in large programs, it is wise to use some kind of convention that minimizes the chance of conflicts. Possible conventions include capitalizing method names, prefixing data attribute names with a small unique string (perhaps just an underscore), or using verbs for methods and nouns for data attributes.

Data attributes may be referenced by methods as well as by ordinary users ("clients") of an object. In other words, classes are not usable to implement pure abstract data types. In fact, nothing in Python makes it possible to enforce data hiding — it is all based upon convention. (On the other hand, the Python implementation, written in C, can completely hide implementation details and control access to an object if necessary; this can be used by extensions to Python written in C.)

Clients should use data attributes with care — clients may mess up invariants maintained by the methods by stamping on their data attributes. Note that clients may add data attributes of their own to an instance object without affecting the validity of the methods, as long as name conflicts are avoided — again, a naming convention can save a lot of headaches here.

There is no shorthand for referencing data attributes (or other methods!) from within methods. I find that this actually increases the readability of methods: there is no chance of confusing local variables and instance variables when glancing through a method.

Often, the first argument of a method is called \texttt{self}. This is nothing more than a convention: the name \texttt{self} has absolutely no special meaning to Python. (Note, however, that by not following the
convention your code may be less readable to other Python programmers, and it is also conceivable that a class browser program might be written that relies upon such a convention.)

Any function object that is a class attribute defines a method for instances of that class. It is not necessary that the function definition is textually enclosed in the class definition: assigning a function object to a local variable in the class is also ok. For example:

```python
# Function defined outside the class
def f1(self, x, y):
    return min(x, x+y)

class C:
    f = f1
    def g(self):
        return 'hello world'
    h = g
```

Now f, g and h are all attributes of class c that refer to function objects, and consequently they are all methods of instances of c — h being exactly equivalent to g. Note that this practice usually only serves to confuse the reader of a program.

Methods may call other methods by using method attributes of the self argument:

```python
class Bag:
    def __init__(self):
        self.data = []
    def add(self, x):
        self.data.append(x)
    def addtwice(self, x):
        self.add(x)
        self.add(x)
```

Methods may reference global names in the same way as ordinary functions. The global scope associated with a method is the module containing the class definition. (The class itself is never used as a
global scope!) While one rarely encounters a good reason for using
global data in a method, there are many legitimate uses of the global
scope: for one thing, functions and modules imported into the global
scope can be used by methods, as well as functions and classes
defined in it. Usually, the class containing the method is itself defined
in this global scope, and in the next section we'll find some good
reasons why a method would want to reference its own class!

Each value is an object, and therefore has a class (also called its
type). It is stored as `object.__class__`. 
Inheritance

Of course, a language feature would not be worthy of the name “class” without supporting inheritance. The syntax for a derived class definition looks like this:

```python
class DerivedClassName(BaseClassName):
    <statement-1>
    ...
    ...
    <statement-N>
```

The name `BaseClassName` must be defined in a scope containing the derived class definition. In place of a base class name, other arbitrary expressions are also allowed. This can be useful, for example, when the base class is defined in another module:

```python
class DerivedClassName(modname.BaseClassName):
```

Execution of a derived class definition proceeds the same as for a base class. When the class object is constructed, the base class is remembered. This is used for resolving attribute references: if a requested attribute is not found in the class, the search proceeds to look in the base class. This rule is applied recursively if the base class itself is derived from some other class.

There's nothing special about instantiation of derived classes: `DerivedClassName()` creates a new instance of the class. Method references are resolved as follows: the corresponding class attribute is searched, descending down the chain of base classes if necessary, and the method reference is valid if this yields a function object.

Derived classes may override methods of their base classes.
Because methods have no special privileges when calling other methods of the same object, a method of a base class that calls another method defined in the same base class may end up calling a method of a derived class that overrides it. (For C++ programmers: all methods in Python are effectively virtual.)

An overriding method in a derived class may in fact want to extend rather than simply replace the base class method of the same name. There is a simple way to call the base class method directly: just call `BaseClassName.methodname(self, arguments)`. This is occasionally useful to clients as well. (Note that this only works if the base class is defined or imported directly in the global scope.)

Python has two built-in functions that work with inheritance:

- Use `isinstance()` to check an object’s type: `isinstance(obj, int)` will be True only if `obj.__class__` is `int` or some class derived from `int`.
- Use `issubclass()` to check class inheritance: `issubclass(bool, int)` is True since `bool` is a subclass of `int`. However, `issubclass(unicode, str)` is False since `unicode` is not a subclass of `str` (they only share a common ancestor, `basestring`).

## Multiple Inheritance

Python supports a limited form of multiple inheritance as well. A class definition with multiple base classes looks like this:

```python
class DerivedClassName(Base1, Base2, Base3):
    <statement-1>
    .
    .
    .
    <statement-N>
```
For old-style classes, the only rule is depth-first, left-to-right. Thus, if an attribute is not found in DerivedClassName, it is searched in Base1, then (recursively) in the base classes of Base1, and only if it is not found there, it is searched in Base2, and so on.

(To some people breadth first — searching Base2 and Base3 before the base classes of Base1 — looks more natural. However, this would require you to know whether a particular attribute of Base1 is actually defined in Base1 or in one of its base classes before you can figure out the consequences of a name conflict with an attribute of Base2. The depth-first rule makes no differences between direct and inherited attributes of Base1.)

For new-style classes, the method resolution order changes dynamically to support cooperative calls to super(). This approach is known in some other multiple-inheritance languages as call-next-method and is more powerful than the super call found in single-inheritance languages.

With new-style classes, dynamic ordering is necessary because all cases of multiple inheritance exhibit one or more diamond relationships (where one at least one of the parent classes can be accessed through multiple paths from the bottommost class). For example, all new-style classes inherit from object, so any case of multiple inheritance provides more than one path to reach object. To keep the base classes from being accessed more than once, the dynamic algorithm linearizes the search order in a way that preserves the left-to-right ordering specified in each class, that calls each parent only once, and that is monotonic (meaning that a class can be subclassed without affecting the precedence order of its parents). Taken together, these properties make it possible to design reliable and extensible classes with multiple inheritance. For more detail, see http://www.python.org/download/releases/2.3/mro/.
Private Variables

There is limited support for class-private identifiers. Any identifier of the form __spam (at least two leading underscores, at most one trailing underscore) is textually replaced with _classname__spam, where classname is the current class name with leading underscore(s) stripped. This mangling is done without regard to the syntactic position of the identifier, so it can be used to define class-private instance and class variables, methods, variables stored in globals, and even variables stored in instances. private to this class on instances of other classes. Truncation may occur when the mangled name would be longer than 255 characters. Outside classes, or when the class name consists of only underscores, no mangling occurs.

Name mangling is intended to give classes an easy way to define “private” instance variables and methods, without having to worry about instance variables defined by derived classes, or mucking with instance variables by code outside the class. Note that the mangling rules are designed mostly to avoid accidents; it still is possible for a determined soul to access or modify a variable that is considered private. This can even be useful in special circumstances, such as in the debugger, and that’s one reason why this loophole is not closed. (Buglet: derivation of a class with the same name as the base class makes use of private variables of the base class possible.)

Notice that code passed to exec, eval() or execfile() does not consider the classname of the invoking class to be the current class; this is similar to the effect of the global statement, the effect of which is likewise restricted to code that is byte-compiled together. The same restriction applies to getattr(), setattr() and delattr(), as well as when referencing __dict__ directly.
Sometimes it is useful to have a data type similar to the Pascal “record” or C “struct”, bundling together a few named data items. An empty class definition will do nicely:

```python
class Employee:
    pass

john = Employee()  # Create an empty employee record

# Fill the fields of the record
john.name = 'John Doe'
john.dept = 'computer lab'
john.salary = 1000
```

A piece of Python code that expects a particular abstract data type can often be passed a class that emulates the methods of that data type instead. For instance, if you have a function that formats some data from a file object, you can define a class with methods `read()` and `readline()` that get the data from a string buffer instead, and pass it as an argument.

Instance method objects have attributes, too: `m.im_self` is the instance object with the method `m()`, and `m.im_func` is the function object corresponding to the method.
Exceptions Are Classes Too

User-defined exceptions are identified by classes as well. Using this mechanism it is possible to create extensible hierarchies of exceptions.

There are two new valid (semantic) forms for the `raise` statement:

```
raise Class, instance
raise instance
```

In the first form, `instance` must be an instance of `class` or of a class derived from it. The second form is a shorthand for:

```
raise instance.__class__, instance
```

A class in an except clause is compatible with an exception if it is the same class or a base class thereof (but not the other way around — an except clause listing a derived class is not compatible with a base class). For example, the following code will print B, C, D in that order:

```
class B:
    pass
class C(B):
    pass
class D(C):
    pass

for c in [B, C, D]:
    try:
        raise c()
    except D:
        print "D"
    except C:
        print "C"
    except B:
        print "B"
```
Note that if the except clauses were reversed (with `except B` first), it would have printed B, B, B — the first matching except clause is triggered.

When an error message is printed for an unhandled exception, the exception's class name is printed, then a colon and a space, and finally the instance converted to a string using the built-in function `str()`.
Iterators

By now you have probably noticed that most container objects can be looped over using a `for` statement:

```python
for element in [1, 2, 3]:
    print element
for element in (1, 2, 3):
    print element
for key in {'one':1, 'two':2}:
    print key
for char in "123":
    print char
for line in open("myfile.txt"):
    print line
```

This style of access is clear, concise, and convenient. The use of iterators pervades and unifies Python. Behind the scenes, the `for` statement calls `iter()` on the container object. The function returns an iterator object that defines the method `next()` which accesses elements in the container one at a time. When there are no more elements, `next()` raises a `StopIteration` exception which tells the `for` loop to terminate. This example shows how it all works:

```python
>>> s = 'abc'
>>> it = iter(s)
>>> it
<iterator object at 0x00A1DB50>
>>> it.next()
'a'
>>> it.next()
'b'
>>> it.next()
'c'
>>> it.next()
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
    it.next()
StopIteration
```
Having seen the mechanics behind the iterator protocol, it is easy to add iterator behavior to your classes. Define a `__iter__()` method which returns an object with a `next()` method. If the class defines `next()`, then `__iter__()` can just return `self`:

```python
class Reverse:
    "Iterator for looping over a sequence backwards"
    def __init__(self, data):
        self.data = data
        self.index = len(data)
    def __iter__(self):
        return self
    def next(self):
        if self.index == 0:
            raise StopIteration
        self.index = self.index - 1
        return self.data[self.index]

>>> for char in Reverse('spam'):
...    print char
...m
a
p
s
```
Generators are a simple and powerful tool for creating iterators. They are written like regular functions but use the `yield` statement whenever they want to return data. Each time `next()` is called, the generator resumes where it left-off (it remembers all the data values and which statement was last executed). An example shows that generators can be trivially easy to create:

```python
def reverse(data):
    for index in range(len(data)-1, -1, -1):
        yield data[index]

>>> for char in reverse('golf'):
...    print char
...f
go l o
```

Anything that can be done with generators can also be done with class based iterators as described in the previous section. What makes generators so compact is that the `__iter__()` and `next()` methods are created automatically.

Another key feature is that the local variables and execution state are automatically saved between calls. This made the function easier to write and much more clear than an approach using instance variables like `self.index` and `self.data`.

In addition to automatic method creation and saving program state, when generators terminate, they automatically raise `StopIteration`. In combination, these features make it easy to create iterators with no more effort than writing a regular function.
Generator Expressions

Some simple generators can be coded succinctly as expressions using a syntax similar to list comprehensions but with parentheses instead of brackets. These expressions are designed for situations where the generator is used right away by an enclosing function. Generator expressions are more compact but less versatile than full generator definitions and tend to be more memory friendly than equivalent list comprehensions.

Examples:

```python
>>> sum(i*i for i in range(10))  # sum of squares
285
>>> xvec = [10, 20, 30]
>>> yvec = [7, 5, 3]
>>> sum(x*y for x, y in zip(xvec, yvec))  # dot product
260
>>> from math import pi, sin
>>> sine_table = dict((x, sin(x*pi/180)) for x in range(0, 91))
>>> unique_words = set(word for line in page for word in line.split)
>>> valedictorian = max((student.gpa, student.name) for student in data)
>>> list(data[i] for i in range(len(data)-1,-1,-1))
['f', 'l', 'o', 'g']
```

Footnotes

Except for one thing. Module objects have a secret read-only attribute called __dict__ which returns the dictionary used to implement the module's namespace; the name __dict__ is an attribute but not a global name. Obviously, using this violates the abstraction of namespace implementation, and should be
restricted to things like post-mortem debuggers.
Brief Tour of the Standard Library
Operating System Interface

The `os` module provides dozens of functions for interacting with the operating system:

```python
>>> import os
>>> os.system('time 0:02')
0
>>> os.getcwd()  # Return the current working directory
'C:\Python26'
>>> os.chdir('/server/accesslogs')
```

Be sure to use the `import os` style instead of `from os import *`. This will keep `os.open()` from shadowing the built-in `open()` function which operates much differently.

The built-in `dir()` and `help()` functions are useful as interactive aids for working with large modules like `os`:

```python
>>> import os
>>> dir(os)
<returns a list of all module functions>
>>> help(os)
<returns an extensive manual page created from the module's doc
```

For daily file and directory management tasks, the `shutil` module provides a higher level interface that is easier to use:

```python
>>> import shutil
>>> shutil.copyfile('data.db', 'archive.db')
>>> shutil.move('/build/executables', 'installdir')
```
File Wildcards

The `glob` module provides a function for making file lists from directory wildcard searches:

```python
>>> import glob
>>> glob.glob('*.py')
['primes.py', 'random.py', 'quote.py']
```
Command Line Arguments

Common utility scripts often need to process command line arguments. These arguments are stored in the `sys` module’s `argv` attribute as a list. For instance the following output results from running `python demo.py one two three` at the command line:

```python
>>> import sys
>>> print sys.argv
['demo.py', 'one', 'two', 'three']
```

The `getopt` module processes `sys.argv` using the conventions of the Unix `getopt()` function. More powerful and flexible command line processing is provided by the `optparse` module.
Error Output Redirection and Program Termination

The `sys` module also has attributes for `stdin`, `stdout`, and `stderr`. The latter is useful for emitting warnings and error messages to make them visible even when `stdout` has been redirected:

```python
>>> sys.stderr.write('Warning, log file not found starting a new one
Warning, log file not found starting a new one
```

The most direct way to terminate a script is to use `sys.exit()`.
String Pattern Matching

The `re` module provides regular expression tools for advanced string processing. For complex matching and manipulation, regular expressions offer succinct, optimized solutions:

```python
>>> import re
>>> re.findall(r'\bf[a-z]*', 'which foot or hand fell fastest')
['foot', 'fell', 'fastest']
>>> re.sub(r'(\b[a-z]+) \1', r'\1', 'cat in the the hat')
'cat in the hat'
```

When only simple capabilities are needed, string methods are preferred because they are easier to read and debug:

```python
>>> 'tea for too'.replace('too', 'two')
'tea for two'
```
Mathematics

The `math` module gives access to the underlying C library functions for floating point math:

```python
>>> import math
>>> math.cos(math.pi / 4.0)
0.70710678118654757
>>> math.log(1024, 2)
10.0
```

The `random` module provides tools for making random selections:

```python
>>> import random
>>> random.choice(['apple', 'pear', 'banana'])
'apple'
>>> random.sample(xrange(100), 10)  # sampling without replace
[30, 83, 16, 4, 8, 81, 41, 50, 18, 33]
>>> random.random()  # random float
0.17970987693706186
>>> random.randrange(6)  # random integer chosen from range(6)
4
```
There are a number of modules for accessing the internet and processing internet protocols. Two of the simplest are `urllib2` for retrieving data from urls and `smtplib` for sending mail:

```python
>>> import urllib2
>>> for line in urllib2.urlopen('http://tycho.usno.navy.mil/cgi...
...   if 'EST' in line or 'EDT' in line: # look for Eastern
...       print line
<BR>Nov. 25, 09:43:32 PM EST

>>> import smtplib
>>> server = smtplib.SMTP('localhost')
>>> server.sendmail('soothsayer@example.org', 'jcaesar@example....
...   """To: jcaesar@example.org
...   From: soothsayer@example.org
...   ...
...   Beware the Ides of March.
...   """
>>> server.quit()
```

(Note that the second example needs a mailserver running on localhost.)
The `datetime` module supplies classes for manipulating dates and times in both simple and complex ways. While date and time arithmetic is supported, the focus of the implementation is on efficient member extraction for output formatting and manipulation. The module also supports objects that are timezone aware.

```python
# dates are easily constructed and formatted
>>> from datetime import date
>>> now = date.today()
>>> now
datetime.date(2003, 12, 2)
>>> now.strftime("%m-%d-%y. %d %b %Y is a %A on the %d day of %m
'12-02-03. 02 Dec 2003 is a Tuesday on the 02 day of December.'

# dates support calendar arithmetic
>>> birthday = date(1964, 7, 31)
>>> age = now - birthday
>>> age.days
14368
```
Data Compression

Common data archiving and compression formats are directly supported by modules including: \texttt{zlib}, \texttt{gzip}, \texttt{bz2}, \texttt{zipfile} and \texttt{tarfile}.

```python
>>> import zlib
>>> s = 'witch which has which witches wrist watch'
>>> len(s)
41
>>> t = zlib.compress(s)
>>> len(t)
37
>>> zlib.decompress(t)
'witch which has which witches wrist watch'
>>> zlib.crc32(s)
226805979
```
Performance Measurement

Some Python users develop a deep interest in knowing the relative performance of different approaches to the same problem. Python provides a measurement tool that answers those questions immediately.

For example, it may be tempting to use the tuple packing and unpacking feature instead of the traditional approach to swapping arguments. The `timeit` module quickly demonstrates a modest performance advantage:

```python
>>> from timeit import Timer
>>> Timer('t=a; a=b; b=t', 'a=1; b=2').timeit()
0.57535828626024577
>>> Timer('a,b = b,a', 'a=1; b=2').timeit()
0.54962537085770791
```

In contrast to `timeit`'s fine level of granularity, the `profile` and `pstats` modules provide tools for identifying time critical sections in larger blocks of code.
Quality Control

One approach for developing high quality software is to write tests for each function as it is developed and to run those tests frequently during the development process.

The `doctest` module provides a tool for scanning a module and validating tests embedded in a program’s docstrings. Test construction is as simple as cutting-and-pasting a typical call along with its results into the docstring. This improves the documentation by providing the user with an example and it allows the doctest module to make sure the code remains true to the documentation:

```python
def average(values):
    """Computes the arithmetic mean of a list of numbers."""
    return sum(values, 0.0) / len(values)

import doctest
doctest.testmod()  # automatically validate the embedded tests
```

The `unittest` module is not as effortless as the `doctest` module, but it allows a more comprehensive set of tests to be maintained in a separate file:

```python
import unittest
class TestStatisticalFunctions(unittest.TestCase):
    def test_average(self):
        self.assertAlmostEqual(average([20, 30, 70]), 40.0)
        self.assertAlmostEqual(average([1, 5, 7]), 1), 4.3
        self.assertRaises(ZeroDivisionError, average, [])
        self.assertRaises(TypeError, average, 20, 30, 70)

unittest.main()  # Calling from the command line invokes all tests
```
Python has a “batteries included” philosophy. This is best seen through the sophisticated and robust capabilities of its larger packages. For example:

- The `xmlrpclib` and `SimpleXMLRPCServer` modules make implementing remote procedure calls into an almost trivial task. Despite the modules names, no direct knowledge or handling of XML is needed.
- The `email` package is a library for managing email messages, including MIME and other RFC 2822-based message documents. Unlike `smtplib` and `poplib` which actually send and receive messages, the email package has a complete toolset for building or decoding complex message structures (including attachments) and for implementing internet encoding and header protocols.
- The `xml.dom` and `xml.sax` packages provide robust support for parsing this popular data interchange format. Likewise, the `csv` module supports direct reads and writes in a common database format. Together, these modules and packages greatly simplify data interchange between python applications and other tools.
- Internationalization is supported by a number of modules including `gettext`, `locale`, and the `codecs` package.
This second tour covers more advanced modules that support professional programming needs. These modules rarely occur in small scripts.
Output Formatting

The `repr` module provides a version of `repr()` customized for abbreviated displays of large or deeply nested containers:

```python
>>> import repr
>>> repr.repr(set('supercalifragilisticexpialidocious'))
"set(['a', 'c', 'd', 'e', 'f', 'g', ...])"
```

The `pprint` module offers more sophisticated control over printing both built-in and user defined objects in a way that is readable by the interpreter. When the result is longer than one line, the "pretty printer" adds line breaks and indentation to more clearly reveal data structure:

```python
>>> import pprint
>>> t = [[[['black', 'cyan'], 'white', ['green', 'red']], [['magenta', 'yellow'], 'blue']]]
... >>> pprint.pprint(t, width=30)
[[[['black', 'cyan'], 'white', ['green', 'red']], [['magenta', 'yellow'], 'blue']]]
```

The `textwrap` module formats paragraphs of text to fit a given screen width:

```python
>>> import textwrap
>>> doc = """The wrap() method is just like fill() except that...
... a list of strings instead of one big string with newlines to
... the wrapped lines."""
... >>> print textwrap.fill(doc, width=40)
The wrap() method is just like fill() except that it returns a list of strings instead of one big string with newlines to separate the wrapped lines.
```
The `locale` module accesses a database of culture specific data formats. The grouping attribute of locale's format function provides a direct way of formatting numbers with group separators:

```python
>>> import locale
>>> locale.setlocale(locale.LC_ALL, 'English_United States.1252')
'English_United States.1252'
>>> conv = locale.localeconv()  # get a mapping of conv
>>> x = 1234567.8
>>> locale.format("%d", x, grouping=True)
'1,234,567'
>>> locale.format("%s.*f", (conv['currency_symbol'],
...    conv['frac_digits'], x), grouping=True)
'$1,234,567.80'
```
Templating

The `string` module includes a versatile `Template` class with a simplified syntax suitable for editing by end-users. This allows users to customize their applications without having to alter the application.

The format uses placeholder names formed by `$` with valid Python identifiers (alphanumeric characters and underscores). Surrounding the placeholder with braces allows it to be followed by more alphanumeric letters with no intervening spaces. Writing `$$` creates a single escaped `$`:

```python
>>> from string import Template
>>> t = Template('${village}folk send $$10 to $cause.')
>>> t.substitute(village='Nottingham', cause='the ditch fund')
'Nottinghamfolk send $10 to the ditch fund.'
```

The `substitute()` method raises a `KeyError` when a placeholder is not supplied in a dictionary or a keyword argument. For mail-merge style applications, user supplied data may be incomplete and the `safe_substitute()` method may be more appropriate — it will leave placeholders unchanged if data is missing:

```python
>>> t = Template('Return the $item to $owner.')
>>> d = dict(item='unladen swallow')
>>> t.substitute(d)
Traceback (most recent call last):
  ...  
  KeyError: 'owner'
>>> t.safe_substitute(d)
'Return the unladen swallow to $owner.'
```

Template subclasses can specify a custom delimiter. For example, a batch renaming utility for a photo browser may elect to use percent signs for placeholders such as the current date, image sequence number, or file format:
Another application for templating is separating program logic from the details of multiple output formats. This makes it possible to substitute custom templates for XML files, plain text reports, and HTML web reports.
The `struct` module provides `pack()` and `unpack()` functions for working with variable length binary record formats. The following example shows how to loop through header information in a ZIP file without using the `zipfile` module. Pack codes "H" and "I" represent two and four byte unsigned numbers respectively. The "<" indicates that they are standard size and in little-endian byte order:

```python
import struct

data = open('myfile.zip', 'rb').read()
start = 0
for i in range(3): # show the first 3 file headers
    start += 14
    fields = struct.unpack('<IIIHH', data[start:start+16])
    crc32, comp_size, uncomp_size, filenamesize, extra_size = fields

    start += 16
    filename = data[start:start+filenamesize]
    start += filenamesize
    extra = data[start:start+extra_size]

    print(filename, hex(crc32), comp_size, uncomp_size)

    start += extra_size + comp_size # skip to the next header
```

---

**Working with Binary Data Record Layouts**

The `struct` module provides `pack()` and `unpack()` functions for working with variable length binary record formats. The following example shows how to loop through header information in a ZIP file without using the `zipfile` module. Pack codes "H" and "I" represent two and four byte unsigned numbers respectively. The "<" indicates that they are standard size and in little-endian byte order:

```python
import struct

data = open('myfile.zip', 'rb').read()
start = 0
for i in range(3): # show the first 3 file headers
    start += 14
    fields = struct.unpack('<IIIHH', data[start:start+16])
    crc32, comp_size, uncomp_size, filenamesize, extra_size = fields

    start += 16
    filename = data[start:start+filenamesize]
    start += filenamesize
    extra = data[start:start+extra_size]

    print(filename, hex(crc32), comp_size, uncomp_size)

    start += extra_size + comp_size # skip to the next header
```
Multi-threading

Threading is a technique for decoupling tasks which are not sequentially dependent. Threads can be used to improve the responsiveness of applications that accept user input while other tasks run in the background. A related use case is running I/O in parallel with computations in another thread.

The following code shows how the high level threading module can run tasks in background while the main program continues to run:

```python
import threading, zipfile

class AsyncZip(threading.Thread):
    def __init__(self, infile, outfile):
        threading.Thread.__init__(self)
        self.infile = infile
        self.outfile = outfile
    def run(self):
        f = zipfile.ZipFile(self.outfile, 'w', zipfile.ZIP_DEFLATED)
        f.write(self.infile)
        f.close()
        print 'Finished background zip of: ', self.infile

background = AsyncZip('mydata.txt', 'myarchive.zip')
background.start()
print 'The main program continues to run in foreground.'

background.join()  # Wait for the background task to finish
print 'Main program waited until background was done.'
```

The principal challenge of multi-threaded applications is coordinating threads that share data or other resources. To that end, the threading module provides a number of synchronization primitives including locks, events, condition variables, and semaphores.

While those tools are powerful, minor design errors can result in problems that are difficult to reproduce. So, the preferred approach
to task coordination is to concentrate all access to a resource in a single thread and then use the `Queue` module to feed that thread with requests from other threads. Applications using `Queue.Queue` objects for inter-thread communication and coordination are easier to design, more readable, and more reliable.
Logging

The `logging` module offers a full featured and flexible logging system. At its simplest, log messages are sent to a file or to `sys.stderr`:

```python
import logging
logging.debug('Debugging information')
logging.info('Informational message')
logging.warning('Warning:config file %s not found', 'server.conf')
logging.error('Error occurred')
logging.critical('Critical error -- shutting down')
```

This produces the following output:

```
WARNING:root:Warning:config file server.conf not found
ERROR:root:Error occurred
CRITICAL:root:Critical error -- shutting down
```

By default, informational and debugging messages are suppressed and the output is sent to standard error. Other output options include routing messages through email, datagrams, sockets, or to an HTTP Server. New filters can select different routing based on message priority: `DEBUG`, `INFO`, `WARNING`, `ERROR`, and `CRITICAL`.

The logging system can be configured directly from Python or can be loaded from a user editable configuration file for customized logging without altering the application.
Weak References

Python does automatic memory management (reference counting for most objects and garbage collection to eliminate cycles). The memory is freed shortly after the last reference to it has been eliminated.

This approach works fine for most applications but occasionally there is a need to track objects only as long as they are being used by something else. Unfortunately, just tracking them creates a reference that makes them permanent. The `weakref` module provides tools for tracking objects without creating a reference. When the object is no longer needed, it is automatically removed from a weakref table and a callback is triggered for weakref objects. Typical applications include caching objects that are expensive to create:

```python
>>> import weakref, gc
>>> class A:
...     def __init__(self, value):
...         self.value = value
...     def __repr__(self):
...         return str(self.value)
...
>>> a = A(10)  # create a reference
>>> d = weakref.WeakValueDictionary()
>>> d['primary'] = a  # does not create a reference
>>> d['primary']  # fetch the object if it is still 10
>>> del a  # remove the one reference
>>> gc.collect()  # run garbage collection right away
0
>>> d['primary']  # entry was automatically removed
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
    d['primary']  # entry was automatically removed
KeyError: 'primary'
```
Many data structure needs can be met with the built-in list type. However, sometimes there is a need for alternative implementations with different performance trade-offs.

The `array` module provides an `array()` object that is like a list that stores only homogeneous data and stores it more compactly. The following example shows an array of numbers stored as two byte unsigned binary numbers (typecode "H") rather than the usual 16 bytes per entry for regular lists of python int objects:

```python
>>> from array import array
>>> a = array('H', [4000, 10, 700, 22222])
>>> sum(a)
26932
>>> a[1:3]
array('H', [10, 700])
```

The `collections` module provides a `deque()` object that is like a list with faster appends and pops from the left side but slower lookups in the middle. These objects are well suited for implementing queues and breadth first tree searches:

```python
>>> from collections import deque
>>> d = deque(["task1", "task2", "task3"])
>>> d.append("task4")
>>> print "Handling", d.popleft()
Handling task1
```

In addition to alternative list implementations, the library also offers
other tools such as the `bisect` module with functions for manipulating sorted lists:

```python
>>> import bisect
>>> scores = [(100, 'perl'), (200, 'tcl'), (400, 'lua'), (500,
>>> bisect.insort(scores, (300, 'ruby'))
>>> scores
[(100, 'perl'), (200, 'tcl'), (300, 'ruby'), (400, 'lua'), (500
```

The `heapq` module provides functions for implementing heaps based on regular lists. The lowest valued entry is always kept at position zero. This is useful for applications which repeatedly access the smallest element but do not want to run a full list sort:

```python
>>> from heapq import heapify, heappop, heappush
>>> data = [1, 3, 5, 7, 9, 2, 4, 6, 8, 0]
>>> heapify(data)  # rearrange the list into heap order
>>> heappush(data, -5)  # add a new entry
>>> [heappop(data) for i in range(3)]  # fetch the three smallest
[-5, 0, 1]
```
The `decimal` module offers a `Decimal` datatype for decimal floating point arithmetic. Compared to the built-in `float` implementation of binary floating point, the new class is especially helpful for financial applications and other uses which require exact decimal representation, control over precision, control over rounding to meet legal or regulatory requirements, tracking of significant decimal places, or for applications where the user expects the results to match calculations done by hand.

For example, calculating a 5% tax on a 70 cent phone charge gives different results in decimal floating point and binary floating point. The difference becomes significant if the results are rounded to the nearest cent:

```python
>>> from decimal import *
>>> Decimal('0.70') * Decimal('1.05')
Decimal('0.7350')
```

```text
0.70 * 1.05
0.73499999999999999
```

The `Decimal` result keeps a trailing zero, automatically inferring four place significance from multiplicands with two place significance. Decimal reproduces mathematics as done by hand and avoids issues that can arise when binary floating point cannot exactly represent decimal quantities.

Exact representation enables the `Decimal` class to perform modulo calculations and equality tests that are unsuitable for binary floating point:

```python
>>> Decimal('1.00') % Decimal('.10')
Decimal('0.00')
```

```text
1.00 % 0.10
0.09999999999999995
```
The `decimal` module provides arithmetic with as much precision as needed:

```python
>>> sum([Decimal('0.1')] * 10) == Decimal('1.0')
True
>>> sum([0.1] * 10) == 1.0
False
```

```python
>>> getcontext().prec = 36
>>> Decimal(1) / Decimal(7)
Decimal("0.142857142857142857142857142857142857")
```
What Now?

Reading this tutorial has probably reinforced your interest in using Python — you should be eager to apply Python to solving your real-world problems. Where should you go to learn more?

This tutorial is part of Python’s documentation set. Some other documents in the set are:

- **The Python Standard Library**:
  
  You should browse through this manual, which gives complete (though terse) reference material about types, functions, and the modules in the standard library. The standard Python distribution includes a lot of additional code. There are modules to read Unix mailboxes, retrieve documents via HTTP, generate random numbers, parse command-line options, write CGI programs, compress data, and many other tasks. Skimming through the Library Reference will give you an idea of what’s available.

- **Installing Python Modules** explains how to install external modules written by other Python users.

- **The Python Language Reference**: A detailed explanation of Python’s syntax and semantics. It’s heavy reading, but is useful as a complete guide to the language itself.

More Python resources:

- **http://www.python.org**: The major Python Web site. It contains code, documentation, and pointers to Python-related pages around the Web. This Web site is mirrored in various places around the world, such as Europe, Japan, and Australia; a mirror may be faster than the main site, depending on your
geographical location.

- **http://docs.python.org**: Fast access to Python’s documentation.
- **http://pypi.python.org**: The Python Package Index, previously also nicknamed the Cheese Shop, is an index of user-created Python modules that are available for download. Once you begin releasing code, you can register it here so that others can find it.
- **http://aspn.activestate.com/ASPN/Python/Cookbook/**: The Python Cookbook is a sizable collection of code examples, larger modules, and useful scripts. Particularly notable contributions are collected in a book also titled Python Cookbook (O'Reilly & Associates, ISBN 0-596-00797-3.)

For Python-related questions and problem reports, you can post to the newsgroup *comp.lang.python*, or send them to the mailing list at *python-list@python.org*. The newsgroup and mailing list are gatewayed, so messages posted to one will automatically be forwarded to the other. There are around 120 postings a day (with peaks up to several hundred), asking (and answering) questions, suggesting new features, and announcing new modules. Before posting, be sure to check the list of *Frequently Asked Questions* (also called the FAQ), or look for it in the *Misc/* directory of the Python source distribution. Mailing list archives are available at *http://mail.python.org/pipermail/*/. The FAQ answers many of the questions that come up again and again, and may already contain the solution for your problem.
Interactive Input Editing and History Substitution

Some versions of the Python interpreter support editing of the current input line and history substitution, similar to facilities found in the Korn shell and the GNU Bash shell. This is implemented using the GNU Readline library, which supports Emacs-style and vi-style editing. This library has its own documentation which I won't duplicate here; however, the basics are easily explained. The interactive editing and history described here are optionally available in the Unix and Cygwin versions of the interpreter.

This chapter does not document the editing facilities of Mark Hammond’s PythonWin package or the Tk-based environment, IDLE, distributed with Python. The command line history recall which operates within DOS boxes on NT and some other DOS and Windows flavors is yet another beast.
Line Editing

If supported, input line editing is active whenever the interpreter prints a primary or secondary prompt. The current line can be edited using the conventional Emacs control characters. The most important of these are:  

- **C-A** (Control-A) moves the cursor to the beginning of the line,  
- **C-E** to the end,  
- **C-B** moves it one position to the left,  
- **C-F** to the right.  
- Backspace erases the character to the left of the cursor,  
- **C-D** the character to its right.  
- **C-K** kills (erases) the rest of the line to the right of the cursor,  
- **C-Y** yanks back the last killed string.  
- **C-underscore** undoes the last change you made; it can be repeated for cumulative effect.
History substitution works as follows. All non-empty input lines issued are saved in a history buffer, and when a new prompt is given you are positioned on a new line at the bottom of this buffer. \texttt{C-P} moves one line up (back) in the history buffer, \texttt{C-N} moves one down. Any line in the history buffer can be edited; an asterisk appears in front of the prompt to mark a line as modified. Pressing the \texttt{Return} key passes the current line to the interpreter. \texttt{C-R} starts an incremental reverse search; \texttt{C-S} starts a forward search.
Key Bindings

The key bindings and some other parameters of the Readline library can be customized by placing commands in an initialization file called ~/.inputrc. Key bindings have the form

```
key-name: function-name
```

or

```
"string": function-name
```

and options can be set with

```
set option-name value
```

For example:

```
# I prefer vi-style editing:
set editing-mode vi

# Edit using a single line:
set horizontal-scroll-mode On

# Rebind some keys:
Meta-h: backward-kill-word
"\C-u": universal-argument
"\C-x\C-r": re-read-init-file
```

Note that the default binding for Tab in Python is to insert a Tab character instead of Readline’s default filename completion function. If you insist, you can override this by putting

```
Tab: complete
```

in your ~/.inputrc. (Of course, this makes it harder to type indented continuation lines if you’re accustomed to using Tab for that
Automatic completion of variable and module names is optionally available. To enable it in the interpreter’s interactive mode, add the following to your startup file: [1]

```python
import rlcompleter, readline
readline.parse_and_bind('tab: complete')
```

This binds the `Tab` key to the completion function, so hitting the `Tab` key twice suggests completions; it looks at Python statement names, the current local variables, and the available module names. For dotted expressions such as `string.a`, it will evaluate the expression up to the final `.` and then suggest completions from the attributes of the resulting object. Note that this may execute application-defined code if an object with a `__getattr__()` method is part of the expression.

A more capable startup file might look like this example. Note that this deletes the names it creates once they are no longer needed; this is done since the startup file is executed in the same namespace as the interactive commands, and removing the names avoids creating side effects in the interactive environment. You may find it convenient to keep some of the imported modules, such as `os`, which turn out to be needed in most sessions with the interpreter.

```python
# Add auto-completion and a stored history file of commands to an interactive interpreter. Requires Python 2.0+, readline. Auto-
# bound to the Esc key by default (you can change it - see read-
#
# Store the file in ~/.pystartup, and set an environment variab.
# to it: "export PYTHONSTARTUP=/home/user/.pystartup" in bash.
#
# Note that PYTHONSTARTUP does *not* expand "~", so you have to
# full path to your home directory.

import atexit
import os
import readline
```
import rlcompleter

historyPath = os.path.expanduser("~/.pyhistory")

def save_history(historyPath=historyPath):
    import readline
    readline.write_history_file(historyPath)

if os.path.exists(historyPath):
    readline.read_history_file(historyPath)

atexit.register(save_history)

del os, atexit, readline, rlcompleter, save_history, historyPath
Commentary

This facility is an enormous step forward compared to earlier versions of the interpreter; however, some wishes are left: It would be nice if the proper indentation were suggested on continuation lines (the parser knows if an indent token is required next). The completion mechanism might use the interpreter’s symbol table. A command to check (or even suggest) matching parentheses, quotes, etc., would also be useful.

Footnotes

Python will execute the contents of a file identified by the [1] PYTHONSTARTUP environment variable when you start an interactive interpreter.
Floating-point numbers are represented in computer hardware as base 2 (binary) fractions. For example, the decimal fraction

0.125

has value 1/10 + 2/100 + 5/1000, and in the same way the binary fraction

0.001

has value 0/2 + 0/4 + 1/8. These two fractions have identical values, the only real difference being that the first is written in base 10 fractional notation, and the second in base 2.

Unfortunately, most decimal fractions cannot be represented exactly as binary fractions. A consequence is that, in general, the decimal floating-point numbers you enter are only approximated by the binary floating-point numbers actually stored in the machine.

The problem is easier to understand at first in base 10. Consider the fraction 1/3. You can approximate that as a base 10 fraction:

0.3

or, better,

0.33

or, better,

0.333
and so on. No matter how many digits you're willing to write down, the result will never be exactly 1/3, but will be an increasingly better approximation of 1/3.

In the same way, no matter how many base 2 digits you're willing to use, the decimal value 0.1 cannot be represented exactly as a base 2 fraction. In base 2, 1/10 is the infinitely repeating fraction

```
0.000110011001100110011001100110011001100110011...
```

Stop at any finite number of bits, and you get an approximation. This is why you see things like:

```python
>>> 0.1
0.10000000000000001
```

On most machines today, that is what you'll see if you enter 0.1 at a Python prompt. You may not, though, because the number of bits used by the hardware to store floating-point values can vary across machines, and Python only prints a decimal approximation to the true decimal value of the binary approximation stored by the machine. On most machines, if Python were to print the true decimal value of the binary approximation stored for 0.1, it would have to display

```python
>>> 0.1
0.1000000000000000055511151231257827021181583404541015625
```

instead! The Python prompt uses the built-in `repr()` function to obtain a string version of everything it displays. For floats, `repr(float)` rounds the true decimal value to 17 significant digits, giving

```
0.1000000000000001
```

`repr(float)` produces 17 significant digits because it turns out that's enough (on most machines) so that `eval(repr(x)) == x` exactly for
all finite floats \( x \), but rounding to 16 digits is not enough to make that true.

Note that this is in the very nature of binary floating-point: this is not a bug in Python, and it is not a bug in your code either. You'll see the same kind of thing in all languages that support your hardware's floating-point arithmetic (although some languages may not display the difference by default, or in all output modes).

Python's built-in \( \text{str()} \) function produces only 12 significant digits, and you may wish to use that instead. It's unusual for \( \text{eval(str(x))} \) to reproduce \( x \), but the output may be more pleasant to look at:

```python
>>> print str(0.1)
0.1
```

It's important to realize that this is, in a real sense, an illusion: the value in the machine is not exactly \( 1/10 \), you're simply rounding the display of the true machine value.

Other surprises follow from this one. For example, after seeing

```python
>>> 0.1
0.1000000000000001
```

you may be tempted to use the \( \text{round()} \) function to chop it back to the single digit you expect. But that makes no difference:

```python
>>> round(0.1, 1)
0.1000000000000001
```

The problem is that the binary floating-point value stored for “0.1” was already the best possible binary approximation to \( 1/10 \), so trying to round it again can’t make it better: it was already as good as it gets.

Another consequence is that since 0.1 is not exactly \( 1/10 \), summing
ten values of 0.1 may not yield exactly 1.0, either:

```python
>>> sum = 0.0
>>> for i in range(10):
...     sum += 0.1
... 
0.9999999999999989
```

Binary floating-point arithmetic holds many surprises like this. The problem with “0.1” is explained in precise detail below, in the “Representation Error” section. See The Perils of Floating Point for a more complete account of other common surprises.

As that says near the end, “there are no easy answers.” Still, don’t be unduly wary of floating-point! The errors in Python float operations are inherited from the floating-point hardware, and on most machines are on the order of no more than 1 part in 2**53 per operation. That’s more than adequate for most tasks, but you do need to keep in mind that it’s not decimal arithmetic, and that every float operation can suffer a new rounding error.

While pathological cases do exist, for most casual use of floating-point arithmetic you’ll see the result you expect in the end if you simply round the display of your final results to the number of decimal digits you expect. `str()` usually suffices, and for finer control see the `str.format()` method's format specifiers in Format String Syntax.
This section explains the “0.1” example in detail, and shows how you can perform an exact analysis of cases like this yourself. Basic familiarity with binary floating-point representation is assumed.

*Representation error* refers to the fact that some (most, actually) decimal fractions cannot be represented exactly as binary (base 2) fractions. This is the chief reason why Python (or Perl, C, C++, Java, Fortran, and many others) often won’t display the exact decimal number you expect:

```python
>>> 0.1
0.10000000000000001
```

Why is that? 1/10 is not exactly representable as a binary fraction. Almost all machines today (November 2000) use IEEE-754 floating point arithmetic, and almost all platforms map Python floats to IEEE-754 “double precision”. 754 doubles contain 53 bits of precision, so on input the computer strives to convert 0.1 to the closest fraction it can of the form $J/2^{**N}$ where $J$ is an integer containing exactly 53 bits. Rewriting

$$1 / 10 \approx J / (2^{**N})$$

as

$$J \approx 2^{**N} / 10$$

and recalling that $J$ has exactly 53 bits (is $\geq 2^{52}$ but $< 2^{53}$), the best value for $N$ is 56:

```python
>>> 2**52
4503599627370496L
>>> 2**53
```
That is, 56 is the only value for $N$ that leaves $J$ with exactly 53 bits. The best possible value for $J$ is then that quotient rounded:

```python
divmod(2**56, 10)
```

Since the remainder is more than half of 10, the best approximation is obtained by rounding up:

```python
q+1
```

Therefore the best possible approximation to $1/10$ in 754 double precision is that over $2^{56}$, or

$7205759403792794 / 72057594037927936$

Note that since we rounded up, this is actually a little bit larger than $1/10$; if we had not rounded up, the quotient would have been a little bit smaller than $1/10$. But in no case can it be *exactly* $1/10$!

So the computer never “sees” $1/10$: what it sees is the exact fraction given above, the best 754 double approximation it can get:

```python
.1 * 2**56
```

If we multiply that fraction by $10^{30}$, we can see the (truncated) value of its 30 most significant decimal digits:
meaning that the exact number stored in the computer is approximately equal to the decimal value 0.10000000000000005551115123125. Rounding that to 17 significant digits gives the 0.10000000000000001 that Python displays (well, will display on any 754-conforming platform that does best-possible input and output conversions in its C library — yours may not!).
Command line and environment

The CPython interpreter scans the command line and the environment for various settings.

**Note:** Other implementations’ command line schemes may differ. See *Alternate Implementations* for further resources.
Command line

When invoking Python, you may specify any of these options:

```
python [-dEiQsStuUvxX3?] [-c command | -m module-name | script]
```

The most common use case is, of course, a simple invocation of a script:

```
python myscript.py
```

Interface options

The interpreter interface resembles that of the UNIX shell, but provides some additional methods of invocation:

- When called with standard input connected to a tty device, it prompts for commands and executes them until an EOF (an end-of-file character, you can produce that with `Ctrl-D` on UNIX or `Ctrl-Z, Enter` on Windows) is read.
- When called with a file name argument or with a file as standard input, it reads and executes a script from that file.
- When called with a directory name argument, it reads and executes an appropriately named script from that directory.
- When called with `-c command`, it executes the Python statement(s) given as `command`. Here `command` may contain multiple statements separated by newlines. Leading whitespace is significant in Python statements!
- When called with `-m module-name`, the given module is located on the Python module path and executed as a script.

In non-interactive mode, the entire input is parsed before it is executed.
An interface option terminates the list of options consumed by the interpreter, all consecutive arguments will end up in `sys.argv` – note that the first element, subscript zero (`sys.argv[0]`), is a string reflecting the program’s source.

**-c <command>**

Execute the Python code in `command`. `command` can be one or more statements separated by newlines, with significant leading whitespace as in normal module code.

If this option is given, the first element of `sys.argv` will be `"-c"` and the current directory will be added to the start of `sys.path` (allowing modules in that directory to be imported as top level modules).

**-m <module-name>**

Search `sys.path` for the named module and execute its contents as the `__main__` module.

Since the argument is a module name, you must not give a file extension (`.py`). The `module-name` should be a valid Python module name, but the implementation may not always enforce this (e.g. it may allow you to use a name that includes a hyphen).

**Note:** This option cannot be used with builtin modules and extension modules written in C, since they do not have Python module files. However, it can still be used for precompiled modules, even if the original source file is not available.

If this option is given, the first element of `sys.argv` will be the full path to the module file. As with the `-c` option, the current directory will be added to the start of `sys.path`.

Many standard library modules contain code that is invoked on their execution as a script. An example is the `timeit` module:
See also:
runpy.run_module()

The actual implementation of this feature.

**PEP 338** – Executing modules as scripts

*New in version 2.4.*

*Changed in version 2.5:* The named module can now be located inside a package.

- Read commands from standard input (**sys.stdin**). If standard input is a terminal, `-i` is implied.

  If this option is given, the first element of **sys.argv** will be "-" and the current directory will be added to the start of **sys.path**.

<**script**>

Execute the Python code contained in **script**, which must be a filesystem path (absolute or relative) referring to either a Python file, a directory containing a **__main__.py** file, or a zipfile containing a **__main__.py** file.

If this option is given, the first element of **sys.argv** will be the script name as given on the command line.

If the script name refers directly to a Python file, the directory containing that file is added to the start of **sys.path**, and the file is executed as the **__main__** module.

If the script name refers to a directory or zipfile, the script name is
added to the start of `sys.path` and the `__main__.py` file in that location is executed as the `__main__` module.

**Changed in version 2.5:** Directories and zipfiles containing a `__main__.py` file at the top level are now considered valid Python scripts.

If no interface option is given, `-i` is implied, `sys.argv[0]` is an empty string (""), and the current directory will be added to the start of `sys.path`.

**See also:** *Invoking the Interpreter*

### Generic options

- `?-`  
  - `-h`  
  - `--help`
    
    Print a short description of all command line options.

    **Changed in version 2.5:** The `--help` variant.

- `V`  
  - `--version`

    Print the Python version number and exit. Example output could be:

    ```
    Python 2.5.1
    ```

    **Changed in version 2.5:** The `--version` variant.

### Miscellaneous options

- `B`
If given, Python won’t try to write .pyc or .pyo files on the import of source modules. See also PYTHONDONTWRITEBYTECODE.

New in version 2.6.

-d

Turn on parser debugging output (for wizards only, depending on compilation options). See also PYTHONDEBUG.

-E

Ignore all PYTHON* environment variables, e.g. PYTHONPATH and PYTHONHOME, that might be set.

New in version 2.2.

-i

When a script is passed as first argument or the -c option is used, enter interactive mode after executing the script or the command, even when sys.stdin does not appear to be a terminal. The PYTHONSTARTUP file is not read.

This can be useful to inspect global variables or a stack trace when a script raises an exception. See also PYTHONINSPECT.

-O

Turn on basic optimizations. This changes the filename extension for compiled (bytecode) files from .pyc to .pyo. See also PYTHONOPTIMIZE.

-OO

Discard docstrings in addition to the -O optimizations.

-Q <arg>

Division control. The argument must be one of the following:

old
division of int/int and long/long return an int or long (default)

new

new division semantics, i.e. division of int/int and long/long returns a float

warn

old division semantics with a warning for int/int and long/long

warnall

old division semantics with a warning for all uses of the division operator

See also:
Tools/scripts/fixdiv.py
for a use of warnall

PEP 238 – Changing the division operator

-s

Don’t add user site directory to sys.path

New in version 2.6.

See also: PEP 370 – Per user site-packages directory

-S

Disable the import of the module site and the site-dependent manipulations of sys.path that it entails.

-t

Issue a warning when a source file mixes tabs and spaces for indentation in a way that makes it depend on the worth of a tab expressed in spaces. Issue an error when the option is given twice (-tt).

-u
Force stdin, stdout and stderr to be totally unbuffered. On systems where it matters, also put stdin, stdout and stderr in binary mode.

Note that there is internal buffering in `file.readlines()` and `File Objects` (for `line in sys.stdin`) which is not influenced by this option. To work around this, you will want to use `file.readline()` inside a `while 1:` loop.

See also `PYTHONUNBUFFERED`.

- **v**

  Print a message each time a module is initialized, showing the place (filename or built-in module) from which it is loaded. When given twice (-vv), print a message for each file that is checked for when searching for a module. Also provides information on module cleanup at exit. See also `PYTHONVERBOSE`.

- **W** **arg**

  Warning control. Python’s warning machinery by default prints warning messages to `sys.stderr`. A typical warning message has the following form:

  ```
  file:line: category: message
  ```

  By default, each warning is printed once for each source line where it occurs. This option controls how often warnings are printed.

  Multiple `-W` options may be given; when a warning matches more than one option, the action for the last matching option is performed. Invalid `-W` options are ignored (though, a warning message is printed about invalid options when the first warning is issued).
Warnings can also be controlled from within a Python program using the `warnings` module.

The simplest form of argument is one of the following action strings (or a unique abbreviation):

- **ignore**
  - Ignore all warnings.

- **default**
  - Explicitly request the default behavior (printing each warning once per source line).

- **all**
  - Print a warning each time it occurs (this may generate many messages if a warning is triggered repeatedly for the same source line, such as inside a loop).

- **module**
  - Print each warning only the first time it occurs in each module.

- **once**
  - Print each warning only the first time it occurs in the program.

- **error**
  - Raise an exception instead of printing a warning message.

The full form of argument is:

```
action:message:category:module:line
```

Here, `action` is as explained above but only applies to messages that match the remaining fields. Empty fields match all values; trailing empty fields may be omitted. The `message` field matches the start of the warning message printed; this match is case-insensitive. The `category` field matches the warning category.
This must be a class name; the match test whether the actual warning category of the message is a subclass of the specified warning category. The full class name must be given. The `module` field matches the (fully-qualified) module name; this match is case-sensitive. The `line` field matches the line number, where zero matches all line numbers and is thus equivalent to an omitted line number.

See also: warnings – the warnings module PEP 230 – Warning framework

-x

Skip the first line of the source, allowing use of non-Unix forms of `#!cmd`. This is intended for a DOS specific hack only.

Warning: The line numbers in error messages will be off by one!

-3

Warn about Python 3.x incompatibilities. Among these are:

- `dict.has_key()`
- `apply()`
- `callable()`
- `coerce()`
- `execfile()`
- `reduce()`
- `reload()`

Using these will emit a `DeprecationWarning`.

*New in version 2.6.*
Environment variables

These environment variables influence Python’s behavior.

**PYTHONHOME**

Change the location of the standard Python libraries. By default, the libraries are searched in `prefix/lib/pythonversion` and `exec_prefix/lib/pythonversion`, where `prefix` and `exec_prefix` are installation-dependent directories, both defaulting to `/usr/local`.

When **PYTHONHOME** is set to a single directory, its value replaces both `prefix` and `exec_prefix`. To specify different values for these, set **PYTHONHOME** to `prefix:exec_prefix`.

**PYTHONPATH**

Augment the default search path for module files. The format is the same as the shell’s **PATH**: one or more directory pathnames separated by `os.pathsep` (e.g. colons on Unix or semicolons on Windows). Non-existent directories are silently ignored.

In addition to normal directories, individual **PYTHONPATH** entries may refer to zipfiles containing pure Python modules (in either source or compiled form). Extension modules cannot be imported from zipfiles.

The default search path is installation dependent, but generally begins with `prefix/lib/pythonversion` (see **PYTHONHOME** above). It is always appended to **PYTHONPATH**.

An additional directory will be inserted in the search path in front of **PYTHONPATH** as described above under **Interface options**. The search path can be manipulated from within a Python
program as the variable `sys.path`.

**PYTHONSTARTUP**

If this is the name of a readable file, the Python commands in that file are executed before the first prompt is displayed in interactive mode. The file is executed in the same namespace where interactive commands are executed so that objects defined or imported in it can be used without qualification in the interactive session. You can also change the prompts `sys.ps1` and `sys.ps2` in this file.

**PYTHONY2K**

Set this to a non-empty string to cause the `time` module to require dates specified as strings to include 4-digit years, otherwise 2-digit years are converted based on rules described in the `time` module documentation.

**PYTHONOPTIMIZE**

If this is set to a non-empty string it is equivalent to specifying the `-O` option. If set to an integer, it is equivalent to specifying `-O` multiple times.

**PYTHONDEBUG**

If this is set to a non-empty string it is equivalent to specifying the `-d` option. If set to an integer, it is equivalent to specifying `-d` multiple times.

**PYTHONINSPECT**

If this is set to a non-empty string it is equivalent to specifying the `-i` option.

This variable can also be modified by Python code using `os.environ` to force inspect mode on program termination.

**PYTHONUNBUFFERED**

If this is set to a non-empty string it is equivalent to specifying the
-u option.

**PYTHONVERBOSE**
If this is set to a non-empty string it is equivalent to specifying the -v option. If set to an integer, it is equivalent to specifying -v multiple times.

**PYTHONCASEOK**
If this is set, Python ignores case in import statements. This only works on Windows.

**PYTHONDONTWRITEBYTECODE**
If this is set, Python won’t try to write .pyc or .pyo files on the import of source modules.

*New in version 2.6.*

**PYTHONIOENCODING**
Overides the encoding used for stdin/stdout/stderr, in the syntax encodingname:errrorhandler. The :errorhandler part is optional and has the same meaning as in str.encode().

*New in version 2.6.*

**PYTHONNOUSERSITE**
If this is set, Python won’t add the user site directory to sys.path

*New in version 2.6.*

See also: PEP 370 – Per user site-packages directory

**PYTHONUSERBASE**
Sets the base directory for the user site directory

*New in version 2.6.*
See also: PEP 370 – Per user site-packages directory

**PYTHONEXECUTABLE**

If this environment variable is set, `sys.argv[0]` will be set to its value instead of the value got through the C runtime. Only works on Mac OS X.

### Debug-mode variables

Setting these variables only has an effect in a debug build of Python, that is, if Python was configured with the `--with-pydebug` build option.

**PYTHONTREADDEBUG**

If set, Python will print threading debug info.

*Changed in version 2.6:* Previously, this variable was called `THREADDEBUG`.

**PYTHONDUMPREFS**

If set, Python will dump objects and reference counts still alive after shutting down the interpreter.

**PYTHONMALLOCSTATS**

If set, Python will print memory allocation statistics every time a new object arena is created, and on shutdown.
Using Python on Unix platforms
Getting and installing the latest version of Python

On Linux

Python comes preinstalled on most Linux distributions, and is available as a package on all others. However there are certain features you might want to use that are not available on your distro's package. You can easily compile the latest version of Python from source.

In the event that Python doesn’t come preinstalled and isn’t in the repositories as well, you can easily make packages for your own distro. Have a look at the following links:

**See also:**

http://www.linux.com/articles/60383  
for Debian users

http://linuxmafia.com/pub/linux/suse-linux-internals/chapter35.html  
for OpenSuse users

for Fedora users

for Slackware users

On FreeBSD and OpenBSD
• FreeBSD users, to add the package use:

```bash
pkg_add -r python
```

• OpenBSD users use:

```bash
```

For example i386 users get the 2.5.1 version of Python using:

```bash
pkg_add ftp://ftp.openbsd.org/pub/OpenBSD/4.2/packages/i386/python-2.5.1p2.tgz
```

**On OpenSolaris**

To install the newest Python versions on OpenSolaris, install blastwave ([http://www.blastwave.org/howto.html](http://www.blastwave.org/howto.html)) and type “pkg_get -i python” at the prompt.
Building Python

If you want to compile CPython yourself, first thing you should do is get the source. You can download either the latest release’s source or just grab a fresh checkout.

The build process consists the usual

```
./configure
make
make install
```

invocations. Configuration options and caveats for specific Unix platforms are extensively documented in the README file in the root of the Python source tree.

**Warning:** `make install` can overwrite or masquerade the `python` binary. `make altinstall` is therefore recommended instead of `make install` since it only installs `exec_prefix/bin/pythonversion`. 
Python-related paths and files

These are subject to difference depending on local installation conventions; \texttt{prefix} ($\{\texttt{prefix}\}$) and \texttt{exec\_prefix} ($\{\texttt{exec\_prefix}\}$) are installation-dependent and should be interpreted as for GNU software; they may be the same.

For example, on most Linux systems, the default for both is /usr.

<table>
<thead>
<tr>
<th>File/directory</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>\texttt{exec_prefix}/bin/python</td>
<td>Recommended location of the interpreter.</td>
</tr>
<tr>
<td>\texttt{prefix}/lib/python\texttt{version}, \texttt{exec_prefix}/lib/python\texttt{version}</td>
<td>Recommended locations of the directories containing the standard modules.</td>
</tr>
<tr>
<td>\texttt{prefix}/include/python\texttt{version}, \texttt{exec_prefix}/include/python\texttt{version}</td>
<td>Recommended locations of the directories containing the include files needed for developing Python extensions and embedding the interpreter.</td>
</tr>
<tr>
<td>~/.pythonrc.py</td>
<td>User-specific initialization file loaded by the user module; not used by default or by most applications.</td>
</tr>
</tbody>
</table>
To easily use Python scripts on Unix, you need to make them executable, e.g. with

```
$ chmod +x script
```

and put an appropriate Shebang line at the top of the script. A good choice is usually

```
#!/usr/bin/env python
```

which searches for the Python interpreter in the whole PATH. However, some Unices may not have the env command, so you may need to hardcode `/usr/bin/python` as the interpreter path.

To use shell commands in your python scripts, look at the subprocess module.
Editors

Vim and Emacs are excellent editors which support Python very well. For more information on how to code in python in these editors, look at:

http://sourceforge.net/projects/python-mode

Geany is an excellent IDE with support for a lot of languages. For more information, read: http://geany.uvena.de/

Komodo edit is another extremely good IDE. It also has support for a lot of languages. For more information, read: http://www.activestate.com/store/productdetail.aspx?prdGuid=20f4ed15-6684-4118-a78b-d37ff4058c5f
This document aims to give an overview of Windows-specific behaviour you should know about when using Python on Microsoft Windows.
Installing Python

Unlike most Unix systems and services, Windows does not require Python natively and thus does not pre-install a version of Python. However, the CPython team has compiled Windows installers (MSI packages) with every release for many years.

With ongoing development of Python, some platforms that used to be supported earlier are no longer supported (due to the lack of users or developers). Check PEP 11 for details on all unsupported platforms.

- DOS and Windows 3.x are deprecated since Python 2.0 and code specific to these systems was removed in Python 2.1.
- Up to 2.5, Python was still compatible with Windows 95, 98 and ME (but already raised a deprecation warning on installation). For Python 2.6 (and all following releases), this support was dropped and new releases are just expected to work on the Windows NT family.
- Windows CE is still supported.
- The Cygwin installer offers to install the Python interpreter as well; it is located under “Interpreters.” (cf. Cygwin package source, Maintainer releases)

See Python for Windows (and DOS) for detailed information about platforms with precompiled installers.

Python on XP

“7 Minutes to “Hello World!”” by Richard Dooling, 2006

Installing on Windows

in “Dive into Python: Python from novice to pro” by Mark
For Windows users
Alternative bundles

Besides the standard CPython distribution, there are modified packages including additional functionality. The following is a list of popular versions and their key features:

ActivePython
  Installer with multi-platform compatibility, documentation, PyWin32

Python Enthought Edition
  Popular modules (such as PyWin32) with their respective documentation, tool suite for building extensible python applications

Notice that these packages are likely to install *older* versions of Python.
Configuring Python

In order to run Python flawlessly, you might have to change certain environment settings in Windows.

Excursus: Setting environment variables

Windows has a built-in dialog for changing environment variables (following guide applies to XP classical view): Right-click the icon for your machine (usually located on your Desktop and called “My Computer”) and choose Properties there. Then, open the Advanced tab and click the Environment Variables button.

In short, your path is:

My Computer ▶ Properties ▶ Advanced ▶ Environment Variables

In this dialog, you can add or modify User and System variables. To change System variables, you need non-restricted access to your machine (i.e. Administrator rights).

Another way of adding variables to your environment is using the set command:

```
set PYTHONPATH=%PYTHONPATH%;C:\My_python_lib
```

To make this setting permanent, you could add the corresponding command line to your autoexec.bat. msconfig is a graphical interface to this file.

Viewing environment variables can also be done more straightforward: The command prompt will expand strings wrapped into percent signs automatically:

```
echo %PATH%
```
Consult **set /?** for details on this behaviour.

**See also:**

  How To Manage Environment Variables in Windows XP
- [http://www.chem.gla.ac.uk/~louis/software/faq/q1.html](http://www.chem.gla.ac.uk/~louis/software/faq/q1.html)
  Setting Environment variables, Louis J. Farrugia

**Finding the Python executable**

Besides using the automatically created start menu entry for the Python interpreter, you might want to start Python in the DOS prompt. To make this work, you need to set your `%PATH%` environment variable to include the directory of your Python distribution, delimited by a semicolon from other entries. An example variable could look like this (assuming the first two entries are Windows’ default):

```
C:\WINDOWS\system32;C:\WINDOWS;C:\Python25
```

Typing **python** on your command prompt will now fire up the Python interpreter. Thus, you can also execute your scripts with command line options, see *Command line* documentation.

**Finding modules**

Python usually stores its library (and thereby your site-packages folder) in the installation directory. So, if you had installed Python to `C:\Python\`, the default library would reside in `C:\Python\Lib\` and
third-party modules should be stored in `C:\Python\Lib\site-packages\`.

You can add folders to your search path to make Python's import mechanism search in these directories as well. Use `PYTHONPATH`, as described in *Environment variables*, to modify `sys.path`. On Windows, paths are separated by semicolons, though, to distinguish them from drive identifiers (`c:\` etc.).

Modifying the module search path can also be done through the Windows registry: Edit `HKEY_LOCAL_MACHINE\SOFTWARE\Python\PythonCore\version\PythonPath\`, as described above for the environment variable `%PYTHONPATH%`. A convenient registry editor is `regedit` (start it by typing “regedit” into `Start ‣ Run`).

### Executing scripts

Python scripts (files with the extension `.py`) will be executed by `python.exe` by default. This executable opens a terminal, which stays open even if the program uses a GUI. If you do not want this to happen, use the extension `.pyw` which will cause the script to be executed by `pythonw.exe` by default (both executables are located in the top-level of your Python installation directory). This suppresses the terminal window on startup.

You can also make all `.py` scripts execute with `pythonw.exe`, setting this through the usual facilities, for example (might require administrative rights):

1. Launch a command prompt.
2. Associate the correct file group with `.py` scripts:
3. Redirect all Python files to the new executable:

```plaintext
ftype Python.File=C:\Path\to\pythonw.exe "%1" %*
```
Additional modules

Even though Python aims to be portable among all platforms, there are features that are unique to Windows. A couple of modules, both in the standard library and external, and snippets exist to use these features.

The Windows-specific standard modules are documented in *MS Windows Specific Services*.

PyWin32

The PyWin32 module by Mark Hammond is a collection of modules for advanced Windows-specific support. This includes utilities for:

- Component Object Model (COM)
- Win32 API calls
- Registry
- Event log
- Microsoft Foundation Classes (MFC) user interfaces

PythonWin is a sample MFC application shipped with PyWin32. It is an embeddable IDE with a built-in debugger.

**Win32 How Do I...?**
by Tim Golden

**Python and COM**
by David and Paul Boddie

Py2exe
Py2exe is a `distutils` extension (see `Extending Distutils`) which wraps Python scripts into executable Windows programs (*.exe files). When you have done this, you can distribute your application without requiring your users to install Python.

**WConio**

Since Python's advanced terminal handling layer, `curses`, is restricted to Unix-like systems, there is a library exclusive to Windows as well: Windows Console I/O for Python.

*WConio* is a wrapper for Turbo-C's `CONIO.H`, used to create text user interfaces.
Compiling Python on Windows

If you want to compile CPython yourself, first thing you should do is get the source. You can download either the latest release’s source or just grab a fresh checkout.

For Microsoft Visual C++, which is the compiler with which official Python releases are built, the source tree contains solutions/project files. View the readme.txt in their respective directories:

<table>
<thead>
<tr>
<th>Directory</th>
<th>MSVC version</th>
<th>Visual Studio version</th>
</tr>
</thead>
<tbody>
<tr>
<td>PC/VC6/</td>
<td>6.0</td>
<td>97</td>
</tr>
<tr>
<td>PC/VS7.1/</td>
<td>7.1</td>
<td>2003</td>
</tr>
<tr>
<td>PC/VS8.0/</td>
<td>8.0</td>
<td>2005</td>
</tr>
<tr>
<td>PCbuild/</td>
<td>9.0</td>
<td>2008</td>
</tr>
</tbody>
</table>

Note that not all of these build directories are fully supported. Read the release notes to see which compiler version the official releases for your version are built with.

Check PC/readme.txt for general information on the build process.

For extension modules, consult Building C and C++ Extensions on Windows.

**Python Programming On Win32**

**A Python for Windows Tutorial**

by Amanda Birmingham, 2004
Using Python on a Macintosh

Author: Bob Savage <bobsavage@mac.com>

Python on a Macintosh running Mac OS X is in principle very similar to Python on any other Unix platform, but there are a number of additional features such as the IDE and the Package Manager that are worth pointing out.

The Mac-specific modules are documented in Mac OS X specific services.

Python on Mac OS 9 or earlier can be quite different from Python on Unix or Windows, but is beyond the scope of this manual, as that platform is no longer supported, starting with Python 2.4. See http://www.cwi.nl/~jack/macpython for installers for the latest 2.3 release for Mac OS 9 and related documentation.
Getting and Installing MacPython

Mac OS X 10.5 comes with Python 2.5.1 pre-installed by Apple. If you wish, you are invited to install the most recent version of Python from the Python website (http://www.python.org). A current “universal binary” build of Python, which runs natively on the Mac’s new Intel and legacy PPC CPU’s, is available there.

What you get after installing is a number of things:

- A MacPython 2.5 folder in your Applications folder. In here you find IDLE, the development environment that is a standard part of official Python distributions; PythonLauncher, which handles double-clicking Python scripts from the Finder; and the “Build Applet” tool, which allows you to package Python scripts as standalone applications on your system.
- A framework /Library/Frameworks/Python.framework, which includes the Python executable and libraries. The installer adds this location to your shell path. To uninstall MacPython, you can simply remove these three things. A symlink to the Python executable is placed in /usr/local/bin/.

The Apple-provided build of Python is installed in /System/Library/Frameworks/Python.framework and /usr/bin/python, respectively. You should never modify or delete these, as they are Apple-controlled and are used by Apple- or third-party software. Remember that if you choose to install a newer Python version from python.org, you will have two different but functional Python installations on your computer, so it will be important that your paths and usages are consistent with what you want to do.

IDLE includes a help menu that allows you to access Python
documentation. If you are completely new to Python you should start reading the tutorial introduction in that document.

If you are familiar with Python on other Unix platforms you should read the section on running Python scripts from the Unix shell.

How to run a Python script

Your best way to get started with Python on Mac OS X is through the IDLE integrated development environment, see section The IDE and use the Help menu when the IDE is running.

If you want to run Python scripts from the Terminal window command line or from the Finder you first need an editor to create your script. Mac OS X comes with a number of standard Unix command line editors, vim and emacs among them. If you want a more Mac-like editor, BBEdit or TextWrangler from Bare Bones Software (see http://www.barebones.com/products/bbedit/index.shtml) are good choices, as is TextMate (see http://macromates.com/). Other editors include Gvim (http://macvim.org) and Aquamacs (http://aquamacs.org).

To run your script from the Terminal window you must make sure that /usr/local/bin is in your shell search path.

To run your script from the Finder you have two options:

- Drag it to PythonLauncher
- Select PythonLauncher as the default application to open your script (or any .py script) through the finder Info window and double-click it. PythonLauncher has various preferences to control how your script is launched. Option-dragging allows you to change these for one invocation, or use its Preferences menu to change things globally.
Running scripts with a GUI

With older versions of Python, there is one Mac OS X quirk that you need to be aware of: programs that talk to the Aqua window manager (in other words, anything that has a GUI) need to be run in a special way. Use `pythonw` instead of `python` to start such scripts.

With Python 2.5, you can use either `python` or `pythonw`.

Configuration

Python on OS X honors all standard Unix environment variables such as `PYTHONPATH`, but setting these variables for programs started from the Finder is non-standard as the Finder does not read your `.profile` or `.cshrc` at startup. You need to create a file ~/.MacOSX/environment.plist. See Apple’s Technical Document QA1067 for details.

For more information on installation Python packages in MacPython, see section *Installing Additional Python Packages*. 
The IDE

MacPython ships with the standard IDLE development environment. A good introduction to using IDLE can be found at http://hkn.eecs.berkeley.edu/~dyoo/python/idle_intro/index.html.
Installing Additional Python Packages

There are several methods to install additional Python packages:

- [http://pythonmac.org/packages/](http://pythonmac.org/packages/) contains selected compiled packages for Python 2.5, 2.4, and 2.3.
- Packages can be installed via the standard Python distutils mode (`python setup.py install`).
- Many packages can also be installed via the `setuptools` extension.
GUI Programming on the Mac

There are several options for building GUI applications on the Mac with Python.

*PyObjC* is a Python binding to Apple’s Objective-C/Cocoa framework, which is the foundation of most modern Mac development. Information on PyObjC is available from [http://pyobjc.sourceforge.net](http://pyobjc.sourceforge.net).

The standard Python GUI toolkit is *Tkinter*, based on the cross-platform Tk toolkit ([http://www.tcl.tk](http://www.tcl.tk)). An Aqua-native version of Tk is bundled with OS X by Apple, and the latest version can be downloaded and installed from [http://www.activestate.com](http://www.activestate.com); it can also be built from source.

*wxPython* is another popular cross-platform GUI toolkit that runs natively on Mac OS X. Packages and documentation are available from [http://www.wxpython.org](http://www.wxpython.org).

*PyQt* is another popular cross-platform GUI toolkit that runs natively on Mac OS X. More information can be found at [http://www.riverbankcomputing.co.uk/pyqt/](http://www.riverbankcomputing.co.uk/pyqt/).
Distributing Python Applications on the Mac

The “Build Applet” tool that is placed in the MacPython 2.5 folder is fine for packaging small Python scripts on your own machine to run as a standard Mac application. This tool, however, is not robust enough to distribute Python applications to other users.

The standard tool for deploying standalone Python applications on the Mac is **py2app**. More information on installing and using py2app can be found at [http://undefined.org/python/#py2app](http://undefined.org/python/#py2app).
Python can also be used to script other Mac applications via Apple's Open Scripting Architecture (OSA); see http://appscript.sourceforge.net. Appscript is a high-level, user-friendly Apple event bridge that allows you to control scriptable Mac OS X applications using ordinary Python scripts. Appscript makes Python a serious alternative to Apple's own AppleScript language for automating your Mac. A related package, PyOSA, is an OSA language component for the Python scripting language, allowing Python code to be executed by any OSA-enabled application (Script Editor, Mail, iTunes, etc.). PyOSA makes Python a full peer to AppleScript.
Other Resources

The MacPython mailing list is an excellent support resource for Python users and developers on the Mac:

http://www.python.org/community/sigs/current/pythonmac-sig/

Another useful resource is the MacPython wiki:

http://wiki.python.org/moin/MacPython
Introduction

This reference manual describes the Python programming language. It is not intended as a tutorial.

While I am trying to be as precise as possible, I chose to use English rather than formal specifications for everything except syntax and lexical analysis. This should make the document more understandable to the average reader, but will leave room for ambiguities. Consequently, if you were coming from Mars and tried to re-implement Python from this document alone, you might have to guess things and in fact you would probably end up implementing quite a different language. On the other hand, if you are using Python and wonder what the precise rules about a particular area of the language are, you should definitely be able to find them here. If you would like to see a more formal definition of the language, maybe you could volunteer your time — or invent a cloning machine :-).

It is dangerous to add too many implementation details to a language reference document — the implementation may change, and other implementations of the same language may work differently. On the other hand, there is currently only one Python implementation in widespread use (although alternate implementations exist), and its particular quirks are sometimes worth being mentioned, especially where the implementation imposes additional limitations. Therefore, you’ll find short “implementation notes” sprinkled throughout the text.

Every Python implementation comes with a number of built-in and standard modules. These are documented in The Python Standard Library. A few built-in modules are mentioned when they interact in a significant way with the language definition.
Alternate Implementations

Though there is one Python implementation which is by far the most popular, there are some alternate implementations which are of particular interest to different audiences.

Known implementations include:

CPython
This is the original and most-maintained implementation of Python, written in C. New language features generally appear here first.

Jython
Python implemented in Java. This implementation can be used as a scripting language for Java applications, or can be used to create applications using the Java class libraries. It is also often used to create tests for Java libraries. More information can be found at the Jython website.

Python for .NET
This implementation actually uses the CPython implementation, but is a managed .NET application and makes .NET libraries available. It was created by Brian Lloyd. For more information, see the Python for .NET home page.

IronPython
An alternate Python for .NET. Unlike Python.NET, this is a complete Python implementation that generates IL, and compiles Python code directly to .NET assemblies. It was created by Jim Hugunin, the original creator of Jython. For more information, see the IronPython website.

PyPy
An implementation of Python written in Python; even the bytecode interpreter is written in Python. This is executed using
CPython as the underlying interpreter. One of the goals of the project is to encourage experimentation with the language itself by making it easier to modify the interpreter (since it is written in Python). Additional information is available on the PyPy project's home page.

Each of these implementations varies in some way from the language as documented in this manual, or introduces specific information beyond what's covered in the standard Python documentation. Please refer to the implementation-specific documentation to determine what else you need to know about the specific implementation you're using.
The descriptions of lexical analysis and syntax use a modified BNF grammar notation. This uses the following style of definition:

```plaintext
name ::= lc_letter (lc_letter | "_")*
lc_letter ::= "a"..."z"
```

The first line says that a `name` is an `lc_letter` followed by a sequence of zero or more `lc_letter`s and underscores. An `lc_letter` in turn is any of the single characters 'a' through 'z'. (This rule is actually adhered to for the names defined in lexical and grammar rules in this document.)

Each rule begins with a name (which is the name defined by the rule) and ::=. A vertical bar (|) is used to separate alternatives; it is the least binding operator in this notation. A star (*) means zero or more repetitions of the preceding item; likewise, a plus (+) means one or more repetitions, and a phrase enclosed in square brackets ([ ]]) means zero or one occurrences (in other words, the enclosed phrase is optional). The * and + operators bind as tightly as possible; parentheses are used for grouping. Literal strings are enclosed in quotes. White space is only meaningful to separate tokens. Rules are normally contained on a single line; rules with many alternatives may be formatted alternatively with each line after the first beginning with a vertical bar.

In lexical definitions (as the example above), two more conventions are used: Two literal characters separated by three dots mean a choice of any single character in the given (inclusive) range of ASCII characters. A phrase between angular brackets (<...>) gives an informal description of the symbol defined; e.g., this could be used to describe the notion of ‘control character’ if needed.
Even though the notation used is almost the same, there is a big difference between the meaning of lexical and syntactic definitions: a lexical definition operates on the individual characters of the input source, while a syntax definition operates on the stream of tokens generated by the lexical analysis. All uses of BNF in the next chapter (“Lexical Analysis”) are lexical definitions; uses in subsequent chapters are syntactic definitions.
Lexical analysis

A Python program is read by a parser. Input to the parser is a stream of tokens, generated by the lexical analyzer. This chapter describes how the lexical analyzer breaks a file into tokens.

Python uses the 7-bit ASCII character set for program text.

*New in version 2.3:* An encoding declaration can be used to indicate that string literals and comments use an encoding different from ASCII.

For compatibility with older versions, Python only warns if it finds 8-bit characters; those warnings should be corrected by either declaring an explicit encoding, or using escape sequences if those bytes are binary data, instead of characters.

The run-time character set depends on the I/O devices connected to the program but is generally a superset of ASCII.

**Future compatibility note:** It may be tempting to assume that the character set for 8-bit characters is ISO Latin-1 (an ASCII superset that covers most western languages that use the Latin alphabet), but it is possible that in the future Unicode text editors will become common. These generally use the UTF-8 encoding, which is also an ASCII superset, but with very different use for the characters with ordinals 128-255. While there is no consensus on this subject yet, it is unwise to assume either Latin-1 or UTF-8, even though the current implementation appears to favor Latin-1. This applies both to the source character set and the run-time character set.
A Python program is divided into a number of *logical lines*.

**Logical lines**

The end of a logical line is represented by the token NEWLINE. Statements cannot cross logical line boundaries except where NEWLINE is allowed by the syntax (e.g., between statements in compound statements). A logical line is constructed from one or more *physical lines* by following the explicit or implicit *line joining* rules.

**Physical lines**

A physical line is a sequence of characters terminated by an end-of-line sequence. In source files, any of the standard platform line termination sequences can be used - the Unix form using ASCII LF (linefeed), the Windows form using the ASCII sequence CR LF (return followed by linefeed), or the old Macintosh form using the ASCII CR (return) character. All of these forms can be used equally, regardless of platform.

When embedding Python, source code strings should be passed to Python APIs using the standard C conventions for newline characters (the \n character, representing ASCII LF, is the line terminator).

**Comments**

A comment starts with a hash character (#) that is not part of a string literal, and ends at the end of the physical line. A comment signifies the end of the logical line unless the implicit line joining rules are
invoked. Comments are ignored by the syntax; they are not tokens.

Encoding declarations

If a comment in the first or second line of the Python script matches the regular expression `coding[:=:]\s*([-\w.]+)`, this comment is processed as an encoding declaration; the first group of this expression names the encoding of the source code file. The recommended forms of this expression are

```
# -*- coding: <encoding-name> -*-
```

which is recognized also by GNU Emacs, and

```
# vim:fileencoding=<encoding-name>
```

which is recognized by Bram Moolenaar’s VIM. In addition, if the first bytes of the file are the UTF-8 byte-order mark (`\xef\xbb\xbf`), the declared file encoding is UTF-8 (this is supported, among others, by Microsoft’s notepad).

If an encoding is declared, the encoding name must be recognized by Python. The encoding is used for all lexical analysis, in particular to find the end of a string, and to interpret the contents of Unicode literals. String literals are converted to Unicode for syntactical analysis, then converted back to their original encoding before interpretation starts. The encoding declaration must appear on a line of its own.

Explicit line joining

Two or more physical lines may be joined into logical lines using backslash characters (`\`), as follows: when a physical line ends in a backslash that is not part of a string literal or comment, it is joined
with the following forming a single logical line, deleting the backslash and the following end-of-line character. For example:

```python
if 1900 < year < 2100 and 1 <= month <= 12 \
    and 1 <= day <= 31 and 0 <= hour < 24 \
    and 0 <= minute < 60 and 0 <= second < 60:  # Looks like a
    return 1
```

A line ending in a backslash cannot carry a comment. A backslash does not continue a comment. A backslash does not continue a token except for string literals (i.e., tokens other than string literals cannot be split across physical lines using a backslash). A backslash is illegal elsewhere on a line outside a string literal.

### Implicit line joining

Expressions in parentheses, square brackets or curly braces can be split over more than one physical line without using backslashes. For example:

```python
month_names = ['Januari', 'Februari', 'Maart',       # These are
               'April', 'Mei', 'Juni',          # Dutch nam
               'Juli', 'Augustus', 'September', # for the m
               'Oktober', 'November', 'December'] # of the ye
```

Implicitly continued lines can carry comments. The indentation of the continuation lines is not important. Blank continuation lines are allowed. There is no NEWLINE token between implicit continuation lines. Implicitly continued lines can also occur within triple-quoted strings (see below); in that case they cannot carry comments.

### Blank lines

A logical line that contains only spaces, tabs, formfeeds and possibly a comment, is ignored (i.e., no NEWLINE token is generated).
During interactive input of statements, handling of a blank line may differ depending on the implementation of the read-eval-print loop. In the standard implementation, an entirely blank logical line (i.e. one containing not even whitespace or a comment) terminates a multi-line statement.

## Indentation

Leading whitespace (spaces and tabs) at the beginning of a logical line is used to compute the indentation level of the line, which in turn is used to determine the grouping of statements.

First, tabs are replaced (from left to right) by one to eight spaces such that the total number of characters up to and including the replacement is a multiple of eight (this is intended to be the same rule as used by Unix). The total number of spaces preceding the first non-blank character then determines the line’s indentation. Indentation cannot be split over multiple physical lines using backslashes; the whitespace up to the first backslash determines the indentation.

**Cross-platform compatibility note:** because of the nature of text editors on non-UNIX platforms, it is unwise to use a mixture of spaces and tabs for the indentation in a single source file. It should also be noted that different platforms may explicitly limit the maximum indentation level.

A formfeed character may be present at the start of the line; it will be ignored for the indentation calculations above. Formfeed characters occurring elsewhere in the leading whitespace have an undefined effect (for instance, they may reset the space count to zero).

The indentation levels of consecutive lines are used to generate INDENT and DEDENT tokens, using a stack, as follows.
Before the first line of the file is read, a single zero is pushed on the stack; this will never be popped off again. The numbers pushed on the stack will always be strictly increasing from bottom to top. At the beginning of each logical line, the line's indentation level is compared to the top of the stack. If it is equal, nothing happens. If it is larger, it is pushed on the stack, and one INDENT token is generated. If it is smaller, it must be one of the numbers occurring on the stack; all numbers on the stack that are larger are popped off, and for each number popped off a DEDENT token is generated. At the end of the file, a DEDENT token is generated for each number remaining on the stack that is larger than zero.

Here is an example of a correctly (though confusingly) indented piece of Python code:

```python
def perm(l):
    # Compute the list of all permutations of l
    if len(l) <= 1:
        return [l]
    r = []
    for i in range(len(l)):
        s = l[:i] + l[i+1:]
        p = perm(s)
        for x in p:
            r.append(l[i:i+1] + x)
    return r
```

The following example shows various indentation errors:

```python
def perm(l):
    for i in range(len(l)):
        s = l[:i] + l[i+1:]
        p = perm(l[:i] + l[i+1:]) # error: unexpected indent
        for x in p:
            r.append(l[i:i+1] + x)
    return r # error: inconsistent dedent
```

(Actually, the first three errors are detected by the parser; only the last error is found by the lexical analyzer — the indentation of return
Except at the beginning of a logical line or in string literals, the whitespace characters space, tab and formfeed can be used interchangeably to separate tokens. Whitespace is needed between two tokens only if their concatenation could otherwise be interpreted as a different token (e.g., ab is one token, but a b is two tokens).
Other tokens

Besides NEWLINE, INDENT and DEDENT, the following categories of tokens exist: identifiers, keywords, literals, operators, and delimiters. Whitespace characters (other than line terminators, discussed earlier) are not tokens, but serve to delimit tokens. Where ambiguity exists, a token comprises the longest possible string that forms a legal token, when read from left to right.
Identifiers and keywords

Identifiers (also referred to as names) are described by the following lexical definitions:

```
identifier ::= (letter|"_") (letter | digit | ")*''
letter ::= lowercase | uppercase
lowercase ::= "a"..."z"
uppercase ::= "A"..."Z"
digit ::= "0"..."9"
```

Identifiers are unlimited in length. Case is significant.

Keywords

The following identifiers are used as reserved words, or keywords of the language, and cannot be used as ordinary identifiers. They must be spelled exactly as written here:

```
and del from not while
as elif global or with
assert else if pass yield
break except import print
class exec in raise
continue finally is return
def for lambda try
```

*Changed in version 2.4:* None became a constant and is now recognized by the compiler as a name for the built-in object None. Although it is not a keyword, you cannot assign a different object to it.

*Changed in version 2.5:* Both as and with are only recognized when the with_statement future feature has been enabled. It will always be enabled in Python 2.6. See section The with statement for details. Note that using as and with as identifiers will always issue a
warning, even when the `with_statement` future directive is not in effect.

Reserved classes of identifiers

Certain classes of identifiers (besides keywords) have special meanings. These classes are identified by the patterns of leading and trailing underscore characters:

```python
_ *
```

Not imported by `from module import *`. The special identifier `_` is used in the interactive interpreter to store the result of the last evaluation; it is stored in the `__builtin__` module. When not in interactive mode, `_` has no special meaning and is not defined. See section *The import statement*.

**Note:** The name `_` is often used in conjunction with internationalization; refer to the documentation for the `gettext` module for more information on this convention.

```python
__*__
```

System-defined names. These names are defined by the interpreter and its implementation (including the standard library); applications should not expect to define additional names using this convention. The set of names of this class defined by Python may be extended in future versions. See section *Special method names*.

```python
__*__
```

Class-private names. Names in this category, when used within the context of a class definition, are re-written to use a mangled form to help avoid name clashes between “private” attributes of base and derived classes. See section *Identifiers (Names)*.
## Literals

Literals are notations for constant values of some built-in types.

### String literals

String literals are described by the following lexical definitions:

<table>
<thead>
<tr>
<th>Grammar Symbol</th>
<th>Definition</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>stringliteral</code></td>
<td>`[stringprefix](shortstring</td>
</tr>
<tr>
<td><code>stringprefix</code></td>
<td>&quot;r&quot;</td>
</tr>
<tr>
<td><code>shortstring</code></td>
<td>&quot;&quot; shortstringitem* &quot;&quot;</td>
</tr>
<tr>
<td><code>longstring</code></td>

</tr>
</tbody>
</table>

One syntactic restriction not indicated by these productions is that whitespace is not allowed between the `stringprefix` and the rest of the string literal. The source character set is defined by the encoding declaration; it is ASCII if no encoding declaration is given in the source file; see section *Encoding declarations*.

In plain English: String literals can be enclosed in matching single quotes (') or double quotes ("). They can also be enclosed in matching groups of three single or double quotes (these are generally referred to as *triple-quoted strings*). The backslash (\) character is used to escape characters that otherwise have a special meaning, such as newline, backslash itself, or the quote character. String literals may optionally be prefixed with a letter 'r' or 'R'; such strings are called *raw strings* and use different rules for interpreting backslash escape sequences. A prefix of 'u' or 'U' makes the string a Unicode string. Unicode strings use the Unicode
character set as defined by the Unicode Consortium and ISO 10646. Some additional escape sequences, described below, are available in Unicode strings. The two prefix characters may be combined; in this case, 'u' must appear before 'r'.

In triple-quoted strings, unescaped newlines and quotes are allowed (and are retained), except that three unescaped quotes in a row terminate the string. (A “quote” is the character used to open the string, i.e. either ' or ").

Unless an 'r' or 'R' prefix is present, escape sequences in strings are interpreted according to rules similar to those used by Standard C. The recognized escape sequences are:

<table>

</tr>
</tbody>
</table>
Notes:

1. Individual code units which form parts of a surrogate pair can be encoded using this escape sequence.
2. Any Unicode character can be encoded this way, but characters outside the Basic Multilingual Plane (BMP) will be encoded using a surrogate pair if Python is compiled to use 16-bit code units (the default). Individual code units which form parts of a surrogate pair can be encoded using this escape sequence.
3. As in Standard C, up to three octal digits are accepted.
4. Unlike in Standard C, exactly two hex digits are required.
5. In a string literal, hexadecimal and octal escapes denote the byte with the given value; it is not necessary that the byte encodes a character in the source character set. In a Unicode literal, these escapes denote a Unicode character with the given value.

Unlike Standard C, all unrecognized escape sequences are left in the string unchanged, i.e., *the backslash is left in the string*. (This behavior is useful when debugging: if an escape sequence is mistyped, the resulting output is more easily recognized as broken.) It is also important to note that the escape sequences marked as “(Unicode only)” in the table above fall into the category of unrecognized escapes for non-Unicode string literals.

When an `'r'` or `'R'` prefix is present, a character following a backslash is included in the string without change, and *all backslashes are left in the string*. For example, the string literal `r"\n"` consists of two characters: a backslash and a lowercase `\n`. String quotes can be escaped with a backslash, but the backslash remains in the string; for example, `r"\""` is a valid string literal consisting of two characters: a backslash and a double quote; `r"\"` is not a valid string literal (even a raw string cannot end in an odd number of
backslashes). Specifically, a *raw string cannot end in a single backslash* (since the backslash would escape the following quote character). Note also that a single backslash followed by a newline is interpreted as those two characters as part of the string, *not* as a line continuation.

When an `r` or `R` prefix is used in conjunction with a `u` or `U` prefix, then the \uXXXX and \uxxxxxxxx escape sequences are processed while *all other backslashes are left in the string*. For example, the string literal ur'"\u0062\n" consists of three Unicode characters: ‘LATIN SMALL LETTER B’, ‘REVERSE SOLIDUS’, and ‘LATIN SMALL LETTER N’. Backslashes can be escaped with a preceding backslash; however, both remain in the string. As a result, \uxxxx escape sequences are only recognized when there are an odd number of backslashes.

### String literal concatenation

Multiple adjacent string literals (delimited by whitespace), possibly using different quoting conventions, are allowed, and their meaning is the same as their concatenation. Thus, "hello" 'world' is equivalent to "helloworld". This feature can be used to reduce the number of backslashes needed, to split long strings conveniently across long lines, or even to add comments to parts of strings, for example:

```python
re.compile("[A-Za-z_]"  # letter or underscore
           "[A-Za-z0-9_]*")   # letter, digit or underscore
)
```

Note that this feature is defined at the syntactical level, but implemented at compile time. The `+` operator must be used to concatenate string expressions at run time. Also note that literal concatenation can use different quoting styles for each component (even mixing raw strings and triple quoted strings).
Numeric literals

There are four types of numeric literals: plain integers, long integers, floating point numbers, and imaginary numbers. There are no complex literals (complex numbers can be formed by adding a real number and an imaginary number).

Note that numeric literals do not include a sign; a phrase like `-1` is actually an expression composed of the unary operator `-' and the literal `1`.

Integer and long integer literals

Integer and long integer literals are described by the following lexical definitions:

```
longinteger ::= integer ("l" | "L")
integer ::= decimalinteger | octinteger | hexinteger
decimalinteger ::= nonzerodigit digit* | "0"
octinteger ::= "0" octdigit+
hexinteger ::= "0" ("x" | "X") hexdigit+
nonzerodigit ::= "1"..."9"
ocdigit ::= "0"..."7"
hexdigit ::= digit | "a"..."f" | "A"..."F"
```

Although both lower case `l` and upper case `L` are allowed as suffix for long integers, it is strongly recommended to always use `L`, since the letter `l` looks too much like the digit `1`.

Plain integer literals that are above the largest representable plain integer (e.g., 2147483647 when using 32-bit arithmetic) are accepted as if they were long integers instead. [1] There is no limit for long integer literals apart from what can be stored in available memory.

Some examples of plain integer literals (first row) and long integer
Floating point literals

Floating point literals are described by the following lexical definitions:

```
floatnumber ::= pointfloat | exponentfloat
pointfloat ::= [intpart] fraction | intpart "."
exponentfloat ::= (intpart | pointfloat) exponent
intpart ::= digit+
fraction ::= "." digit+
exponent ::= ("e" | "E") ["+" | "-"] digit+
```

Note that the integer and exponent parts of floating point numbers can look like octal integers, but are interpreted using radix 10. For example, 077e010 is legal, and denotes the same number as 77e10. The allowed range of floating point literals is implementation-dependent. Some examples of floating point literals:

```
3.14  10.  .001  1e100  3.14e-10  0e0
```

Note that numeric literals do not include a sign; a phrase like -1 is actually an expression composed of the unary operator - and the literal 1.

Imaginary literals

Imaginary literals are described by the following lexical definitions:

```
imagnumber ::= (floatnumber | intpart) ("j" | "J")
```

An imaginary literal yields a complex number with a real part of 0.0.
Complex numbers are represented as a pair of floating point numbers and have the same restrictions on their range. To create a complex number with a nonzero real part, add a floating point number to it, e.g., \((3+4j)\). Some examples of imaginary literals:

| 3.14j | 10.j | 10j | .001j | 1e100j | 3.14e-10j |
Operators

The following tokens are operators:

<table>
<thead>
<tr>
<th>+</th>
<th>-</th>
<th>*</th>
<th>**</th>
<th>/</th>
<th>//</th>
<th>%</th>
</tr>
</thead>
<tbody>
<tr>
<td>&lt;&lt;</td>
<td>&gt;&gt;</td>
<td>&amp;</td>
<td></td>
<td></td>
<td>^</td>
<td>~</td>
</tr>
<tr>
<td>&lt;</td>
<td>&gt;</td>
<td>&lt;=</td>
<td>&gt;=</td>
<td>==</td>
<td>!=</td>
<td>&lt;&gt;</td>
</tr>
</tbody>
</table>

The comparison operators `<>` and `!=` are alternate spellings of the same operator. `!=` is the preferred spelling; `<>` is obsolescent.
Delimiters

The following tokens serve as delimiters in the grammar:

(   )   [   ]   {   }   @
,   :   .   \   =   ;
+=  -=  *=  /=  //=  %=  
&=  |=  ^=  >>=  <<=  **=

The period can also occur in floating-point and imaginary literals. A sequence of three periods has a special meaning as an ellipsis in slices. The second half of the list, the augmented assignment operators, serve lexically as delimiters, but also perform an operation.

The following printing ASCII characters have special meaning as part of other tokens or are otherwise significant to the lexical analyzer:

'   "   #   \ 

The following printing ASCII characters are not used in Python. Their occurrence outside string literals and comments is an unconditional error:

$   ?

Footnotes

In versions of Python prior to 2.4, octal and hexadecimal literals in the range just above the largest representable plain integer but below the largest unsigned 32-bit number (on a machine using 32-bit arithmetic), 4294967296, were taken as the negative plain integer obtained by subtracting 4294967296 from their unsigned value.

[1]
The Python Language Reference
Data model
Objects are Python’s abstraction for data. All data in a Python program is represented by objects or by relations between objects. (In a sense, and in conformance to Von Neumann’s model of a “stored program computer,” code is also represented by objects.)

Every object has an identity, a type and a value. An object’s identity never changes once it has been created; you may think of it as the object’s address in memory. The ‘is’ operator compares the identity of two objects; the id() function returns an integer representing its identity (currently implemented as its address). An object’s type is also unchangeable. An object’s type determines the operations that the object supports (e.g., “does it have a length?”) and also defines the possible values for objects of that type. The type() function returns an object’s type (which is an object itself). The value of some objects can change. Objects whose value can change are said to be mutable; objects whose value is unchangeable once they are created are called immutable. (The value of an immutable container object that contains a reference to a mutable object can change when the latter’s value is changed; however the container is still considered immutable, because the collection of objects it contains cannot be changed. So, immutability is not strictly the same as having an unchangeable value, it is more subtle.) An object’s mutability is determined by its type; for instance, numbers, strings and tuples are immutable, while dictionaries and lists are mutable.

Objects are never explicitly destroyed; however, when they become unreachable they may be garbage-collected. An implementation is allowed to postpone garbage collection or omit it altogether — it is a matter of implementation quality how garbage collection is implemented, as long as no objects are collected that are still reachable. (Implementation note: the current implementation uses a
reference-counting scheme with (optional) delayed detection of cyclically linked garbage, which collects most objects as soon as they become unreachable, but is not guaranteed to collect garbage containing circular references. See the documentation of the gc module for information on controlling the collection of cyclic garbage.)

Note that the use of the implementation’s tracing or debugging facilities may keep objects alive that would normally be collectable. Also note that catching an exception with a ‘try...except‘ statement may keep objects alive.

Some objects contain references to “external” resources such as open files or windows. It is understood that these resources are freed when the object is garbage-collected, but since garbage collection is not guaranteed to happen, such objects also provide an explicit way to release the external resource, usually a close() method. Programs are strongly recommended to explicitly close such objects. The ‘try...finally‘ statement provides a convenient way to do this.

Some objects contain references to other objects; these are called containers. Examples of containers are tuples, lists and dictionaries. The references are part of a container’s value. In most cases, when we talk about the value of a container, we imply the values, not the identities of the contained objects; however, when we talk about the mutability of a container, only the identities of the immediately contained objects are implied. So, if an immutable container (like a tuple) contains a reference to a mutable object, its value changes if that mutable object is changed.

Types affect almost all aspects of object behavior. Even the importance of object identity is affected in some sense: for immutable types, operations that compute new values may actually return a reference to any existing object with the same type and
value, while for mutable objects this is not allowed. E.g., after `a = 1; b = 1`, `a` and `b` may or may not refer to the same object with the value one, depending on the implementation, but after `c = []; d = []`, `c` and `d` are guaranteed to refer to two different, unique, newly created empty lists. (Note that `c = d = []` assigns the same object to both `c` and `d`.)
The standard type hierarchy

Below is a list of the types that are built into Python. Extension modules (written in C, Java, or other languages, depending on the implementation) can define additional types. Future versions of Python may add types to the type hierarchy (e.g., rational numbers, efficiently stored arrays of integers, etc.).

Some of the type descriptions below contain a paragraph listing ‘special attributes.’ These are attributes that provide access to the implementation and are not intended for general use. Their definition may change in the future.

None

This type has a single value. There is a single object with this value. This object is accessed through the built-in name `None`. It is used to signify the absence of a value in many situations, e.g., it is returned from functions that don’t explicitly return anything. Its truth value is false.

NotImplemented

This type has a single value. There is a single object with this value. This object is accessed through the built-in name `NotImplemented`. Numeric methods and rich comparison methods may return this value if they do not implement the operation for the operands provided. (The interpreter will then try the reflected operation, or some other fallback, depending on the operator.) Its truth value is true.

Ellipsis

This type has a single value. There is a single object with this value. This object is accessed through the built-in name `Ellipsis`. It is used to indicate the presence of the `...` syntax in
a slice. Its truth value is true.

**numbers.Number**

These are created by numeric literals and returned as results by arithmetic operators and arithmetic built-in functions. Numeric objects are immutable; once created their value never changes. Python numbers are of course strongly related to mathematical numbers, but subject to the limitations of numerical representation in computers.

Python distinguishes between integers, floating point numbers, and complex numbers:

**numbers.Integral**

These represent elements from the mathematical set of integers (positive and negative).

There are three types of integers:

Plain integers

These represent numbers in the range -2147483648 through 2147483647. (The range may be larger on machines with a larger natural word size, but not smaller.) When the result of an operation would fall outside this range, the result is normally returned as a long integer (in some cases, the exception `OverflowError` is raised instead). For the purpose of shift and mask operations, integers are assumed to have a binary, 2’s complement notation using 32 or more bits, and hiding no bits from the user (i.e., all 4294967296 different bit patterns correspond to different values).

Long integers

These represent numbers in an unlimited range, subject to available (virtual) memory only. For the purpose of shift
and mask operations, a binary representation is assumed, and negative numbers are represented in a variant of 2’s complement which gives the illusion of an infinite string of sign bits extending to the left.

Booleans

These represent the truth values False and True. The two objects representing the values False and True are the only Boolean objects. The Boolean type is a subtype of plain integers, and Boolean values behave like the values 0 and 1, respectively, in almost all contexts, the exception being that when converted to a string, the strings "False" or "True" are returned, respectively.

The rules for integer representation are intended to give the most meaningful interpretation of shift and mask operations involving negative integers and the least surprises when switching between the plain and long integer domains. Any operation, if it yields a result in the plain integer domain, will yield the same result in the long integer domain or when using mixed operands. The switch between domains is transparent to the programmer.

numbers.Real (float)

These represent machine-level double precision floating point numbers. You are at the mercy of the underlying machine architecture (and C or Java implementation) for the accepted range and handling of overflow. Python does not support single-precision floating point numbers; the savings in processor and memory usage that are usually the reason for using these is dwarfed by the overhead of using objects in Python, so there is no reason to complicate the language with two kinds of floating point numbers.
numbers.Complex

These represent complex numbers as a pair of machine-level double precision floating point numbers. The same caveats apply as for floating point numbers. The real and imaginary parts of a complex number \( z \) can be retrieved through the read-only attributes \( z.real \) and \( z.imag \).

Sequences
These represent finite ordered sets indexed by non-negative numbers. The built-in function \( \text{len()} \) returns the number of items of a sequence. When the length of a sequence is \( n \), the index set contains the numbers 0, 1, ..., \( n-1 \). Item \( i \) of sequence \( a \) is selected by \( a[i] \).

Sequences also support slicing: \( a[i:j] \) selects all items with index \( k \) such that \( i \leq k < j \). When used as an expression, a slice is a sequence of the same type. This implies that the index set is renumbered so that it starts at 0.

Some sequences also support “extended slicing” with a third “step” parameter: \( a[i:j:k] \) selects all items of \( a \) with index \( x \) where \( x = i + n*k, n \geq 0 \) and \( i \leq x < j \).

Sequences are distinguished according to their mutability:

Immutable sequences
An object of an immutable sequence type cannot change once it is created. (If the object contains references to other objects, these other objects may be mutable and may be changed; however, the collection of objects directly referenced by an immutable object cannot change.)

The following types are immutable sequences:

Strings
The items of a string are characters. There is no separate character type; a character is represented by a string of one item. Characters represent (at least) 8-bit bytes. The built-in functions \texttt{chr()} and \texttt{ord()} convert between characters and nonnegative integers representing the byte values. Bytes with the values 0-127 usually represent the corresponding ASCII values, but the interpretation of values is up to the program. The string data type is also used to represent arrays of bytes, e.g., to hold data read from a file.

(On systems whose native character set is not ASCII, strings may use EBCDIC in their internal representation, provided the functions \texttt{chr()} and \texttt{ord()} implement a mapping between ASCII and EBCDIC, and string comparison preserves the ASCII order. Or perhaps someone can propose a better rule?)

Unicode

The items of a Unicode object are Unicode code units. A Unicode code unit is represented by a Unicode object of one item and can hold either a 16-bit or 32-bit value representing a Unicode ordinal (the maximum value for the ordinal is given in \texttt{sys.maxunicode}, and depends on how Python is configured at compile time). Surrogate pairs may be present in the Unicode object, and will be reported as two separate items. The built-in functions \texttt{unichr()} and \texttt{ord()} convert between code units and nonnegative integers representing the Unicode ordinals as defined in the Unicode Standard 3.0. Conversion from and to other encodings are possible through the Unicode method \texttt{encode()} and the built-in function \texttt{unicode()}.

Tuples
The items of a tuple are arbitrary Python objects. Tuples of two or more items are formed by comma-separated lists of expressions. A tuple of one item (a ‘singleton’) can be formed by affixing a comma to an expression (an expression by itself does not create a tuple, since parentheses must be usable for grouping of expressions). An empty tuple can be formed by an empty pair of parentheses.

Mutable sequences
Mutable sequences can be changed after they are created. The subscription and slicing notations can be used as the target of assignment and `del` (delete) statements.

There is currently a single intrinsic mutable sequence type:

Lists
The items of a list are arbitrary Python objects. Lists are formed by placing a comma-separated list of expressions in square brackets. (Note that there are no special cases needed to form lists of length 0 or 1.)

The extension module `array` provides an additional example of a mutable sequence type.

Set types
These represent unordered, finite sets of unique, immutable objects. As such, they cannot be indexed by any subscript. However, they can be iterated over, and the built-in function `len()` returns the number of items in a set. Common uses for sets are fast membership testing, removing duplicates from a sequence, and computing mathematical operations such as intersection, union, difference, and symmetric difference.

For set elements, the same immutability rules apply as for
dictionary keys. Note that numeric types obey the normal rules for numeric comparison: if two numbers compare equal (e.g., 1 and 1.0), only one of them can be contained in a set.

There are currently two intrinsic set types:

Sets
These represent a mutable set. They are created by the built-in `set()` constructor and can be modified afterwards by several methods, such as `add()`.

Frozen sets
These represent an immutable set. They are created by the built-in `frozenset()` constructor. As a frozenset is immutable and `hashable`, it can be used again as an element of another set, or as a dictionary key.

Mappings
These represent finite sets of objects indexed by arbitrary index sets. The subscript notation `a[k]` selects the item indexed by `k` from the mapping `a`; this can be used in expressions and as the target of assignments or `del` statements. The built-in function `len()` returns the number of items in a mapping.

There is currently a single intrinsic mapping type:

Dictionaries
These represent finite sets of objects indexed by nearly arbitrary values. The only types of values not acceptable as keys are values containing lists or dictionaries or other mutable types that are compared by value rather than by object identity, the reason being that the efficient implementation of dictionaries requires a key's hash value to remain constant. Numeric types used for keys obey the
normal rules for numeric comparison: if two numbers compare equal (e.g., 1 and 1.0) then they can be used interchangeably to index the same dictionary entry.

Dictionaries are mutable; they can be created by the {...} notation (see section Dictionary displays).

The extension modules dbm, gdbm, and bsddb provide additional examples of mapping types.

Callable types
These are the types to which the function call operation (see section Calls) can be applied:

User-defined functions
A user-defined function object is created by a function definition (see section Function definitions). It should be called with an argument list containing the same number of items as the function’s formal parameter list.

Special attributes:

<table>
<thead>
<tr>
<th>Attribute</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>func_doc</td>
<td>The function’s documentation string, or None if unavailable</td>
</tr>
<tr>
<td><strong>doc</strong></td>
<td>Another way of spelling func_doc</td>
</tr>
<tr>
<td>func_name</td>
<td>The function’s name</td>
</tr>
<tr>
<td><strong>name</strong></td>
<td>Another way of spelling func_name</td>
</tr>
<tr>
<td><strong>module</strong></td>
<td>The name of the module the function was defined in, or None if unavailable.</td>
</tr>
</tbody>
</table>

A tuple containing default argument values for those
<table>
<thead>
<tr>
<th>func_defaults</th>
<th>arguments that have defaults, or None if no arguments have a default value</th>
<th>Writable</th>
</tr>
</thead>
<tbody>
<tr>
<td>func_code</td>
<td>The code object representing the compiled function body.</td>
<td>Writable</td>
</tr>
<tr>
<td>func_globals</td>
<td>A reference to the dictionary that holds the function's global variables — the global namespace of the module in which the function was defined.</td>
<td>Read-only</td>
</tr>
<tr>
<td>func_dict</td>
<td>The namespace supporting arbitrary function attributes.</td>
<td>Writable</td>
</tr>
<tr>
<td>func_closure</td>
<td>None or a tuple of cells that contain bindings for the function's free variables.</td>
<td>Read-only</td>
</tr>
</tbody>
</table>

Most of the attributes labelled “Writable” check the type of the assigned value.

*Changed in version 2.4: `func_name` is now writable.*

Function objects also support getting and setting arbitrary attributes, which can be used, for example, to attach metadata to functions. Regular attribute dot-notation is used to get and set such attributes. *Note that the current implementation only supports function attributes on user-defined functions. Function attributes on built-in functions may be supported in the future.*

Additional information about a function's definition can be retrieved from its code object; see the description of internal types below.

User-defined methods
A user-defined method object combines a class, a class instance (or None) and any callable object (normally a user-defined function).

Special read-only attributes: \texttt{im\_self} is the class instance object, \texttt{im\_func} is the function object; \texttt{im\_class} is the class of \texttt{im\_self} for bound methods or the class that asked for the method for unbound methods; \texttt{\_doc\_} is the method's documentation (same as \texttt{im\_func.\_doc\_}); \texttt{\_name\_} is the method name (same as \texttt{im\_func.\_name\_}); \texttt{\_module\_} is the name of the module the method was defined in, or None if unavailable.

\textit{Changed in version 2.2}: \texttt{im\_self} used to refer to the class that defined the method.

\textit{Changed in version 2.6}: For 3.0 forward-compatibility, \texttt{im\_func} is also available as \texttt{\_func\_}, and \texttt{im\_self} as \texttt{\_self\_}.

Methods also support accessing (but not setting) the arbitrary function attributes on the underlying function object.

User-defined method objects may be created when getting an attribute of a class (perhaps via an instance of that class), if that attribute is a user-defined function object, an unbound user-defined method object, or a class method object. When the attribute is a user-defined method object, a new method object is only created if the class from which it is being retrieved is the same as, or a derived class of, the class stored in the original method object; otherwise, the original method object is used as it is.

When a user-defined method object is created by retrieving a user-defined function object from a class, its \texttt{im\_self} attribute
is None and the method object is said to be unbound. When one is created by retrieving a user-defined function object from a class via one of its instances, its im_self attribute is the instance, and the method object is said to be bound. In either case, the new method's im_class attribute is the class from which the retrieval takes place, and its im_func attribute is the original function object.

When a user-defined method object is created by retrieving another method object from a class or instance, the behaviour is the same as for a function object, except that the im_func attribute of the new instance is not the original method object but its im_func attribute.

When a user-defined method object is created by retrieving a class method object from a class or instance, its im_self attribute is the class itself (the same as the im_class attribute), and its im_func attribute is the function object underlying the class method.

When an unbound user-defined method object is called, the underlying function (im_func) is called, with the restriction that the first argument must be an instance of the proper class (im_class) or of a derived class thereof.

When a bound user-defined method object is called, the underlying function (im_func) is called, inserting the class instance (im_self) in front of the argument list. For instance, when c is a class which contains a definition for a function f(), and x is an instance of c, calling x.f(1) is equivalent to calling c.f(x, 1).

When a user-defined method object is derived from a class
method object, the “class instance” stored in im_self will actually be the class itself, so that calling either \texttt{x.f(1)} or \texttt{c.f(1)} is equivalent to calling \texttt{f(c,1)} where \texttt{f} is the underlying function.

Note that the transformation from function object to (unbound or bound) method object happens each time the attribute is retrieved from the class or instance. In some cases, a fruitful optimization is to assign the attribute to a local variable and call that local variable. Also notice that this transformation only happens for user-defined functions; other callable objects (and all non-callable objects) are retrieved without transformation. It is also important to note that user-defined functions which are attributes of a class instance are not converted to bound methods; this \textit{only} happens when the function is an attribute of the class.

Generator functions
A function or method which uses the \texttt{yield} statement (see section \textit{The yield statement}) is called a \textit{generator function}. Such a function, when called, always returns an iterator object which can be used to execute the body of the function: calling the iterator’s \texttt{next()} method will cause the function to execute until it provides a value using the \texttt{yield} statement. When the function executes a \texttt{return} statement or falls off the end, a \texttt{StopIteration} exception is raised and the iterator will have reached the end of the set of values to be returned.

Built-in functions
A built-in function object is a wrapper around a C function. Examples of built-in functions are \texttt{len()} and \texttt{math.sin()} (\texttt{math} is a standard built-in module). The number and type of the arguments are determined by the C function. Special read-
only attributes: __doc__ is the function’s documentation string, or None if unavailable; __name__ is the function’s name; __self__ is set to None (but see the next item); __module__ is the name of the module the function was defined in or None if unavailable.

Built-in methods
This is really a different disguise of a built-in function, this time containing an object passed to the C function as an implicit extra argument. An example of a built-in method is alist.append(), assuming alist is a list object. In this case, the special read-only attribute __self__ is set to the object denoted by list.

Class Types
Class types, or “new-style classes,” are callable. These objects normally act as factories for new instances of themselves, but variations are possible for class types that override __new__(). The arguments of the call are passed to __new__() and, in the typical case, to __init__() to initialize the new instance.

Classic Classes
Class objects are described below. When a class object is called, a new class instance (also described below) is created and returned. This implies a call to the class’s __init__() method if it has one. Any arguments are passed on to the __init__() method. If there is no __init__() method, the class must be called without arguments.

Class instances
Class instances are described below. Class instances are callable only when the class has a __call__() method;
x(arguments) is a shorthand for x.__call__(arguments).
Modules

Modules are imported by the `import` statement (see section *The import statement*). A module object has a namespace implemented by a dictionary object (this is the dictionary referenced by the `func_globals` attribute of functions defined in the module). Attribute references are translated to lookups in this dictionary, e.g., `m.x` is equivalent to `m.__dict__["x"]`. A module object does not contain the code object used to initialize the module (since it isn’t needed once the initialization is done).

Attribute assignment updates the module’s namespace dictionary, e.g., `m.x = 1` is equivalent to `m.__dict__["x"] = 1`.

Special read-only attribute: `__dict__` is the module’s namespace as a dictionary object.

Predefined (writable) attributes: `__name__` is the module’s name; `__doc__` is the module’s documentation string, or `None` if unavailable; `__file__` is the pathname of the file from which the module was loaded, if it was loaded from a file. The `__file__` attribute is not present for C modules that are statically linked into the interpreter; for extension modules loaded dynamically from a shared library, it is the pathname of the shared library file.

Classes

Both class types (new-style classes) and class objects (old-style/classic classes) are typically created by class definitions (see section *Class definitions*). A class has a namespace implemented by a dictionary object. Class attribute references are translated to lookups in this dictionary, e.g., `c.x` is translated to `c.__dict__["x"]` (although for new-style classes in particular there are a number of hooks which allow for other means of locating attributes). When the attribute name is not found there, the attribute search continues in the base classes. For old-style
classes, the search is depth-first, left-to-right in the order of occurrence in the base class list. New-style classes use the more complex C3 method resolution order which behaves correctly even in the presence of ‘diamond’ inheritance structures where there are multiple inheritance paths leading back to a common ancestor. Additional details on the C3 MRO used by new-style classes can be found in the documentation accompanying the 2.3 release at http://www.python.org/download/releases/2.3/mro/.

When a class attribute reference (for class `c`, say) would yield a user-defined function object or an unbound user-defined method object whose associated class is either `c` or one of its base classes, it is transformed into an unbound user-defined method object whose `im_class` attribute is `c`. When it would yield a class method object, it is transformed into a bound user-defined method object whose `im_class` and `im_self` attributes are both `c`. When it would yield a static method object, it is transformed into the object wrapped by the static method object. See section *Implementing Descriptors* for another way in which attributes retrieved from a class may differ from those actually contained in its `__dict__` (note that only new-style classes support descriptors).

Class attribute assignments update the class’s dictionary, never the dictionary of a base class.

A class object can be called (see above) to yield a class instance (see below).

Special attributes: `__name__` is the class name; `__module__` is the module name in which the class was defined; `__dict__` is the dictionary containing the class’s namespace; `__bases__` is a tuple (possibly empty or a singleton) containing the base classes, in the order of their occurrence in the base class list; `__doc__` is the
class’s documentation string, or None if undefined.

Class instances

A class instance is created by calling a class object (see above). A class instance has a namespace implemented as a dictionary which is the first place in which attribute references are searched. When an attribute is not found there, and the instance's class has an attribute by that name, the search continues with the class attributes. If a class attribute is found that is a user-defined function object or an unbound user-defined method object whose associated class is the class (call it c) of the instance for which the attribute reference was initiated or one of its bases, it is transformed into a bound user-defined method object whose im_class attribute is c and whose im_self attribute is the instance. Static method and class method objects are also transformed, as if they had been retrieved from class c; see above under “Classes”. See section Implementing Descriptors for another way in which attributes of a class retrieved via its instances may differ from the objects actually stored in the class's __dict__. If no class attribute is found, and the object's class has a __getattr__() method, that is called to satisfy the lookup.

Attribute assignments and deletions update the instance's dictionary, never a class's dictionary. If the class has a __setattr__() or __delattr__() method, this is called instead of updating the instance dictionary directly.

Class instances can pretend to be numbers, sequences, or mappings if they have methods with certain special names. See section Special method names.

Special attributes: __dict__ is the attribute dictionary; __class__ is the instance's class.

Files
A file object represents an open file. File objects are created by the `open()` built-in function, and also by `os.popen()`, `os.fdopen()`, and the `makefile()` method of socket objects (and perhaps by other functions or methods provided by extension modules). The objects `sys.stdin`, `sys.stdout` and `sys.stderr` are initialized to file objects corresponding to the interpreter's standard input, output and error streams. See *File Objects* for complete documentation of file objects.

Internal types
A few types used internally by the interpreter are exposed to the user. Their definitions may change with future versions of the interpreter, but they are mentioned here for completeness.

Code objects
Code objects represent byte-compiled executable Python code, or *bytecode*. The difference between a code object and a function object is that the function object contains an explicit reference to the function's globals (the module in which it was defined), while a code object contains no context; also the default argument values are stored in the function object, not in the code object (because they represent values calculated at run-time). Unlike function objects, code objects are immutable and contain no references (directly or indirectly) to mutable objects.

Special read-only attributes: `co_name` gives the function name; `co_argcount` is the number of positional arguments (including arguments with default values); `co_nlocals` is the number of local variables used by the function (including arguments); `co_varnames` is a tuple containing the names of the local variables (starting with the argument names); `co_cellvars` is a tuple containing the names of local variables that are referenced by nested functions; `co_freevars` is a tuple
containing the names of free variables; co_code is a string representing the sequence of bytecode instructions; co_consts is a tuple containing the literals used by the bytecode; co_names is a tuple containing the names used by the bytecode; co_filename is the filename from which the code was compiled; co_firstlineno is the first line number of the function; co_lnotab is a string encoding the mapping from bytecode offsets to line numbers (for details see the source code of the interpreter); co_stacksize is the required stack size (including local variables); co_flags is an integer encoding a number of flags for the interpreter.

The following flag bits are defined for co_flags: bit 0x04 is set if the function uses the *arguments syntax to accept an arbitrary number of positional arguments; bit 0x08 is set if the function uses the **keywords syntax to accept arbitrary keyword arguments; bit 0x20 is set if the function is a generator.

Future feature declarations (from __future__ import division) also use bits in co_flags to indicate whether a code object was compiled with a particular feature enabled: bit 0x2000 is set if the function was compiled with future division enabled; bits 0x10 and 0x1000 were used in earlier versions of Python.

Other bits in co_flags are reserved for internal use.

If a code object represents a function, the first item in co_consts is the documentation string of the function, or None if undefined.

Frame objects
Frame objects represent execution frames. They may occur in traceback objects (see below).

Special read-only attributes: `f_back` is to the previous stack frame (towards the caller), or `None` if this is the bottom stack frame; `f_code` is the code object being executed in this frame; `f_locals` is the dictionary used to look up local variables; `f_globals` is used for global variables; `f_builtins` is used for built-in (intrinsic) names; `f_restricted` is a flag indicating whether the function is executing in restricted execution mode; `f_lasti` gives the precise instruction (this is an index into the bytecode string of the code object).

Special writable attributes: `f_trace`, if not `None`, is a function called at the start of each source code line (this is used by the debugger); `f_exc_type`, `f_exc_value`, `f_exc_traceback` represent the last exception raised in the parent frame provided another exception was ever raised in the current frame (in all other cases they are `None`); `f_lineno` is the current line number of the frame — writing to this from within a trace function jumps to the given line (only for the bottom-most frame). A debugger can implement a Jump command (aka Set Next Statement) by writing to `f_lineno`.

Traceback objects

Traceback objects represent a stack trace of an exception. A traceback object is created when an exception occurs. When the search for an exception handler unwinds the execution stack, at each unwound level a traceback object is inserted in front of the current traceback. When an exception handler is entered, the stack trace is made available to the program. (See section *The try statement.*) It is accessible as `sys.exc_traceback`, and also as the third item of the tuple
returned by \texttt{sys.exc_info()}. The latter is the preferred interface, since it works correctly when the program is using multiple threads. When the program contains no suitable handler, the stack trace is written (nicely formatted) to the standard error stream; if the interpreter is interactive, it is also made available to the user as \texttt{sys.last_traceback}.

Special read-only attributes: \texttt{tb\_next} is the next level in the stack trace (towards the frame where the exception occurred), or \texttt{None} if there is no next level; \texttt{tb\_frame} points to the execution frame of the current level; \texttt{tb\_lineno} gives the line number where the exception occurred; \texttt{tb\_lasti} indicates the precise instruction. The line number and last instruction in the traceback may differ from the line number of its frame object if the exception occurred in a \texttt{try} statement with no matching \texttt{except} clause or with a finally clause.

Slice objects
Slice objects are used to represent slices when \textit{extended slice syntax} is used. This is a slice using two colons, or multiple slices or ellipses separated by commas, e.g., \texttt{a[i:j:step]}, \texttt{a[i:j, k:l]}, or \texttt{a[...}, \texttt{i:j]}. They are also created by the built-in \texttt{slice()} function.

Special read-only attributes: \texttt{start} is the lower bound; \texttt{stop} is the upper bound; \texttt{step} is the step value; each is \texttt{None} if omitted. These attributes can have any type.

Slice objects support one method:

\texttt{slice.\textit{indices}(self, length)}
This method takes a single integer argument \texttt{length} and computes information about the extended slice that the slice object would describe if applied to a sequence of
length items. It returns a tuple of three integers; respectively these are the start and stop indices and the step or stride length of the slice. Missing or out-of-bounds indices are handled in a manner consistent with regular slices.

*New in version 2.3.*

Static method objects

Static method objects provide a way of defeating the transformation of function objects to method objects described above. A static method object is a wrapper around any other object, usually a user-defined method object. When a static method object is retrieved from a class or a class instance, the object actually returned is the wrapped object, which is not subject to any further transformation. Static method objects are not themselves callable, although the objects they wrap usually are. Static method objects are created by the built-in `staticmethod()` constructor.

Class method objects

A class method object, like a static method object, is a wrapper around another object that alters the way in which that object is retrieved from classes and class instances. The behaviour of class method objects upon such retrieval is described above, under “User-defined methods”. Class method objects are created by the built-in `classmethod()` constructor.
New-style and classic classes

Classes and instances come in two flavors: old-style (or classic) and new-style.

Up to Python 2.1, old-style classes were the only flavor available to the user. The concept of (old-style) class is unrelated to the concept of type: if \( x \) is an instance of an old-style class, then \( x.__class__ \) designates the class of \( x \), but \( \text{type}(x) \) is always \(<\text{type 'instance'>}\). This reflects the fact that all old-style instances, independently of their class, are implemented with a single built-in type, called \text{instance}.

New-style classes were introduced in Python 2.2 to unify classes and types. A new-style class is neither more nor less than a user-defined type. If \( x \) is an instance of a new-style class, then \( \text{type}(x) \) is typically the same as \( x.__class__ \) (although this is not guaranteed - a new-style class instance is permitted to override the value returned for \( x.__class__ \)).

The major motivation for introducing new-style classes is to provide a unified object model with a full meta-model. It also has a number of practical benefits, like the ability to subclass most built-in types, or the introduction of “descriptors”, which enable computed properties.

For compatibility reasons, classes are still old-style by default. New-style classes are created by specifying another new-style class (i.e. a type) as a parent class, or the “top-level type” \text{object} if no other parent is needed. The behaviour of new-style classes differs from that of old-style classes in a number of important details in addition to what \( \text{type()} \) returns. Some of these changes are fundamental to the new object model, like the way special methods are invoked. Others are “fixes” that could not be implemented before for
compatibility concerns, like the method resolution order in case of multiple inheritance.

While this manual aims to provide comprehensive coverage of Python's class mechanics, it may still be lacking in some areas when it comes to its coverage of new-style classes. Please see http://www.python.org/doc/newstyle/ for sources of additional information.

Old-style classes are removed in Python 3.0, leaving only the semantics of new-style classes.
Special method names

A class can implement certain operations that are invoked by special syntax (such as arithmetic operations or subscripting and slicing) by defining methods with special names. This is Python’s approach to operator overloading, allowing classes to define their own behavior with respect to language operators. For instance, if a class defines a method named `__getitem__`, and `x` is an instance of this class, then `x[i]` is roughly equivalent to `x.__getitem__(i)` for old-style classes and `type(x).__getitem__(x, i)` for new-style classes. Except where mentioned, attempts to execute an operation raise an exception when no appropriate method is defined (typically `AttributeError` or `TypeError`).

When implementing a class that emulates any built-in type, it is important that the emulation only be implemented to the degree that it makes sense for the object being modelled. For example, some sequences may work well with retrieval of individual elements, but extracting a slice may not make sense. (One example of this is the `NodeList` interface in the W3C’s Document Object Model.)

Basic customization

```
object.__new__(cls[, ...])
```

Called to create a new instance of class `cls`. `__new__` is a static method (special-cased so you need not declare it as such) that takes the class of which an instance was requested as its first argument. The remaining arguments are those passed to the object constructor expression (the call to the class). The return value of `__new__` should be the new object instance (usually an instance of `cls`).
Typical implementations create a new instance of the class by invoking the superclass's `__new__()` method using

```
super(currentclass, cls).__new__(cls, ...)  
```

with appropriate arguments and then modifying the newly-created instance as necessary before returning it.

If `__new__()` returns an instance of `cls`, then the new instance's `__init__()` method will be invoked like `__init__(self[, ...])`, where `self` is the new instance and the remaining arguments are the same as were passed to `__new__()`.

If `__new__()` does not return an instance of `cls`, then the new instance's `__init__()` method will not be invoked.

`__new__()` is intended mainly to allow subclasses of immutable types (like `int`, `str`, or `tuple`) to customize instance creation. It is also commonly overridden in custom metaclasses in order to customize class creation.

```
object.__init__(self[, ...])  
```

Called when the instance is created. The arguments are those passed to the class constructor expression. If a base class has an `__init__()` method, the derived class's `__init__()` method, if any, must explicitly call it to ensure proper initialization of the base class part of the instance; for example:

```
BaseClass.__init__(self, [args...]).  
```

As a special constraint on constructors, no value may be returned; doing so will cause a `TypeError` to be raised at runtime.

```
object.__del__(self)  
```

Called when the instance is about to be destroyed. This is also called a destructor. If a base class has a `__del__()` method, the derived class's `__del__()` method, if any, must explicitly call it to
ensure proper deletion of the base class part of the instance. Note that it is possible (though not recommended!) for the __del__() method to postpone destruction of the instance by creating a new reference to it. It may then be called at a later time when this new reference is deleted. It is not guaranteed that __del__() methods are called for objects that still exist when the interpreter exits.

**Note:** del x doesn’t directly call x.__del__() — the former decrements the reference count for x by one, and the latter is only called when x’s reference count reaches zero. Some common situations that may prevent the reference count of an object from going to zero include: circular references between objects (e.g., a doubly-linked list or a tree data structure with parent and child pointers); a reference to the object on the stack frame of a function that caught an exception (the traceback stored in sys.exc_traceback keeps the stack frame alive); or a reference to the object on the stack frame that raised an unhandled exception in interactive mode (the traceback stored in sys.last_traceback keeps the stack frame alive). The first situation can only be remedied by explicitly breaking the cycles; the latter two situations can be resolved by storing None in sys.exc_traceback or sys.last_traceback. Circular references which are garbage are detected when the option cycle detector is enabled (it’s on by default), but can only be cleaned up if there are no Python-level __del__() methods involved. Refer to the documentation for the gc module for more information about how __del__() methods are handled by the cycle detector, particularly the description of the garbage value.

**Warning:** Due to the precarious circumstances under which __del__() methods are invoked, exceptions that occur during
their execution are ignored, and a warning is printed to `sys.stderr` instead. Also, when `__del__()` is invoked in response to a module being deleted (e.g., when execution of the program is done), other globals referenced by the `__del__()` method may already have been deleted. For this reason, `__del__()` methods should do the absolute minimum needed to maintain external invariants. Starting with version 1.5, Python guarantees that globals whose name begins with a single underscore are deleted from their module before other globals are deleted; if no other references to such globals exist, this may help in assuring that imported modules are still available at the time when the `__del__()` method is called.

```python
object.__repr__(self)
```

Called by the `repr()` built-in function and by string conversions (reverse quotes) to compute the “official” string representation of an object. If at all possible, this should look like a valid Python expression that could be used to recreate an object with the same value (given an appropriate environment). If this is not possible, a string of the form `<...some useful description...>` should be returned. The return value must be a string object. If a class defines `__repr__()` but not `__str__()`, then `__repr__()` is also used when an “informal” string representation of instances of that class is required.

This is typically used for debugging, so it is important that the representation is information-rich and unambiguous.

```python
object.__str__(self)
```

Called by the `str()` built-in function and by the `print` statement to compute the “informal” string representation of an object. This differs from `__repr__()` in that it does not have to be a valid Python expression: a more convenient or concise representation
may be used instead. The return value must be a string object.

```
object.__lt__(self, other)
object.__le__(self, other)
object.__eq__(self, other)
object.__ne__(self, other)
object.__gt__(self, other)
object.__ge__(self, other)
```

*New in version 2.1.*

These are the so-called “rich comparison” methods, and are called for comparison operators in preference to `__cmp__()` below. The correspondence between operator symbols and method names is as follows: \( x < y \) calls `x.__lt__(y)`; \( x \leq y \) calls `x.__le__(y)`; \( x = y \) calls `x.__eq__(y)`; \( x \neq y \) and \( x <> y \) call `x.__ne__(y)`; \( x > y \) calls `x.__gt__(y)`, and \( x \geq y \) calls `x.__ge__(y)`.

A rich comparison method may return the singleton `NotImplemented` if it does not implement the operation for a given pair of arguments. By convention, `False` and `True` are returned for a successful comparison. However, these methods can return any value, so if the comparison operator is used in a Boolean context (e.g., in the condition of an `if` statement), Python will call `bool()` on the value to determine if the result is true or false.

There are no implied relationships among the comparison operators. The truth of \( x = y \) does not imply that \( x \neq y \) is false. Accordingly, when defining `__eq__()`, one should also define `__ne__()` so that the operators will behave as expected. See the paragraph on `__hash__()` for some important notes on creating `hashable` objects which support custom comparison operations and are usable as dictionary keys.

There are no swapped-argument versions of these methods (to
be used when the left argument does not support the operation but the right argument does); rather, \_\_lt\_\_(\) and \_\_gt\_\_(\) are each other’s reflection, \_\_le\_\_(\) and \_\_ge\_\_(\) are each other’s reflection, and \_\_eq\_\_(\) and \_\_ne\_\_(\) are their own reflection.

Arguments to rich comparison methods are never coerced.

object.\_\_cmp\_\_(\texttt{self}, \texttt{other})

Called by comparison operations if rich comparison (see above) is not defined. Should return a negative integer if \texttt{self < other}, zero if \texttt{self == other}, a positive integer if \texttt{self > other}. If no \_\_cmp\_\_(\), \_\_eq\_\_(\) or \_\_ne\_\_(\) operation is defined, class instances are compared by object identity (“address”). See also the description of \_\_hash\_\_(\) for some important notes on creating \texttt{hashable} objects which support custom comparison operations and are usable as dictionary keys. (Note: the restriction that exceptions are not propagated by \_\_cmp\_\_(\) has been removed since Python 1.5.)

object.\_\_rcmp\_\_(\texttt{self}, \texttt{other})

\textit{Changed in version 2.1:} No longer supported.

object.\_\_hash\_\_(\texttt{self})

Called for the key object for dictionary operations, and by the built-in function \texttt{hash()}. Should return an integer usable as a hash value for dictionary operations. The only required property is that objects which compare equal have the same hash value; it is advised to somehow mix together (e.g., using exclusive or) the hash values for the components of the object that also play a part in comparison of objects.

If a class does not define a \_\_cmp\_\_(\) or \_\_eq\_\_(\) method it should not define a \_\_hash\_\_(\) operation either; if it defines
__cmp__() or __eq__() but not __hash__(), its instances will not be usable as dictionary keys. If a class defines mutable objects and implements a __cmp__() or __eq__() method, it should not implement __hash__(), since the dictionary implementation requires that a key's hash value is immutable (if the object's hash value changes, it will be in the wrong hash bucket).

User-defined classes have __cmp__() and __hash__() methods by default; with them, all objects compare unequal (except with themselves) and x.__hash__() returns id(x).

Classes which inherit a __hash__() method from a parent class but change the meaning of __cmp__() or __eq__() such that the hash value returned is no longer appropriate (e.g. by switching to a value-based concept of equality instead of the default identity based equality) can explicitly flag themselves as being unhashable by setting __hash__ = None in the class definition. Doing so means that not only will instances of the class raise an appropriate TypeError when a program attempts to retrieve their hash value, but they will also be correctly identified as unhashable when checking isinstance(obj, collections.Hashable) (unlike classes which define their own __hash__() to explicitly raise TypeError).

*Changed in version 2.5:* __hash__() may now also return a long integer object; the 32-bit integer is then derived from the hash of that object.

*Changed in version 2.6:* __hash__ may now be set to None to explicitly flag instances of a class as unhashable.

object.__nonzero__(self)

Called to implement truth value testing, and the built-in operation
bool(); should return False or True, or their integer equivalents 0 or 1. When this method is not defined, __len__() is called, if it is defined (see below). If a class defines neither __len__() nor __nonzero__(), all its instances are considered true.

object.__unicode__(self)
Called to implement unicode() builtin; should return a Unicode object. When this method is not defined, string conversion is attempted, and the result of string conversion is converted to Unicode using the system default encoding.

Customizing attribute access

The following methods can be defined to customize the meaning of attribute access (use of, assignment to, or deletion of x.name) for class instances.

object.__getattr__(self, name)
Called when an attribute lookup has not found the attribute in the usual places (i.e. it is not an instance attribute nor is it found in the class tree for self). name is the attribute name. This method should return the (computed) attribute value or raise an AttributeError exception.

Note that if the attribute is found through the normal mechanism, __getattr__() is not called. (This is an intentional asymmetry between __getattr__() and __setattr__.) This is done both for efficiency reasons and because otherwise __getattr__() would have no way to access other attributes of the instance. Note that at least for instance variables, you can fake total control by not inserting any values in the instance attribute dictionary (but instead inserting them in another object). See the __getattribute__() method below for a way to actually get total
control in new-style classes.

**object.** __**setattr**__(**self**, **name**, **value**)

Called when an attribute assignment is attempted. This is called instead of the normal mechanism (i.e. store the value in the instance dictionary). **name** is the attribute name, **value** is the value to be assigned to it.

If __**setattr**__() wants to assign to an instance attribute, it should not simply execute `self.name = value` — this would cause a recursive call to itself. Instead, it should insert the value in the dictionary of instance attributes, e.g., `self.__dict__[name] = value`. For new-style classes, rather than accessing the instance dictionary, it should call the base class method with the same name, for example, `object.__setattr__(self, name, value).

**object.** __**delattr**__(**self**, **name**)

Like __**setattr**__() but for attribute deletion instead of assignment. This should only be implemented if `del obj.name` is meaningful for the object.

---

**More attribute access for new-style classes**

The following methods only apply to new-style classes.

**object.** __**getattr**__(**self**, **name**)

Called unconditionally to implement attribute accesses for instances of the class. If the class also defines __**getattr**__(), the latter will not be called unless __**getattr**__() either calls it explicitly or raises an AttributeError. This method should return the (computed) attribute value or raise an AttributeError exception. In order to avoid infinite recursion in this method, its implementation should always call the base class method with
the same name to access any attributes it needs, for example, `object.__getattribute__(self, name).

**Note:** This method may still be bypassed when looking up special methods as the result of implicit invocation via language syntax or builtin functions. See *Special method lookup for new-style classes.*

### Implementing Descriptors

The following methods only apply when an instance of the class containing the method (a so-called descriptor class) appears in the class dictionary of another new-style class, known as the owner class. In the examples below, “the attribute” refers to the attribute whose name is the key of the property in the owner class’ `__dict__`. Descriptors can only be implemented as new-style classes themselves.

**object.** `__get__(self, instance, owner)`

Called to get the attribute of the owner class (class attribute access) or of an instance of that class (instance attribute access). `owner` is always the owner class, while `instance` is the instance that the attribute was accessed through, or `None` when the attribute is accessed through the `owner`. This method should return the (computed) attribute value or raise an `AttributeError` exception.

**object.** `__set__(self, instance, value)`

Called to set the attribute on an instance `instance` of the owner class to a new value, `value`.

**object.** `__delete__(self, instance)`

Called to delete the attribute on an instance `instance` of the owner class.
Invoking Descriptors

In general, a descriptor is an object attribute with “binding behavior”, one whose attribute access has been overridden by methods in the descriptor protocol: `__get__()`, `__set__()`, and `__delete__()`. If any of those methods are defined for an object, it is said to be a descriptor.

The default behavior for attribute access is to get, set, or delete the attribute from an object’s dictionary. For instance, `a.x` has a lookup chain starting with `a.__dict__['x']`, then `type(a).__dict__['x']`, and continuing through the base classes of `type(a)` excluding metaclasses.

However, if the looked-up value is an object defining one of the descriptor methods, then Python may override the default behavior and invoke the descriptor method instead. Where this occurs in the precedence chain depends on which descriptor methods were defined and how they were called. Note that descriptors are only invoked for new style objects or classes (ones that subclass `object()` or `type()`).

The starting point for descriptor invocation is a binding, `a.x`. How the arguments are assembled depends on `a`:

Direct Call
The simplest and least common call is when user code directly invokes a descriptor method: `x.__get__(a)`.

Instance Binding
If binding to a new-style object instance, `a.x` is transformed into the call: `type(a).__dict__['x'].__get__(a, type(a))`.

Class Binding
If binding to a new-style class, `A.x` is transformed into the call:
Super Binding

If `a` is an instance of `super`, then the binding `super(B, obj).m()` searches `obj.__class__.__mro__` for the base class `A` immediately preceding `B` and then invokes the descriptor with the call: `A.__dict__['m'].__get__(obj, A).

For instance bindings, the precedence of descriptor invocation depends on the which descriptor methods are defined. Normally, data descriptors define both `__get__()` and `__set__()`, while non-data descriptors have just the `__get__()` method. Data descriptors always override a redefinition in an instance dictionary. In contrast, non-data descriptors can be overridden by instances. [2]

Python methods (including `staticmethod()` and `classmethod()`) are implemented as non-data descriptors. Accordingly, instances can redefine and override methods. This allows individual instances to acquire behaviors that differ from other instances of the same class.

The `property()` function is implemented as a data descriptor. Accordingly, instances cannot override the behavior of a property.

---

**__slots__**

By default, instances of both old and new-style classes have a dictionary for attribute storage. This wastes space for objects having very few instance variables. The space consumption can become acute when creating large numbers of instances.

The default can be overridden by defining `__slots__` in a new-style class definition. The `__slots__` declaration takes a sequence of instance variables and reserves just enough space in each instance to hold a value for each variable. Space is saved because `__dict__` is not created for each instance.
__slots__

This class variable can be assigned a string, iterable, or sequence of strings with variable names used by instances. If defined in a new-style class, __slots__ reserves space for the declared variables and prevents the automatic creation of __dict__ and __weakref__ for each instance.

New in version 2.2.

Notes on using __slots__

- When inheriting from a class without __slots__, the __dict__ attribute of that class will always be accessible, so a __slots__ definition in the subclass is meaningless.

- Without a __dict__ variable, instances cannot be assigned new variables not listed in the __slots__ definition. Attempts to assign to an unlisted variable name raises AttributeError. If dynamic assignment of new variables is desired, then add '__dict__' to the sequence of strings in the __slots__ declaration.

  Changed in version 2.3: Previously, adding '__dict__' to the __slots__ declaration would not enable the assignment of new attributes not specifically listed in the sequence of instance variable names.

- Without a __weakref__ variable for each instance, classes defining __slots__ do not support weak references to its instances. If weak reference support is needed, then add '__weakref__' to the sequence of strings in the __slots__ declaration.

  Changed in version 2.3: Previously, adding '__weakref__' to the __slots__ declaration would not enable support for weak
references.

- __slots__ are implemented at the class level by creating descriptors (Implementing Descriptors) for each variable name. As a result, class attributes cannot be used to set default values for instance variables defined by __slots__; otherwise, the class attribute would overwrite the descriptor assignment.

- If a class defines a slot also defined in a base class, the instance variable defined by the base class slot is inaccessible (except by retrieving its descriptor directly from the base class). This renders the meaning of the program undefined. In the future, a check may be added to prevent this.

- The action of a __slots__ declaration is limited to the class where it is defined. As a result, subclasses will have a __dict__ unless they also define __slots__.

- __slots__ do not work for classes derived from “variable-length” built-in types such as long, str and tuple.

- Any non-string iterable may be assigned to __slots__. Mappings may also be used; however, in the future, special meaning may be assigned to the values corresponding to each key.

- __class__ assignment works only if both classes have the same __slots__.

    Changed in version 2.6: Previously, __class__ assignment raised an error if either new or old class had __slots__.

### Customizing class creation

By default, new-style classes are constructed using type(). A class definition is read into a separate namespace and the value of class
name is bound to the result of \texttt{type(name, bases, dict)}.

When the class definition is read, if \texttt{__metaclass__} is defined then the callable assigned to it will be called instead of \texttt{type()}. This allows classes or functions to be written which monitor or alter the class creation process:

- Modifying the class dictionary prior to the class being created.
- Returning an instance of another class – essentially performing the role of a factory function.

These steps will have to be performed in the metaclass's \texttt{__new__() } method – \texttt{type.__new__()} can then be called from this method to create a class with different properties. This example adds a new element to the class dictionary before creating the class:

```python
class metacls(type):
    def __new__(mcs, name, bases, dict):
        dict['foo'] = 'metacls was here'
        return type.__new__(mcs, name, bases, dict)
```

You can of course also override other class methods (or add new methods); for example defining a custom \texttt{__call__() } method in the metaclass allows custom behavior when the class is called, e.g. not always creating a new instance.

\texttt{__metaclass__}

This variable can be any callable accepting arguments for \texttt{name}, \texttt{bases}, and \texttt{dict}. Upon class creation, the callable is used instead of the built-in \texttt{type()}.  

\textit{New in version 2.2.}

The appropriate metaclass is determined by the following precedence rules:
- If `dict['__metaclass__']` exists, it is used.
- Otherwise, if there is at least one base class, its metaclass is used (this looks for a `__class__` attribute first and if not found, uses its type).
- Otherwise, if a global variable named `__metaclass__` exists, it is used.
- Otherwise, the old-style, classic metaclass (types.ClassType) is used.

The potential uses for metaclasses are boundless. Some ideas that have been explored including logging, interface checking, automatic delegation, automatic property creation, proxies, frameworks, and automatic resource locking/synchronization.

**Emulating callable objects**

```
object.__call__(self[, args...])
```

Called when the instance is “called” as a function; if this method is defined, `x(arg1, arg2, ...)` is a shorthand for `x.__call__(arg1, arg2, ...)`.  

**Emulating container types**

The following methods can be defined to implement container objects. Containers usually are sequences (such as lists or tuples) or mappings (like dictionaries), but can represent other containers as well. The first set of methods is used either to emulate a sequence or to emulate a mapping; the difference is that for a sequence, the allowable keys should be the integers `k` for which `0 <= k < N` where `N` is the length of the sequence, or slice objects, which define a range of items. (For backwards compatibility, the method `__getslice__() (see below) can also be defined to handle simple, but not extended slices.) It is also recommended that mappings
provide the methods `keys()`, `values()`, `items()`, `has_key()`, `get()`,
clear(), `setdefault()`, `iterkeys()`, `itervalues()`, `iternums()`, `pop()`, `popitem()`, `copy()`, and `update()` behaving similar to those for
Python's standard dictionary objects. The `UserDict` module provides
a `DictMixin` class to help create those methods from a base set of
`__getitem__()`, `__setitem__()`, `__delitem__()`, and `keys()`. Mutable
sequences should provide methods `append()`, `count()`, `index()`,
`extend()`, `insert()`, `pop()`, `remove()`, `reverse()` and `sort()`, like
Python standard list objects. Finally, sequence types should implement addition (meaning concatenation) and multiplication
(meaning repetition) by defining the methods `__add__()`, `__radd__()`,
`__iadd__()`, `__mul__()`, `__rmul__()` and `__imul__()` described below;
they should not define `__coerce__()` or other numerical operators. It
is recommended that both mappings and sequences implement the
`__contains__()` method to allow efficient use of the `in` operator; for
mappings, `in` should be equivalent of `has_key()`; for sequences, it
should search through the values. It is further recommended that
both mappings and sequences implement the `__iter__()` method to
allow efficient iteration through the container; for mappings,
`__iter__()` should be the same as `iterkeys()`; for sequences, it
should iterate through the values.

object. `__len__(self)

Called to implement the built-in function `len()`. Should return the
length of the object, an integer >= 0. Also, an object that doesn't
define a `__nonzero__()` method and whose `__len__()` method
returns zero is considered to be false in a Boolean context.

object. `__getitem__(self, key)

Called to implement evaluation of `self[key]`. For sequence
types, the accepted keys should be integers and slice objects.
Note that the special interpretation of negative indexes (if the
class wishes to emulate a sequence type) is up to the
__getitem__() method. If key is of an inappropriate type,
TypeError may be raised; if of a value outside the set of indexes
for the sequence (after any special interpretation of negative
values), IndexError should be raised. For mapping types, if key is
missing (not in the container), KeyError should be raised.

Note: for loops expect that an IndexError will be raised for
illegal indexes to allow proper detection of the end of the
sequence.

object.__setitem__(self, key, value)
Called to implement assignment to self[key]. Same note as for
__getitem__(). This should only be implemented for mappings if
the objects support changes to the values for keys, or if new keys
can be added, or for sequences if elements can be replaced. The
same exceptions should be raised for improper key values as for
the __getitem__() method.

object.__delitem__(self, key)
Called to implement deletion of self[key]. Same note as for
__getitem__(). This should only be implemented for mappings if
the objects support removal of keys, or for sequences if elements
can be removed from the sequence. The same exceptions should
be raised for improper key values as for the __getitem__() method.

object.__iter__(self)
This method is called when an iterator is required for a container.
This method should return a new iterator object that can iterate
over all the objects in the container. For mappings, it should
iterate over the keys of the container, and should also be made
available as the method iterkeys().
Iterator objects also need to implement this method; they are required to return themselves. For more information on iterator objects, see Iterator Types.

```
object.__reversed__(self)
```

Called (if present) by the reversed() builtin to implement reverse iteration. It should return a new iterator object that iterates over all the objects in the container in reverse order.

If the `__reversed__()` method is not provided, the reversed() builtin will fall back to using the sequence protocol (`__len__()` and `__getitem__()`). Objects should normally only provide `__reversed__()` if they do not support the sequence protocol and an efficient implementation of reverse iteration is possible.

*New in version 2.6.*

The membership test operators (`in` and `not in`) are normally implemented as an iteration through a sequence. However, container objects can supply the following special method with a more efficient implementation, which also does not require the object be a sequence.

```
object.__contains__(self, item)
```

Called to implement membership test operators. Should return true if `item` is in `self`, false otherwise. For mapping objects, this should consider the keys of the mapping rather than the values or the key-item pairs.

---

**Additional methods for emulation of sequence types**

The following optional methods can be defined to further emulate sequence objects. Immutable sequences methods should at most
only define __getslice__(); mutable sequences might define all three methods.

object.__getslice__(self, i, j)

*Deprecated since version 2.0:* Support slice objects as parameters to the __getitem__() method. (However, built-in types in CPython currently still implement __getslice__(). Therefore, you have to override it in derived classes when implementing slicing.)

Called to implement evaluation of self[i:j]. The returned object should be of the same type as self. Note that missing i or j in the slice expression are replaced by zero or sys.maxint, respectively. If negative indexes are used in the slice, the length of the sequence is added to that index. If the instance does not implement the __len__() method, an AttributeError is raised. No guarantee is made that indexes adjusted this way are not still negative. Indexes which are greater than the length of the sequence are not modified. If no __getslice__() is found, a slice object is created instead, and passed to __getitem__() instead.

object.__setslice__(self, i, j, sequence)

Called to implement assignment to self[i:j]. Same notes for i and j as for __getslice__().

This method is deprecated. If no __setslice__() is found, or for extended slicing of the form self[i:j:k], a slice object is created, and passed to __setitem__(), instead of __setslice__() being called.

object.__delslice__(self, i, j)

Called to implement deletion of self[i:j]. Same notes for i and j as for __getslice__(). This method is deprecated. If no
__delslice__() is found, or for extended slicing of the form self[i:j:k], a slice object is created, and passed to __delitem__(), instead of __delslice__() being called.

Notice that these methods are only invoked when a single slice with a single colon is used, and the slice method is available. For slice operations involving extended slice notation, or in absence of the slice methods, __getitem__(), __setitem__() or __delitem__() is called with a slice object as argument.

The following example demonstrate how to make your program or module compatible with earlier versions of Python (assuming that methods __getitem__(), __setitem__() and __delitem__() support slice objects as arguments):

```python
class MyClass:
    ...
    def __getitem__(self, index):
        ...
    def __setitem__(self, index, value):
        ...
    def __delitem__(self, index):
        ...

    if sys.version_info < (2, 0):
        # They won't be defined if version is at least 2.0 final

        def __getslice__(self, i, j):
            return self[max(0, i):max(0, j):]
        def __setslice__(self, i, j, seq):
            self[max(0, i):max(0, j):] = seq
        def __delslice__(self, i, j):
            del self[max(0, i):max(0, j):]
    ...
```

Note the calls to max(); these are necessary because of the handling of negative indices before the __*slice__() methods are called. When negative indexes are used, the __*item__() methods receive them as provided, but the __*slice__() methods get a “cooked” form
of the index values. For each negative index value, the length of the sequence is added to the index before calling the method (which may still result in a negative index); this is the customary handling of negative indexes by the built-in sequence types, and the __*item__() methods are expected to do this as well. However, since they should already be doing that, negative indexes cannot be passed in; they must be constrained to the bounds of the sequence before being passed to the __*item__() methods. Calling max(0, i) conveniently returns the proper value.

**Emulating numeric types**

The following methods can be defined to emulate numeric objects. Methods corresponding to operations that are not supported by the particular kind of number implemented (e.g., bitwise operations for non-integral numbers) should be left undefined.

```python
object.__add__(self, other)
object.__sub__(self, other)
object.__mul__(self, other)
object.__floordiv__(self, other)
object.__mod__(self, other)
object.__divmod__(self, other)
object.__pow__(self, other[, modulo])
object.__lshift__(self, other)
object.__rshift__(self, other)
object.__and__(self, other)
object.__xor__(self, other)
object.__or__(self, other)
```

These methods are called to implement the binary arithmetic operations (+, -=, *, //, %, divmod(), pow(), **, <<, >>, &, ^, |). For instance, to evaluate the expression x + y, where x is an instance of a class that has an __add__() method, x.__add__(y)
is called. The __divmod__() method should be the equivalent to using __floordiv__() and __mod__(); it should not be related to __truediv__() (described below). Note that __pow__() should be defined to accept an optional third argument if the ternary version of the built-in pow() function is to be supported.

If one of those methods does not support the operation with the supplied arguments, it should return NotImplemented.

```
object.__div__(self, other)
object.__truediv__(self, other)

The division operator (/) is implemented by these methods. The __truediv__() method is used when __future__.division is in effect, otherwise __div__() is used. If only one of these two methods is defined, the object will not support division in the alternate context; TypeError will be raised instead.
```

```
object.__radd__(self, other)
object.__rsub__(self, other)
object.__rmul__(self, other)
object.__rdiv__(self, other)
object.__rtruediv__(self, other)
object.__rfloordiv__(self, other)
object.__rmod__(self, other)
object.__rdivmod__(self, other)
object.__rpow__(self, other)
object.__rlshift__(self, other)
object.__rrshift__(self, other)
object.__rand__(self, other)
object.__rxor__(self, other)
object.__ror__(self, other)
```

These methods are called to implement the binary arithmetic operations (+, -, *, /, %, divmod(), pow(), **, <<, >>, &, ^, |) with
reflected (swapped) operands. These functions are only called if the left operand does not support the corresponding operation and the operands are of different types. [3] For instance, to evaluate the expression \( x - y \), where \( y \) is an instance of a class that has an \( \_\_rsub\_\_() \) method, \( y._\_rsub\_\_(x) \) is called if \( x._\_sub\_\_(y) \) returns \texttt{NotImplemented}.

Note that ternary \texttt{pow()} will not try calling \texttt{\_\_rpow\_\_()} (the coercion rules would become too complicated).

\begin{quote}
\textbf{Note: } If the right operand's type is a subclass of the left operand's type and that subclass provides the reflected method for the operation, this method will be called before the left operand's non-reflected method. This behavior allows subclasses to override their ancestors' operations.
\end{quote}

```
object._iadd_(self, other)
object._isub_(self, other)
object._imul_(self, other)
object._idiv_(self, other)
object._itruediv_(self, other)
object._ifloordiv_(self, other)
object._imod_(self, other)
object._ipow_(self, other)
object._ilshift_(self, other)
object._irshift_(self, other)
object._iand_(self, other)
object._ixor_(self, other)
object._ior_(self, other)
```

These methods are called to implement the augmented arithmetic operations (\(+=, -=, *=, /=, //=, %=, **=, <<=, >>=, &=, ^=, |\)=). These methods should attempt to do the operation in-place (modifying \texttt{self}) and return the result (which could be, but
does not have to be, `self`). If a specific method is not defined, the augmented operation falls back to the normal methods. For instance, to evaluate the expression `x += y`, where `x` is an instance of a class that has an `__iadd__()` method, `x.__iadd__(y)` is called. If `x` is an instance of a class that does not define a `__iadd__()` method, `x.__add__(y)` and `y.__radd__(x)` are considered, as with the evaluation of `x + y`.

```python
object.__neg__(self)
object.__pos__(self)
object.__abs__(self)
object.__invert__(self)
```

Called to implement the unary arithmetic operations (`-`, `+`, `abs()` and `~`).

```python
object.__complex__(self)
object.__int__(self)
object.__long__(self)
object.__float__(self)
```

Called to implement the built-in functions `complex()`, `int()`, `long()`, and `float()`. Should return a value of the appropriate type.

```python
object.__oct__(self)
object.__hex__(self)
```

Called to implement the built-in functions `oct()` and `hex()`. Should return a string value.

```python
object.__index__(self)
```

Called to implement `operator.index()`. Also called whenever Python needs an integer object (such as in slicing). Must return an integer (int or long).
New in version 2.5.

object. __coerce__(self, other)
Called to implement “mixed-mode” numeric arithmetic. Should either return a 2-tuple containing self and other converted to a common numeric type, or None if conversion is impossible. When the common type would be the type of other, it is sufficient to return None, since the interpreter will also ask the other object to attempt a coercion (but sometimes, if the implementation of the other type cannot be changed, it is useful to do the conversion to the other type here). A return value of NotImplemented is equivalent to returning None.

Coercion rules

This section used to document the rules for coercion. As the language has evolved, the coercion rules have become hard to document precisely; documenting what one version of one particular implementation does is undesirable. Instead, here are some informal guidelines regarding coercion. In Python 3.0, coercion will not be supported.

- If the left operand of a % operator is a string or Unicode object, no coercion takes place and the string formatting operation is invoked instead.

- It is no longer recommended to define a coercion operation. Mixed-mode operations on types that don’t define coercion pass the original arguments to the operation.

- New-style classes (those derived from object) never invoke the __coerce__() method in response to a binary operator; the only time __coerce__() is invoked is when the built-in function coerce() is called.
• For most intents and purposes, an operator that returns `NotImplemented` is treated the same as one that is not implemented at all.

• Below, `__op__()`, `__rop__()`, and `__iop__()` are used to signify the generic method names corresponding to an operator; `__iop__()` is used for the corresponding in-place operator. For example, for the operator `'+', `__add__()`, `__radd__()`, `__iadd__()` are used for the left and right variant of the binary operator, and `__iadd__()` for the in-place variant.

• For objects `x` and `y`, first `x.__op__(y)` is tried. If this is not implemented or returns `NotImplemented` or returns `NotImplemented`, `y.__rop__(x)` is tried. If this is also not implemented or returns `NotImplemented`, a `TypeError` exception is raised. But see the following exception:

Exception to the previous item: if the left operand is an instance of a built-in type or a new-style class, and the right operand is an instance of a proper subclass of that type or class and overrides the base’s `__rop__()` method, the right operand’s `__rop__()` method is tried before the left operand’s `__op__()` method.

This is done so that a subclass can completely override binary operators. Otherwise, the left operand’s `__op__()` method would always accept the right operand: when an instance of a given class is expected, an instance of a subclass of that class is always acceptable.

• When either operand type defines a coercion, this coercion is called before that type’s `__op__()` or `__rop__()` method is called, but no sooner. If the coercion returns an object of a different type for the operand whose coercion is invoked, part of the process is redone using the new object.
• When an in-place operator (like `+=`) is used, if the left operand implements `__iop__()`, it is invoked without any coercion. When the operation falls back to `__op__()` and/or `__rop__()`, the normal coercion rules apply.

• In `x + y`, if `x` is a sequence that implements sequence concatenation, sequence concatenation is invoked.

• In `x * y`, if one operator is a sequence that implements sequence repetition, and the other is an integer (`int` or `long`), sequence repetition is invoked.

• Rich comparisons (implemented by methods `__eq__()`, and so on) never use coercion. Three-way comparison (implemented by `__cmp__()`) does use coercion under the same conditions as other binary operations use it.

• In the current implementation, the built-in numeric types `int`, `long` and `float` do not use coercion; the type `complex` however does use it. The difference can become apparent when subclassing these types. Over time, the type `complex` may be fixed to avoid coercion. All these types implement a `__coerce__()` method, for use by the built-in `coerce()` function.

### With Statement Context Managers

*New in version 2.5.*

A context manager is an object that defines the runtime context to be established when executing a `with` statement. The context manager handles the entry into, and the exit from, the desired runtime context for the execution of the block of code. Context managers are normally invoked using the `with` statement (described in section *The with statement*), but can also be used by directly invoking their
methods.

Typical uses of context managers include saving and restoring various kinds of global state, locking and unlocking resources, closing opened files, etc.

For more information on context managers, see Context Manager Types.

object.__enter__(self)

Enter the runtime context related to this object. The with statement will bind this method’s return value to the target(s) specified in the as clause of the statement, if any.

object.__exit__(self, exc_type, exc_value, traceback)

Exit the runtime context related to this object. The parameters describe the exception that caused the context to be exited. If the context was exited without an exception, all three arguments will be None.

If an exception is supplied, and the method wishes to suppress the exception (i.e., prevent it from being propagated), it should return a true value. Otherwise, the exception will be processed normally upon exit from this method.

Note that __exit__() methods should not reraise the passed-in exception; this is the caller’s responsibility.

See also:

PEP 0343 - The “with” statement

The specification, background, and examples for the Python with statement.
Special method lookup for old-style classes

For old-style classes, special methods are always looked up in exactly the same way as any other method or attribute. This is the case regardless of whether the method is being looked up explicitly as in `x.__getitem__(i)` or implicitly as in `x[i]`.

This behaviour means that special methods may exhibit different behaviour for different instances of a single old-style class if the appropriate special attributes are set differently:

```python
>>> class C:
...    pass
... >>> c1 = C()
>>> c2 = C()
>>> c1.__len__ = lambda: 5
>>> c2.__len__ = lambda: 9
>>> len(c1)
5
>>> len(c2)
9
```

Special method lookup for new-style classes

For new-style classes, implicit invocations of special methods are only guaranteed to work correctly if defined on an object's type, not in the object's instance dictionary. That behaviour is the reason why the following code raises an exception (unlike the equivalent example with old-style classes):

```python
>>> class C(object):
...    pass
... >>> c = C()
>>> c.__len__ = lambda: 5
>>> len(c)
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
TypeError: object of type 'C' has no len()
```
The rationale behind this behaviour lies with a number of special methods such as \_	exttt{\_hash\_}() and \_	exttt{\_repr\_}() that are implemented by all objects, including type objects. If the implicit lookup of these methods used the conventional lookup process, they would fail when invoked on the type object itself:

```python
>>> 1.__hash__() == hash(1)
True
>>> int.__hash__() == hash(int)
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
TypeError: descriptor '__hash__' of 'int' object needs an argument
```

Incorrectly attempting to invoke an unbound method of a class in this way is sometimes referred to as ‘metaclass confusion’, and is avoided by bypassing the instance when looking up special methods:

```python
>>> type(1).__hash__(1) == hash(1)
True
>>> type(int).__hash__(int) == hash(int)
True
```

In addition to bypassing any instance attributes in the interest of correctness, implicit special method lookup may also bypass the \_	exttt{\_getattribute\_}() method even of the object's metaclass:

```python
>>> class Meta(type):
...     def __getattribute__(*args):
...         print "Metaclass getattribute invoked"
...         return type.__getattribute__(*args)
...
>>> class C(object):
...     __metaclass__ = Meta
...     def __len__(self):
...         return 10
...     def __getattribute__(*args):
...         print "Class getattribute invoked"
...         return object.__getattribute__(*args)
...
>>> c = C()
```
Bypassing the \_\_getattribute\_\_() machinery in this fashion provides significant scope for speed optimisations within the interpreter, at the cost of some flexibility in the handling of special methods (the special method \textit{must} be set on the class object itself in order to be consistently invoked by the interpreter).

Footnotes

[1] It is possible in some cases to change an object's type, under certain controlled conditions. It generally isn't a good idea though, since it can lead to some very strange behaviour if it is handled incorrectly.

A descriptor can define any combination of \_\_get\_\_(), \_\_set\_\_() and \_\_delete\_\_(). If it does not define \_\_get\_\_(), then accessing the attribute even on an instance will return the descriptor object itself. If the descriptor defines \_\_set\_\_() and/or \_\_delete\_\_(), it is a data descriptor; if it defines neither, it is a non-data descriptor.

For operands of the same type, it is assumed that if the non-reflected method (such as \_\_add\_\_()) fails the operation is not supported, which is why the reflected method is not called.
Execution model
Names refer to objects. Names are introduced by name binding operations. Each occurrence of a name in the program text refers to the binding of that name established in the innermost function block containing the use.

A block is a piece of Python program text that is executed as a unit. The following are blocks: a module, a function body, and a class definition. Each command typed interactively is a block. A script file (a file given as standard input to the interpreter or specified on the interpreter command line the first argument) is a code block. A script command (a command specified on the interpreter command line with the ‘-c’ option) is a code block. The file read by the built-in function execfile() is a code block. The string argument passed to the built-in function eval() and to the exec statement is a code block. The expression read and evaluated by the built-in function input() is a code block.

A code block is executed in an execution frame. A frame contains some administrative information (used for debugging) and determines where and how execution continues after the code block’s execution has completed.

A scope defines the visibility of a name within a block. If a local variable is defined in a block, its scope includes that block. If the definition occurs in a function block, the scope extends to any blocks contained within the defining one, unless a contained block introduces a different binding for the name. The scope of names defined in a class block is limited to the class block; it does not extend to the code blocks of methods – this includes generator expressions since they are implemented using a function scope. This means that the following will fail:
```python
class A:
a = 42
b = list(a + i for i in range(10))
```

When a name is used in a code block, it is resolved using the nearest enclosing scope. The set of all such scopes visible to a code block is called the block’s *environment*.

If a name is bound in a block, it is a local variable of that block. If a name is bound at the module level, it is a global variable. (The variables of the module code block are local and global.) If a variable is used in a code block but not defined there, it is a *free variable*.

When a name is not found at all, a *NameError* exception is raised. If the name refers to a local variable that has not been bound, a *UnboundLocalError* exception is raised. *UnboundLocalError* is a subclass of *NameError*.

The following constructs bind names: formal parameters to functions, *import* statements, class and function definitions (these bind the class or function name in the defining block), and targets that are identifiers if occurring in an assignment, *for* loop header, or in the second position of an *except* clause header. The *import* statement of the form “`from ...import *`” binds all names defined in the imported module, except those beginning with an underscore. This form may only be used at the module level.

A target occurring in a *del* statement is also considered bound for this purpose (though the actual semantics are to unbind the name). It is illegal to unbind a name that is referenced by an enclosing scope; the compiler will report a *SyntaxError*.

Each assignment or import statement occurs within a block defined by a class or function definition or at the module level (the top-level code block).
If a name binding operation occurs anywhere within a code block, all uses of the name within the block are treated as references to the current block. This can lead to errors when a name is used within a block before it is bound. This rule is subtle. Python lacks declarations and allows name binding operations to occur anywhere within a code block. The local variables of a code block can be determined by scanning the entire text of the block for name binding operations.

If the global statement occurs within a block, all uses of the name specified in the statement refer to the binding of that name in the top-level namespace. Names are resolved in the top-level namespace by searching the global namespace, i.e. the namespace of the module containing the code block, and the builtin namespace, the namespace of the module __builtins__. The global namespace is searched first. If the name is not found there, the builtin namespace is searched. The global statement must precede all uses of the name.

The built-in namespace associated with the execution of a code block is actually found by looking up the name __builtins__ in its global namespace; this should be a dictionary or a module (in the latter case the module’s dictionary is used). By default, when in the __main__ module, __builtins__ is the built-in module __builtin__ (note: no ‘s’); when in any other module, __builtins__ is an alias for the dictionary of the __builtin__ module itself. __builtins__ can be set to a user-created dictionary to create a weak form of restricted execution.

**Note:** Users should not touch __builtins__; it is strictly an implementation detail. Users wanting to override values in the built-in namespace should import the __builtin__ (no ‘s’) module and modify its attributes appropriately.

The namespace for a module is automatically created the first time a
module is imported. The main module for a script is always called

$\texttt{__main__}$. 

The global statement has the same scope as a name binding operation in the same block. If the nearest enclosing scope for a free variable contains a global statement, the free variable is treated as a global.

A class definition is an executable statement that may use and define names. These references follow the normal rules for name resolution. The namespace of the class definition becomes the attribute dictionary of the class. Names defined at the class scope are not visible in methods.

### Interaction with dynamic features

There are several cases where Python statements are illegal when used in conjunction with nested scopes that contain free variables.

If a variable is referenced in an enclosing scope, it is illegal to delete the name. An error will be reported at compile time.

If the wild card form of import — $\texttt{import \*}$ — is used in a function and the function contains or is a nested block with free variables, the compiler will raise a $\texttt{SyntaxError}$.

If $\texttt{exec}$ is used in a function and the function contains or is a nested block with free variables, the compiler will raise a $\texttt{SyntaxError}$ unless the exec explicitly specifies the local namespace for the $\texttt{exec}$. (In other words, $\texttt{exec \ obj}$ would be illegal, but $\texttt{exec \ obj \ in \ ns}$ would be legal.)

The $\texttt{eval()}$, $\texttt{execfile()}$, and $\texttt{input()}$ functions and the $\texttt{exec}$ statement do not have access to the full environment for resolving names. Names may be resolved in the local and global namespaces
of the caller. Free variables are not resolved in the nearest enclosing
namespace, but in the global namespace. [1] The `exec` statement
and the `eval()` and `execfile()` functions have optional arguments to
override the global and local namespace. If only one namespace is
specified, it is used for both.
Exceptions

Exceptions are a means of breaking out of the normal flow of control of a code block in order to handle errors or other exceptional conditions. An exception is *raised* at the point where the error is detected; it may be *handled* by the surrounding code block or by any code block that directly or indirectly invoked the code block where the error occurred.

The Python interpreter raises an exception when it detects a runtime error (such as division by zero). A Python program can also explicitly raise an exception with the *raise* statement. Exception handlers are specified with the *try ... except* statement. The *finally* clause of such a statement can be used to specify cleanup code which does not handle the exception, but is executed whether an exception occurred or not in the preceding code.

Python uses the “termination” model of error handling: an exception handler can find out what happened and continue execution at an outer level, but it cannot repair the cause of the error and retry the failing operation (except by re-entering the offending piece of code from the top).

When an exception is not handled at all, the interpreter terminates execution of the program, or returns to its interactive main loop. In either case, it prints a stack backtrace, except when the exception is *SystemExit*.

Exceptions are identified by class instances. The *except* clause is selected depending on the class of the instance: it must reference the class of the instance or a base class thereof. The instance can be received by the handler and can carry additional information about the exceptional condition.
Exceptions can also be identified by strings, in which case the `except` clause is selected by object identity. An arbitrary value can be raised along with the identifying string which can be passed to the handler.

**Warning:** Messages to exceptions are not part of the Python API. Their contents may change from one version of Python to the next without warning and should not be relied on by code which will run under multiple versions of the interpreter.

See also the description of the `try` statement in section *The try statement* and `raise` statement in section *The raise statement*.

**Footnotes**

This limitation occurs because the code that is executed by these operations is not available at the time the module is compiled.
Expressions

This chapter explains the meaning of the elements of expressions in Python.

**Syntax Notes:** In this and the following chapters, extended BNF notation will be used to describe syntax, not lexical analysis. When (one alternative of) a syntax rule has the form

\[
\text{name} ::= \text{othername}
\]

and no semantics are given, the semantics of this form of *name* are the same as for *othername*. 
**Arithmetic conversions**

When a description of an arithmetic operator below uses the phrase “the numeric arguments are converted to a common type,” the arguments are coerced using the coercion rules listed at *Coercion rules*. If both arguments are standard numeric types, the following coercions are applied:

- If either argument is a complex number, the other is converted to complex;
- otherwise, if either argument is a floating point number, the other is converted to floating point;
- otherwise, if either argument is a long integer, the other is converted to long integer;
- otherwise, both must be plain integers and no conversion is necessary.

Some additional rules apply for certain operators (e.g., a string left argument to the ‘%’ operator). Extensions can define their own coercions.
Atoms

Atoms are the most basic elements of expressions. The simplest atoms are identifiers or literals. Forms enclosed in reverse quotes or in parentheses, brackets or braces are also categorized syntactically as atoms. The syntax for atoms is:

\[
\begin{align*}
\text{atom} & \::= \text{identifier} \mid \text{literal} \mid \text{enclosure} \\
\text{enclosure} & \::= \text{parenth_form} \mid \text{list_display} \\
& \quad \mid \text{generator_expression} \mid \text{dict_display} \\
& \quad \mid \text{string_conversion} \mid \text{yield_atom}
\end{align*}
\]

Identifiers (Names)

An identifier occurring as an atom is a name. See section *Identifiers and keywords* for lexical definition and section *Naming and binding* for documentation of naming and binding.

When the name is bound to an object, evaluation of the atom yields that object. When a name is not bound, an attempt to evaluate it raises a *NameError* exception.

**Private name mangling:** When an identifier that textually occurs in a class definition begins with two or more underscore characters and does not end in two or more underscores, it is considered a *private name* of that class. Private names are transformed to a longer form before code is generated for them. The transformation inserts the class name in front of the name, with leading underscores removed, and a single underscore inserted in front of the class name. For example, the identifier `__spam` occurring in a class named `Ham` will be transformed to `__Ham__spam`. This transformation is independent of the syntactical context in which the identifier is used. If the transformed name is extremely long (longer than 255 characters), implementation defined truncation may happen. If the class name consists only of
underscores, no transformation is done.

**Literals**

Python supports string literals and various numeric literals:

| literal ::= | stringliteral | integer | longinteger |
|            | floatnumber   | imagnumber |

Evaluation of a literal yields an object of the given type (string, integer, long integer, floating point number, complex number) with the given value. The value may be approximated in the case of floating point and imaginary (complex) literals. See section *Literals* for details.

All literals correspond to immutable data types, and hence the object's identity is less important than its value. Multiple evaluations of literals with the same value (either the same occurrence in the program text or a different occurrence) may obtain the same object or a different object with the same value.

**Parenthesized forms**

A parenthesized form is an optional expression list enclosed in parentheses:

```
parenth_form ::= "(" [expression_list] ")"
```

A parenthesized expression list yields whatever that expression list yields: if the list contains at least one comma, it yields a tuple; otherwise, it yields the single expression that makes up the expression list.

An empty pair of parentheses yields an empty tuple object. Since tuples are immutable, the rules for literals apply (i.e., two
occurrences of the empty tuple may or may not yield the same object).

Note that tuples are not formed by the parentheses, but rather by use of the comma operator. The exception is the empty tuple, for which parentheses are required — allowing unparenthesized “nothing” in expressions would cause ambiguities and allow common typos to pass uncaught.

List displays

A list display is a possibly empty series of expressions enclosed in square brackets:

```
list_display ::= "[" [expression_list | list_comprehension]"
list_comprehension ::= expression list_for
list_for ::= "for" target_list "in" old_expression_list
old_expression_list ::= old_expression ["," old_expression]*
list_iter ::= list_for | list_if
list_if ::= "if" old_expression [list_iter]
```

A list display yields a new list object. Its contents are specified by providing either a list of expressions or a list comprehension. When a comma-separated list of expressions is supplied, its elements are evaluated from left to right and placed into the list object in that order. When a list comprehension is supplied, it consists of a single expression followed by at least one `for` clause and zero or more `for` or `if` clauses. In this case, the elements of the new list are those that would be produced by considering each of the `for` or `if` clauses a block, nesting from left to right, and evaluating the expression to produce a list element each time the innermost block is reached [1].

Generator expressions

A generator expression is a compact generator notation in
A generator expression yields a new generator object. It consists of a single expression followed by at least one for clause and zero or more for or if clauses. The iterating values of the new generator are those that would be produced by considering each of the for or if clauses a block, nesting from left to right, and evaluating the expression to yield a value that is reached the innermost block for each iteration.

Variables used in the generator expression are evaluated lazily in a separate scope when the next() method is called for the generator object (in the same fashion as for normal generators). However, the in expression of the leftmost for clause is immediately evaluated in the current scope so that an error produced by it can be seen before any other possible error in the code that handles the generator expression. Subsequent for and if clauses cannot be evaluated immediately since they may depend on the previous for loop. For example: (x*y for x in range(10) for y in bar(x)).

The parentheses can be omitted on calls with only one argument. See section Calls for the detail.

**Dictionary displays**

A dictionary display is a possibly empty series of key/datum pairs enclosed in curly braces:

```
dict_display ::= "{% [key_datum_list] "}"
key_datum_list ::= key_datum ("," key_datum)* [","败]```
A dictionary display yields a new dictionary object.

The key/datum pairs are evaluated from left to right to define the entries of the dictionary: each key object is used as a key into the dictionary to store the corresponding datum.

Restrictions on the types of the key values are listed earlier in section *The standard type hierarchy*. (To summarize, the key type should be *hashable*, which excludes all mutable objects.) Clashes between duplicate keys are not detected; the last datum (textually rightmost in the display) stored for a given key value prevails.

### String conversions

A string conversion is an expression list enclosed in reverse (a.k.a. backward) quotes:

```
string_conversion ::= "" expression_list ""
```

A string conversion evaluates the contained expression list and converts the resulting object into a string according to rules specific to its type.

If the object is a string, a number, `None`, or a tuple, list or dictionary containing only objects whose type is one of these, the resulting string is a valid Python expression which can be passed to the built-in function `eval()` to yield an expression with the same value (or an approximation, if floating point numbers are involved).

(In particular, converting a string adds quotes around it and converts “funny” characters to escape sequences that are safe to print.)

Recursive objects (for example, lists or dictionaries that contain a
reference to themselves, directly or indirectly) use ... to indicate a recursive reference, and the result cannot be passed to `eval()` to get an equal value (`SyntaxError` will be raised instead).

The built-in function `repr()` performs exactly the same conversion in its argument as enclosing it in parentheses and reverse quotes does. The built-in function `str()` performs a similar but more user-friendly conversion.

### Yield expressions

```
yield_atom      ::= "(" yield_expression ")"
yield_expression ::= "yield" [expression_list]
```

*New in version 2.5.*

The `yield` expression is only used when defining a generator function, and can only be used in the body of a function definition. Using a `yield` expression in a function definition is sufficient to cause that definition to create a generator function instead of a normal function.

When a generator function is called, it returns an iterator known as a generator. That generator then controls the execution of a generator function. The execution starts when one of the generator’s methods is called. At that time, the execution proceeds to the first `yield` expression, where it is suspended again, returning the value of `expression_list` to generator’s caller. By suspended we mean that all local state is retained, including the current bindings of local variables, the instruction pointer, and the internal evaluation stack. When the execution is resumed by calling one of the generator’s methods, the function can proceed exactly as if the `yield` expression was just another external call. The value of the `yield` expression after resuming depends on the method which resumed the
All of this makes generator functions quite similar to coroutines; they yield multiple times, they have more than one entry point and their execution can be suspended. The only difference is that a generator function cannot control where should the execution continue after it yields; the control is always transferred to the generator’s caller.

The following generator’s methods can be used to control the execution of a generator function:

**generator.next()**

Starts the execution of a generator function or resumes it at the last executed `yield` expression. When a generator function is resumed with a `next()` method, the current `yield` expression always evaluates to `None`. The execution then continues to the next `yield` expression, where the generator is suspended again, and the value of the `expression_list` is returned to `next()`'s caller. If the generator exits without yielding another value, a `StopIteration` exception is raised.

**generator.send(value)**

Resumes the execution and “sends” a value into the generator function. The `value` argument becomes the result of the current `yield` expression. The `send()` method returns the next value yielded by the generator, or raises `StopIteration` if the generator exits without yielding another value. When `send()` is called to start the generator, it must be called with `None` as the argument, because there is no `yield` expression that could receive the value.

**generator.throw(type[, value[, traceback]])**

Raises an exception of type `type` at the point where generator
was paused, and returns the next value yielded by the generator function. If the generator exits without yielding another value, a StopIteration exception is raised. If the generator function does not catch the passed-in exception, or raises a different exception, then that exception propagates to the caller.

generator.close()

Raises a GeneratorExit at the point where the generator function was paused. If the generator function then raises StopIteration (by exiting normally, or due to already being closed) or GeneratorExit (by not catching the exception), close returns to its caller. If the generator yields a value, a RuntimeError is raised. If the generator raises any other exception, it is propagated to the caller. close() does nothing if the generator has already exited due to an exception or normal exit.

Here is a simple example that demonstrates the behavior of generators and generator functions:

```python
>>> def echo(value=None):
...     print "Execution starts when 'next()' is called for the first time."
...     try:
...         while True:
...             try:
...                 value = (yield value)
...             except Exception, e:
...                 value = e
...     finally:
...         print "Don't forget to clean up when 'close()' is called."
...
>>> generator = echo(1)
>>> print generator.next()
Execution starts when 'next()' is called for the first time.
1
>>> print generator.next()
None
>>> print generator.send(2)
2
>>> generator.throw(TypeError, "spam")
TypeError('spam',)
>>> generator.close()
```
Don't forget to clean up when 'close()' is called.

**PEP 0342 - Coroutines via Enhanced Generators**

The proposal to enhance the API and syntax of generators, making them usable as simple coroutines.
Primaries

Primaries represent the most tightly bound operations of the language. Their syntax is:

\[
\text{primary} ::= \text{atom} \mid \text{attributeref} \mid \text{subscription} \mid \text{slicing} \mid \text{call}
\]

Attribute references

An attribute reference is a primary followed by a period and a name:

\[
\text{attributeref} ::= \text{primary} \cdot \text{identifier}
\]

The primary must evaluate to an object of a type that supports attribute references, e.g., a module, list, or an instance. This object is then asked to produce the attribute whose name is the identifier. If this attribute is not available, the exception \text{AttributeError} is raised. Otherwise, the type and value of the object produced is determined by the object. Multiple evaluations of the same attribute reference may yield different objects.

Subscriptions

A subscription selects an item of a sequence (string, tuple or list) or mapping (dictionary) object:

\[
\text{subscription} ::= \text{primary} \cdot [ \text{expression_list} ]
\]

The primary must evaluate to an object of a sequence or mapping type.

If the primary is a mapping, the expression list must evaluate to an object whose value is one of the keys of the mapping, and the
subscription selects the value in the mapping that corresponds to that key. (The expression list is a tuple except if it has exactly one item.)

If the primary is a sequence, the expression (list) must evaluate to a plain integer. If this value is negative, the length of the sequence is added to it (so that, e.g., \( x[-1] \) selects the last item of \( x \)). The resulting value must be a nonnegative integer less than the number of items in the sequence, and the subscription selects the item whose index is that value (counting from zero).

A string's items are characters. A character is not a separate data type but a string of exactly one character.

### Slicings

A slicing selects a range of items in a sequence object (e.g., a string, tuple or list). Slicings may be used as expressions or as targets in assignment or `del` statements. The syntax for a slicing:

```
slicing ::= simple_slicing | extended_slicing
simple_slicing ::= primary "[" short_slice "]"
extended_slicing ::= primary "[" slice_list "]"
slice_list ::= slice_item ("," slice_item)* [","]
slice_item ::= expression | proper_slice | ellipsis
proper_slice ::= short_slice | long_slice
short_slice ::= [lower_bound] ";" [upper_bound]
long_slice ::= short_slice ";" [stride]
lower_bound ::= expression
upper_bound ::= expression
stride ::= expression
ellipsis ::= "..."
```

There is ambiguity in the formal syntax here: anything that looks like an expression list also looks like a slice list, so any subscription can be interpreted as a slicing. Rather than further complicating the syntax, this is disambiguated by defining that in this case the interpretation as a subscription takes priority over the interpretation
as a slicing (this is the case if the slice list contains no proper slice nor ellipses). Similarly, when the slice list has exactly one short slice and no trailing comma, the interpretation as a simple slicing takes priority over that as an extended slicing.

The semantics for a simple slicing are as follows. The primary must evaluate to a sequence object. The lower and upper bound expressions, if present, must evaluate to plain integers; defaults are zero and the `sys.maxint`, respectively. If either bound is negative, the sequence's length is added to it. The slicing now selects all items with index $k$ such that $i \leq k < j$ where $i$ and $j$ are the specified lower and upper bounds. This may be an empty sequence. It is not an error if $i$ or $j$ lie outside the range of valid indexes (such items don't exist so they aren't selected).

The semantics for an extended slicing are as follows. The primary must evaluate to a mapping object, and it is indexed with a key that is constructed from the slice list, as follows. If the slice list contains at least one comma, the key is a tuple containing the conversion of the slice items; otherwise, the conversion of the lone slice item is the key. The conversion of a slice item that is an expression is that expression. The conversion of an ellipsis slice item is the built-in `Ellipsis` object. The conversion of a proper slice is a slice object (see section *The standard type hierarchy*) whose `start`, `stop` and `step` attributes are the values of the expressions given as lower bound, upper bound and stride, respectively, substituting `None` for missing expressions.

## Calls

A call calls a callable object (e.g., a function) with a possibly empty series of arguments:

```
call ::= primary "(" [argument_list [","]]
```
A trailing comma may be present after the positional and keyword arguments but does not affect the semantics.

The primary must evaluate to a callable object (user-defined functions, built-in functions, methods of built-in objects, class objects, methods of class instances, and certain class instances themselves are callable; extensions may define additional callable object types). All argument expressions are evaluated before the call is attempted. Please refer to section *Function definitions* for the syntax of formal parameter lists.

If keyword arguments are present, they are first converted to positional arguments, as follows. First, a list of unfilled slots is created for the formal parameters. If there are N positional arguments, they are placed in the first N slots. Next, for each keyword argument, the identifier is used to determine the corresponding slot (if the identifier is the same as the first formal parameter name, the first slot is used, and so on). If the slot is already filled, a `TypeError` exception is raised. Otherwise, the value of the argument is placed in the slot, filling it (even if the expression is `None`, it fills the slot). When all arguments have been processed, the slots that are still unfilled are filled with the corresponding default value from the function definition. (Default values are calculated, once, when the function is defined; thus, a mutable object such as a list or dictionary used as default value will be shared by all calls that
don’t specify an argument value for the corresponding slot; this should usually be avoided.) If there are any unfilled slots for which no default value is specified, a **TypeError** exception is raised. Otherwise, the list of filled slots is used as the argument list for the call.

**Note:** An implementation may provide builtin functions whose positional parameters do not have names, even if they are ‘named’ for the purpose of documentation, and which therefore cannot be supplied by keyword. In CPython, this is the case for functions implemented in C that use **PyArg_ParseTuple** to parse their arguments.

If there are more positional arguments than there are formal parameter slots, a **TypeError** exception is raised, unless a formal parameter using the syntax *identifier* is present; in this case, that formal parameter receives a tuple containing the excess positional arguments (or an empty tuple if there were no excess positional arguments).

If any keyword argument does not correspond to a formal parameter name, a **TypeError** exception is raised, unless a formal parameter using the syntax **identifier** is present; in this case, that formal parameter receives a dictionary containing the excess keyword arguments (using the keywords as keys and the argument values as corresponding values), or a (new) empty dictionary if there were no excess keyword arguments.

If the syntax *expression* appears in the function call, *expression* must evaluate to a sequence. Elements from this sequence are treated as if they were additional positional arguments; if there are positional arguments \(x_1, \ldots, x_N\), and \(expression\) evaluates to a sequence \(y_1, \ldots, y_M\), this is equivalent to a call with \(M+N\) positional arguments \(x_1, \ldots, x_N, y_1, \ldots, y_M\).
A consequence of this is that although the *expression syntax may appear after some keyword arguments, it is processed before the keyword arguments (and the **expression argument, if any – see below). So:

```python
>>> def f(a, b):
    ... print a, b
    ...
>>> f(b=1, *(2,))
2 1
>>> f(a=1, *(2,))
Traceback (most recent call last):
  File "<stdin>", line 1, in 
TypeError: f() got multiple values for keyword argument 'a'
>>> f(1, *(2,))
1 2
```

It is unusual for both keyword arguments and the *expression syntax to be used in the same call, so in practice this confusion does not arise.

If the syntax **expression appears in the function call, expression must evaluate to a mapping, the contents of which are treated as additional keyword arguments. In the case of a keyword appearing in both expression and as an explicit keyword argument, a TypeError exception is raised.

Formal parameters using the syntax *identifier or **identifier cannot be used as positional argument slots or as keyword argument names. Formal parameters using the syntax (sublist) cannot be used as keyword argument names; the outermost sublist corresponds to a single unnamed argument slot, and the argument value is assigned to the sublist using the usual tuple assignment rules after all other parameter processing is done.

A call always returns some value, possibly None, unless it raises an exception. How this value is computed depends on the type of the
callable object.

If it is—

a user-defined function:
   The code block for the function is executed, passing it the argument list. The first thing the code block will do is bind the formal parameters to the arguments; this is described in section *Function definitions*. When the code block executes a `return` statement, this specifies the return value of the function call.

a built-in function or method:
   The result is up to the interpreter; see *Built-in Functions* for the descriptions of built-in functions and methods.

a class object:
   A new instance of that class is returned.

a class instance method:
   The corresponding user-defined function is called, with an argument list that is one longer than the argument list of the call: the instance becomes the first argument.

a class instance:
   The class must define a `__call__()` method; the effect is then the same as if that method was called.
The power operator

The power operator binds more tightly than unary operators on its left; it binds less tightly than unary operators on its right. The syntax is:

\[
\text{power ::= primary } ["**" \text{ u_expr}]
\]

Thus, in an unparenthesized sequence of power and unary operators, the operators are evaluated from right to left (this does not constrain the evaluation order for the operands): \(-1**2\) results in \(-1\).

The power operator has the same semantics as the built-in \texttt{pow()} function, when called with two arguments: it yields its left argument raised to the power of its right argument. The numeric arguments are first converted to a common type. The result type is that of the arguments after coercion.

With mixed operand types, the coercion rules for binary arithmetic operators apply. For \texttt{int} and \texttt{long int} operands, the result has the same type as the operands (after coercion) unless the second argument is negative; in that case, all arguments are converted to float and a float result is delivered. For example, \(10**2\) returns \(100\), but \(10**-2\) returns \(0.01\). (This last feature was added in Python 2.2. In Python 2.1 and before, if both arguments were of integer types and the second argument was negative, an exception was raised).

Raising \(0.0\) to a negative power results in a \texttt{ZeroDivisionError}. Raising a negative number to a fractional power results in a \texttt{ValueError}. 
Unary arithmetic operations

All unary arithmetic (and bitwise) operations have the same priority:

\[
\text{u_expr ::= power | "-" u_expr | "+" u_expr | "~" u_expr}
\]

The unary \( - \) (minus) operator yields the negation of its numeric argument.

The unary \( + \) (plus) operator yields its numeric argument unchanged.

The unary \( \sim \) (invert) operator yields the bitwise inversion of its plain or long integer argument. The bitwise inversion of \( x \) is defined as \(- (x + 1)\). It only applies to integral numbers.

In all three cases, if the argument does not have the proper type, a \texttt{TypeError} exception is raised.
Binary arithmetic operations

The binary arithmetic operations have the conventional priority levels. Note that some of these operations also apply to certain non-numeric types. Apart from the power operator, there are only two levels, one for multiplicative operators and one for additive operators:

```
m_expr ::= u_expr | m_expr "*" u_expr | m_expr "/" u_expr |
      | m_expr "%" u_expr
a_expr ::= m_expr | a_expr "+" m_expr | a_expr "-" m_expr
```

The `*` (multiplication) operator yields the product of its arguments. The arguments must either both be numbers, or one argument must be an integer (plain or long) and the other must be a sequence. In the former case, the numbers are converted to a common type and then multiplied together. In the latter case, sequence repetition is performed; a negative repetition factor yields an empty sequence.

The `/` (division) and `//` (floor division) operators yield the quotient of their arguments. The numeric arguments are first converted to a common type. Plain or long integer division yields an integer of the same type; the result is that of mathematical division with the ‘floor’ function applied to the result. Division by zero raises the `ZeroDivisionError` exception.

The `%` (modulo) operator yields the remainder from the division of the first argument by the second. The numeric arguments are first converted to a common type. A zero right argument raises the `ZeroDivisionError` exception. The arguments may be floating point numbers, e.g., `3.14%0.7` equals `0.34` (since `3.14` equals `4*0.7 + 0.34.`) The modulo operator always yields a result with the same sign as its second operand (or zero); the absolute value of the result is
strictly smaller than the absolute value of the second operand [2].

The integer division and modulo operators are connected by the following identity: \( x \equiv (x/y)y + (x\%y) \). Integer division and modulo are also connected with the built-in function \( \text{divmod}(x, y) \equiv (x/y, x\%y) \). These identities don’t hold for floating point numbers; there similar identities hold approximately where \( x/y \) is replaced by \( \text{floor}(x/y) \) or \( \text{floor}(x/y) - 1 \) [3].

In addition to performing the modulo operation on numbers, the % operator is also overloaded by string and unicode objects to perform string formatting (also known as interpolation). The syntax for string formatting is described in the Python Library Reference, section \( \text{String Formatting Operations} \).

\textit{Deprecated since version 2.3}: The floor division operator, the modulo operator, and the \( \text{divmod()} \) function are no longer defined for complex numbers. Instead, convert to a floating point number using the \( \text{abs()} \) function if appropriate.

The + (addition) operator yields the sum of its arguments. The arguments must either both be numbers or both sequences of the same type. In the former case, the numbers are converted to a common type and then added together. In the latter case, the sequences are concatenated.

The - (subtraction) operator yields the difference of its arguments. The numeric arguments are first converted to a common type.
Shifting operations

The shifting operations have lower priority than the arithmetic operations:

```
shift_expr ::= a_expr | shift_expr ( "<<" | ">>" ) a_expr
```

These operators accept plain or long integers as arguments. The arguments are converted to a common type. They shift the first argument to the left or right by the number of bits given by the second argument.

A right shift by $n$ bits is defined as division by $\text{pow}(2, n)$. A left shift by $n$ bits is defined as multiplication with $\text{pow}(2, n)$. Negative shift counts raise a `ValueError` exception.
Binary bitwise operations

Each of the three bitwise operations has a different priority level:

<table>
<thead>
<tr>
<th>Syntax</th>
<th>Expression</th>
</tr>
</thead>
<tbody>
<tr>
<td>and_expr</td>
<td>shift_expr</td>
</tr>
<tr>
<td>xor_expr</td>
<td>and_expr</td>
</tr>
<tr>
<td>or_expr</td>
<td>xor_expr</td>
</tr>
</tbody>
</table>

The & operator yields the bitwise AND of its arguments, which must be plain or long integers. The arguments are converted to a common type.

The ^ operator yields the bitwise XOR (exclusive OR) of its arguments, which must be plain or long integers. The arguments are converted to a common type.

The | operator yields the bitwise (inclusive) OR of its arguments, which must be plain or long integers. The arguments are converted to a common type.
Comparisons

Unlike C, all comparison operations in Python have the same priority, which is lower than that of any arithmetic, shifting or bitwise operation. Also unlike C, expressions like \( a < b < c \) have the interpretation that is conventional in mathematics:

\[
\text{comparison ::= or_expr ( comp_operator or_expr )}^*
\]

\[
\text{comp_operator ::= "<" | ">" | "==" | ">=" | "<<" | "><" | ">=" | "is" ["not"] | ["not"] "in"
\]

Comparisons yield boolean values: \text{True} or \text{False}.

Comparisons can be chained arbitrarily, e.g., \( x < y \leq z \) is equivalent to \( x < y \) and \( y \leq z \), except that \( y \) is evaluated only once (but in both cases \( z \) is not evaluated at all when \( x < y \) is found to be false).

Formally, if \( a, b, c, \ldots, y, z \) are expressions and \text{op1, op2, \ldots, opN} are comparison operators, then \( a \text{ op1 b op2 c \ldots y opN z} \) is equivalent to \( a \text{ op1 b and b op2 c and \ldots y opN z} \), except that each expression is evaluated at most once.

Note that \( a \text{ op1 b op2 c} \) doesn’t imply any kind of comparison between \( a \) and \( c \), so that, e.g., \( x < y > z \) is perfectly legal (though perhaps not pretty).

The forms \( <> \) and \( != \) are equivalent; for consistency with C, \( != \) is preferred; where \( != \) is mentioned below \( <> \) is also accepted. The \( <> \) spelling is considered obsolescent.

The operators \( <, >, ==, >=, <=, != \) compare the values of two objects. The objects need not have the same type. If both are
numbers, they are converted to a common type. Otherwise, objects of different types always compare unequal, and are ordered consistently but arbitrarily. You can control comparison behavior of objects of non-built-in types by defining a \_\_cmp\_\_ method or rich comparison methods like \_\_gt\_\_, described in section Special method names.

(This unusual definition of comparison was used to simplify the definition of operations like sorting and the \texttt{in} and \texttt{not in} operators. In the future, the comparison rules for objects of different types are likely to change.)

Comparison of objects of the same type depends on the type:

- Numbers are compared arithmetically.
- Strings are compared lexicographically using the numeric equivalents (the result of the built-in function \texttt{ord()}) of their characters. Unicode and 8-bit strings are fully interoperable in this behavior. [4]
- Tuples and lists are compared lexicographically using comparison of corresponding elements. This means that to compare equal, each element must compare equal and the two sequences must be of the same type and have the same length.

If not equal, the sequences are ordered the same as their first differing elements. For example, \texttt{cmp([1,2,x], [1,2,y])} returns the same as \texttt{cmp(x,y)}. If the corresponding element does not exist, the shorter sequence is ordered first (for example, \texttt{[1,2] < [1,2,3]}).

- Mappings (dictionaries) compare equal if and only if their sorted (key, value) lists compare equal. [5] Outcomes other than equality are resolved consistently, but are not otherwise defined.
Most other objects of builtin types compare unequal unless they are the same object; the choice whether one object is considered smaller or larger than another one is made arbitrarily but consistently within one execution of a program.

The operators `in` and `not in` test for collection membership. `x in s` evaluates to true if `x` is a member of the collection `s`, and false otherwise. `x not in s` returns the negation of `x in s`. The collection membership test has traditionally been bound to sequences; an object is a member of a collection if the collection is a sequence and contains an element equal to that object. However, it make sense for many other object types to support membership tests without being a sequence. In particular, dictionaries (for keys) and sets support membership testing.

For the list and tuple types, `x in y` is true if and only if there exists an index `i` such that `x == y[i]` is true.

For the Unicode and string types, `x in y` is true if and only if `x` is a substring of `y`. An equivalent test is `y.find(x) != -1`. Note, `x` and `y` need not be the same type; consequently, `u'ab' in 'abc'` will return `True`. Empty strings are always considered to be a substring of any other string, so `'' in 'abc'` will return `True`.

* Changed in version 2.3: Previously, `x` was required to be a string of length 1.

For user-defined classes which define the `__contains__()` method, `x in y` is true if and only if `y.__contains__(x)` is true.

For user-defined classes which do not define `__contains__()` and do define `__getitem__`, `x in y` is true if and only if there is a non-
negative integer index \( i \) such that \( x == y[i] \), and all lower integer indices do not raise \texttt{IndexError} \ exception. (If any other exception is raised, it is as if \texttt{in} raised that exception).

The operator \texttt{not in} is defined to have the inverse true value of \texttt{in}.

The operators \texttt{is} and \texttt{is not} test for object identity: \texttt{x is y} is true if and only if \( x \) and \( y \) are the same object. \texttt{x is not y} yields the inverse truth value.\[7\]
### Boolean operations

Boolean operations have the lowest priority of all Python operations:

<table>
<thead>
<tr>
<th>expression</th>
<th>::=</th>
<th>conditional_expression</th>
<th>or_test</th>
</tr>
</thead>
<tbody>
<tr>
<td>old_expression</td>
<td>::=</td>
<td>or_test</td>
<td>old_lambda_form</td>
</tr>
<tr>
<td>conditional_expression</td>
<td>::=</td>
<td>or_test</td>
<td>&quot;if&quot;</td>
</tr>
<tr>
<td>or_test</td>
<td>::=</td>
<td>and_test</td>
<td>or_test</td>
</tr>
<tr>
<td>and_test</td>
<td>::=</td>
<td>not_test</td>
<td>and_test</td>
</tr>
<tr>
<td>not_test</td>
<td>::=</td>
<td>comparison</td>
<td>&quot;not&quot;</td>
</tr>
</tbody>
</table>

In the context of Boolean operations, and also when expressions are used by control flow statements, the following values are interpreted as false: `False`, `None`, numeric zero of all types, and empty strings and containers (including strings, tuples, lists, dictionaries, sets and frozensets). All other values are interpreted as true. (See the `__nonzero__()` special method for a way to change this.)

The operator `not` yields `True` if its argument is false, `False` otherwise.

The expression `x if C else y` first evaluates `C (not x)`; if `C` is true, `x` is evaluated and its value is returned; otherwise, `y` is evaluated and its value is returned.

*New in version 2.5.*

The expression `x and y` first evaluates `x`; if `x` is false, its value is returned; otherwise, `y` is evaluated and the resulting value is returned.

The expression `x or y` first evaluates `x`; if `x` is true, its value is returned; otherwise, `y` is evaluated and the resulting value is returned.

(Note that neither `and` nor `or` restrict the value and type they return to
False and True, but rather return the last evaluated argument. This is sometimes useful, e.g., if s is a string that should be replaced by a default value if it is empty, the expression s or 'foo' yields the desired value. Because not has to invent a value anyway, it does not bother to return a value of the same type as its argument, so e.g., not 'foo' yields False, not ''.)
Lambda forms (lambda expressions) have the same syntactic position as expressions. They are a shorthand to create anonymous functions; the expression `lambda arguments: expression` yields a function object. The unnamed object behaves like a function object defined with

```
def name(arguments):
    return expression
```

See section *Function definitions* for the syntax of parameter lists. Note that functions created with lambda forms cannot contain statements.
Expression lists

expression_list ::= expression ( "," expression )* ["","]

An expression list containing at least one comma yields a tuple. The length of the tuple is the number of expressions in the list. The expressions are evaluated from left to right.

The trailing comma is required only to create a single tuple (a.k.a. a singleton); it is optional in all other cases. A single expression without a trailing comma doesn’t create a tuple, but rather yields the value of that expression. (To create an empty tuple, use an empty pair of parentheses: ().).
Evaluation order

Python evaluates expressions from left to right. Notice that while evaluating an assignment, the right-hand side is evaluated before the left-hand side.

In the following lines, expressions will be evaluated in the arithmetic order of their suffixes:

expr1, expr2, expr3, expr4
(expr1, expr2, expr3, expr4)
{expr1: expr2, expr3: expr4}
expr1 + expr2 * (expr3 - expr4)
expr1(expr2, expr3, *expr4, **expr5)
expr3, expr4 = expr1, expr2
The following table summarizes the operator precedences in Python, from lowest precedence (least binding) to highest precedence (most binding). Operators in the same box have the same precedence. Unless the syntax is explicitly given, operators are binary. Operators in the same box group left to right (except for comparisons, including tests, which all have the same precedence and chain from left to right — see section *Comparisons* — and exponentiation, which groups from right to left).

Footnotes

In Python 2.3 and later releases, a list comprehension “leaks” the control variables of each for it contains into the containing scope. However, this behavior is deprecated, and relying on it will not work in Python 3.0.

While $\text{abs}(x \% y) < \text{abs}(y)$ is true mathematically, for floats it may not be true numerically due to roundoff. For example, and assuming a platform on which a Python float is an IEEE 754 double-precision number, in order that $-1e-100 \% 1e100$ have the same sign as $1e100$, the computed result is $-1e-100 + 1e100$, which is numerically exactly equal to $1e100$. Function $\text{fmod()}$ in the $\text{math}$ module returns a result whose sign matches the sign of the first argument instead, and so returns $-1e-100$ in this case. Which approach is more appropriate depends on the application.

If $x$ is very close to an exact integer multiple of $y$, it’s possible for $\text{floor}(x/y)$ to be one larger than $(x-x\%y)/y$ due to rounding. In such cases, Python returns the latter result, in order to preserve that $\text{divmod}(x,y)[0] * y + x \% y$ be very close to $x$.

While comparisons between unicode strings make sense at the byte level, they may be counter-intuitive to users. For example, the strings $u"\u00c7$ and $u"\u0043\u0327$ compare differently, even though they both represent the same unicode character (LATIN CAPITAL LETTER C WITH CEDILLA). To compare strings in a human recognizable way, compare using $\text{unicodedata.normalize()}$.

The implementation computes this efficiently, without constructing lists or sorting.

Earlier versions of Python used lexicographic comparison of the
sorted (key, value) lists, but this was very expensive for the common case of comparing for equality. An even earlier version of Python compared dictionaries by identity only, but this caused surprises because people expected to be able to test a dictionary for emptiness by comparing it to `{}`.

Due to automatic garbage-collection, free lists, and the dynamic nature of descriptors, you may notice seemingly unusual behaviour in certain uses of the `is` operator, like those involving comparisons between instance methods, or constants. Check their documentation for more info.
Simple statements

Simple statements are comprised within a single logical line. Several simple statements may occur on a single line separated by semicolons. The syntax for simple statements is:

```
simple_stmt ::= expression_stmt
               | assert_stmt
               | assignment_stmt
               | augmented_assignment_stmt
               | pass_stmt
               | del_stmt
               | print_stmt
               | return_stmt
               | yield_stmt
               | raise_stmt
               | break_stmt
               | continue_stmt
               | import_stmt
               | global_stmt
               | exec_stmt
```
Expression statements

Expression statements are used (mostly interactively) to compute and write a value, or (usually) to call a procedure (a function that returns no meaningful result; in Python, procedures return the value None). Other uses of expression statements are allowed and occasionally useful. The syntax for an expression statement is:

```
expression_stmt ::= expression_list
```

An expression statement evaluates the expression list (which may be a single expression).

In interactive mode, if the value is not `None`, it is converted to a string using the built-in `repr()` function and the resulting string is written to standard output (see section *The print statement*) on a line by itself. (Expression statements yielding `None` are not written, so that procedure calls do not cause any output.)
Assignment statements are used to (re)bind names to values and to modify attributes or items of mutable objects:

Assignment statements are used to (re)bind names to values and to modify attributes or items of mutable objects:

assignment_stmt ::= (target_list "=")+ (expression_list | yield_expression)

| target_list ::= target ("," target)* ["",""]
| target ::= identifier
| "(" target_list ")"
| "[" target_list "]"
| attributeref
| subscription
| slicing

(See section Primaries for the syntax definitions for the last three symbols.)

An assignment statement evaluates the expression list (remember that this can be a single expression or a comma-separated list, the latter yielding a tuple) and assigns the single resulting object to each of the target lists, from left to right.

Assignment is defined recursively depending on the form of the target (list). When a target is part of a mutable object (an attribute reference, subscription or slicing), the mutable object must ultimately perform the assignment and decide about its validity, and may raise an exception if the assignment is unacceptable. The rules observed by various types and the exceptions raised are given with the definition of the object types (see section The standard type hierarchy).

Assignment of an object to a target list is recursively defined as follows.

- If the target list is a single target: The object is assigned to that target.
• If the target list is a comma-separated list of targets: The object must be a sequence with the same number of items as there are targets in the target list, and the items are assigned, from left to right, to the corresponding targets. (This rule is relaxed as of Python 1.5; in earlier versions, the object had to be a tuple. Since strings are sequences, an assignment like \( a, b = \) "xy" is now legal as long as the string has the right length.)

Assignment of an object to a single target is recursively defined as follows.

• If the target is an identifier (name):
  
  ◦ If the name does not occur in a `global` statement in the current code block: the name is bound to the object in the current local namespace.
  ◦ Otherwise: the name is bound to the object in the current global namespace.

  The name is rebound if it was already bound. This may cause the reference count for the object previously bound to the name to reach zero, causing the object to be deallocated and its destructor (if it has one) to be called.

• If the target is a target list enclosed in parentheses or in square brackets: The object must be a sequence with the same number of items as there are targets in the target list, and its items are assigned, from left to right, to the corresponding targets.

• If the target is an attribute reference: The primary expression in the reference is evaluated. It should yield an object with assignable attributes; if this is not the case, `TypeError` is raised. That object is then asked to assign the assigned object to the given attribute; if it cannot perform the assignment, it raises an exception (usually but not necessarily `AttributeError`).
• If the target is a subscription: The primary expression in the reference is evaluated. It should yield either a mutable sequence object (such as a list) or a mapping object (such as a dictionary). Next, the subscript expression is evaluated.

If the primary is a mutable sequence object (such as a list), the subscript must yield a plain integer. If it is negative, the sequence’s length is added to it. The resulting value must be a nonnegative integer less than the sequence’s length, and the sequence is asked to assign the assigned object to its item with that index. If the index is out of range, IndexError is raised (assignment to a subscripted sequence cannot add new items to a list).

If the primary is a mapping object (such as a dictionary), the subscript must have a type compatible with the mapping’s key type, and the mapping is then asked to create a key/datum pair which maps the subscript to the assigned object. This can either replace an existing key/value pair with the same key value, or insert a new key/value pair (if no key with the same value existed).

• If the target is a slicing: The primary expression in the reference is evaluated. It should yield a mutable sequence object (such as a list). The assigned object should be a sequence object of the same type. Next, the lower and upper bound expressions are evaluated, insofar they are present; defaults are zero and the sequence’s length. The bounds should evaluate to (small) integers. If either bound is negative, the sequence’s length is added to it. The resulting bounds are clipped to lie between zero and the sequence’s length, inclusive. Finally, the sequence object is asked to replace the slice with the items of the assigned sequence. The length of the slice may be different from the length of the assigned sequence, thus changing the length of the target sequence, if the object allows it.
(In the current implementation, the syntax for targets is taken to be the same as for expressions, and invalid syntax is rejected during the code generation phase, causing less detailed error messages.)

**WARNING:** Although the definition of assignment implies that overlaps between the left-hand side and the right-hand side are ‘safe’ (for example \(a, b = b, a\) swaps two variables), overlaps within the collection of assigned-to variables are not safe! For instance, the following program prints \([0, 2]\):

```
x = [0, 1]
i = 0
i, x[i] = 1, 2
print x
```

**Augmented assignment statements**

Augmented assignment is the combination, in a single statement, of a binary operation and an assignment statement:

```
augmented_assignment_stmt ::= target augop (expression_list | yield_expression)
augop ::= "+=" | "-=" | "*=" | "/=" | "/= |
| ">>=" | "<<=" | "&=" | "^=" | "^=" | "^=" |
```

(See section *Primaries* for the syntax definitions for the last three symbols.)

An augmented assignment evaluates the target (which, unlike normal assignment statements, cannot be an unpacking) and the expression list, performs the binary operation specific to the type of assignment on the two operands, and assigns the result to the original target. The target is only evaluated once.

An augmented assignment expression like \(x += 1\) can be rewritten as \(x = x + 1\) to achieve a similar, but not exactly equal effect. In the
augmented version, \( x \) is only evaluated once. Also, when possible, the actual operation is performed \textit{in-place}, meaning that rather than creating a new object and assigning that to the target, the old object is modified instead.

With the exception of assigning to tuples and multiple targets in a single statement, the assignment done by augmented assignment statements is handled the same way as normal assignments. Similarly, with the exception of the possible \textit{in-place} behavior, the binary operation performed by augmented assignment is the same as the normal binary operations.

For targets which are attribute references, the initial value is retrieved with a \texttt{getattr()} and the result is assigned with a \texttt{setattr()}. Notice that the two methods do not necessarily refer to the same variable. When \texttt{getattr()} refers to a class variable, \texttt{setattr()} still writes to an instance variable. For example:

```python
class A:
    x = 3  # class variable
a = A()
a.x += 1 # writes a.x as 4 leaving A.x as 3
```
The assert statement

Assert statements are a convenient way to insert debugging assertions into a program:

```
assert_stmt ::= "assert" expression ["," expression]
```

The simple form, `assert expression`, is equivalent to

```
if __debug__:
    if not expression: raise AssertionError
```

The extended form, `assert expression1, expression2`, is equivalent to

```
if __debug__:
    if not expression1: raise AssertionError, expression2
```

These equivalences assume that `__debug__` and `AssertionError` refer to the built-in variables with those names. In the current implementation, the built-in variable `__debug__` is `True` under normal circumstances, `False` when optimization is requested (command line option `-O`). The current code generator emits no code for an assert statement when optimization is requested at compile time. Note that it is unnecessary to include the source code for the expression that failed in the error message; it will be displayed as part of the stack trace.

Assignments to `__debug__` are illegal. The value for the built-in variable is determined when the interpreter starts.
**The `pass` statement**

`pass_stmt ::= "pass"

`pass` is a null operation — when it is executed, nothing happens. It is useful as a placeholder when a statement is required syntactically, but no code needs to be executed, for example:

```python
def f(arg): pass  # a function that does nothing (yet)
class C: pass     # a class with no methods (yet)
```
The `del` statement

```plaintext
del_stmt ::= "del" target_list
```

Deletion is recursively defined very similar to the way assignment is defined. Rather that spelling it out in full details, here are some hints.

Deletion of a target list recursively deletes each target, from left to right.

Deletion of a name removes the binding of that name from the local or global namespace, depending on whether the name occurs in a `global` statement in the same code block. If the name is unbound, a `NameError` exception will be raised.

It is illegal to delete a name from the local namespace if it occurs as a free variable in a nested block.

Deletion of attribute references, subscriptions and slicings is passed to the primary object involved; deletion of a slicing is in general equivalent to assignment of an empty slice of the right type (but even this is determined by the sliced object).
The print statement

```
print_stmt ::= "print" ([expression ("," expression)* ["",""] ]
               | ">>" expression [""," expression]+ ["",""])
```

`print` evaluates each expression in turn and writes the resulting object to standard output (see below). If an object is not a string, it is first converted to a string using the rules for string conversions. The (resulting or original) string is then written. A space is written before each object is (converted and) written, unless the output system believes it is positioned at the beginning of a line. This is the case (1) when no characters have yet been written to standard output, (2) when the last character written to standard output is `'\n'`, or (3) when the last write operation on standard output was not a `print` statement. (In some cases it may be functional to write an empty string to standard output for this reason.)

**Note:** Objects which act like file objects but which are not the built-in file objects often do not properly emulate this aspect of the file object’s behavior, so it is best not to rely on this.

A `'\n'` character is written at the end, unless the `print` statement ends with a comma. This is the only action if the statement contains just the keyword `print`.

Standard output is defined as the file object named `stdout` in the built-in module `sys`. If no such object exists, or if it does not have a `write()` method, a `RuntimeError` exception is raised.

`print` also has an extended form, defined by the second portion of the syntax described above. This form is sometimes referred to as “`print` chevron.” In this form, the first expression after the `>>` must evaluate to a “file-like” object, specifically an object that has a
write() method as described above. With this extended form, the subsequent expressions are printed to this file object. If the first expression evaluates to None, then sys.stdout is used as the file for output.
The `return` statement

```
return_stmt ::= "return" [expression_list]
```

`return` may only occur syntactically nested in a function definition, not within a nested class definition.

If an expression list is present, it is evaluated, else `None` is substituted.

`return` leaves the current function call with the expression list (or `None`) as return value.

When `return` passes control out of a `try` statement with a `finally` clause, that `finally` clause is executed before really leaving the function.

In a generator function, the `return` statement is not allowed to include an `expression_list`. In that context, a bare `return` indicates that the generator is done and will cause `StopIteration` to be raised.
The `yield` statement

```
yield_stmt ::= yield_expression
```

The `yield` statement is only used when defining a generator function, and is only used in the body of the generator function. Using a `yield` statement in a function definition is sufficient to cause that definition to create a generator function instead of a normal function.

When a generator function is called, it returns an iterator known as a generator iterator, or more commonly, a generator. The body of the generator function is executed by calling the generator's `next()` method repeatedly until it raises an exception.

When a `yield` statement is executed, the state of the generator is frozen and the value of `expression_list` is returned to `next()`'s caller. By “frozen” we mean that all local state is retained, including the current bindings of local variables, the instruction pointer, and the internal evaluation stack: enough information is saved so that the next time `next()` is invoked, the function can proceed exactly as if the `yield` statement were just another external call.

As of Python version 2.5, the `yield` statement is now allowed in the `try` clause of a `try ... finally` construct. If the generator is not resumed before it is finalized (by reaching a zero reference count or by being garbage collected), the generator-iterator’s `close()` method will be called, allowing any pending `finally` clauses to execute.

**Note:** In Python 2.2, the `yield` statement was only allowed when the `generators` feature has been enabled. This `__future__` import statement was used to enable the feature:
See also:

**PEP 0255 - Simple Generators**
The proposal for adding generators and the `yield` statement to Python.

**PEP 0342 - Coroutines via Enhanced Generators**
The proposal that, among other generator enhancements, proposed allowing `yield` to appear inside a `try ... finally` block.
The *raise* statement

\[
\text{raise_stmt ::= "raise" [expression ["," expression ["," expression]]]}
\]

If no expressions are present, *raise* re-raises the last exception that was active in the current scope. If no exception is active in the current scope, a `TypeError` exception is raised indicating that this is an error (if running under IDLE, a `Queue.Empty` exception is raised instead).

Otherwise, *raise* evaluates the expressions to get three objects, using `None` as the value of omitted expressions. The first two objects are used to determine the `type` and `value` of the exception.

If the first object is an instance, the type of the exception is the class of the instance, the instance itself is the value, and the second object must be `None`.

If the first object is a class, it becomes the type of the exception. The second object is used to determine the exception value: If it is an instance of the class, the instance becomes the exception value. If the second object is a tuple, it is used as the argument list for the class constructor; if it is `None`, an empty argument list is used, and any other object is treated as a single argument to the constructor. The instance so created by calling the constructor is used as the exception value.

If a third object is present and not `None`, it must be a traceback object (see section *The standard type hierarchy*), and it is substituted instead of the current location as the place where the exception occurred. If the third object is present and not a traceback object or `None`, a `TypeError` exception is raised. The three-expression form of
raise is useful to re-raise an exception transparently in an except clause, but raise with no expressions should be preferred if the exception to be re-raised was the most recently active exception in the current scope.

Additional information on exceptions can be found in section *Exceptions*, and information about handling exceptions is in section *The try statement*. 
**The `break` statement**

`break_stmt ::= "break"

`break` may only occur syntactically nested in a `for` or `while` loop, but not nested in a function or class definition within that loop.

It terminates the nearest enclosing loop, skipping the optional `else` clause if the loop has one.

If a `for` loop is terminated by `break`, the loop control target keeps its current value.

When `break` passes control out of a `try` statement with a `finally` clause, that `finally` clause is executed before really leaving the loop.
The `continue` statement

```
continue_stmt ::= "continue"
```

`continue` may only occur syntactically nested in a `for` or `while` loop, but not nested in a function or class definition or `finally` clause within that loop. It continues with the next cycle of the nearest enclosing loop.

When `continue` passes control out of a `try` statement with a `finally` clause, that `finally` clause is executed before really starting the next loop cycle.
The *import* statement

```
import_stmt ::= "import" module ["as" name] ( "," module |
                   "from" relative_module "import" identifier |
                   "from" relative_module "import" "(" identifier ("," identifier ["as" name])*
                  "from" module "import" "(" identifier ("," identifier ["as" name])*
                  ")"
                  |
                   "from" module "import" "*")"
module ::= (identifier ".")* identifier
relative_module ::= "."* module | "."+
name ::= identifier
```

Import statements are executed in two steps: (1) find a module, and initialize it if necessary; (2) define a name or names in the local namespace (of the scope where the *import* statement occurs). The first form (without *from*) repeats these steps for each identifier in the list. The form with *from* performs step (1) once, and then performs step (2) repeatedly.

In this context, to “initialize” a built-in or extension module means to call an initialization function that the module must provide for the purpose (in the reference implementation, the function’s name is obtained by prepending string “init” to the module’s name); to “initialize” a Python-coded module means to execute the module’s body.

The system maintains a table of modules that have been or are being initialized, indexed by module name. This table is accessible as `sys.modules`. When a module name is found in this table, step (1) is finished. If not, a search for a module definition is started. When a module is found, it is loaded. Details of the module searching and loading process are implementation and platform specific. It generally involves searching for a “built-in” module with the given name and then searching a list of locations given as `sys.path`. 

If a built-in module is found, its built-in initialization code is executed and step (1) is finished. If no matching file is found, ImportError is raised. If a file is found, it is parsed, yielding an executable code block. If a syntax error occurs, SyntaxError is raised. Otherwise, an empty module of the given name is created and inserted in the module table, and then the code block is executed in the context of this module. Exceptions during this execution terminate step (1).

When step (1) finishes without raising an exception, step (2) can begin.

The first form of import statement binds the module name in the local namespace to the module object, and then goes on to import the next identifier, if any. If the module name is followed by as, the name following as is used as the local name for the module.

The from form does not bind the module name: it goes through the list of identifiers, looks each one of them up in the module found in step (1), and binds the name in the local namespace to the object thus found. As with the first form of import, an alternate local name can be supplied by specifying “as localname”. If a name is not found, ImportError is raised. If the list of identifiers is replaced by a star ('*'), all public names defined in the module are bound in the local namespace of the import statement.

The public names defined by a module are determined by checking the module's namespace for a variable named __all__; if defined, it must be a sequence of strings which are names defined or imported by that module. The names given in __all__ are all considered public and are required to exist. If __all__ is not defined, the set of public names includes all names found in the module's namespace which do not begin with an underscore character ('_'). __all__ should contain the entire public API. It is intended to avoid
accidentally exporting items that are not part of the API (such as library modules which were imported and used within the module).

The `from` form with `*` may only occur in a module scope. If the wild card form of import — `import *` — is used in a function and the function contains or is a nested block with free variables, the compiler will raise a `SyntaxError`.

**Hierarchical module names:** when the module names contains one or more dots, the module search path is carried out differently. The sequence of identifiers up to the last dot is used to find a “package”; the final identifier is then searched inside the package. A package is generally a subdirectory of a directory on `sys.path` that has a file `__init__.py`.

The built-in function `__import__()` is provided to support applications that determine which modules need to be loaded dynamically; refer to *Built-in Functions* for additional information.

### Future statements

A *future statement* is a directive to the compiler that a particular module should be compiled using syntax or semantics that will be available in a specified future release of Python. The future statement is intended to ease migration to future versions of Python that introduce incompatible changes to the language. It allows use of the new features on a per-module basis before the release in which the feature becomes standard.

```
future_statement ::= "from" "__future__" "import" feature ["as ("," feature ["as" name]]*
| "from" "__future__" "import" "(" feature ("," feature ["as" name]]* [","])")
feature ::= identifier
name ::= identifier
```
A future statement must appear near the top of the module. The only lines that can appear before a future statement are:

- the module docstring (if any),
- comments,
- blank lines, and
- other future statements.

The features recognized by Python 2.5 are `absolute_import`, `division`, `generators`, `nested_scopes` and `with_statement`. `generators` and `nested_scopes` are redundant in Python version 2.3 and above because they are always enabled.

A future statement is recognized and treated specially at compile time: Changes to the semantics of core constructs are often implemented by generating different code. It may even be the case that a new feature introduces new incompatible syntax (such as a new reserved word), in which case the compiler may need to parse the module differently. Such decisions cannot be pushed off until runtime.

For any given release, the compiler knows which feature names have been defined, and raises a compile-time error if a future statement contains a feature not known to it.

The direct runtime semantics are the same as for any import statement: there is a standard module `__future__`, described later, and it will be imported in the usual way at the time the future statement is executed.

The interesting runtime semantics depend on the specific feature enabled by the future statement.

Note that there is nothing special about the statement:

```python
import __future__ [as name]
```
That is not a future statement; it's an ordinary import statement with no special semantics or syntax restrictions.

Code compiled by an `exec` statement or calls to the built-in functions `compile()` and `execfile()` that occur in a module \texttt{M} containing a future statement will, by default, use the new syntax or semantics associated with the future statement. This can, starting with Python 2.2 be controlled by optional arguments to `compile()` — see the documentation of that function for details.

A future statement typed at an interactive interpreter prompt will take effect for the rest of the interpreter session. If an interpreter is started with the `-i` option, is passed a script name to execute, and the script includes a future statement, it will be in effect in the interactive session started after the script is executed.
The global statement

global_stmt ::= "global" identifier ("," identifier)*

The global statement is a declaration which holds for the entire current code block. It means that the listed identifiers are to be interpreted as globals. It would be impossible to assign to a global variable without global, although free variables may refer to globals without being declared global.

Names listed in a global statement must not be used in the same code block textually preceding that global statement.

Names listed in a global statement must not be defined as formal parameters or in a for loop control target, class definition, function definition, or import statement.

(The current implementation does not enforce the latter two restrictions, but programs should not abuse this freedom, as future implementations may enforce them or silently change the meaning of the program.)

Programmer’s note: the global is a directive to the parser. It applies only to code parsed at the same time as the global statement. In particular, a global statement contained in an exec statement does not affect the code block containing the exec statement, and code contained in an exec statement is unaffected by global statements in the code containing the exec statement. The same applies to the eval(), execfile() and compile() functions.
The **exec** statement

```
exec_stmt ::= "exec" or_expr ["in" expression ["," expression]]
```

This statement supports dynamic execution of Python code. The first expression should evaluate to either a string, an open file object, or a code object. If it is a string, the string is parsed as a suite of Python statements which is then executed (unless a syntax error occurs). If it is an open file, the file is parsed until EOF and executed. If it is a code object, it is simply executed. In all cases, the code that’s executed is expected to be valid as file input (see section *File input*). Be aware that the **return** and **yield** statements may not be used outside of function definitions even within the context of code passed to the **exec** statement.

In all cases, if the optional parts are omitted, the code is executed in the current scope. If only the first expression after **in** is specified, it should be a dictionary, which will be used for both the global and the local variables. If two expressions are given, they are used for the global and local variables, respectively. If provided, **locals** can be any mapping object.

*Changed in version 2.4:* Formerly, **locals** was required to be a dictionary.

As a side effect, an implementation may insert additional keys into the dictionaries given besides those corresponding to variable names set by the executed code. For example, the current implementation may add a reference to the dictionary of the built-in module **__builtin__** under the key **__builtins__** (!).

**Programmer’s hints:** dynamic evaluation of expressions is supported by the built-in function **eval()**. The built-in functions
`globals()` and `locals()` return the current global and local dictionary, respectively, which may be useful to pass around for use by `exec`.
Compound statements

Compound statements contain (groups of) other statements; they affect or control the execution of those other statements in some way. In general, compound statements span multiple lines, although in simple incarnations a whole compound statement may be contained in one line.

The if, while and for statements implement traditional control flow constructs. try specifies exception handlers and/or cleanup code for a group of statements. Function and class definitions are also syntactically compound statements.

Compound statements consist of one or more ‘clauses.’ A clause consists of a header and a ‘suite.’ The clause headers of a particular compound statement are all at the same indentation level. Each clause header begins with a uniquely identifying keyword and ends with a colon. A suite is a group of statements controlled by a clause. A suite can be one or more semicolon-separated simple statements on the same line as the header, following the header’s colon, or it can be one or more indented statements on subsequent lines. Only the latter form of suite can contain nested compound statements; the following is illegal, mostly because it wouldn’t be clear to which if clause a following else clause would belong:

```plaintext
if test1: if test2: print x
```

Also note that the semicolon binds tighter than the colon in this context, so that in the following example, either all or none of the print statements are executed:

```plaintext
if x < y < z: print x; print y; print z
```

Summarizing:
Note that statements always end in a `NEWLINE` possibly followed by a `DEDENT`. Also note that optional continuation clauses always begin with a keyword that cannot start a statement, thus there are no ambiguities (the ‘dangling `else`‘ problem is solved in Python by requiring nested `if` statements to be indented).

The formatting of the grammar rules in the following sections places each clause on a separate line for clarity.
The **if statement**

The *if* statement is used for conditional execution:

```
if_stmt ::=  "if" expression ":" suite
            ( "elif" expression ":" suite )*
            ["else" ":" suite]
```

It selects exactly one of the suites by evaluating the expressions one by one until one is found to be true (see section *Boolean operations* for the definition of true and false); then that suite is executed (and no other part of the *if* statement is executed or evaluated). If all expressions are false, the suite of the *else* clause, if present, is executed.
The **while** statement

The **while** statement is used for repeated execution as long as an expression is true:

```
while_stmt ::= "while" expression ":" suite 
              ["else" ":" suite]
```

This repeatedly tests the expression and, if it is true, executes the first suite; if the expression is false (which may be the first time it is tested) the suite of the **else** clause, if present, is executed and the loop terminates.

A **break** statement executed in the first suite terminates the loop without executing the **else** clause's suite. A **continue** statement executed in the first suite skips the rest of the suite and goes back to testing the expression.
The for statement

The for statement is used to iterate over the elements of a sequence (such as a string, tuple or list) or other iterable object:

```
for_stmt ::= "for" target_list "in" expression_list "::" suite
            ["else" "::" suite]
```

The expression list is evaluated once; it should yield an iterable object. An iterator is created for the result of the expression_list. The suite is then executed once for each item provided by the iterator, in the order of ascending indices. Each item in turn is assigned to the target list using the standard rules for assignments, and then the suite is executed. When the items are exhausted (which is immediately when the sequence is empty), the suite in the else clause, if present, is executed, and the loop terminates.

A break statement executed in the first suite terminates the loop without executing the else clause's suite. A continue statement executed in the first suite skips the rest of the suite and continues with the next item, or with the else clause if there was no next item.

The suite may assign to the variable(s) in the target list; this does not affect the next item assigned to it.

The target list is not deleted when the loop is finished, but if the sequence is empty, it will not have been assigned to at all by the loop. Hint: the built-in function range() returns a sequence of integers suitable to emulate the effect of Pascal's for i := a to b do; e.g., range(3) returns the list [0, 1, 2].

**Warning:** There is a subtlety when the sequence is being
modified by the loop (this can only occur for mutable sequences, i.e. lists). An internal counter is used to keep track of which item is used next, and this is incremented on each iteration. When this counter has reached the length of the sequence the loop terminates. This means that if the suite deletes the current (or a previous) item from the sequence, the next item will be skipped (since it gets the index of the current item which has already been treated). Likewise, if the suite inserts an item in the sequence before the current item, the current item will be treated again the next time through the loop. This can lead to nasty bugs that can be avoided by making a temporary copy using a slice of the whole sequence, e.g.,

```python
for x in a[:]:
    if x < 0: a.remove(x)
```
The **try** statement

The **try** statement specifies exception handlers and/or cleanup code for a group of statements:

```
try_stmt ::= try1_stmt | try2_stmt
try1_stmt ::= "try" ":" suite
             ("except" [expression ["," target]] ":" suite)+
             ["else" ":" suite]
             ["finally" ":" suite]
try2_stmt ::= "try" ":" suite
             "finally" ":" suite
```

*Changed in version 2.5:* In previous versions of Python, **try...except...finally** did not work. **try...except** had to be nested in **try...finally**.

The **except** clause(s) specify one or more exception handlers. When no exception occurs in the **try** clause, no exception handler is executed. When an exception occurs in the **try** suite, a search for an exception handler is started. This search inspects the except clauses in turn until one is found that matches the exception. An expression-less except clause, if present, must be last; it matches any exception. For an except clause with an expression, that expression is evaluated, and the clause matches the exception if the resulting object is “compatible” with the exception. An object is compatible with an exception if it is the class or a base class of the exception object, a tuple containing an item compatible with the exception, or, in the (deprecated) case of string exceptions, is the raised string itself (note that the object identities must match, i.e. it must be the same string object, not just a string with the same value).

If no except clause matches the exception, the search for an
exception handler continues in the surrounding code and on the invocation stack. [1]

If the evaluation of an expression in the header of an except clause raises an exception, the original search for a handler is canceled and a search starts for the new exception in the surrounding code and on the call stack (it is treated as if the entire try statement raised the exception).

When a matching except clause is found, the exception is assigned to the target specified in that except clause, if present, and the except clause's suite is executed. All except clauses must have an executable block. When the end of this block is reached, execution continues normally after the entire try statement. (This means that if two nested handlers exist for the same exception, and the exception occurs in the try clause of the inner handler, the outer handler will not handle the exception.)

Before an except clause’s suite is executed, details about the exception are assigned to three variables in the sys module: sys.exc_type receives the object identifying the exception; sys.exc_value receives the exception’s parameter; sys.exc_traceback receives a traceback object (see section The standard type hierarchy) identifying the point in the program where the exception occurred. These details are also available through the sys.exc_info() function, which returns a tuple (exc_type, exc_value, exc_traceback). Use of the corresponding variables is deprecated in favor of this function, since their use is unsafe in a threaded program. As of Python 1.5, the variables are restored to their previous values (before the call) when returning from a function that handled an exception.

The optional else clause is executed if and when control flows off the end of the try clause. [2] Exceptions in the else clause are not
handled by the preceding except clauses.

If finally is present, it specifies a ‘cleanup’ handler. The try clause is executed, including any except and else clauses. If an exception occurs in any of the clauses and is not handled, the exception is temporarily saved. The finally clause is executed. If there is a saved exception, it is re-raised at the end of the finally clause. If the finally clause raises another exception or executes a return or break statement, the saved exception is lost. The exception information is not available to the program during execution of the finally clause.

When a return, break or continue statement is executed in the try suite of a try...finally statement, the finally clause is also executed ‘on the way out.’ A continue statement is illegal in the finally clause. (The reason is a problem with the current implementation — this restriction may be lifted in the future).

Additional information on exceptions can be found in section Exceptions, and information on using the raise statement to generate exceptions may be found in section The raise statement.
The **with** statement

*New in version 2.5.*

The **with** statement is used to wrap the execution of a block with methods defined by a context manager (see section *With Statement Context Managers*). This allows common `try...except...finally` usage patterns to be encapsulated for convenient reuse.

```
with_stmt ::= "with" expression ["as" target] ":" suite
```

The execution of the **with** statement proceeds as follows:

1. The context expression is evaluated to obtain a context manager.
2. The context manager's `__enter__()` method is invoked.
3. If a target was included in the **with** statement, the return value from `__enter__()` is assigned to it.

**Note:** The **with** statement guarantees that if the `__enter__()` method returns without an error, then `__exit__()` will always be called. Thus, if an error occurs during the assignment to the target list, it will be treated the same as an error occurring within the suite would be. See step 5 below.

4. The suite is executed.
5. The context manager's `__exit__()` method is invoked. If an exception caused the suite to be exited, its type, value, and traceback are passed as arguments to `__exit__()`. Otherwise, three `None` arguments are supplied.
If the suite was exited due to an exception, and the return value from the `__exit__() method was false, the exception is reraised. If the return value was true, the exception is suppressed, and execution continues with the statement following the `with` statement.

If the suite was exited for any reason other than an exception, the return value from `__exit__() is ignored, and execution proceeds at the normal location for the kind of exit that was taken.

**Note:** In Python 2.5, the `with` statement is only allowed when the `with_statement` feature has been enabled. It is always enabled in Python 2.6.

**See also:**

**PEP 0343 - The “with” statement**

The specification, background, and examples for the Python `with` statement.
A function definition defines a user-defined function object (see section *The standard type hierarchy*):

A function definition is an executable statement. Its execution binds the function name in the current local namespace to a function object (a wrapper around the executable code for the function). This function object contains a reference to the current global namespace as the global namespace to be used when the function is called.

The function definition does not execute the function body; this gets executed only when the function is called. [3]

A function definition may be wrapped by one or more *decorator* expressions. Decorator expressions are evaluated when the function is defined, in the scope that contains the function definition. The result must be a callable, which is invoked with the function object as the only argument. The returned value is bound to the function name instead of the function object. Multiple decorators are applied in nested fashion. For example, the following code:

@f1(arg)
@f2
def func(): pass

is equivalent to:

def func(): pass
func = f1(arg)(f2(func))

When one or more top-level parameters have the form `parameter = expression`, the function is said to have “default parameter values.” For a parameter with a default value, the corresponding argument may be omitted from a call, in which case the parameter’s default value is substituted. If a parameter has a default value, all following parameters must also have a default value — this is a syntactic restriction that is not expressed by the grammar.

**Default parameter values are evaluated when the function definition is executed.** This means that the expression is evaluated once, when the function is defined, and that that same “pre-computed” value is used for each call. This is especially important to understand when a default parameter is a mutable object, such as a list or a dictionary: if the function modifies the object (e.g. by appending an item to a list), the default value is in effect modified. This is generally not what was intended. A way around this is to use `None` as the default, and explicitly test for it in the body of the function, e.g.:

```python
def whats_on_the_telly(penguin=None):
    if penguin is None:
        penguin = []
penguin.append("property of the zoo")
    return penguin
```

Function call semantics are described in more detail in section *Calls.* A function call always assigns values to all parameters mentioned in the parameter list, either from position arguments, from keyword arguments, or from default values. If the form “*identifier” is
present, it is initialized to a tuple receiving any excess positional parameters, defaulting to the empty tuple. If the form “**identifier” is present, it is initialized to a new dictionary receiving any excess keyword arguments, defaulting to a new empty dictionary.

It is also possible to create anonymous functions (functions not bound to a name), for immediate use in expressions. This uses lambda forms, described in section Expression lists. Note that the lambda form is merely a shorthand for a simplified function definition; a function defined in a “def” statement can be passed around or assigned to another name just like a function defined by a lambda form. The “def” form is actually more powerful since it allows the execution of multiple statements.

**Programmer’s note:** Functions are first-class objects. A “def” form executed inside a function definition defines a local function that can be returned or passed around. Free variables used in the nested function can access the local variables of the function containing the def. See section Naming and binding for details.
A class definition defines a class object (see section *The standard type hierarchy*):

```
classdef    ::=  "class" classname [inheritance] "::" suite
inheritance ::=  "(" [expression_list] ")"
classname   ::=  identifier
```

A class definition is an executable statement. It first evaluates the inheritance list, if present. Each item in the inheritance list should evaluate to a class object or class type which allows subclassing. The class’s suite is then executed in a new execution frame (see section *Naming and binding*), using a newly created local namespace and the original global namespace. (Usually, the suite contains only function definitions.) When the class's suite finishes execution, its execution frame is discarded but its local namespace is saved. [4] A class object is then created using the inheritance list for the base classes and the saved local namespace for the attribute dictionary. The class name is bound to this class object in the original local namespace.

**Programmer's note:** Variables defined in the class definition are class variables; they are shared by all instances. To create instance variables, they can be set in a method with `self.name = value`. Both class and instance variables are accessible through the notation `"self.name"`, and an instance variable hides a class variable with the same name when accessed in this way. Class variables can be used as defaults for instance variables, but using mutable values there can lead to unexpected results. For *new-style classes*, descriptors can be used to create instance variables with different implementation details.

Class definitions, like function definitions, may be wrapped by one or
more \texttt{decorator} expressions. The evaluation rules for the decorator expressions are the same as for functions. The result must be a class object, which is then bound to the class name.

\textbf{Footnotes}

[1] The exception is propagated to the invocation stack only if there is no \texttt{finally} clause that negates the exception.

Currently, control “flows off the end” except in the case of an exception or the execution of a \texttt{return}, \texttt{continue}, or \texttt{break} statement.

A string literal appearing as the first statement in the function body is transformed into the function’s \texttt{__doc__} attribute and therefore the function’s \texttt{docstring}.

A string literal appearing as the first statement in the class body is transformed into the namespace’s \texttt{__doc__} item and therefore the class's \texttt{docstring}.
Top-level components

The Python interpreter can get its input from a number of sources: from a script passed to it as standard input or as program argument, typed in interactively, from a module source file, etc. This chapter gives the syntax used in these cases.
Complete Python programs

While a language specification need not prescribe how the language interpreter is invoked, it is useful to have a notion of a complete Python program. A complete Python program is executed in a minimally initialized environment: all built-in and standard modules are available, but none have been initialized, except for `sys` (various system services), `__builtin__` (built-in functions, exceptions and `None`) and `__main__`. The latter is used to provide the local and global namespace for execution of the complete program.

The syntax for a complete Python program is that for file input, described in the next section.

The interpreter may also be invoked in interactive mode; in this case, it does not read and execute a complete program but reads and executes one statement (possibly compound) at a time. The initial environment is identical to that of a complete program; each statement is executed in the namespace of `__main__`.

Under Unix, a complete program can be passed to the interpreter in three forms: with the `-c string` command line option, as a file passed as the first command line argument, or as standard input. If the file or standard input is a tty device, the interpreter enters interactive mode; otherwise, it executes the file as a complete program.
File input

All input read from non-interactive files has the same form:

```
file_input ::= (NEWLINE | statement)*
```

This syntax is used in the following situations:

- when parsing a complete Python program (from a file or from a string);
- when parsing a module;
- when parsing a string passed to the `exec` statement;
Interactive input

Input in interactive mode is parsed using the following grammar:

```
interactive_input ::= [stmt_list] NEWLINE | compound_stmt NEWLINE
```

Note that a (top-level) compound statement must be followed by a blank line in interactive mode; this is needed to help the parser detect the end of the input.
Expression input

There are two forms of expression input. Both ignore leading whitespace. The string argument to `eval()` must have the following form:

```
expr_input ::= expression_list \n
```

The input line read by `input()` must have the following form:

```
input_input ::= expression_list \n
```

Note: to read ‘raw’ input line without interpretation, you can use the built-in function `raw_input()` or the `readline()` method of file objects.
This is the full Python grammar, as it is read by the parser generator and used to parse Python source files:

```
# Grammar for Python

# Note: Changing the grammar specified in this file will most likely require corresponding changes in the parser module
#       (../Modules/parsermodule.c). If you can't make the changes yourself, please co-ordinate the required
#       with someone who can; ask around on python-dev for help.
#       Drake <fdrake@acm.org> will probably be listening there.

# NOTE WELL: You should also follow all the steps listed in PEP 306, "How to Change Python's Grammar"

# Commands for Kees Blom's railroad program

# Start symbols for the grammar:
```

Introduction

The “Python library” contains several different kinds of components.

It contains data types that would normally be considered part of the "core" of a language, such as numbers and lists. For these types, the Python language core defines the form of literals and places some constraints on their semantics, but does not fully define the semantics. (On the other hand, the language core does define syntactic properties like the spelling and priorities of operators.)

The library also contains built-in functions and exceptions — objects that can be used by all Python code without the need of an `import` statement. Some of these are defined by the core language, but many are not essential for the core semantics and are only described here.

The bulk of the library, however, consists of a collection of modules. There are many ways to dissect this collection. Some modules are written in C and built in to the Python interpreter; others are written in Python and imported in source form. Some modules provide interfaces that are highly specific to Python, like printing a stack trace; some provide interfaces that are specific to particular operating systems, such as access to specific hardware; others provide interfaces that are specific to a particular application domain, like the World Wide Web. Some modules are available in all versions and ports of Python; others are only available when the underlying system supports or requires them; yet others are available only when a particular configuration option was chosen at the time when Python was compiled and installed.

This manual is organized “from the inside out:” it first describes the built-in data types, then the built-in functions and exceptions, and finally the modules, grouped in chapters of related modules. The
ordering of the chapters as well as the ordering of the modules within each chapter is roughly from most relevant to least important.

This means that if you start reading this manual from the start, and skip to the next chapter when you get bored, you will get a reasonable overview of the available modules and application areas that are supported by the Python library. Of course, you don’t have to read it like a novel — you can also browse the table of contents (in front of the manual), or look for a specific function, module or term in the index (in the back). And finally, if you enjoy learning about random subjects, you choose a random page number (see module `random`) and read a section or two. Regardless of the order in which you read the sections of this manual, it helps to start with chapter `Built-in Objects`, as the remainder of the manual assumes familiarity with this material.

Let the show begin!
**Built-in Functions**

The Python interpreter has a number of functions built into it that are always available. They are listed here in alphabetical order.

```
__import__(name[, globals[, locals[, fromlist[, level]]]])
```

**Note:** This is an advanced function that is not needed in everyday Python programming.

The function is invoked by the `import` statement. It mainly exists so that you can replace it with another function that has a compatible interface, in order to change the semantics of the `import` statement. For examples of why and how you would do this, see the standard library modules `ihooks` and `reexec`. See also the built-in module `imp`, which defines some useful operations out of which you can build your own `__import__()` function.

For example, the statement `import spam` results in the following call: `__import__('spam', globals(), locals(), [], -1)'; the statement `from spam.ham import eggs` results in `__import__('spam.ham', globals(), locals(), ['eggs'], -1)`. Note that even though `locals()` and `['eggs']` are passed in as arguments, the `__import__()` function does not set the local variable named `eggs`; this is done by subsequent code that is generated for the import statement. (In fact, the standard implementation does not use its `locals` argument at all, and uses its `globals` only to determine the package context of the `import` statement.)

When the `name` variable is of the form `package.module`, normally, the top-level package (the name up till the first dot) is returned,
not the module named by name. However, when a non-empty fromlist argument is given, the module named by name is returned. This is done for compatibility with the bytecode generated for the different kinds of import statement; when using import spam.ham.eggs, the top-level package spam must be placed in the importing namespace, but when using from spam.ham import eggs, the spam.ham subpackage must be used to find the eggs variable. As a workaround for this behavior, use getattr() to extract the desired components. For example, you could define the following helper:

```python
def my_import(name):
    mod = __import__(name)
    components = name.split('.
    for comp in components[1:]:
        mod = getattr(mod, comp)
    return mod
```

level specifies whether to use absolute or relative imports. The default is -1 which indicates both absolute and relative imports will be attempted. 0 means only perform absolute imports. Positive values for level indicate the number of parent directories to search relative to the directory of the module calling __import__().

Changed in version 2.5: The level parameter was added.

Changed in version 2.5: Keyword support for parameters was added.

abs(x)

Return the absolute value of a number. The argument may be a plain or long integer or a floating point number. If the argument is a complex number, its magnitude is returned.
all(iterable)
Return True if all elements of the iterable are true. Equivalent to:

```python
def all(iterable):
    for element in iterable:
        if not element:
            return False
    return True
```

New in version 2.5.

any(iterable)
Return True if any element of the iterable is true. Equivalent to:

```python
def any(iterable):
    for element in iterable:
        if element:
            return True
    return False
```

New in version 2.5.

basestring()
This abstract type is the superclass for str and unicode. It cannot be called or instantiated, but it can be used to test whether an object is an instance of str or unicode. `isinstance(obj, basestring)` is equivalent to `isinstance(obj, (str, unicode)).`

New in version 2.3.

bool([x])
Convert a value to a Boolean, using the standard truth testing procedure. If x is false or omitted, this returns False; otherwise it returns True. bool is also a class, which is a subclass of int.
Class `bool` cannot be subclassed further. Its only instances are `False` and `True`.

*New in version 2.2.1.*

*Changed in version 2.3:* If no argument is given, this function returns `False`.

**callable(object)**

Return `True` if the `object` argument appears callable, `False` if not. If this returns true, it is still possible that a call fails, but if it is false, calling `object` will never succeed. Note that classes are callable (calling a class returns a new instance); class instances are callable if they have a `__call__()` method.

**chr(i)**

Return a string of one character whose ASCII code is the integer `i`. For example, `chr(97)` returns the string `'a'`. This is the inverse of `ord()`. The argument must be in the range `[0..255]`, inclusive; `ValueError` will be raised if `i` is outside that range. See also `unichr()`.

**classmethod(function)**

Return a class method for `function`.

A class method receives the class as implicit first argument, just like an instance method receives the instance. To declare a class method, use this idiom:

```python
class C:
    @classmethod
    def f(cls, arg1, arg2, ...):
        ...
```

The `@classmethod` form is a function `decorator` – see the
description of function definitions in _Function definitions_ for details.

It can be called either on the class (such as `c.f()`) or on an instance (such as `c().f()`). The instance is ignored except for its class. If a class method is called for a derived class, the derived class object is passed as the implied first argument.

Class methods are different than C++ or Java static methods. If you want those, see `staticmethod()` in this section.

For more information on class methods, consult the documentation on the standard type hierarchy in _The standard type hierarchy_.

*New in version 2.2.*

*Changed in version 2.4:* Function decorator syntax added.

`cmp(x, y)`

Compare the two objects `x` and `y` and return an integer according to the outcome. The return value is negative if `x < y`, zero if `x == y` and strictly positive if `x > y`.

`compile(source, filename, mode[, flags[, dont_inherit]])`

Compile the `source` into a code or AST object. Code objects can be executed by an `exec` statement or evaluated by a call to `eval()`. `source` can either be a string or an AST object. Refer to the `_ast` module documentation for information on how to compile into and from AST objects.

When compiling a string with multi-line statements, two caveats apply: line endings must be represented by a single newline character (`'\n'`), and the input must be terminated by at least
one newline character. If line endings are represented by '\r\n', use the string `replace()` method to change them into '\n'.

The `filename` argument should give the file from which the code was read; pass some recognizable value if it wasn't read from a file ('<string>' is commonly used).

The `mode` argument specifies what kind of code must be compiled; it can be 'exec' if `source` consists of a sequence of statements, 'eval' if it consists of a single expression, or 'single' if it consists of a single interactive statement (in the latter case, expression statements that evaluate to something else than `None` will be printed).

The optional arguments `flags` and `dont_inherit` (which are new in Python 2.2) control which future statements (see PEP 236) affect the compilation of `source`. If neither is present (or both are zero) the code is compiled with those future statements that are in effect in the code that is calling `compile`. If the `flags` argument is given and `dont_inherit` is not (or is zero) then the future statements specified by the `flags` argument are used in addition to those that would be used anyway. If `dont_inherit` is a non-zero integer then the `flags` argument is it – the future statements in effect around the call to `compile` are ignored.

Future statements are specified by bits which can be bitwise ORed together to specify multiple statements. The bitfield required to specify a given feature can be found as the `compiler_flag` attribute on the `_Feature` instance in the `__future__` module.

This function raises `SyntaxError` if the compiled source is invalid, and `TypeError` if the source contains null bytes.
New in version 2.6: Support for compiling AST objects.

**complex([real[, imag]])**
Create a complex number with the value \( real + imag \times j \) or convert a string or number to a complex number. If the first parameter is a string, it will be interpreted as a complex number and the function must be called without a second parameter. The second parameter can never be a string. Each argument may be any numeric type (including complex). If \( imag \) is omitted, it defaults to zero and the function serves as a numeric conversion function like \( \text{int}() \), \( \text{long}() \) and \( \text{float}() \). If both arguments are omitted, returns \( 0j \).

The complex type is described in *Numeric Types — int, float, long, complex*.

**delattr(object, name)**
This is a relative of \( \text{setattr}() \). The arguments are an object and a string. The string must be the name of one of the object's attributes. The function deletes the named attribute, provided the object allows it. For example, \( \text{delattr}(x, \text{'foobar'}) \) is equivalent to \( \text{del} \ x.\text{foobar} \).

**dict([arg])**
Create a new data dictionary, optionally with items taken from \( arg \). The dictionary type is described in *Mapping Types — dict*.

For other containers see the built in \( \text{list} \), \( \text{set} \), and \( \text{tuple} \) classes, and the \text{collections} module.

**dir([object])**
Without arguments, return the list of names in the current local scope. With an argument, attempt to return a list of valid
attributes for that object.

If the object has a method named `__dir__()`, this method will be called and must return the list of attributes. This allows objects that implement a custom `__getattr__() ` or `__getattribute__() ` function to customize the way `dir()` reports their attributes.

If the object does not provide `__dir__()`, the function tries its best to gather information from the object's `__dict__` attribute, if defined, and from its type object. The resulting list is not necessarily complete, and may be inaccurate when the object has a custom `__getattr__()`.

The default `dir()` mechanism behaves differently with different types of objects, as it attempts to produce the most relevant, rather than complete, information:

- If the object is a module object, the list contains the names of the module’s attributes.
- If the object is a type or class object, the list contains the names of its attributes, and recursively of the attributes of its bases.
- Otherwise, the list contains the object's attributes' names, the names of its class's attributes, and recursively of the attributes of its class's base classes.

The resulting list is sorted alphabetically. For example:

```python
>>> import struct
>>> dir()  # doctest: +SKIP
['__builtins__', '__doc__', '__name__', 'struct']
>>> dir(struct)  # doctest: +NORMALIZE_WHITESPACE
['Struct', '__builtins__', '__doc__', '__file__', '__name__', '__package__', '_clearcache', 'calcsiz...']
```
>>> class Foo(object):
...     def __dir__(self):
...         return ['kan', 'ga', 'roo']
...
>>> f = Foo()
>>> dir(f)
['ga', 'kan', 'roo']

Note: Because `dir()` is supplied primarily as a convenience for use at an interactive prompt, it tries to supply an interesting set of names more than it tries to supply a rigorously or consistently defined set of names, and its detailed behavior may change across releases. For example, metaclass attributes are not in the result list when the argument is a class.

divmod(a, b)
Take two (non complex) numbers as arguments and return a pair of numbers consisting of their quotient and remainder when using long division. With mixed operand types, the rules for binary arithmetic operators apply. For plain and long integers, the result is the same as `(a // b, a % b)`. For floating point numbers the result is `(q, a % b)`, where `q` is usually `math.floor(a / b)` but may be 1 less than that. In any case `q * b + a % b` is very close to `a`, if `a % b` is non-zero it has the same sign as `b`, and `0 <= abs(a % b) < abs(b)`.

Changed in version 2.3: Using `divmod()` with complex numbers is deprecated.

enumerate(sequence[, start=0])
Return an enumerate object. `sequence` must be a sequence, an `iterator`, or some other object which supports iteration. The
**next()** method of the iterator returned by **enumerate()** returns a tuple containing a count (from **start** which defaults to 0) and the corresponding value obtained from iterating over **iterable**. **enumerate()** is useful for obtaining an indexed series: (0, seq[0]), (1, seq[1]), (2, seq[2]), .... For example:

```python
>>> for i, season in enumerate(['Spring', 'Summer', 'Fall', ...
...     print i, season
0 Spring
1 Summer
2 Fall
3 Winter
```

*New in version 2.3.*

*New in version 2.6:* The **start** parameter.

**eval**(expression[, globals[, locals]])

The arguments are a string and optional globals and locals. If provided, **globals** must be a dictionary. If provided, **locals** can be any mapping object.

*Changed in version 2.4:* formerly **locals** was required to be a dictionary.

The **expression** argument is parsed and evaluated as a Python expression (technically speaking, a condition list) using the **globals** and **locals** dictionaries as global and local namespace. If the **globals** dictionary is present and lacks ‘__builtins__’, the current globals are copied into **globals** before **expression** is parsed. This means that **expression** normally has full access to the standard **_builtin_** module and restricted environments are propagated. If the **locals** dictionary is omitted it defaults to the **globals** dictionary. If both dictionaries are omitted, the expression
is executed in the environment where `eval()` is called. The return value is the result of the evaluated expression. Syntax errors are reported as exceptions. Example:

```python
>>> x = 1
>>> print eval('x+1')
2
```

This function can also be used to execute arbitrary code objects (such as those created by `compile()`). In this case pass a code object instead of a string. If the code object has been compiled with `exec` as the kind argument, `eval()`'s return value will be `None`.

Hints: dynamic execution of statements is supported by the `exec` statement. Execution of statements from a file is supported by the `execfile()` function. The `globals()` and `locals()` functions returns the current global and local dictionary, respectively, which may be useful to pass around for use by `eval()` or `execfile()`.

```python
execfile(filename[, globals[, locals]])
```

This function is similar to the `exec` statement, but parses a file instead of a string. It is different from the `import` statement in that it does not use the module administration — it reads the file unconditionally and does not create a new module. [1]

The arguments are a file name and two optional dictionaries. The file is parsed and evaluated as a sequence of Python statements (similarly to a module) using the `globals` and `locals` dictionaries as global and local namespace. If provided, `locals` can be any mapping object.

*Changed in version 2.4:* formerly `locals` was required to be a dictionary.
If the `locals` dictionary is omitted it defaults to the `globals` dictionary. If both dictionaries are omitted, the expression is executed in the environment where `execfile()` is called. The return value is `None`.

**Warning:** The default `locals` act as described for function `locals()` below: modifications to the default `locals` dictionary should not be attempted. Pass an explicit `locals` dictionary if you need to see effects of the code on `locals` after function `execfile()` returns. `execfile()` cannot be used reliably to modify a function’s locals.

`file(filename[, mode[, bufsize]])`
Constructor function for the `file` type, described further in section *File Objects*. The constructor’s arguments are the same as those of the `open()` built-in function described below.

When opening a file, it’s preferable to use `open()` instead of invoking this constructor directly. `file` is more suited to type testing (for example, writing `isinstance(f, file)`).

*New in version 2.2.*

`filter(function, iterable)`
Construct a list from those elements of `iterable` for which `function` returns true. `iterable` may be either a sequence, a container which supports iteration, or an iterator. If `iterable` is a string or a tuple, the result also has that type; otherwise it is always a list. If `function` is `None`, the identity function is assumed, that is, all elements of `iterable` that are false are removed.

Note that `filter(function, iterable)` is equivalent to `[item for item in iterable if function(item)]` if function is not `None` and
Convert a string or a number to floating point. If the argument is a string, it must contain a possibly signed decimal or floating point number, possibly embedded in whitespace. The argument may also be [+|-]nan or [+|-]inf. Otherwise, the argument may be a plain or long integer or a floating point number, and a floating point number with the same value (within Python’s floating point precision) is returned. If no argument is given, returns 0.0.

**Note:** When passing in a string, values for NaN and Infinity may be returned, depending on the underlying C library. Float accepts the strings nan, inf and -inf for NaN and positive or negative infinity. The case and a leading + are ignored as well as a leading - is ignored for NaN. Float always represents NaN and infinity as nan, inf or -inf.

The float type is described in *Numeric Types — int, float, long, complex*.

Return a frozenset object, optionally with elements taken from iterable. The frozenset type is described in *Set Types — set, frozenset*.

For other containers see the built in `dict`, `list`, and `tuple` classes, and the `collections` module.

New in version 2.4.
the result is the value of that attribute. For example, `getattr(x, 'foobar')` is equivalent to `x.foobar`. If the named attribute does not exist, `default` is returned if provided, otherwise `AttributeError` is raised.

**globals()**

Return a dictionary representing the current global symbol table. This is always the dictionary of the current module (inside a function or method, this is the module where it is defined, not the module from which it is called).

**hasattr(object, name)**

The arguments are an object and a string. The result is `True` if the string is the name of one of the object's attributes, `False` if not. (This is implemented by calling `getattr(object, name)` and seeing whether it raises an exception or not.)

**hash(object)**

Return the hash value of the object (if it has one). Hash values are integers. They are used to quickly compare dictionary keys during a dictionary lookup. Numeric values that compare equal have the same hash value (even if they are of different types, as is the case for `1` and `1.0`).

**help([object])**

Invoke the built-in help system. (This function is intended for interactive use.) If no argument is given, the interactive help system starts on the interpreter console. If the argument is a string, then the string is looked up as the name of a module, function, class, method, keyword, or documentation topic, and a help page is printed on the console. If the argument is any other kind of object, a help page on the object is generated.

This function is added to the built-in namespace by the `site`
module.

*New in version 2.2.*

**hex(x)**

Convert an integer number (of any size) to a hexadecimal string. The result is a valid Python expression.

*Changed in version 2.4:* Formerly only returned an unsigned literal.

**id(object)**

Return the "identity" of an object. This is an integer (or long integer) which is guaranteed to be unique and constant for this object during its lifetime. Two objects with non-overlapping lifetimes may have the same `id()` value. (Implementation note: this is the address of the object.)

**input([prompt])**

Equivalent to `eval(raw_input(prompt))`.

**Warning:** This function is not safe from user errors! It expects a valid Python expression as input; if the input is not syntactically valid, a `SyntaxError` will be raised. Other exceptions may be raised if there is an error during evaluation. (On the other hand, sometimes this is exactly what you need when writing a quick script for expert use.)

If the `readline` module was loaded, then `input()` will use it to provide elaborate line editing and history features.

Consider using the `raw_input()` function for general input from users.
\( \text{int}([x, \text{radix}]) \)

Convert a string or number to a plain integer. If the argument is a string, it must contain a possibly signed decimal number representable as a Python integer, possibly embedded in whitespace. The \textit{radix} parameter gives the base for the conversion (which is 10 by default) and may be any integer in the range \([2, 36]\), or zero. If \textit{radix} is zero, the proper radix is determined based on the contents of string; the interpretation is the same as for integer literals. (See \textit{Numeric literals}.) If \textit{radix} is specified and \(x\) is not a string, \texttt{TypeError} is raised. Otherwise, the argument may be a plain or long integer or a floating point number. Conversion of floating point numbers to integers truncates (towards zero). If the argument is outside the integer range a long object will be returned instead. If no arguments are given, returns \(0\).

The integer type is described in \textit{Numeric Types — int, float, long, complex}.

\texttt{isinstance(object, classinfo)}

Return true if the \textit{object} argument is an instance of the \textit{classinfo} argument, or of a (direct or indirect) subclass thereof. Also return true if \textit{classinfo} is a type object (new-style class) and \textit{object} is an object of that type or of a (direct or indirect) subclass thereof. If \textit{object} is not a class instance or an object of the given type, the function always returns false. If \textit{classinfo} is neither a class object nor a type object, it may be a tuple of class or type objects, or may recursively contain other such tuples (other sequence types are not accepted). If \textit{classinfo} is not a class, type, or tuple of classes, types, and such tuples, a \texttt{TypeError} exception is raised.

\textit{Changed in version 2.2}: Support for a tuple of type information was added.
**issubclass**(*class, classinfo*)

Return true if *class* is a subclass (direct or indirect) of *classinfo*. A class is considered a subclass of itself. *classinfo* may be a tuple of class objects, in which case every entry in *classinfo* will be checked. In any other case, a *TypeError* exception is raised.

*Changed in version 2.3:* Support for a tuple of type information was added.

**iter**(o[, sentinel])

Return an *iterator* object. The first argument is interpreted very differently depending on the presence of the second argument. Without a second argument, *o* must be a collection object which supports the iteration protocol (the __iter__() method), or it must support the sequence protocol (the __getitem__() method with integer arguments starting at 0). If it does not support either of those protocols, *TypeError* is raised. If the second argument, *sentinel*, is given, then *o* must be a callable object. The iterator created in this case will call *o* with no arguments for each call to its next() method; if the value returned is equal to *sentinel*, *StopIteration* will be raised, otherwise the value will be returned.

*New in version 2.2.*

**len**(s)

Return the length (the number of items) of an object. The argument may be a sequence (string, tuple or list) or a mapping (dictionary).

**list**(iterable)

Return a list whose items are the same and in the same order as *iterable*'s items. *iterable* may be either a sequence, a container that supports iteration, or an iterator object. If *iterable* is already a
list, a copy is made and returned, similar to iterable[:]. For instance, list('abc') returns ['a', 'b', 'c'] and list((1, 2, 3)) returns [1, 2, 3]. If no argument is given, returns a new empty list, [].

list is a mutable sequence type, as documented in Sequence Types — str, unicode, list, tuple, buffer, xrange. For other containers see the built in dict, set, and tuple classes, and the collections module.

locals()
Update and return a dictionary representing the current local symbol table.

**Warning:** The contents of this dictionary should not be modified; changes may not affect the values of local variables used by the interpreter.

Free variables are returned by locals() when it is called in a function block. Modifications of free variables may not affect the values used by the interpreter. Free variables are not returned in class blocks.

long([x[, radix]])
Convert a string or number to a long integer. If the argument is a string, it must contain a possibly signed number of arbitrary size, possibly embedded in whitespace. The radix argument is interpreted in the same way as for int(), and may only be given when x is a string. Otherwise, the argument may be a plain or long integer or a floating point number, and a long integer with the same value is returned. Conversion of floating point numbers to integers truncates (towards zero). If no arguments are given, returns 0L.
The long type is described in *Numeric Types — int, float, long, complex*.

**map**(function, iterable, ...)  
Apply *function* to every item of *iterable* and return a list of the results. If additional *iterable* arguments are passed, *function* must take that many arguments and is applied to the items from all iterables in parallel. If one iterable is shorter than another it is assumed to be extended with *None* items. If *function* is *None*, the identity function is assumed; if there are multiple arguments, *map()* returns a list consisting of tuples containing the corresponding items from all iterables (*a kind of transpose operation*). The *iterable* arguments may be a sequence or any iterable object; the result is always a list.

**max**(iterable[, args...][, key])  
With a single argument *iterable*, return the largest item of a non-empty iterable (such as a string, tuple or list). With more than one argument, return the largest of the arguments.

The optional *key* argument specifies a one-argument ordering function like that used for *list.sort()*.

*Changed in version 2.5*: Added support for the optional *key* argument.

**min**(iterable[, args...][, key])  
With a single argument *iterable*, return the smallest item of a non-empty iterable (such as a string, tuple or list). With more than one argument, return the smallest of the arguments.

The optional *key* argument specifies a one-argument ordering
function like that used for `list.sort()`. The `key` argument, if supplied, must be in keyword form (for example, `min(a, b, c, key=func)`).

*Changed in version 2.5:* Added support for the optional `key` argument.

`next(iterator[, default])`
Retrieve the next item from the `iterator` by calling its `next()` method. If `default` is given, it is returned if the iterator is exhausted, otherwise `StopIteration` is raised.

*New in version 2.6.*

`object()`
Return a new featureless object. `object` is a base for all new style classes. It has the methods that are common to all instances of new style classes.

*New in version 2.2.*

*Changed in version 2.3:* This function does not accept any arguments. Formerly, it accepted arguments but ignored them.

`oct(x)`
Convert an integer number (of any size) to an octal string. The result is a valid Python expression.

*Changed in version 2.4:* Formerly only returned an unsigned literal.

`open(filename[, mode[, bufsize]])`
Open a file, returning an object of the `file` type described in section *File Objects*. If the file cannot be opened, `IOError` is
When opening a file, it's preferable to use `open()` instead of invoking the `file` constructor directly.

The first two arguments are the same as for `stdio`'s `fopen`: `filename` is the file name to be opened, and `mode` is a string indicating how the file is to be opened.

The most commonly-used values of `mode` are `'r'` for reading, `'w'` for writing (truncating the file if it already exists), and `'a'` for appending (which on some Unix systems means that `all` writes append to the end of the file regardless of the current seek position). If `mode` is omitted, it defaults to `'r'`. The default is to use text mode, which may convert `
` characters to a platform-specific representation on writing and back on reading. Thus, when opening a binary file, you should append `'b'` to the `mode` value to open the file in binary mode, which will improve portability. (Appending `'b'` is useful even on systems that don't treat binary and text files differently, where it serves as documentation.) See below for more possible values of `mode`.

The optional `bufsize` argument specifies the file's desired buffer size: 0 means unbuffered, 1 means line buffered, any other positive value means use a buffer of (approximately) that size. A negative `bufsize` means to use the system default, which is usually line buffered for tty devices and fully buffered for other files. If omitted, the system default is used. [2]

Modes `'r+'`, `'w+'` and `'a+'` open the file for updating (note that `'w+'` truncates the file). Append `'b'` to the mode to open the file in binary mode, on systems that differentiate between binary and text files; on systems that don't have this distinction, adding the `'b'` has no effect.

In addition to the standard `fopen` values `mode` may be `'u'` or
'ru'. Python is usually built with universal newline support; supplying 'u' opens the file as a text file, but lines may be terminated by any of the following: the Unix end-of-line convention '\n', the Macintosh convention '\r', or the Windows convention '\r\n'. All of these external representations are seen as '\n' by the Python program. If Python is built without universal newline support a mode with 'u' is the same as normal text mode. Note that file objects so opened also have an attribute called newlines which has a value of None (if no newlines have yet been seen), '\n', '\r', '\r\n', or a tuple containing all the newline types seen.

Python enforces that the mode, after stripping 'u', begins with 'r', 'w' or 'a'.

Python provides many file handling modules including fileinput, os, os.path, tempfile, and shutil.

*Changed in version 2.5:* Restriction on first letter of mode string introduced.

**ord(c)**

Given a string of length one, return an integer representing the Unicode code point of the character when the argument is a unicode object, or the value of the byte when the argument is an 8-bit string. For example, `ord('a')` returns the integer 97, `ord(u'\u2020')` returns 8224. This is the inverse of `chr()` for 8-bit strings and of `unichr()` for unicode objects. If a unicode argument is given and Python was built with UCS2 Unicode, then the character's code point must be in the range [0..65535] inclusive; otherwise the string length is two, and a TypeError will be raised.
\texttt{pow(x, y[, z])}

Return \( x \) to the power \( y \); if \( z \) is present, return \( x \) to the power \( y \), modulo \( z \) (computed more efficiently than \( \text{pow}(x, y) \mod z \)). The two-argument form \( \text{pow}(x, y) \) is equivalent to using the power operator: \( x**y \).

The arguments must have numeric types. With mixed operand types, the coercion rules for binary arithmetic operators apply. For int and long int operands, the result has the same type as the operands (after coercion) unless the second argument is negative; in that case, all arguments are converted to float and a float result is delivered. For example, \( 10**2 \) returns \( 100 \), but \( 10**-2 \) returns \( 0.01 \). (This last feature was added in Python 2.2. In Python 2.1 and before, if both arguments were of integer types and the second argument was negative, an exception was raised.) If the second argument is negative, the third argument must be omitted. If \( z \) is present, \( x \) and \( y \) must be of integer types, and \( y \) must be non-negative. (This restriction was added in Python 2.2. In Python 2.1 and before, floating 3-argument \( \text{pow}() \) returned platform-dependent results depending on floating-point rounding accidents.)

\texttt{print([object, ...][, sep=’ ’][, end=’n’][, file=sys.stdout])}

Print \texttt{object(s)} to the stream \texttt{file}, separated by \texttt{sep} and followed by \texttt{end}. \texttt{sep}, \texttt{end} and \texttt{file}, if present, must be given as keyword arguments.

All non-keyword arguments are converted to strings like \texttt{str()} does and written to the stream, separated by \texttt{sep} and followed by \texttt{end}. Both \texttt{sep} and \texttt{end} must be strings; they can also be \texttt{None}, which means to use the default values. If no \texttt{object} is given, \texttt{print()} will just write \texttt{end}. 
The `file` argument must be an object with a `write(string)` method; if it is not present or `None`, `sys.stdout` will be used.

**Note:** This function is not normally available as a builtin since the name `print` is recognized as the `print` statement. To disable the statement and use the `print()` function, use this future statement at the top of your module:

```python
from __future__ import print_function
```

*New in version 2.6.*

```python
property([fget[, fset[, fdel[, doc]]]])
```

Return a property attribute for *new-style classes* (classes that derive from `object`).

`fget` is a function for getting an attribute value, likewise `fset` is a function for setting, and `fdel` a function for del'ing, an attribute. Typical use is to define a managed attribute `x`:

```python
class C(object):
    def __init__(self):
        self._x = None

    def getx(self):
        return self._x

    def setx(self, value):
        self._x = value

    def delx(self):
        del self._x

x = property(getx, setx, delx, "I'm the 'x' property.")
```

If given, `doc` will be the docstring of the property attribute.
Otherwise, the property will copy fget’s docstring (if it exists). This makes it possible to create read-only properties easily using property() as a decorator:

```python
class Parrot(object):
    def __init__(self):
        self._voltage = 100000

@property
    def voltage(self):
        """Get the current voltage."""
        return self._voltage
```

This turns the voltage() method into a “getter” for a read-only attribute with the same name.

A property object has getter, setter, and deleter methods usable as decorators that create a copy of the property with the corresponding accessor function set to the decorated function. This is best explained with an example:

```python
class C(object):
    def __init__(self): self._x = None

@property
    def x(self):
        """I'm the 'x' property."""
        return self._x

@x.setter
    def x(self, value):
        self._x = value

@x.deleter
```

```python
def x(self):
    del self._x
```

This code is exactly equivalent to the first example. Be sure to give the additional functions the same name as the original property (x in this case.)

The returned property also has the attributes `fget`, `fset`, and `fdel` corresponding to the constructor arguments.

*New in version 2.2.*

*Changed in version 2.5:* Use `fget`'s docstring if no `doc` given.

*Changed in version 2.6:* The `getter`, `setter`, and `deleter` attributes were added.

```python
range([start], stop[, step])
```

This is a versatile function to create lists containing arithmetic progressions. It is most often used in `for` loops. The arguments must be plain integers. If the `step` argument is omitted, it defaults to 1. If the `start` argument is omitted, it defaults to 0. The full form returns a list of plain integers `[start, start + step, start + 2 * step, ...]`. If `step` is positive, the last element is the largest `start + i * step` less than `stop`; if `step` is negative, the last element is the smallest `start + i * step` greater than `stop`. `step` must not be zero (or else `ValueError` is raised). Example:

```python
>>> range(10)
[0, 1, 2, 3, 4, 5, 6, 7, 8, 9]
>>> range(1, 11)
[1, 2, 3, 4, 5, 6, 7, 8, 9, 10]
>>> range(0, 30, 5)
[0, 5, 10, 15, 20, 25]
```
raw_input([prompt])

If the prompt argument is present, it is written to standard output without a trailing newline. The function then reads a line from input, converts it to a string (stripping a trailing newline), and returns that. When EOF is read, EOFError is raised. Example:

```python
>>> s = raw_input('--> ')  
--> Monty Python's Flying Circus
>>> s
"Monty Python's Flying Circus"
```

If the readline module was loaded, then raw_input() will use it to provide elaborate line editing and history features.

reduce(function, iterable[, initializer])

Apply function of two arguments cumulatively to the items of iterable, from left to right, so as to reduce the iterable to a single value. For example, reduce(lambda x, y: x+y, [1, 2, 3, 4, 5]) calculates ((((1+2)+3)+4)+5). The left argument, x, is the accumulated value and the right argument, y, is the update value from the iterable. If the optional initializer is present, it is placed before the items of the iterable in the calculation, and serves as a default when the iterable is empty. If initializer is not given and iterable contains only one item, the first item is returned.
**reload(module)**

Reload a previously imported `module`. The argument must be a module object, so it must have been successfully imported before. This is useful if you have edited the module source file using an external editor and want to try out the new version without leaving the Python interpreter. The return value is the module object (the same as the `module` argument).

When `reload(module)` is executed:

- Python modules’ code is recompiled and the module-level code reexecuted, defining a new set of objects which are bound to names in the module’s dictionary. The `init` function of extension modules is not called a second time.
- As with all other objects in Python the old objects are only reclaimed after their reference counts drop to zero.
- The names in the module namespace are updated to point to any new or changed objects.
- Other references to the old objects (such as names external to the module) are not rebound to refer to the new objects and must be updated in each namespace where they occur if that is desired.

There are a number of other caveats:

If a module is syntactically correct but its initialization fails, the first `import` statement for it does not bind its name locally, but does store a (partially initialized) module object in `sys.modules`. To reload the module you must first `import` it again (this will bind the name to the partially initialized module object) before you can `reload()` it.

When a module is reloaded, its dictionary (containing the module’s global variables) is retained. Redefinitions of names will override the old definitions, so this is generally not a problem. If
the new version of a module does not define a name that was defined by the old version, the old definition remains. This feature can be used to the module’s advantage if it maintains a global table or cache of objects — with a try statement it can test for the table’s presence and skip its initialization if desired:

```python
try:
    cache
except NameError:
    cache = {}  
```

It is legal though generally not very useful to reload built-in or dynamically loaded modules, except for `sys`, `__main__` and `__builtin__`. In many cases, however, extension modules are not designed to be initialized more than once, and may fail in arbitrary ways when reloaded.

If a module imports objects from another module using `from ... import ...`, calling `reload()` for the other module does not redefine the objects imported from it — one way around this is to re-execute the `from` statement, another is to use `import` and qualified names (`module.*name*`) instead.

If a module instantiates instances of a class, reloading the module that defines the class does not affect the method definitions of the instances — they continue to use the old class definition. The same is true for derived classes.

`repr(object)`

Return a string containing a printable representation of an object. This is the same value yielded by conversions (reverse quotes). It is sometimes useful to be able to access this operation as an ordinary function. For many types, this function makes an attempt to return a string that would yield an object with the same value
when passed to `eval()`, otherwise the representation is a string
enclosed in angle brackets that contains the name of the type of
the object together with additional information often including the
name and address of the object. A class can control what this
function returns for its instances by defining a `__repr__()`
method.

```python
reversed(seq)
```
Return a reverse `iterator`. `seq` must be an object which has a
`__reversed__()` method or supports the sequence protocol (the
`__len__()` method and the `__getitem__()` method with integer
arguments starting at 0).

*New in version 2.4.*

*Changed in version 2.6:* Added the possibility to write a custom
`__reversed__()` method.

```python
round(x[, n])
```
Return the floating point value `x` rounded to `n` digits after the
decimal point. If `n` is omitted, it defaults to zero. The result is a
floating point number. Values are rounded to the closest multiple
of 10 to the power minus `n`; if two multiples are equally close,
rounding is done away from 0 (so, for example, `round(0.5)` is `1.0`
and `round(-0.5)` is `-1.0`).

```python
set([iterable])
```
Return a new set, optionally with elements are taken from
`iterable`. The set type is described in `Set Types — set, frozenset`.

For other containers see the built in `dict`, `list`, and `tuple`
classes, and the `collections` module.

*New in version 2.4.*
**setattr**(object, name, value)

This is the counterpart of **getattr()**. The arguments are an object, a string and an arbitrary value. The string may name an existing attribute or a new attribute. The function assigns the value to the attribute, provided the object allows it. For example, `setattr(x, 'foobar', 123)` is equivalent to `x.foobar = 123`.

**slice**([start], stop[, step])

Return a **slice** object representing the set of indices specified by `range(start, stop, step)`. The **start** and **step** arguments default to **None**. Slice objects have read-only data attributes **start**, **stop** and **step** which merely return the argument values (or their default). They have no other explicit functionality; however they are used by Numerical Python and other third party extensions. Slice objects are also generated when extended indexing syntax is used. For example: `a[start:stop:step]` or `a[start:stop, i]`.

**sorted**(iterable[, cmp[, key[, reverse]]])

Return a new sorted list from the items in **iterable**.

The optional arguments **cmp**, **key**, and **reverse** have the same meaning as those for the list.sort() method (described in section **Mutable Sequence Types**).

**cmp** specifies a custom comparison function of two arguments (iterable elements) which should return a negative, zero or positive number depending on whether the first argument is considered smaller than, equal to, or larger than the second argument: `cmp=lambda x,y: cmp(x.lower(), y.lower())`. The default value is **None**.

**key** specifies a function of one argument that is used to extract a comparison key from each list element: `key=str.lower`. The
default value is None.

reverse is a boolean value. If set to True, then the list elements are sorted as if each comparison were reversed.

In general, the key and reverse conversion processes are much faster than specifying an equivalent cmp function. This is because cmp is called multiple times for each list element while key and reverse touch each element only once.

New in version 2.4.

staticmethod(function)
Return a static method for function.

A static method does not receive an implicit first argument. To declare a static method, use this idiom:

```
class C:
    @staticmethod
    def f(arg1, arg2, ...): ...
```

The @staticmethod form is a function decorator – see the description of function definitions in Function definitions for details.

It can be called either on the class (such as c.f()) or on an instance (such as c().f()). The instance is ignored except for its class.

Static methods in Python are similar to those found in Java or C++. For a more advanced concept, see classmethod() in this section.

For more information on static methods, consult the
documentation on the standard type hierarchy in *The standard type hierarchy*.

*New in version 2.2.*

*Changed in version 2.4:* Function decorator syntax added.

```python
str([object])
```

Return a string containing a nicely printable representation of an object. For strings, this returns the string itself. The difference with `repr(object)` is that `str(object)` does not always attempt to return a string that is acceptable to `eval()`; its goal is to return a printable string. If no argument is given, returns the empty string, `' '`. For more information on strings see *Sequence Types* — `str`, `unicode`, `list`, `tuple`, `buffer`, `xrange` which describes sequence functionality (strings are sequences), and also the string-specific methods described in the *String Methods* section. To output formatted strings use template strings or the `%` operator described in the *String Formatting Operations* section. In addition see the *String Services* section. See also `unicode()`.

```python
sum(iterable[, start])
```

Sums `start` and the items of an `iterable` from left to right and returns the total. `start` defaults to 0. The `iterable`'s items are normally numbers, and are not allowed to be strings. The fast, correct way to concatenate a sequence of strings is by calling `'' . join(sequence)`. Note that `sum(range(n), m)` is equivalent to `reduce(operator.add, range(n), m)`.

*New in version 2.3.*

```python
super(type[, object-or-type])
```
Return a “super” object that acts like the superclass of `type`.

If the second argument is omitted the super object returned is unbound. If the second argument is an object, `isinstance(obj, type)` must be true. If the second argument is a type, `issubclass(type2, type)` must be true. `super()` only works for new-style classes.

There are two typical use cases for “super”. In a class hierarchy with single inheritance, “super” can be used to refer to parent classes without naming them explicitly, thus making the code more maintainable. This use closely parallels the use of “super” in other programming languages.

The second use case is to support cooperative multiple inheritance in a dynamic execution environment. This use case is unique to Python and is not found in statically compiled languages or languages that only support single inheritance. This makes it possible to implement “diamond diagrams” where multiple base classes implement the same method. Good design dictates that this method have the same calling signature in every case (because the order of parent calls is determined at runtime and because that order adapts to changes in the class hierarchy).

For both use cases, a typical superclass call looks like this:

```python
class C(B):
    def meth(self, arg):
        super(C, self).meth(arg)
```

Note that `super()` is implemented as part of the binding process for explicit dotted attribute lookups such as `super(C, self).__getitem__(name)`. It does so by implementing its own `__getattribute__()` method for searching parent classes in a
predictable order that supports cooperative multiple inheritance. Accordingly, \texttt{super()} is undefined for implicit lookups using statements or operators such as \texttt{super(C, self)[name]}.

\textit{New in version 2.2.}

\texttt{tuple([iterable])}

Return a tuple whose items are the same and in the same order as \texttt{iterable}'s items. \texttt{iterable} may be a sequence, a container that supports iteration, or an iterator object. If \texttt{iterable} is already a tuple, it is returned unchanged. For instance, \texttt{tuple('abc')} returns ('a', 'b', 'c') and \texttt{tuple([1, 2, 3])} returns (1, 2, 3). If no argument is given, returns a new empty tuple, ()

\texttt{tuple} is an immutable sequence type, as documented in \textit{Sequence Types — str, unicode, list, tuple, buffer, xrange}. For other containers see the built in \texttt{dict, list, and set} classes, and the \texttt{collections} module.

\texttt{type(object)}

Return the type of an \texttt{object}. The return value is a type object. The \texttt{isinstance()} built-in function is recommended for testing the type of an object.

With three arguments, \texttt{type()} functions as a constructor as detailed below.

\texttt{type(name, bases, dict)}

Return a new type object. This is essentially a dynamic form of the \texttt{class} statement. The \texttt{name} string is the class name and becomes the \texttt{__name__} attribute; the \texttt{bases} tuple itemizes the base classes and becomes the \texttt{__bases__} attribute; and the \texttt{dict} dictionary is the namespace containing definitions for class body
and becomes the __dict__ attribute. For example, the following two statements create identical type objects:

```python
>>> class X(object):
...    a = 1
...
>>> X = type('X', (object,), dict(a=1))
```

New in version 2.2.

unichr(i)

Return the Unicode string of one character whose Unicode code is the integer i. For example, unichr(97) returns the string u'a'. This is the inverse of ord() for Unicode strings. The valid range for the argument depends how Python was configured – it may be either UCS2 [0..0xFFFF] or UCS4 [0..0x10FFFF]. ValueError is raised otherwise. For ASCII and 8-bit strings see chr().

New in version 2.0.

unicode([object[, encoding[, errors]]])

Return the Unicode string version of object using one of the following modes:

If encoding and/or errors are given, unicode() will decode the object which can either be an 8-bit string or a character buffer using the codec for encoding. The encoding parameter is a string giving the name of an encoding; if the encoding is not known, LookupError is raised. Error handling is done according to errors; this specifies the treatment of characters which are invalid in the input encoding. If errors is 'strict' (the default), a ValueError is raised on errors, while a value of 'ignore' causes errors to be silently ignored, and a value of 'replace' causes the official
Unicode replacement character, \texttt{U+FFFD}, to be used to replace input characters which cannot be decoded. See also the \texttt{codecs} module.

If no optional parameters are given, \texttt{unicode()} will mimic the behaviour of \texttt{str()} except that it returns Unicode strings instead of 8-bit strings. More precisely, if \texttt{object} is a Unicode string or subclass it will return that Unicode string without any additional decoding applied.

For objects which provide a \texttt{\_unicode\_()} method, it will call this method without arguments to create a Unicode string. For all other objects, the 8-bit string version or representation is requested and then converted to a Unicode string using the codec for the default encoding in \texttt{'strict'} mode.

For more information on Unicode strings see \textit{Sequence Types — \texttt{str}, \texttt{unicode}, \texttt{list}, \texttt{tuple}, \texttt{buffer}, \texttt{xrange}} which describes sequence functionality (Unicode strings are sequences), and also the string-specific methods described in the \textit{String Methods} section. To output formatted strings use template strings or the \texttt{\%} operator described in the \textit{String Formatting Operations} section. In addition see the \textit{String Services} section. See also \texttt{str()}.

\textit{New in version 2.0.}

\textit{Changed in version 2.2: Support for \texttt{\_unicode\_()} added.}

\texttt{vars([object])}

Without arguments, return a dictionary corresponding to the current local symbol table. With a module, class or class instance object as argument (or anything else that has a \texttt{\_dict\_} attribute), returns a dictionary corresponding to the object's symbol table. The returned dictionary should not be modified: the
effects on the corresponding symbol table are undefined. [3]

\textbf{xrange}([\textit{start}], \textit{stop}[\textit{step}])

This function is very similar to \texttt{range()}, but returns an “xrange object” instead of a list. This is an opaque sequence type which yields the same values as the corresponding list, without actually storing them all simultaneously. The advantage of \texttt{xrange()} over \texttt{range()} is minimal (since \texttt{xrange()} still has to create the values when asked for them) except when a very large range is used on a memory-starved machine or when all of the range’s elements are never used (such as when the loop is usually terminated with \texttt{break}).

\textbf{Note:} \texttt{xrange()} is intended to be simple and fast. Implementations may impose restrictions to achieve this. The C implementation of Python restricts all arguments to native C longs (“short” Python integers), and also requires that the number of elements fit in a native C long.

\textbf{zip}([\textit{iterable}, ...])

This function returns a list of tuples, where the \textit{i}-th tuple contains the \textit{i}-th element from each of the argument sequences or iterables. The returned list is truncated in length to the length of the shortest argument sequence. When there are multiple arguments which are all of the same length, \texttt{zip()} is similar to \texttt{map()} with an initial argument of \texttt{None}. With a single sequence argument, it returns a list of 1-tuples. With no arguments, it returns an empty list.

The left-to-right evaluation order of the iterables is guaranteed. This makes possible an idiom for clustering a data series into \texttt{n}-length groups using \texttt{zip(*[iter(s)]*n)}.
New in version 2.0.

Changed in version 2.4: Formerly, `zip()` required at least one argument and `zip()` raised a `TypeError` instead of returning an empty list.
Non-essential Built-in Functions

There are several built-in functions that are no longer essential to learn, know or use in modern Python programming. They have been kept here to maintain backwards compatibility with programs written for older versions of Python.

Python programmers, trainers, students and book writers should feel free to bypass these functions without concerns about missing something important.

apply(function, args[, keywords])

The function argument must be a callable object (a user-defined or built-in function or method, or a class object) and the args argument must be a sequence. The function is called with args as the argument list; the number of arguments is the length of the tuple. If the optional keywords argument is present, it must be a dictionary whose keys are strings. It specifies keyword arguments to be added to the end of the argument list. Calling apply() is different from just calling function(args), since in that case there is always exactly one argument. The use of apply() is equivalent to function(*args, **keywords).

Deprecated since version 2.3: Use the extended call syntax with *args and **keywords instead.

buffer(object[, offset[, size]])

The object argument must be an object that supports the buffer call interface (such as strings, arrays, and buffers). A new buffer object will be created which references the object argument. The buffer object will be a slice from the beginning of object (or from the specified offset). The slice will extend to the end of object (or will have a length given by the size argument).
coerce\((x, y)\)
Return a tuple consisting of the two numeric arguments converted to a common type, using the same rules as used by arithmetic operations. If coercion is not possible, raise \texttt{TypeError}.

\texttt{intern(string)}
Enter \texttt{string} in the table of “interned” strings and return the interned string – which is \texttt{string} itself or a copy. Interning strings is useful to gain a little performance on dictionary lookup – if the keys in a dictionary are interned, and the lookup key is interned, the key comparisons (after hashing) can be done by a pointer compare instead of a string compare. Normally, the names used in Python programs are automatically interned, and the dictionaries used to hold module, class or instance attributes have interned keys.

\textit{Changed in version 2.3:} Interned strings are not immortal (like they used to be in Python 2.2 and before); you must keep a reference to the return value of \texttt{intern()} around to benefit from it.

Footnotes

[1] It is used relatively rarely so does not warrant being made into a statement.

[2] Specifying a buffer size currently has no effect on systems that don’t have \texttt{setvbuf}. The interface to specify the buffer size is not done using a method that calls \texttt{setvbuf}, because that may dump core when called after any I/O has been performed, and there’s no reliable way to determine whether this is the case.

[3] In the current implementation, local variable bindings cannot normally be affected this way, but variables retrieved from other scopes (such as modules) can be. This may change.
### Built-in Constants

A small number of constants live in the built-in namespace. They are:

**False**
- The false value of the `bool` type.
  
  *New in version 2.3.*

**True**
- The true value of the `bool` type.
  
  *New in version 2.3.*

**None**
- The sole value of `types.NoneType`. `None` is frequently used to represent the absence of a value, as when default arguments are not passed to a function.

  *Changed in version 2.4: Assignments to `None` are illegal and raise a `SyntaxError`.*

**NotImplemented**
- Special value which can be returned by the “rich comparison” special methods (`__eq__()`, `__lt__()`, and friends), to indicate that the comparison is not implemented with respect to the other type.

**Ellipsis**
- Special value used in conjunction with extended slicing syntax.

**__debug__**
- This constant is true if Python was not started with an `-O` option. Assignments to `__debug__` are illegal and raise a `SyntaxError`. See also the `assert` statement.
Constants added by the site module

The `site` module (which is imported automatically during startup, except if the `-S` command-line option is given) adds several constants to the built-in namespace. They are useful for the interactive interpreter built-in shell and should not be used in programs.

```python
quit([code=None])
exit([code=None])
```

Objects that when printed, print a message like “Use quit() or Ctrl-D (i.e. EOF) to exit”, and when called, raise `SystemExit` with the specified exit code, and when .

```python
copyright
license
credits
```

Objects that when printed, print a message like “Type license() to see the full license text”, and when called, display the corresponding text in a pager-like fashion (one screen at a time).
Built-in Objects

Names for built-in exceptions and functions and a number of constants are found in a separate symbol table. This table is searched last when the interpreter looks up the meaning of a name, so local and global user-defined names can override built-in names. Built-in types are described together here for easy reference.

The tables in this chapter document the priorities of operators by listing them in order of ascending priority (within a table) and grouping operators that have the same priority in the same box. Binary operators of the same priority group from left to right. (Unary operators group from right to left, but there you have no real choice.) See Summary for the complete picture on operator priorities.
Built-in Types

The following sections describe the standard types that are built into the interpreter.

**Note:** Historically (until release 2.2), Python's built-in types have differed from user-defined types because it was not possible to use the built-in types as the basis for object-oriented inheritance. This limitation no longer exists.

The principal built-in types are numerics, sequences, mappings, files, classes, instances and exceptions.

Some operations are supported by several object types; in particular, practically all objects can be compared, tested for truth value, and converted to a string (with the `repr()` function or the slightly different `str()` function). The latter function is implicitly used when an object is written by the `print()` function.
Truth Value Testing

Any object can be tested for truth value, for use in an if or while condition or as operand of the Boolean operations below. The following values are considered false:

- None
- False
- zero of any numeric type, for example, 0, 0L, 0.0, 0j.
- any empty sequence, for example, '', (), [].
- any empty mapping, for example, {}.
- instances of user-defined classes, if the class defines a __nonzero__() or __len__() method, when that method returns the integer zero or bool value False. [1]

All other values are considered true — so objects of many types are always true.

Operations and built-in functions that have a Boolean result always return 0 or False for false and 1 or True for true, unless otherwise stated. (Important exception: the Boolean operations or and and always return one of their operands.)
## Boolean Operations — and, or, not

These are the Boolean operations, ordered by ascending priority:

<table>
<thead>
<tr>
<th>Operation</th>
<th>Result</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>( x \lor y )</td>
<td>if ( x ) is false, then ( y ), else ( x )</td>
<td>(1)</td>
</tr>
<tr>
<td>( x \land y )</td>
<td>if ( x ) is false, then ( x ), else ( y )</td>
<td>(2)</td>
</tr>
<tr>
<td>not ( x )</td>
<td>if ( x ) is false, then \textbf{True}, else \textbf{False}</td>
<td>(3)</td>
</tr>
</tbody>
</table>

Notes:

1. This is a short-circuit operator, so it only evaluates the second argument if the first one is \textbf{False}.
2. This is a short-circuit operator, so it only evaluates the second argument if the first one is \textbf{True}.
3. \texttt{not} has a lower priority than non-Boolean operators, so \texttt{not a == b} is interpreted as \texttt{not (a == b)}, and \texttt{a == not b} is a syntax error.
Comparison operations are supported by all objects. They all have the same priority (which is higher than that of the Boolean operations). Comparisons can be chained arbitrarily; for example, \( x < y \leq z \) is equivalent to \( x < y \) and \( y \leq z \), except that \( y \) is evaluated only once (but in both cases \( z \) is not evaluated at all when \( x < y \) is found to be false).

This table summarizes the comparison operations:

<table>
<thead>
<tr>
<th>Operation</th>
<th>Meaning</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>&lt;</td>
<td>strictly less than</td>
<td></td>
</tr>
<tr>
<td>&lt;=</td>
<td>less than or equal</td>
<td></td>
</tr>
<tr>
<td>&gt;</td>
<td>strictly greater than</td>
<td></td>
</tr>
<tr>
<td>&gt;=</td>
<td>greater than or equal</td>
<td></td>
</tr>
<tr>
<td>==</td>
<td>equal</td>
<td></td>
</tr>
<tr>
<td>!=</td>
<td>not equal</td>
<td>(1)</td>
</tr>
<tr>
<td>is</td>
<td>object identity</td>
<td></td>
</tr>
<tr>
<td>is not</td>
<td>negated object identity</td>
<td></td>
</tr>
</tbody>
</table>

Notes:

1. \( != \) can also be written \( <> \), but this is an obsolete usage kept for backwards compatibility only. New code should always use \( != \).

Objects of different types, except different numeric types and different string types, never compare equal; such objects are ordered consistently but arbitrarily (so that sorting a heterogeneous array yields a consistent result). Furthermore, some types (for example, file objects) support only a degenerate notion of comparison where any two objects of that type are unequal. Again, such objects are
ordered arbitrarily but consistently. The <, <=, > and >= operators will raise a TypeError exception when any operand is a complex number.

Instances of a class normally compare as non-equal unless the class defines the __cmp__() method. Refer to Basic customization) for information on the use of this method to effect object comparisons.

**Implementation note:** Objects of different types except numbers are ordered by their type names; objects of the same types that don't support proper comparison are ordered by their address.

Two more operations with the same syntactic priority, in and not in, are supported only by sequence types (below).
There are four distinct numeric types: *plain integers*, *long integers*, *floating point numbers*, and *complex numbers*. In addition, Booleans are a subtype of plain integers. Plain integers (also just called *integers*) are implemented using `long` in C, which gives them at least 32 bits of precision (`sys.maxint` is always set to the maximum plain integer value for the current platform, the minimum value is `-sys.maxint - 1`). Long integers have unlimited precision. Floating point numbers are implemented using `double` in C. All bets on their precision are off unless you happen to know the machine you are working with.

Complex numbers have a real and imaginary part, which are each implemented using `double` in C. To extract these parts from a complex number $z$, use $z.real$ and $z.imag$.

Numbers are created by numeric literals or as the result of built-in functions and operators. Unadorned integer literals (including hex and octal numbers) yield plain integers unless the value they denote is too large to be represented as a plain integer, in which case they yield a long integer. Integer literals with an `'L'` or `'l'` suffix yield long integers (`'L'` is preferred because `1l` looks too much like eleven!). Numeric literals containing a decimal point or an exponent sign yield floating point numbers. Appending `'j'` or `'J'` to a numeric literal yields a complex number with a zero real part. A complex numeric literal is the sum of a real and an imaginary part.

Python fully supports mixed arithmetic: when a binary arithmetic operator has operands of different numeric types, the operand with the “narrower” type is widened to that of the other, where plain integer is narrower than long integer is narrower than floating point is
narrower than complex. Comparisons between numbers of mixed type use the same rule. [2] The constructors `int()`, `long()`, `float()`, and `complex()` can be used to produce numbers of a specific type.

All builtin numeric types support the following operations. See *The power operator* and later sections for the operators’ priorities.

<table>
<thead>
<tr>
<th>Operation</th>
<th>Result</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>x + y</td>
<td>sum of x and y</td>
<td></td>
</tr>
<tr>
<td>x - y</td>
<td>difference of x and y</td>
<td></td>
</tr>
<tr>
<td>x * y</td>
<td>product of x and y</td>
<td></td>
</tr>
<tr>
<td>x / y</td>
<td>quotient of x and y</td>
<td>(1)</td>
</tr>
<tr>
<td>x // y</td>
<td>(floored) quotient of x and y</td>
<td>(4)(5)</td>
</tr>
<tr>
<td>x % y</td>
<td>remainder of x / y</td>
<td>(4)</td>
</tr>
<tr>
<td>-x</td>
<td>x negated</td>
<td></td>
</tr>
<tr>
<td>+x</td>
<td>x unchanged</td>
<td></td>
</tr>
<tr>
<td>abs(x)</td>
<td>absolute value or magnitude of x</td>
<td>(3)</td>
</tr>
<tr>
<td>int(x)</td>
<td>x converted to integer</td>
<td>(2)</td>
</tr>
<tr>
<td>long(x)</td>
<td>x converted to long integer</td>
<td>(2)</td>
</tr>
<tr>
<td>float(x)</td>
<td>x converted to floating point</td>
<td>(6)</td>
</tr>
<tr>
<td>complex(re,im)</td>
<td>a complex number with real part re,</td>
<td></td>
</tr>
<tr>
<td></td>
<td>imaginary part im. im defaults to zero.</td>
<td></td>
</tr>
<tr>
<td>c.conjugate()</td>
<td>conjugate of the complex number c.</td>
<td></td>
</tr>
<tr>
<td></td>
<td>(Identity on real numbers)</td>
<td></td>
</tr>
<tr>
<td>divmod(x, y)</td>
<td>the pair (x // y, x % y)</td>
<td>(3)(4)</td>
</tr>
<tr>
<td>pow(x, y)</td>
<td>x to the power y</td>
<td>(3)(7)</td>
</tr>
<tr>
<td>x ** y</td>
<td>x to the power y</td>
<td>(7)</td>
</tr>
</tbody>
</table>

Notes:

1. For (plain or long) integer division, the result is an integer. The result is always rounded towards minus infinity: 1/2 is 0, (-1)/2 is -1, 1/(-2) is -1, and (-1)/(-2) is 0. Note that the result is a long
integer if either operand is a long integer, regardless of the numeric value.

2. Conversion from floating point to (long or plain) integer may round or truncate as in C; see functions `math.floor()` and `math.ceil()` for well-defined conversions.

   *Deprecated since version 2.6:* Instead, convert floats to long explicitly with `trunc()`.

3. See *Built-in Functions* for a full description.

4. Complex floor division operator, modulo operator, and `divmod()`.

   *Deprecated since version 2.3:* Instead convert to float using `abs()` if appropriate.

5. Also referred to as integer division. The resultant value is a whole integer, though the result’s type is not necessarily `int`.

6. `float` also accepts the strings “nan” and “inf” with an optional prefix “+” or “-” for Not a Number (NaN) and positive or negative infinity.

   *New in version 2.6.*

7. Python defines `pow(0, 0)` and `0 ** 0` to be 1, as is common for programming languages.

All *numbers.Real* types (`int`, `long`, and `float`) also include the following operations:

<table>
<thead>
<tr>
<th>Operation</th>
<th>Result</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>trunc(x)</code></td>
<td>$x$ truncated to Integral</td>
<td></td>
</tr>
<tr>
<td><code>round(x[, n])</code></td>
<td>$x$ rounded to n digits, rounding half to</td>
<td>even. If n is omitted, it defaults to 0.</td>
</tr>
</tbody>
</table>

All numbers.Real types (int, long, and float) also include the following operations:
\[
\text{math.floor}(x) \quad \text{the greatest integral float} \leq x
\]
\[
\text{math.ceil}(x) \quad \text{the least integral float} \geq x
\]

**Bit-string Operations on Integer Types**

Plain and long integer types support additional operations that make sense only for bit-strings. Negative numbers are treated as their 2's complement value (for long integers, this assumes a sufficiently large number of bits that no overflow occurs during the operation).

The priorities of the binary bitwise operations are all lower than the numeric operations and higher than the comparisons; the unary operation \( \sim \) has the same priority as the other unary numeric operations (\(+\) and \(-\)).

This table lists the bit-string operations sorted in ascending priority:

<table>
<thead>
<tr>
<th>Operation</th>
<th>Result</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>( x</td>
<td>y )</td>
<td>bitwise or of ( x ) and ( y )</td>
</tr>
<tr>
<td>( x ^ y )</td>
<td>bitwise exclusive or of ( x ) and ( y )</td>
<td></td>
</tr>
<tr>
<td>( x &amp; y )</td>
<td>bitwise and of ( x ) and ( y )</td>
<td></td>
</tr>
<tr>
<td>( x &lt;&lt; n )</td>
<td>( x ) shifted left by ( n ) bits</td>
<td>(1)(2)</td>
</tr>
<tr>
<td>( x &gt;&gt; n )</td>
<td>( x ) shifted right by ( n ) bits</td>
<td>(1)(3)</td>
</tr>
<tr>
<td>( \sim x )</td>
<td>the bits of ( x ) inverted</td>
<td></td>
</tr>
</tbody>
</table>

**Notes:**

1. Negative shift counts are illegal and cause a `ValueError` to be raised.
2. A left shift by \( n \) bits is equivalent to multiplication by \( \text{pow}(2, n) \).
   A long integer is returned if the result exceeds the range of plain integers.
3. A right shift by \( n \) bits is equivalent to division by \( \text{pow}(2, n) \).
Additional Methods on Float

The float type has some additional methods.

**float.as_integer_ratio()**

Return a pair of integers whose ratio is exactly equal to the original float and with a positive denominator. Raises `OverflowError` on infinities and a `ValueError` on NaNs.

*New in version 2.6.*

Two methods support conversion to and from hexadecimal strings. Since Python’s floats are stored internally as binary numbers, converting a float to or from a *decimal* string usually involves a small rounding error. In contrast, hexadecimal strings allow exact representation and specification of floating-point numbers. This can be useful when debugging, and in numerical work.

**float.hex()**

Return a representation of a floating-point number as a hexadecimal string. For finite floating-point numbers, this representation will always include a leading `0x` and a trailing `p` and exponent.

*New in version 2.6.*

**float.fromhex(s)**

Class method to return the float represented by a hexadecimal string `s`. The string `s` may have leading and trailing whitespace.

*New in version 2.6.*

Note that `float.hex()` is an instance method, while `float.fromhex()` is a class method.
A hexadecimal string takes the form:

```
[sign] ['0x'] integer ['.' fraction] ['p' exponent]
```

where the optional sign may by either + or -, integer and fraction are strings of hexadecimal digits, and exponent is a decimal integer with an optional leading sign. Case is not significant, and there must be at least one hexadecimal digit in either the integer or the fraction. This syntax is similar to the syntax specified in section 6.4.4.2 of the C99 standard, and also to the syntax used in Java 1.5 onwards. In particular, the output of `float.hex()` is usable as a hexadecimal floating-point literal in C or Java code, and hexadecimal strings produced by C's `%a` format character or Java's `Double.toHexString` are accepted by `float.fromhex()`.

Note that the exponent is written in decimal rather than hexadecimal, and that it gives the power of 2 by which to multiply the coefficient. For example, the hexadecimal string `0x3.a7p10` represents the floating-point number \((3 + 10./16 + 7./16^{*}2) * 2.0^{*}10\), or 3740.0:

```
>>> float.fromhex('0x3.a7p10')
3740.0
```

Applying the reverse conversion to 3740.0 gives a different hexadecimal string representing the same number:

```
>>> float.hex(3740.0)
'0x1.d38000000000p+11'
```
**Iterator Types**

*New in version 2.2.*

Python supports a concept of iteration over containers. This is implemented using two distinct methods; these are used to allow user-defined classes to support iteration. Sequences, described below in more detail, always support the iteration methods.

One method needs to be defined for container objects to provide iteration support:

```
container. __iter__ ()
```

Return an iterator object. The object is required to support the iterator protocol described below. If a container supports different types of iteration, additional methods can be provided to specifically request iterators for those iteration types. (An example of an object supporting multiple forms of iteration would be a tree structure which supports both breadth-first and depth-first traversal.) This method corresponds to the `tp_iter` slot of the type structure for Python objects in the Python/C API.

The iterator objects themselves are required to support the following two methods, which together form the *iterator protocol*:

```
iterator. __iter__ ()
```

Return the iterator object itself. This is required to allow both containers and iterators to be used with the `for` and `in` statements. This method corresponds to the `tp_iter` slot of the type structure for Python objects in the Python/C API.

```
iterator. next ()
```

Return the next item from the container. If there are no further
items, raise the `StopIteration` exception. This method corresponds to the `tp_iternext` slot of the type structure for Python objects in the Python/C API.

Python defines several iterator objects to support iteration over general and specific sequence types, dictionaries, and other more specialized forms. The specific types are not important beyond their implementation of the iterator protocol.

The intention of the protocol is that once an iterator's `next()` method raises `StopIteration`, it will continue to do so on subsequent calls. Implementations that do not obey this property are deemed broken. (This constraint was added in Python 2.3; in Python 2.2, various iterators are broken according to this rule.)

Python's `generators` provide a convenient way to implement the iterator protocol. If a container object's `__iter__()` method is implemented as a generator, it will automatically return an iterator object (technically, a generator object) supplying the `__iter__()` and `next()` methods.
Sequence Types — str, unicode, list, tuple, buffer, xrange

There are six sequence types: strings, Unicode strings, lists, tuples, buffers, and xrange objects. (For other containers see the built in dict, list, set, and tuple classes, and the collections module.)

String literals are written in single or double quotes: 'xyzzy', "frobozz". See String literals for more about string literals. Unicode strings are much like strings, but are specified in the syntax using a preceding u' character: u'abc', u"def". In addition to the functionality described here, there are also string-specific methods described in the String Methods section. Lists are constructed with square brackets, separating items with commas: [a, b, c]. Tuples are constructed by the comma operator (not within square brackets), with or without enclosing parentheses, but an empty tuple must have the enclosing parentheses, such as a, b, c or (). A single item tuple must have a trailing comma, such as (d,).

Buffer objects are not directly supported by Python syntax, but can be created by calling the builtin function buffer(). They don't support concatenation or repetition.

Objects of type xrange are similar to buffers in that there is no specific syntax to create them, but they are created using the xrange() function. They don't support slicing, concatenation or repetition, and using in, not in, min() or max() on them is inefficient.

Most sequence types support the following operations. The in and not in operations have the same priorities as the comparison operations. The + and * operations have the same priority as the
corresponding numeric operations. [3] Additional methods are provided for *Mutable Sequence Types*.

This table lists the sequence operations sorted in ascending priority (operations in the same box have the same priority). In the table, \( s \) and \( t \) are sequences of the same type; \( n, i \) and \( j \) are integers:

<table>
<thead>
<tr>
<th>Operation</th>
<th>Result</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>( x ) in ( s )</td>
<td>True if an item of ( s ) is equal to ( x ), else False</td>
<td>(1)</td>
</tr>
<tr>
<td>( x ) not in ( s )</td>
<td>False if an item of ( s ) is equal to ( x ), else True</td>
<td>(1)</td>
</tr>
<tr>
<td>( s + t )</td>
<td>the concatenation of ( s ) and ( t )</td>
<td>(6)</td>
</tr>
<tr>
<td>( s * n, n * s )</td>
<td>( n ) shallow copies of ( s ) concatenated</td>
<td>(2)</td>
</tr>
<tr>
<td>( s[i] )</td>
<td>( i )'th item of ( s ), origin 0</td>
<td>(3)</td>
</tr>
<tr>
<td>( s[i:j] )</td>
<td>slice of ( s ) from ( i ) to ( j )</td>
<td>(3)(4)</td>
</tr>
<tr>
<td>( s[i:j:k] )</td>
<td>slice of ( s ) from ( i ) to ( j ) with step ( k )</td>
<td>(3)(5)</td>
</tr>
<tr>
<td>( \text{len}(s) )</td>
<td>length of ( s )</td>
<td></td>
</tr>
<tr>
<td>( \text{min}(s) )</td>
<td>smallest item of ( s )</td>
<td></td>
</tr>
<tr>
<td>( \text{max}(s) )</td>
<td>largest item of ( s )</td>
<td></td>
</tr>
</tbody>
</table>

Sequence types also support comparisons. In particular, tuples and lists are compared lexicographically by comparing corresponding elements. This means that to compare equal, every element must compare equal and the two sequences must be of the same type and have the same length. (For full details see *Comparisons* in the language reference.)

Notes:

1. When \( s \) is a string or Unicode string object the `in` and `not in` operations act like a substring test. In Python versions before 2.3, \( x \) had to be a string of length 1. In Python 2.3 and beyond, \( x \) may be a string of any length.
2. Values of $n$ less than 0 are treated as 0 (which yields an empty sequence of the same type as $s$). Note also that the copies are shallow; nested structures are not copied. This often haunts new Python programmers; consider:

```python
>>> lists = [[]] * 3
>>> lists
[[], [], []]
>>> lists[0].append(3)
>>> lists
[[3], [3], [3]]
```

What has happened is that [[]] is a one-element list containing an empty list, so all three elements of [[]] * 3 are (pointers to) this single empty list. Modifying any of the elements of `lists` modifies this single list. You can create a list of different lists this way:

```python
>>> lists = [[] for i in range(3)]
>>> lists[0].append(3)
>>> lists[1].append(5)
>>> lists[2].append(7)
>>> lists
[[3], [5], [7]]
```

3. If $i$ or $j$ is negative, the index is relative to the end of the string: `len(s) + i` or `len(s) + j` is substituted. But note that `-0` is still 0.

4. The slice of $s$ from $i$ to $j$ is defined as the sequence of items with index $k$ such that $i \leq k < j$. If $i$ or $j$ is greater than `len(s)`, use `len(s)`. If $i$ is omitted or `None`, use 0. If $j$ is omitted or `None`, use `len(s)`. If $i$ is greater than or equal to $j$, the slice is empty.
5. The slice of \( s \) from \( i \) to \( j \) with step \( k \) is defined as the sequence of items with index \( x = i + n*k \) such that \( 0 \leq n < (j-i)/k \). In other words, the indices are \( i, i+k, i+2*k, i+3*k \) and so on, stopping when \( j \) is reached (but never including \( j \)). If \( i \) or \( j \) is greater than \( \text{len}(s) \), use \( \text{len}(s) \). If \( i \) or \( j \) are omitted or \text{None}, they become “end” values (which end depends on the sign of \( k \)). Note, \( k \) cannot be zero. If \( k \) is \text{None}, it is treated like \( 1 \).

6. If \( s \) and \( t \) are both strings, some Python implementations such as CPython can usually perform an in-place optimization for assignments of the form \( s=s+t \) or \( s+=t \). When applicable, this optimization makes quadratic run-time much less likely. This optimization is both version and implementation dependent. For performance sensitive code, it is preferable to use the \text{str.join()} \ method which assures consistent linear concatenation performance across versions and implementations.

\textit{Changed in version 2.4:} Formerly, string concatenation never occurred in-place.

### String Methods

Below are listed the string methods which both 8-bit strings and Unicode objects support. Note that none of these methods take keyword arguments.

In addition, Python’s strings support the sequence type methods described in the \textit{Sequence Types — str, unicode, list, tuple, buffer, xrange} section. To output formatted strings use template strings or the \% operator described in the \textit{String Formatting Operations} section. Also, see the \texttt{re} module for string functions based on regular expressions.
str. **capitalize()**

Return a copy of the string with only its first character capitalized.

For 8-bit strings, this method is locale-dependent.

str. **center**(width[, fillchar])

Return centered in a string of length `width`. Padding is done using the specified `fillchar` (default is a space).

*Changed in version 2.4:* Support for the `fillchar` argument.

str. **count**(sub[, start[, end]])

Return the number of occurrences of substring `sub` in the range `[start, end]`. Optional arguments `start` and `end` are interpreted as in slice notation.

str. **decode**(encoding[, errors])

Decodes the string using the codec registered for `encoding`. `encoding` defaults to the default string encoding. `errors` may be given to set a different error handling scheme. The default is `'strict'`, meaning that encoding errors raise **UnicodeError**. Other possible values are 'ignore', 'replace' and any other name registered via `codecs.register_error()`, see section *Codec Base Classes*.

*New in version 2.2.*

*Changed in version 2.3:* Support for other error handling schemes added.

str. **encode**(encoding[, errors])

Return an encoded version of the string. Default encoding is the current default string encoding. `errors` may be given to set a different error handling scheme. The default for `errors` is
'strict', meaning that encoding errors raise a UnicodeError. Other possible values are 'ignore', 'replace', 'xmlcharrefreplace', 'backslashreplace' and any other name registered via codecs.register_error(), see section Codec Base Classes. For a list of possible encodings, see section Standard Encodings.

New in version 2.0.

Changed in version 2.3: Support for 'xmlcharrefreplace' and 'backslashreplace' and other error handling schemes added.

str.endswith(suffix[, start[, end]])
Return True if the string ends with the specified suffix, otherwise return False. suffix can also be a tuple of suffixes to look for. With optional start, test beginning at that position. With optional end, stop comparing at that position.

Changed in version 2.5: Accept tuples as suffix.

str.expandtabs([tabsize])
Return a copy of the string where all tab characters are replaced by one or more spaces, depending on the current column and the given tab size. The column number is reset to zero after each newline occurring in the string. If tabsize is not given, a tab size of 8 characters is assumed. This doesn't understand other non-printing characters or escape sequences.

str.find(sub[, start[, end]])
Return the lowest index in the string where substring sub is found, such that sub is contained in the range [start, end]. Optional arguments start and end are interpreted as in slice notation. Return -1 if sub is not found.
str.format(format_string, *args, **kwargs)

Perform a string formatting operation. The format_string argument can contain literal text or replacement fields delimited by braces {}. Each replacement field contains either the numeric index of a positional argument, or the name of a keyword argument. Returns a copy of format_string where each replacement field is replaced with the string value of the corresponding argument.

>>> "The sum of 1 + 2 is {0}".format(1+2)
'The sum of 1 + 2 is 3'

See Format String Syntax for a description of the various formatting options that can be specified in format strings.

This method of string formatting is the new standard in Python 3.0, and should be preferred to the % formatting described in String Formatting Operations in new code.

New in version 2.6.

str.index(sub[, start[, end]])

Like find(), but raise ValueError when the substring is not found.

str.isalnum()

Return true if all characters in the string are alphanumeric and there is at least one character, false otherwise.

For 8-bit strings, this method is locale-dependent.

str.isalpha()

Return true if all characters in the string are alphabetic and there is at least one character, false otherwise.
For 8-bit strings, this method is locale-dependent.

**str. isdigit()**
Return true if all characters in the string are digits and there is at least one character, false otherwise.

For 8-bit strings, this method is locale-dependent.

**str. islower()**
Return true if all cased characters in the string are lowercase and there is at least one cased character, false otherwise.

For 8-bit strings, this method is locale-dependent.

**str. isspace()**
Return true if there are only whitespace characters in the string and there is at least one character, false otherwise.

For 8-bit strings, this method is locale-dependent.

**str. istitle()**
Return true if the string is a titlecased string and there is at least one character, for example uppercase characters may only follow uncased characters and lowercase characters only cased ones. Return false otherwise.

For 8-bit strings, this method is locale-dependent.

**str. isupper()**
Return true if all cased characters in the string are uppercase and there is at least one cased character, false otherwise.

For 8-bit strings, this method is locale-dependent.

**str. join(seq)**
Return a string which is the concatenation of the strings in the
sequence `seq`. The separator between elements is the string providing this method.

```python
str. ljust(width[, fillchar])
```
Return the string left justified in a string of length `width`. Padding is done using the specified `fillchar` (default is a space). The original string is returned if `width` is less than `len(s)`.

*Changed in version 2.4:* Support for the `fillchar` argument.

```python
str. lower()
```
Return a copy of the string converted to lowercase.

For 8-bit strings, this method is locale-dependent.

```python
str. lstrip([chars])
```
Return a copy of the string with leading characters removed. The `chars` argument is a string specifying the set of characters to be removed. If omitted or `None`, the `chars` argument defaults to removing whitespace. The `chars` argument is not a prefix; rather, all combinations of its values are stripped:

```python
>>> '   spacious   '.lstrip()
'spacious   '
>>> 'www.example.com'.lstrip('cmowz.')</br>'example.com'
```

*Changed in version 2.2.2:* Support for the `chars` argument.

```python
str. partition(sep)
```
Split the string at the first occurrence of `sep`, and return a 3-tuple containing the part before the separator, the separator itself, and the part after the separator. If the separator is not found, return a 3-tuple containing the string itself, followed by two empty strings.
New in version 2.5.

str. **replace**(old, new[, count])

Return a copy of the string with all occurrences of substring *old* replaced by *new*. If the optional argument *count* is given, only the first *count* occurrences are replaced.

str. **rfind**(sub[, start[, end]])

Return the highest index in the string where substring *sub* is found, such that *sub* is contained within s[start,end]. Optional arguments *start* and *end* are interpreted as in slice notation. Return -1 on failure.

str. **rindex**(sub[, start[, end]])

Like rfind() but raises **ValueError** when the substring *sub* is not found.

str. **rjust**(width[, fillchar])

Return the string right justified in a string of length *width*. Padding is done using the specified *fillchar* (default is a space). The original string is returned if *width* is less than len(s).

*Changed in version 2.4:* Support for the *fillchar* argument.

str. **rpartition**(sep)

Split the string at the last occurrence of *sep*, and return a 3-tuple containing the part before the separator, the separator itself, and the part after the separator. If the separator is not found, return a 3-tuple containing two empty strings, followed by the string itself.

New in version 2.5.

str. **rsplit**(sep[, maxsplit])

Return a list of the words in the string, using *sep* as the delimiter
string. If *maxsplit* is given, at most *maxsplit* splits are done, the rightmost ones. If *sep* is not specified or *None*, any whitespace string is a separator. Except for splitting from the right, *rsplit()* behaves like *split()* which is described in detail below.

*New in version 2.4.*

str.*rstrip([chars])*

Return a copy of the string with trailing characters removed. The *chars* argument is a string specifying the set of characters to be removed. If omitted or *None*, the *chars* argument defaults to removing whitespace. The *chars* argument is not a suffix; rather, all combinations of its values are stripped:

```python
>>> '   spacious   '.rstrip()
'   spacious'
>>> 'mississippi'.rstrip('ipz')
'mississ'
```

*Changed in version 2.2.2:* Support for the *chars* argument.

str.*split([sep[, maxsplit]])*

Return a list of the words in the string, using *sep* as the delimiter string. If *maxsplit* is given, at most *maxsplit* splits are done (thus, the list will have at most *maxsplit+1* elements). If *maxsplit* is not specified, then there is no limit on the number of splits (all possible splits are made).

If *sep* is given, consecutive delimiters are not grouped together and are deemed to delimit empty strings (for example, '1,,2'.split(',')) returns ['1', '', '2']. The *sep* argument may consist of multiple characters (for example, '1<>2<>3'.split('<>')) returns ['1', '2', '3']. Splitting an empty string with a specified separator returns [''].
If sep is not specified or is `None`, a different splitting algorithm is applied: runs of consecutive whitespace are regarded as a single separator, and the result will contain no empty strings at the start or end if the string has leading or trailing whitespace. Consequently, splitting an empty string or a string consisting of just whitespace with a `None` separator returns `[]`.

For example, `' 1 2 3 '`.split() returns `['1', '2', '3']`, and `' 1 2 3 '`.split(`None, 1`) returns `['1', '2 3 ']

**str.splitlines([keepends])**

Return a list of the lines in the string, breaking at line boundaries. Line breaks are not included in the resulting list unless `keepends` is given and true.

**str.startswith(prefix[, start[, end]])**

Return `True` if string starts with the `prefix`, otherwise return `False`. `prefix` can also be a tuple of prefixes to look for. With optional `start`, test string beginning at that position. With optional `end`, stop comparing string at that position.

*Changed in version 2.5: Accept tuples as `prefix`.*

**str.strip([chars])**

Return a copy of the string with the leading and trailing characters removed. The `chars` argument is a string specifying the set of characters to be removed. If omitted or `None`, the `chars` argument defaults to removing whitespace. The `chars` argument is not a prefix or suffix; rather, all combinations of its values are stripped:

```python
>>> 'spacious '.strip()
'spacious'
```
>>> 'www.example.com'.strip('cmowz.')
'example'

Changed in version 2.2.2: Support for the chars argument.

str.swapcase()
Return a copy of the string with uppercase characters converted to lowercase and vice versa.

For 8-bit strings, this method is locale-dependent.

str.title()
Return a titlecased version of the string: words start with uppercase characters, all remaining cased characters are lowercase.

For 8-bit strings, this method is locale-dependent.

str.translate(table[, deletechars])
Return a copy of the string where all characters occurring in the optional argument deletechars are removed, and the remaining characters have been mapped through the given translation table, which must be a string of length 256.

You can use the maketrans() helper function in the string module to create a translation table. For string objects, set the table argument to None for translations that only delete characters:

>>> 'read this short text'.translate(None, 'aeiou')
'rd ths shrt txt'

New in version 2.6: Support for a None table argument.

For Unicode objects, the translate() method does not accept
the optional \texttt{deletechars} argument. Instead, it returns a copy of
the \texttt{s} where all characters have been mapped through the given
translation table which must be a mapping of Unicode ordinals to
Unicode ordinals, Unicode strings or \texttt{None}. Unmapped characters
are left untouched. Characters mapped to \texttt{None} are deleted. Note,
a more flexible approach is to create a custom character mapping
codec using the \texttt{codecs} module (see \texttt{encodings.cp1251} for an
eexample).

\texttt{str.upper()}

Return a copy of the string converted to uppercase.

For 8-bit strings, this method is locale-dependent.

\texttt{str.zfill(width)}

Return the numeric string left filled with zeros in a string of length
\texttt{width}. A sign prefix is handled correctly. The original string is
returned if \texttt{width} is less than \texttt{len(s)}.

\textit{New in version 2.2.2.}

The following methods are present only on unicode objects:

\texttt{unicode.isnumeric()}\n
Return \texttt{True} if there are only numeric characters in \texttt{S}, \texttt{False}
otherwise. Numeric characters include digit characters, and all
characters that have the Unicode numeric value property, e.g.
U+2155, VULGAR FRACTION ONE FIFTH.

\texttt{unicode.isdecimal()}\n
Return \texttt{True} if there are only decimal characters in \texttt{S}, \texttt{False}
otherwise. Decimal characters include digit characters, and all
characters that that can be used to form decimal-radix numbers,
e.g. U+0660, ARABIC-INDIC DIGIT ZERO.
String and Unicode objects have one unique built-in operation: the % operator (modulo). This is also known as the string formatting or interpolation operator. Given `format % values` (where `format` is a string or Unicode object), % conversion specifications in `format` are replaced with zero or more elements of `values`. The effect is similar to the using `sprintf` in the C language. If `format` is a Unicode object, or if any of the objects being converted using the `%s` conversion are Unicode objects, the result will also be a Unicode object.

If `format` requires a single argument, `values` may be a single non-tuple object. Otherwise, `values` must be a tuple with exactly the number of items specified by the format string, or a single mapping object (for example, a dictionary).

A conversion specifier contains two or more characters and has the following components, which must occur in this order:

1. The `%` character, which marks the start of the specifier.
2. Mapping key (optional), consisting of a parenthesised sequence of characters (for example, `(somename)`).
3. Conversion flags (optional), which affect the result of some conversion types.
4. Minimum field width (optional). If specified as an `*' (asterisk), the actual width is read from the next element of the tuple in `values`, and the object to convert comes after the minimum field width and optional precision.
5. Precision (optional), given as a `.` (dot) followed by the precision. If specified as `*' (an asterisk), the actual width is read from the next element of the tuple in `values`, and the value to convert comes after the precision.
7. Conversion type.

When the right argument is a dictionary (or other mapping type), then the formats in the string *must* include a parenthesised mapping key into that dictionary inserted immediately after the '%s' character. The mapping key selects the value to be formatted from the mapping. For example:

```python
>>> print '%(language)s has %(#)03d quote types.' % 
... {'language': "Python", "#": 2}
Python has 002 quote types.
```

In this case no * specifiers may occur in a format (since they require a sequential parameter list).

The conversion flag characters are:

<table>
<thead>
<tr>
<th>Flag</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>'s'</td>
<td>The value conversion will use the “alternate form” (where defined below).</td>
</tr>
<tr>
<td>'0'</td>
<td>The conversion will be zero padded for numeric values.</td>
</tr>
<tr>
<td>'-'</td>
<td>The converted value is left adjusted (overrides the '0' conversion if both are given).</td>
</tr>
<tr>
<td>' '</td>
<td>(a space) A blank should be left before a positive number (or empty string) produced by a signed conversion.</td>
</tr>
<tr>
<td>'+'</td>
<td>A sign character ('+' or '-') will precede the conversion (overrides a “space” flag).</td>
</tr>
</tbody>
</table>

A length modifier (h, l, or L) may be present, but is ignored as it is not necessary for Python – so e.g. %1d is identical to %d.

The conversion types are:

<table>
<thead>
<tr>
<th>Conversion</th>
<th>Meaning</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>'d'</td>
<td>Signed integer decimal.</td>
<td></td>
</tr>
<tr>
<td>'i'</td>
<td>Signed integer decimal.</td>
<td></td>
</tr>
<tr>
<td>Format</td>
<td>Description</td>
<td></td>
</tr>
<tr>
<td>--------</td>
<td>-------------</td>
<td></td>
</tr>
<tr>
<td>'o'</td>
<td>Signed octal value. (1)</td>
<td></td>
</tr>
<tr>
<td>'u'</td>
<td>Obsolete type – it is identical to 'd'. (7)</td>
<td></td>
</tr>
<tr>
<td>'x'</td>
<td>Signed hexadecimal (lowercase). (2)</td>
<td></td>
</tr>
<tr>
<td>'X'</td>
<td>Signed hexadecimal (uppercase). (2)</td>
<td></td>
</tr>
<tr>
<td>'e'</td>
<td>Floating point exponential format (lowercase). (3)</td>
<td></td>
</tr>
<tr>
<td>'E'</td>
<td>Floating point exponential format (uppercase). (3)</td>
<td></td>
</tr>
<tr>
<td>'f'</td>
<td>Floating point decimal format. (3)</td>
<td></td>
</tr>
<tr>
<td>'F'</td>
<td>Floating point decimal format. (3)</td>
<td></td>
</tr>
<tr>
<td>'g'</td>
<td>Floating point format. Uses lowercase exponential format if exponent is less than -4 or not less than precision, decimal format otherwise. (4)</td>
<td></td>
</tr>
<tr>
<td>'G'</td>
<td>Floating point format. Uses uppercase exponential format if exponent is less than -4 or not less than precision, decimal format otherwise. (4)</td>
<td></td>
</tr>
<tr>
<td>'c'</td>
<td>Single character (accepts integer or single character string).</td>
<td></td>
</tr>
<tr>
<td>'r'</td>
<td>String (converts any python object using \texttt{repr()}). (5)</td>
<td></td>
</tr>
<tr>
<td>'s'</td>
<td>String (converts any python object using \texttt{str()}). (6)</td>
<td></td>
</tr>
<tr>
<td>'%'</td>
<td>No argument is converted, results in a '%' character in the result.</td>
<td></td>
</tr>
</tbody>
</table>

Notes:

1. The alternate form causes a leading zero ('0') to be inserted between left-hand padding and the formatting of the number if the leading character of the result is not already a zero.

2. The alternate form causes a leading '0x' or '0X' (depending on whether the 'x' or 'X' format was used) to be inserted between left-hand padding and the formatting of the number if the leading
character of the result is not already a zero.

3. The alternate form causes the result to always contain a decimal point, even if no digits follow it.

   The precision determines the number of digits after the decimal point and defaults to 6.

4. The alternate form causes the result to always contain a decimal point, and trailing zeroes are not removed as they would otherwise be.

   The precision determines the number of significant digits before and after the decimal point and defaults to 6.

5. The \%r conversion was added in Python 2.0.

   The precision determines the maximal number of characters used.

6. If the object or format provided is a \texttt{unicode} string, the resulting string will also be \texttt{unicode}.

   The precision determines the maximal number of characters used.

7. See \texttt{PEP 237}.

Since Python strings have an explicit length, \%s conversions do not assume that ‘\0’ is the end of the string.

For safety reasons, floating point precisions are clipped to 50; \%f conversions for numbers whose absolute value is over $1e25$ are replaced by \%g conversions. \cite{footnote5} All other errors raise exceptions.

Additional string operations are defined in standard modules \texttt{string}
XRange Type

The `xrange` type is an immutable sequence which is commonly used for looping. The advantage of the `xrange` type is that an `xrange` object will always take the same amount of memory, no matter the size of the range it represents. There are no consistent performance advantages.

XRange objects have very little behavior: they only support indexing, iteration, and the `len()` function.

Mutable Sequence Types

List objects support additional operations that allow in-place modification of the object. Other mutable sequence types (when added to the language) should also support these operations. Strings and tuples are immutable sequence types: such objects cannot be modified once created. The following operations are defined on mutable sequence types (where `x` is an arbitrary object):

<table>
<thead>
<tr>
<th>Operation</th>
<th>Result</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>s[i] = x</code></td>
<td>item <code>i</code> of <code>s</code> is replaced by <code>x</code></td>
<td></td>
</tr>
<tr>
<td><code>s[i:j] = t</code></td>
<td>slice of <code>s</code> from <code>i</code> to <code>j</code> is replaced by the contents of the iterable <code>t</code></td>
<td></td>
</tr>
<tr>
<td><code>del s[i:j]</code></td>
<td>same as <code>s[i:j] = []</code></td>
<td></td>
</tr>
<tr>
<td><code>s[i:j:k] = t</code></td>
<td>the elements of <code>s[i:j:k]</code> are replaced by those of <code>t</code> (1)</td>
<td></td>
</tr>
<tr>
<td><code>del s[i:j:k]</code></td>
<td>removes the elements of <code>s[i:j:k]</code> from the list</td>
<td></td>
</tr>
<tr>
<td><code>s.append(x)</code></td>
<td>same as</td>
<td>(2)</td>
</tr>
<tr>
<td>Method</td>
<td>Description</td>
<td>Notes</td>
</tr>
<tr>
<td>-----------------</td>
<td>------------------------------------------------------------------------------</td>
<td>--------------------------------</td>
</tr>
<tr>
<td><code>s.extend(x)</code></td>
<td>same as <code>s[len(s):len(s)] = x</code></td>
<td>(3)</td>
</tr>
<tr>
<td><code>s.count(x)</code></td>
<td>return number of <code>i</code>'s for which <code>s[i] == x</code></td>
<td></td>
</tr>
<tr>
<td><code>s.index(x[, i[, j]])</code></td>
<td>return smallest <code>k</code> such that <code>s[k] == x</code> and <code>i &lt;= k &lt; j</code></td>
<td>(4)</td>
</tr>
<tr>
<td><code>s.insert(i, x)</code></td>
<td>same as <code>s[i:i] = [x]</code></td>
<td>(5)</td>
</tr>
<tr>
<td><code>s.pop([i])</code></td>
<td>same as <code>x = s[i]; del s[i]; return x</code></td>
<td>(6)</td>
</tr>
<tr>
<td><code>s.remove(x)</code></td>
<td>same as <code>del s[s.index(x)]</code></td>
<td>(4)</td>
</tr>
<tr>
<td><code>s.reverse()</code></td>
<td>reverses the items of <code>s</code> in place</td>
<td>(7)</td>
</tr>
<tr>
<td><code>s.sort([cmp[, key[, reverse]]])</code></td>
<td>sort the items of <code>s</code> in place</td>
<td>(7)(8)(9)(10)</td>
</tr>
</tbody>
</table>

Notes:

1. `t` must have the same length as the slice it is replacing.

2. The C implementation of Python has historically accepted multiple parameters and implicitly joined them into a tuple; this no longer works in Python 2.0. Use of this misfeature has been deprecated since Python 1.4.

3. `x` can be any iterable object.

4. Raises `ValueError` when `x` is not found in `s`. When a negative index is passed as the second or third parameter to the `index()` method, the list length is added, as for slice indices. If it is still negative, it is truncated to zero, as for slice indices.

   *Changed in version 2.3:* Previously, `index()` didn’t have arguments for specifying start and stop positions.
5. When a negative index is passed as the first parameter to the `insert()` method, the list length is added, as for slice indices. If it is still negative, it is truncated to zero, as for slice indices.

   *changed in version 2.3:* Previously, all negative indices were truncated to zero.

6. The `pop()` method is only supported by the list and array types. The optional argument `i` defaults to `-1`, so that by default the last item is removed and returned.

7. The `sort()` and `reverse()` methods modify the list in place for economy of space when sorting or reversing a large list. To remind you that they operate by side effect, they don’t return the sorted or reversed list.

8. The `sort()` method takes optional arguments for controlling the comparisons.

   `cmp` specifies a custom comparison function of two arguments (list items) which should return a negative, zero or positive number depending on whether the first argument is considered smaller than, equal to, or larger than the second argument: `cmp=lambda x,y: cmp(x.lower(), y.lower())`. The default value is `None`.

   `key` specifies a function of one argument that is used to extract a comparison key from each list element: `key=str.lower`. The default value is `None`.

   `reverse` is a boolean value. If set to `True`, then the list elements are sorted as if each comparison were reversed.

   In general, the `key` and `reverse` conversion processes are much faster than specifying an equivalent `cmp` function. This is
because `cmp` is called multiple times for each list element while `key` and `reverse` touch each element only once.

*Changed in version 2.3:* Support for `None` as an equivalent to omitting `cmp` was added.

*Changed in version 2.4:* Support for `key` and `reverse` was added.

9. Starting with Python 2.3, the `sort()` method is guaranteed to be stable. A sort is stable if it guarantees not to change the relative order of elements that compare equal — this is helpful for sorting in multiple passes (for example, sort by department, then by salary grade).

10. While a list is being sorted, the effect of attempting to mutate, or even inspect, the list is undefined. The C implementation of Python 2.3 and newer makes the list appear empty for the duration, and raises `ValueError` if it can detect that the list has been mutated during a sort.
A set object is an unordered collection of distinct *hashable* objects. Common uses include membership testing, removing duplicates from a sequence, and computing mathematical operations such as intersection, union, difference, and symmetric difference. (For other containers see the built in *dict*, *list*, and *tuple* classes, and the *collections* module.)

*New in version 2.4.*

Like other collections, sets support `x in set`, `len(set)`, and `for x in set`. Being an unordered collection, sets do not record element position or order of insertion. Accordingly, sets do not support indexing, slicing, or other sequence-like behavior.

There are currently two builtin set types, *set* and *frozenset*. The *set* type is mutable — the contents can be changed using methods like `add()` and `remove()`. Since it is mutable, it has no hash value and cannot be used as either a dictionary key or as an element of another set. The *frozenset* type is immutable and *hashable* — its contents cannot be altered after it is created; it can therefore be used as a dictionary key or as an element of another set.

The constructors for both classes work the same:

```
class set([iterable])
class frozenset([iterable])
```

Return a new set or frozenset object whose elements are taken from `iterable`. The elements of a set must be hashable. To represent sets of sets, the inner sets must be *frozenset* objects. If `iterable` is not specified, a new empty set is returned.
Instances of `set` and `frozenset` provide the following operations:

`len(s)`
Return the cardinality of set `s`.

`x in s`
Test `x` for membership in `s`.

`x not in s`
Test `x` for non-membership in `s`.

`isdisjoint(other)`
Return True if the set has no elements in common with `other`. Sets are disjoint if and only if their intersection is the empty set.

*New in version 2.6.*

`issubset(other)`
`set <= other`
Test whether every element in the set is in `other`.

`set < other`
Test whether the set is a true subset of `other`, that is, `set <= other` and `set != other`.

`issuperset(other)`
`set >= other`
Test whether every element in `other` is in the set.

`set > other`
Test whether the set is a true superset of `other`, that is, `set >= other` and `set != other`.

`union(other, ...)`
`set | other | ...`
Return a new set with elements from both sets.
Changed in version 2.6: Accepts multiple input iterables.

**intersection**(other,...)
**set** & other & ...
Return a new set with elements common to both sets.

Changed in version 2.6: Accepts multiple input iterables.

**difference**(other,...)
**set** - other - ...
Return a new set with elements in the set that are not in the others.

Changed in version 2.6: Accepts multiple input iterables.

**symmetric_difference**(other)
**set** ^ other
Return a new set with elements in either the set or other but not both.

**copy**()
Return a new set with a shallow copy of s.

Note, the non-operator versions of union(), intersection(), difference(), and symmetric_difference(), issubset(), and issuperset() methods will accept any iterable as an argument. In contrast, their operator based counterparts require their arguments to be sets. This precludes error-prone constructions like `set('abc') & 'cbs'` in favor of the more readable `set('abc').intersection('cbs')`.

Both **set** and **frozenset** support set to set comparisons. Two sets are equal if and only if every element of each set is contained in the other (each is a subset of the other). A set is less than another set if and only if the first set is a proper subset of the second set (is a subset, but is not equal). A set is greater than
another set if and only if the first set is a proper superset of the second set (is a superset, but is not equal).

Instances of `set` are compared to instances of `frozenset` based on their members. For example, `set('abc') == frozenset('abc')` returns `True` and so does `set('abc') in set([frozenset('abc')])`.

The subset and equality comparisons do not generalize to a complete ordering function. For example, any two disjoint sets are not equal and are not subsets of each other, so all of the following return `False`: `a<b`, `a==b`, or `a>b`. Accordingly, sets do not implement the `__cmp__()` method.

Since sets only define partial ordering (subset relationships), the output of the `list.sort()` method is undefined for lists of sets.

Set elements, like dictionary keys, must be `hashable`.

Binary operations that mix `set` instances with `frozenset` return the type of the first operand. For example: `frozenset('ab') | set('bc')` returns an instance of `frozenset`.

The following table lists operations available for `set` that do not apply to immutable instances of `frozenset`:

- `update(other, ...)`
  - `set |= other | ...`
  - Update the set, adding elements from `other`.

  *Changed in version 2.6*: Accepts multiple input iterables.

- `intersection_update(other, ...)`
  - `set &= other & ...`
  - Update the set, keeping only elements found in it and `other`. 
Changed in version 2.6: Accepts multiple input iterables.

difference_update(other, ...)
set -= other | ...
Update the set, removing elements found in others.

Changed in version 2.6: Accepts multiple input iterables.

symmetric_difference_update(other)
set ^= other
Update the set, keeping only elements found in either set, but not in both.

add(elem)
Add element elem to the set.

remove(elem)
Remove element elem from the set. Raises KeyError if elem is not contained in the set.

discard(elem)
Remove element elem from the set if it is present.

pop()
Remove and return an arbitrary element from the set. Raises KeyError if the set is empty.

clear()
Remove all elements from the set.

Note, the non-operator versions of the update(), intersection_update(), difference_update(), and symmetric_difference_update() methods will accept any iterable as an argument.

Note, the elem argument to the __contains__(), remove(), and
discard() methods may be a set. To support searching for an equivalent frozenset, the `elem` set is temporarily mutated during the search and then restored. During the search, the `elem` set should not be read or mutated since it does not have a meaningful value.

**See also:**

*Comparison to the built-in set types*

Differences between the `sets` module and the built-in set types.
Mapping Types — **dict**

A *mapping* object maps *hashable* values to arbitrary objects. Mappings are mutable objects. There is currently only one standard mapping type, the *dictionary*. (For other containers see the built in *list*, *set*, and *tuple* classes, and the *collections* module.)

A dictionary's keys are *almost* arbitrary values. Values that are not *hashable*, that is, values containing lists, dictionaries or other mutable types (that are compared by value rather than by object identity) may not be used as keys. Numeric types used for keys obey the normal rules for numeric comparison: if two numbers compare equal (such as 1 and 1.0) then they can be used interchangeably to index the same dictionary entry. (Note however, that since computers store floating-point numbers as approximations it is usually unwise to use them as dictionary keys.)

Dictionaries can be created by placing a comma-separated list of *key: value* pairs within braces, for example: `{'jack': 4098, 'sjoerd': 4127}` or `{4098: 'jack', 4127: 'sjoerd'}`, or by the *dict* constructor.

```python
class dict([arg])
```

Return a new dictionary initialized from an optional positional argument or from a set of keyword arguments. If no arguments are given, return a new empty dictionary. If the positional argument *arg* is a mapping object, return a dictionary mapping the same keys to the same values as does the mapping object. Otherwise the positional argument must be a sequence, a container that supports iteration, or an iterator object. The elements of the argument must each also be of one of those kinds, and each must in turn contain exactly two objects. The first is used as a key in the new dictionary, and the second as the
key’s value. If a given key is seen more than once, the last value associated with it is retained in the new dictionary.

If keyword arguments are given, the keywords themselves with their associated values are added as items to the dictionary. If a key is specified both in the positional argument and as a keyword argument, the value associated with the keyword is retained in the dictionary. For example, these all return a dictionary equal to `{"one": 2, "two": 3}`:

- `dict(one=2, two=3)`
- `dict({'one': 2, 'two': 3})`
- `dict(zip(('one', 'two'), (2, 3)))`
- `dict([['two', 3], ['one', 2]])`

The first example only works for keys that are valid Python identifiers; the others work with any valid keys.

*New in version 2.2.*

*Changed in version 2.3:* Support for building a dictionary from keyword arguments added.

These are the operations that dictionaries support (and therefore, custom mapping types should support too):

**`len(d)`**

Return the number of items in the dictionary `d`.

**`d[key]`**

Return the item of `d` with key `key`. Raises a `KeyError` if `key` is not in the map.

*New in version 2.5:* If a subclass of dict defines a method `__missing__()`, if the key `key` is not present, the `d[key]` operation calls that method with the key `key` as argument. The
**d[key]** operation then returns or raises whatever is returned or raised by the **missing**(key) call if the key is not present. No other operations or methods invoke **missing**( ). If **missing**( ) is not defined, **KeyError** is raised. **missing**( ) must be a method; it cannot be an instance variable. For an example, see collections.defaultdict.

\[
d[key] = value
\]

Set \(d[key]\) to \(value\).

\[
del \ d[key]
\]

Remove \(d[key]\) from \(d\). Raises a **KeyError** if \(key\) is not in the map.

**key in d**

Return **True** if \(d\) has a key \(key\), else **False**.

*New in version 2.2.*

**key not in d**

Equivalent to **not** key **in** d.

*New in version 2.2.*

**clear()**

Remove all items from the dictionary.

**copy()**

Return a shallow copy of the dictionary.

**fromkeys(seq[, value])**

Create a new dictionary with keys from \(seq\) and values set to \(value\).

**fromkeys()** is a class method that returns a new dictionary.
value defaults to None.

New in version 2.3.

get(key[, default])
Return the value for key if key is in the dictionary, else default. If default is not given, it defaults to None, so that this method never raises a KeyError.

has_key(key)
dict.has_key(key) is equivalent to key in d, but deprecated.

items()
Return a copy of the dictionary’s list of (key, value) pairs.

Note: Keys and values are listed in an arbitrary order which is non-random, varies across Python implementations, and depends on the dictionary’s history of insertions and deletions. If items(), keys(), values(), iteritems(), iterkeys(), and itervalues() are called with no intervening modifications to the dictionary, the lists will directly correspond. This allows the creation of (value, key) pairs using zip(): pairs = zip(d.values(), d.keys()). The same relationship holds for the iterkeys() and itervalues() methods: pairs = zip(d.itervalues(), d.iterkeys()) provides the same value for pairs. Another way to create the same list is pairs = [(v, k) for (k, v) in d.iteritems()].

iteritems()
Return an iterator over the dictionary’s (key, value) pairs. See the note for dict.items().
New in version 2.2.

iterkeys()
Return an iterator over the dictionary’s keys. See the note for dict.items().

New in version 2.2.

itervalues()
Return an iterator over the dictionary’s values. See the note for dict.items().

New in version 2.2.

keys()
Return a copy of the dictionary’s list of keys. See the note for dict.items().

pop(key[, default])
If key is in the dictionary, remove it and return its value, else return default. If default is not given and key is not in the dictionary, a KeyError is raised.

New in version 2.3.

popitem()
Remove and return an arbitrary (key, value) pair from the dictionary.

popitem() is useful to destructively iterate over a dictionary, as often used in set algorithms. If the dictionary is empty, calling popitem() raises a KeyError.

setdefault(key[, default])
If `key` is in the dictionary, return its value. If not, insert `key` with a value of `default` and return `default`. `default` defaults to `None`.

**update([other])**

Update the dictionary with the key/value pairs from `other`, overwriting existing keys. Return `None`.

`update()` accepts either another dictionary object or an iterable of key/value pairs (as a tuple or other iterable of length two). If keyword arguments are specified, the dictionary is then is updated with those key/value pairs: `d.update(red=1, blue=2)`.

*Changed in version 2.4:* Allowed the argument to be an iterable of key/value pairs and allowed keyword arguments.

**values()**

Return a copy of the dictionary's list of values. See the note for `dict.items()`.
**File Objects**

File objects are implemented using C’s `stdio` package and can be created with the built-in `open()` function. File objects are also returned by some other built-in functions and methods, such as `os.popen()` and `os.fdopen()` and the `makefile()` method of socket objects. Temporary files can be created using the `tempfile` module, and high-level file operations such as copying, moving, and deleting files and directories can be achieved with the `shutil` module.

When a file operation fails for an I/O-related reason, the exception `IOError` is raised. This includes situations where the operation is not defined for some reason, like `seek()` on a tty device or writing a file opened for reading.

Files have the following methods:

`file.close()`

Close the file. A closed file cannot be read or written any more. Any operation which requires that the file be open will raise a `ValueError` after the file has been closed. Calling `close()` more than once is allowed.

As of Python 2.5, you can avoid having to call this method explicitly if you use the `with` statement. For example, the following code will automatically close `f` when the `with` block is exited:

```python
from __future__ import with_statement  # This isn't required

with open("hello.txt") as f:
    for line in f:
```
In older versions of Python, you would have needed to do this to get the same effect:

```python
f = open("hello.txt")
try:
    for line in f:
        print line
finally:
    f.close()
```

**Note:** Not all “file-like” types in Python support use as a context manager for the `with` statement. If your code is intended to work with any file-like object, you can use the function `contextlib.closing()` instead of using the object directly.

- `file.flush()`
  Flush the internal buffer, like `stdio's fflush`. This may be a no-op on some file-like objects.

- `file.fileno()`
  Return the integer “file descriptor” that is used by the underlying implementation to request I/O operations from the operating system. This can be useful for other, lower level interfaces that use file descriptors, such as the `fcntl` module or `os.read()` and friends.

  **Note:** File-like objects which do not have a real file descriptor should *not* provide this method!
Return `True` if the file is connected to a tty(-like) device, else `False`.

**Note:** If a file-like object is not associated with a real file, this method should *not* be implemented.

**file.next()**

A file object is its own iterator, for example `iter(f)` returns `f` (unless `f` is closed). When a file is used as an iterator, typically in a `for` loop (for example, `for line in f: print line`), the `next()` method is called repeatedly. This method returns the next input line, or raises `StopIteration` when EOF is hit when the file is open for reading (behavior is undefined when the file is open for writing). In order to make a `for` loop the most efficient way of looping over the lines of a file (a very common operation), the `next()` method uses a hidden read-ahead buffer. As a consequence of using a read-ahead buffer, combining `next()` with other file methods (like `readline()`) does not work right. However, using `seek()` to reposition the file to an absolute position will flush the read-ahead buffer.

*New in version 2.3.*

**file.read([size])**

Read at most `size` bytes from the file (less if the read hits EOF before obtaining `size` bytes). If the `size` argument is negative or omitted, read all data until EOF is reached. The bytes are returned as a string object. An empty string is returned when EOF is encountered immediately. (For certain files, like ttys, it makes sense to continue reading after an EOF is hit.) Note that this method may call the underlying C function `fread` more than once in an effort to acquire as close to `size` bytes as possible. Also note that when in non-blocking mode, less data than was
requested may be returned, even if no size parameter was given.

**Note:** This function is simply a wrapper for the underlying `fread` C function, and will behave the same in corner cases, such as whether the EOF value is cached.

**file.readline([size])**

Read one entire line from the file. A trailing newline character is kept in the string (but may be absent when a file ends with an incomplete line). [6] If the size argument is present and non-negative, it is a maximum byte count (including the trailing newline) and an incomplete line may be returned. An empty string is returned only when EOF is encountered immediately.

**Note:** Unlike stdio's `fgets`, the returned string contains null characters (`'\0'`) if they occurred in the input.

**file.readlines([sizehint])**

Read until EOF using `readline()` and return a list containing the lines thus read. If the optional sizehint argument is present, instead of reading up to EOF, whole lines totalling approximately sizehint bytes (possibly after rounding up to an internal buffer size) are read. Objects implementing a file-like interface may choose to ignore sizehint if it cannot be implemented, or cannot be implemented efficiently.

**file.xreadlines()**

This method returns the same thing as `iter(f)`.

*New in version 2.1.*

*Deprecated since version 2.3:* Use `for line in file` instead.
file.\texttt{seek}(\textit{offset}, \textit{whence})

Set the file's current position, like \texttt{stdio}'s \texttt{fseek}. The \textit{whence} argument is optional and defaults to \texttt{os.SEEK_SET} or 0 (absolute file positioning); other values are \texttt{os.SEEK_CUR} or 1 (seek relative to the current position) and \texttt{os.SEEK_END} or 2 (seek relative to the file's end). There is no return value.

For example, \texttt{f.seek(2, os.SEEK_CUR)} advances the position by two and \texttt{f.seek(-3, os.SEEK_END)} sets the position to the third to last.

Note that if the file is opened for appending (mode \texttt{'a'} or \texttt{'a+'}), any \texttt{seek()} operations will be undone at the next write. If the file is only opened for writing in append mode (mode \texttt{'a'}), this method is essentially a no-op, but it remains useful for files opened in append mode with reading enabled (mode \texttt{'a+'}). If the file is opened in text mode (without \texttt{'b'}), only offsets returned by \texttt{tell()} are legal. Use of other offsets causes undefined behavior.

Note that not all file objects are seekable.

\textit{Changed in version 2.6:} Passing float values as offset has been deprecated.

file.\texttt{tell}()

Return the file's current position, like \texttt{stdio}'s \texttt{ftell}.

\begin{itemize}
\item \textbf{Note:} On Windows, \texttt{tell()} can return illegal values (after an \texttt{fget}\texttt{s}) when reading files with Unix-style line-endings. Use binary mode (\texttt{'rb'}) to circumvent this problem.
\end{itemize}

file.\texttt{truncate}([\textit{size}])
Truncate the file's size. If the optional size argument is present, the file is truncated to (at most) that size. The size defaults to the current position. The current file position is not changed. Note that if a specified size exceeds the file’s current size, the result is platform-dependent: possibilities include that the file may remain unchanged, increase to the specified size as if zero-filled, or increase to the specified size with undefined new content. Availability: Windows, many Unix variants.

```python
def write(str)
    Write a string to the file. There is no return value. Due to buffering, the string may not actually show up in the file until the flush() or close() method is called.
```

```python
def writelines(sequence)
    Write a sequence of strings to the file. The sequence can be any iterable object producing strings, typically a list of strings. There is no return value. (The name is intended to match readlines(); writelines() does not add line separators.)
```

Files support the iterator protocol. Each iteration returns the same result as file.readline(), and iteration ends when the readline() method returns an empty string.

File objects also offer a number of other interesting attributes. These are not required for file-like objects, but should be implemented if they make sense for the particular object.

```python
def closed
    bool indicating the current state of the file object. This is a read-only attribute; the close() method changes the value. It may not be available on all file-like objects.
```

```python
def encoding
    The encoding that this file uses. When Unicode strings are
written to a file, they will be converted to byte strings using this encoding. In addition, when the file is connected to a terminal, the attribute gives the encoding that the terminal is likely to use (that information might be incorrect if the user has misconfigured the terminal). The attribute is read-only and may not be present on all file-like objects. It may also be `None`, in which case the file uses the system default encoding for converting Unicode strings.

*New in version 2.3.*

**file.errors**

The Unicode error handler used along with the encoding.

*New in version 2.6.*

**file.mode**

The I/O mode for the file. If the file was created using the `open()` built-in function, this will be the value of the `mode` parameter. This is a read-only attribute and may not be present on all file-like objects.

**file.name**

If the file object was created using `open()`, the name of the file. Otherwise, some string that indicates the source of the file object, of the form `<...>`. This is a read-only attribute and may not be present on all file-like objects.

**file.newlines**

If Python was built with the `--with-universal-newlines` option to `configure` (the default) this read-only attribute exists, and for files opened in universal newline read mode it keeps track of the types of newlines encountered while reading the file. The values it can take are `'\r'`, `'\n'`, `'\r\n'`, `None` (unknown, no newlines read yet) or a tuple containing all the newline types seen, to indicate that multiple newline conventions were encountered. For files not
opened in universal newline read mode the value of this attribute will be None.

```python
def open(file, mode, **kwargs):
    if mode == 'r':
        return readmode_newline(file, **kwargs)
    else:
        return super().open(file, mode, **kwargs)
```

**note**: This attribute is not used to control the `print` statement, but to allow the implementation of `print` to keep track of its internal state.

**file.softspace**: Boolean that indicates whether a space character needs to be printed before another value when using the `print` statement. Classes that are trying to simulate a file object should also have a writable `softspace` attribute, which should be initialized to zero. This will be automatic for most classes implemented in Python (care may be needed for objects that override attribute access); types implemented in C will have to provide a writable `softspace` attribute.

**Note**: This attribute is not used to control the `print` statement, but to allow the implementation of `print` to keep track of its internal state.
Context Manager Types

New in version 2.5.

Python’s `with` statement supports the concept of a runtime context defined by a context manager. This is implemented using two separate methods that allow user-defined classes to define a runtime context that is entered before the statement body is executed and exited when the statement ends.

The `context management protocol` consists of a pair of methods that need to be provided for a context manager object to define a runtime context:

```python
contextmanager.__enter__()
```

Enter the runtime context and return either this object or another object related to the runtime context. The value returned by this method is bound to the identifier in the `as` clause of `with` statements using this context manager.

An example of a context manager that returns itself is a file object. File objects return themselves from `__enter__()` to allow `open()` to be used as the context expression in a `with` statement.

An example of a context manager that returns a related object is the one returned by `decimal.localcontext()`. These managers set the active decimal context to a copy of the original decimal context and then return the copy. This allows changes to be made to the current decimal context in the body of the `with` statement without affecting code outside the `with` statement.

```python
contextmanager.__exit__(exc_type, exc_val, exc_tb)
```

Exit the runtime context and return a Boolean flag indicating if
any exception that occurred should be suppressed. If an exception occurred while executing the body of the `with` statement, the arguments contain the exception type, value and traceback information. Otherwise, all three arguments are `None`.

Returning a true value from this method will cause the `with` statement to suppress the exception and continue execution with the statement immediately following the `with` statement. Otherwise the exception continues propagating after this method has finished executing. Exceptions that occur during execution of this method will replace any exception that occurred in the body of the `with` statement.

The exception passed in should never be reraised explicitly - instead, this method should return a false value to indicate that the method completed successfully and does not want to suppress the raised exception. This allows context management code (such as `contextlib.nested`) to easily detect whether or not an `__exit__()` method has actually failed.

Python defines several context managers to support easy thread synchronisation, prompt closure of files or other objects, and simpler manipulation of the active decimal arithmetic context. The specific types are not treated specially beyond their implementation of the context management protocol. See the `contextlib` module for some examples.

Python's `generators` and the `contextlib.contextfactory` `decorator` provide a convenient way to implement these protocols. If a generator function is decorated with the `contextlib.contextfactory` decorator, it will return a context manager implementing the necessary `__enter__()` and `__exit__()` methods, rather than the iterator produced by an undecorated generator function.
Note that there is no specific slot for any of these methods in the type structure for Python objects in the Python/C API. Extension types wanting to define these methods must provide them as a normal Python accessible method. Compared to the overhead of setting up the runtime context, the overhead of a single class dictionary lookup is negligible.
Other Built-in Types

The interpreter supports several other kinds of objects. Most of these support only one or two operations.

Modules

The only special operation on a module is attribute access: \texttt{m.name}, where \texttt{m} is a module and \texttt{name} accesses a name defined in \texttt{m}'s symbol table. Module attributes can be assigned to. (Note that the \texttt{import} statement is not, strictly speaking, an operation on a module object; \texttt{import foo} does not require a module object named \texttt{foo} to exist, rather it requires an (external) \textit{definition} for a module named \texttt{foo} somewhere.)

A special member of every module is \texttt{__dict__}. This is the dictionary containing the module's symbol table. Modifying this dictionary will actually change the module's symbol table, but direct assignment to the \texttt{__dict__} attribute is not possible (you can write \texttt{m.__dict__['a']} = 1, which defines \texttt{m.a} to be 1, but you can't write \texttt{m.__dict__ = {}}). Modifying \texttt{__dict__} directly is not recommended.

Modules built into the interpreter are written like this: \texttt{<module 'sys' (built-in)>}. If loaded from a file, they are written as \texttt{<module 'os' from '/usr/local/lib/pythonX.Y/os.pyc'>}.

Classes and Class Instances

See \textit{Objects, values and types} and \textit{Class definitions} for these.

Functions
Function objects are created by function definitions. The only operation on a function object is to call it: `func(argument-list)`.

There are really two flavors of function objects: built-in functions and user-defined functions. Both support the same operation (to call the function), but the implementation is different, hence the different object types.

See *Function definitions* for more information.

## Methods

Methods are functions that are called using the attribute notation. There are two flavors: built-in methods (such as `append()` on lists) and class instance methods. Built-in methods are described with the types that support them.

The implementation adds two special read-only attributes to class instance methods: `m.im_self` is the object on which the method operates, and `m.im_func` is the function implementing the method. Calling `m(arg-1, arg-2, ..., arg-n)` is completely equivalent to calling `m.im_func(m.im_self, arg-1, arg-2, ..., arg-n)`.

Class instance methods are either *bound* or *unbound*, referring to whether the method was accessed through an instance or a class, respectively. When a method is unbound, its `im_self` attribute will be `None` and if called, an explicit `self` object must be passed as the first argument. In this case, `self` must be an instance of the unbound method’s class (or a subclass of that class), otherwise a `TypeError` is raised.

Like function objects, methods objects support getting arbitrary attributes. However, since method attributes are actually stored on the underlying function object (`meth.im_func`), setting method
attributes on either bound or unbound methods is disallowed. Attempting to set a method attribute results in a `TypeError` being raised. In order to set a method attribute, you need to explicitly set it on the underlying function object:

```python
class C:
    def method(self):
        pass

c = C()
c.method.im_func.whoami = 'my name is c'
```

See *The standard type hierarchy* for more information.

**Code Objects**

Code objects are used by the implementation to represent “pseudo-compiled” executable Python code such as a function body. They differ from function objects because they don’t contain a reference to their global execution environment. Code objects are returned by the built-in `compile()` function and can be extracted from function objects through their `func_code` attribute. See also the `code` module.

A code object can be executed or evaluated by passing it (instead of a source string) to the `exec` statement or the built-in `eval()` function.

See *The standard type hierarchy* for more information.

**Type Objects**

Type objects represent the various object types. An object’s type is accessed by the built-in function `type()`. There are no special operations on types. The standard module `types` defines names for all standard built-in types.

Types are written like this: `<type 'int'>`. 
The Null Object

This object is returned by functions that don't explicitly return a value. It supports no special operations. There is exactly one null object, named None (a built-in name).

It is written as None.

The Ellipsis Object

This object is used by extended slice notation (see Slicings). It supports no special operations. There is exactly one ellipsis object, named Ellipsis (a built-in name).

It is written as Ellipsis.

Boolean Values

Boolean values are the two constant objects False and True. They are used to represent truth values (although other values can also be considered false or true). In numeric contexts (for example when used as the argument to an arithmetic operator), they behave like the integers 0 and 1, respectively. The built-in function bool() can be used to cast any value to a Boolean, if the value can be interpreted as a truth value (see section Truth Value Testing above).

They are written as False and True, respectively.

Internal Objects

See The standard type hierarchy for this information. It describes stack frame objects, traceback objects, and slice objects.
Special Attributes

The implementation adds a few special read-only attributes to several object types, where they are relevant. Some of these are not reported by the `dir()` built-in function.

**object.** __dict__
A dictionary or other mapping object used to store an object's (writable) attributes.

**object.** __methods__
*Deprecated since version 2.2:* Use the built-in function `dir()` to get a list of an object’s attributes. This attribute is no longer available.

**object.** __members__
*Deprecated since version 2.2:* Use the built-in function `dir()` to get a list of an object’s attributes. This attribute is no longer available.

**instance.** __class__
The class to which a class instance belongs.

**class.** __bases__
The tuple of base classes of a class object. If there are no base classes, this will be an empty tuple.

**class.** __name__
The name of the class or type.

Footnotes

[1] Additional information on these special methods may be found in the Python Reference Manual (*Basic customization*).
As a consequence, the list `[1, 2]` is considered equal to `[1.0, 2.0]`, and similarly for tuples.

They must have since the parser can’t tell the type of the operands.

To format only a tuple you should therefore provide a singleton tuple whose only element is the tuple to be formatted.

These numbers are fairly arbitrary. They are intended to avoid printing endless strings of meaningless digits without hampering correct use and without having to know the exact precision of floating point values on a particular machine.

The advantage of leaving the newline on is that returning an empty string is then an unambiguous EOF indication. It is also possible (in cases where it might matter, for example, if you want to make an exact copy of a file while scanning its lines) to tell whether the last line of a file ended in a newline or not (yes this happens!).
Built-in Exceptions

Exceptions should be class objects. The exceptions are defined in the module `exceptions`. This module never needs to be imported explicitly: the exceptions are provided in the built-in namespace as well as the `exceptions` module.

For class exceptions, in a `try` statement with an `except` clause that mentions a particular class, that clause also handles any exception classes derived from that class (but not exception classes from which it is derived). Two exception classes that are not related via subclassing are never equivalent, even if they have the same name.

The built-in exceptions listed below can be generated by the interpreter or built-in functions. Except where mentioned, they have an “associated value” indicating the detailed cause of the error. This may be a string or a tuple containing several items of information (e.g., an error code and a string explaining the code). The associated value is the second argument to the `raise` statement. If the exception class is derived from the standard root class `BaseException`, the associated value is present as the exception instance's `args` attribute.

User code can raise built-in exceptions. This can be used to test an exception handler or to report an error condition “just like” the situation in which the interpreter raises the same exception; but beware that there is nothing to prevent user code from raising an inappropriate error.

The built-in exception classes can be sub-classed to define new exceptions; programmers are encouraged to at least derive new exceptions from the `Exception` class and not `BaseException`. More information on defining exceptions is available in the Python Tutorial.
The following exceptions are only used as base classes for other exceptions.

**exception BaseException**

The base class for all built-in exceptions. It is not meant to be directly inherited by user-defined classes (for that use `Exception`). If `str()` or `unicode()` is called on an instance of this class, the representation of the argument(s) to the instance are returned or the empty string when there were no arguments. All arguments are stored in `args` as a tuple.

*New in version 2.5.*

**exception Exception**

All built-in, non-system-exiting exceptions are derived from this class. All user-defined exceptions should also be derived from this class.

*Changed in version 2.5:* Changed to inherit from `BaseException`.

**exception StandardError**

The base class for all built-in exceptions except `StopIteration`, `GeneratorExit`, `KeyboardInterrupt` and `SystemExit`. `StandardError` itself is derived from `Exception`.

**exception ArithmeticError**

The base class for those built-in exceptions that are raised for various arithmetic errors: `OverflowError`, `ZeroDivisionError`, `FloatingPointError`.

**exception LookupError**

The base class for the exceptions that are raised when a key or index used on a mapping or sequence is invalid: `IndexError`,...
**KeyError.** This can be raised directly by `sys.setdefaultencoding()`.

 exception **EnvironmentError**

 The base class for exceptions that can occur outside the Python system: **IOError, OSError.** When exceptions of this type are created with a 2-tuple, the first item is available on the instance’s `errno` attribute (it is assumed to be an error number), and the second item is available on the `strerror` attribute (it is usually the associated error message). The tuple itself is also available on the `args` attribute.

*New in version 1.5.2.*

 When an `EnvironmentError` exception is instantiated with a 3-tuple, the first two items are available as above, while the third item is available on the `filename` attribute. However, for backwards compatibility, the `args` attribute contains only a 2-tuple of the first two constructor arguments.

 The `filename` attribute is `None` when this exception is created with other than 3 arguments. The `errno` and `strerror` attributes are also `None` when the instance was created with other than 2 or 3 arguments. In this last case, `args` contains the verbatim constructor arguments as a tuple.

 The following exceptions are the exceptions that are actually raised.

 exception **AssertionError**

 Raised when an `assert` statement fails.

 exception **AttributeError**

 Raised when an attribute reference (see *Attribute references*) or assignment fails. (When an object does not support attribute
references or attribute assignments at all, **TypeError** is raised.)

exception **EOFError**
Raised when one of the built-in functions (**input()** or **raw_input()**) hits an end-of-file condition (EOF) without reading any data. (N.B.: the **file.read()** and **file.readline()** methods return an empty string when they hit EOF.)

exception **FloatingPointError**
Raised when a floating point operation fails. This exception is always defined, but can only be raised when Python is configured with the **--with-fpectl** option, or the **WANT_SIGFPE_HANDLER** symbol is defined in the **pyconfig.h** file.

exception **GeneratorExit**
Raise when a generator's **close()** method is called. It directly inherits from **BaseException** instead of **StandardError** since it is technically not an error.

*New in version 2.5.*

*Changed in version 2.6*: Changed to inherit from **BaseException**.

exception **IOError**
Raised when an I/O operation (such as a **print** statement, the built-in **open()** function or a method of a file object) fails for an I/O-related reason, e.g., “file not found” or “disk full”.

This class is derived from **EnvironmentError**. See the discussion above for more information on exception instance attributes.

*Changed in version 2.6*: Changed **socket.error** to use this as a base class.

exception **ImportError**
Raised when an `import` statement fails to find the module definition or when a `from ... import` fails to find a name that is to be imported.

**exception IndexError**

Raised when a sequence subscript is out of range. (Slice indices are silently truncated to fall in the allowed range; if an index is not a plain integer, `TypeError` is raised.)

**exception KeyError**

Raised when a mapping (dictionary) key is not found in the set of existing keys.

**exception KeyboardInterrupt**

Raised when the user hits the interrupt key (normally Control-C or Delete). During execution, a check for interrupts is made regularly. Interrupts typed when a built-in function `input()` or `raw_input()` is waiting for input also raise this exception. The exception inherits from `BaseException` so as to not be accidentally caught by code that catches `Exception` and thus prevent the interpreter from exiting.

*Changed in version 2.5:* Changed to inherit from `BaseException`.

**exception MemoryError**

Raised when an operation runs out of memory but the situation may still be rescued (by deleting some objects). The associated value is a string indicating what kind of (internal) operation ran out of memory. Note that because of the underlying memory management architecture (C's `malloc` function), the interpreter may not always be able to completely recover from this situation; it nevertheless raises an exception so that a stack traceback can be printed, in case a run-away program was the cause.
exception **NameError**

Raised when a local or global name is not found. This applies only to unqualified names. The associated value is an error message that includes the name that could not be found.

exception **NotImplementedError**

This exception is derived from `RuntimeError`. In user defined base classes, abstract methods should raise this exception when they require derived classes to override the method.

*New in version 1.5.2.*

exception **OSError**

This exception is derived from `EnvironmentError`. It is raised when a function returns a system-related error (not for illegal argument types or other incidental errors). The `errno` attribute is a numeric error code from `errno`, and the `strerror` attribute is the corresponding string, as would be printed by the C function `perror`. See the module `errno`, which contains names for the error codes defined by the underlying operating system.

For exceptions that involve a file system path (such as `chdir()` or `unlink()`), the exception instance will contain a third attribute, `filename`, which is the file name passed to the function.

*New in version 1.5.2.*

exception **OverflowError**

Raised when the result of an arithmetic operation is too large to be represented. This cannot occur for long integers (which would rather raise `MemoryError` than give up) and for most operations with plain integers, which return a long integer instead. Because of the lack of standardization of floating point exception handling in C, most floating point operations also aren’t checked.
exception **ReferenceError**

This exception is raised when a weak reference proxy, created by the `weakref.proxy()` function, is used to access an attribute of the referent after it has been garbage collected. For more information on weak references, see the `weakref` module.

*New in version 2.2:* Previously known as the `weakref.ReferenceError` exception.

exception **RuntimeError**

Raised when an error is detected that doesn’t fall in any of the other categories. The associated value is a string indicating what precisely went wrong. (This exception is mostly a relic from a previous version of the interpreter; it is not used very much any more.)

exception **StopIteration**

Raised by an iterator’s `next()` method to signal that there are no further values. This is derived from `Exception` rather than `StandardError`, since this is not considered an error in its normal application.

*New in version 2.2.*

exception **SyntaxError**

Raised when the parser encounters a syntax error. This may occur in an `import` statement, in an `exec` statement, in a call to the built-in function `eval()` or `input()`, or when reading the initial script or standard input (also interactively).

Instances of this class have attributes `filename`, `lineno`, `offset` and `text` for easier access to the details. `str()` of the exception instance returns only the message.

exception **SystemError**
Raised when the interpreter finds an internal error, but the situation does not look so serious to cause it to abandon all hope. The associated value is a string indicating what went wrong (in low-level terms).

You should report this to the author or maintainer of your Python interpreter. Be sure to report the version of the Python interpreter (\texttt{sys.version}; it is also printed at the start of an interactive Python session), the exact error message (the exception's associated value) and if possible the source of the program that triggered the error.

\textbf{exception SystemExit}

This exception is raised by the \texttt{sys.exit()} function. When it is not handled, the Python interpreter exits; no stack traceback is printed. If the associated value is a plain integer, it specifies the system exit status (passed to C's \texttt{exit} function); if it is \texttt{None}, the exit status is zero; if it has another type (such as a string), the object's value is printed and the exit status is one.

Instances have an attribute \texttt{code} which is set to the proposed exit status or error message (defaulting to \texttt{None}). Also, this exception derives directly from \texttt{BaseException} and not \texttt{StandardError}, since it is not technically an error.

A call to \texttt{sys.exit()} is translated into an exception so that clean-up handlers (\texttt{finally} clauses of \texttt{try} statements) can be executed, and so that a debugger can execute a script without running the risk of losing control. The \texttt{os._exit()} function can be used if it is absolutely positively necessary to exit immediately (for example, in the child process after a call to \texttt{fork()}.

The exception inherits from \texttt{BaseException} instead of \texttt{StandardError} or \texttt{Exception} so that it is not accidentally caught
by code that catches \texttt{Exception}. This allows the exception to properly propagate up and cause the interpreter to exit.

\textit{Changed in version 2.5:} Changed to inherit from \texttt{BaseException}.

\textbf{exception} \texttt{TypeError}  
Raised when an operation or function is applied to an object of inappropriate type. The associated value is a string giving details about the type mismatch.

\textbf{exception} \texttt{UnboundLocalError}  
Raised when a reference is made to a local variable in a function or method, but no value has been bound to that variable. This is a subclass of \texttt{NameError}.

\textit{New in version 2.0.}

\textbf{exception} \texttt{UnicodeError}  
Raised when a Unicode-related encoding or decoding error occurs. It is a subclass of \texttt{ValueError}.

\textit{New in version 2.0.}

\textbf{exception} \texttt{UnicodeEncodeError}  
Raised when a Unicode-related error occurs during encoding. It is a subclass of \texttt{UnicodeError}.

\textit{New in version 2.3.}

\textbf{exception} \texttt{UnicodeDecodeError}  
Raised when a Unicode-related error occurs during decoding. It is a subclass of \texttt{UnicodeError}.

\textit{New in version 2.3.}

\textbf{exception} \texttt{UnicodeTranslateError}
Raised when a Unicode-related error occurs during translating. It is a subclass of `UnicodeError`.

*New in version 2.3.*

**exception ValueError**
Raised when a built-in operation or function receives an argument that has the right type but an inappropriate value, and the situation is not described by a more precise exception such as `IndexError`.

**exception WindowsError**
Raised when a Windows-specific error occurs or when the error number does not correspond to an `errno` value. The `winerror` and `strerror` values are created from the return values of the `GetLastError` and `FormatMessage` functions from the Windows Platform API. The `errno` value maps the `winerror` value to corresponding `errno.h` values. This is a subclass of `OSError`.

*New in version 2.0.*

*Changed in version 2.5:* Previous versions put the `GetLastError` codes into `errno`.

**exception ZeroDivisionError**
Raised when the second argument of a division or modulo operation is zero. The associated value is a string indicating the type of the operands and the operation.

The following exceptions are used as warning categories; see the `warnings` module for more information.

**exception Warning**
Base class for warning categories.
exception **UserWarning**
Base class for warnings generated by user code.

exception **DeprecationWarning**
Base class for warnings about deprecated features.

exception **PendingDeprecationWarning**
Base class for warnings about features which will be deprecated in the future.

exception **SyntaxWarning**
Base class for warnings about dubious syntax

exception **RuntimeWarning**
Base class for warnings about dubious runtime behavior.

exception **FutureWarning**
Base class for warnings about constructs that will change semantically in the future.

exception **ImportWarning**
Base class for warnings about probable mistakes in module imports.

*New in version 2.5.*

exception **UnicodeWarning**
Base class for warnings related to Unicode.

*New in version 2.5.*

The class hierarchy for built-in exceptions is:

```plaintext
BaseException
       +-- SystemExit
       +-- KeyboardInterrupt
       +-- GeneratorExit
       +-- Exception
```
String Services

The modules described in this chapter provide a wide range of string manipulation operations.

In addition, Python's built-in string classes support the sequence type methods described in the *Sequence Types* — `str`, `unicode`, `list`, `tuple`, `buffer`, `xrange` section, and also the string-specific methods described in the *String Methods* section. To output formatted strings use template strings or the `%` operator described in the *String Formatting Operations* section. Also, see the `re` module for string functions based on regular expressions.

The `string` module contains a number of useful constants and classes, as well as some deprecated legacy functions that are also available as methods on strings. In addition, Python’s built-in string classes support the sequence type methods described in the `Sequence Types — str, unicode, list, tuple, buffer, xrange` section, and also the string-specific methods described in the `String Methods` section. To output formatted strings use template strings or the `%` operator described in the `String Formatting Operations` section. Also, see the `re` module for string functions based on regular expressions.
String constants

The constants defined in this module are:

string. **ascii_letters**
The concatenation of the `ascii_lowercase` and `ascii_uppercase`
constants described below. This value is not locale-dependent.

string. **ascii_lowercase**
The lowercase letters 'abcdefghijklmnopqrstuvwxyz'. This value
is not locale-dependent and will not change.

string. **ascii_uppercase**
The uppercase letters 'ABCDEFGHIJKLMNOPQRSTUVWXYZ'. This value
is not locale-dependent and will not change.

string. **digits**
The string '0123456789'.

string. **hexdigits**
The string '0123456789abcdefABCDEF'.

string. **letters**
The concatenation of the strings `lowercase` and `uppercase`
described below. The specific value is locale-dependent, and will
be updated when `locale.setlocale()` is called.

string. ** lowercase**
A string containing all the characters that are considered
lowercase letters. On most systems this is the string
'abcdefghijklmnopqrstuvwxyz'. Do not change its definition —
the effect on the routines `upper()` and `swapcase()` is undefined.
The specific value is locale-dependent, and will be updated when
`locale.setlocale()` is called.
string. **octdigits**
   The string '\01234567'.

string. **punctuation**
   String of ASCII characters which are considered punctuation characters in the c locale.

string. **printable**
   String of characters which are considered printable. This is a combination of digits, letters, punctuation, and whitespace.

string. **uppercase**
   A string containing all the characters that are considered uppercase letters. On most systems this is the string 'ABCDEFGHIJKLMNOPQRSTUVWXYZ'. Do not change its definition — the effect on the routines lower() and swapcase() is undefined. The specific value is locale-dependent, and will be updated when locale.setlocale() is called.

string. **whitespace**
   A string containing all characters that are considered whitespace. On most systems this includes the characters space, tab, linefeed, return, formfeed, and vertical tab. Do not change its definition — the effect on the routines strip() and split() is undefined.
String Formatting

Starting in Python 2.6, the built-in str and unicode classes provide the ability to do complex variable substitutions and value formatting via the \texttt{str.format()} method described in \textbf{PEP 3101}. The \texttt{Formatter} class in the \texttt{string} module allows you to create and customize your own string formatting behaviors using the same implementation as the built-in \texttt{format()} method.

\begin{verbatim}
class string.Formatter

The \texttt{Formatter} class has the following public methods:

\textbf{format}(\texttt{format_string, *args, **kwargs})

\texttt{format()} is the primary API method. It takes a format template string, and an arbitrary set of positional and keyword argument. \texttt{format()} is just a wrapper that calls \texttt{vformat()}.

\textbf{vformat}(\texttt{format_string, args, kwargs})

This function does the actual work of formatting. It is exposed as a separate function for cases where you want to pass in a predefined dictionary of arguments, rather than unpacking and repacking the dictionary as individual arguments using the \texttt{*args} and \texttt{**kwargs} syntax. \texttt{vformat()} does the work of breaking up the format template string into character data and replacement fields. It calls the various methods described below.

In addition, the \texttt{Formatter} defines a number of methods that are intended to be replaced by subclasses:

\textbf{parse}(\texttt{format_string})

Loop over the format_string and return an iterable of tuples \texttt{(literal_text, field_name, format_spec, conversion)}. This is
used by `vformat()` to break the string in to either literal text, or replacement fields.

The values in the tuple conceptually represent a span of literal text followed by a single replacement field. If there is no literal text (which can happen if two replacement fields occur consecutively), then `literal_text` will be a zero-length string. If there is no replacement field, then the values of `field_name`, `format_spec` and `conversion` will be `None`.

`get_field(field_name, args, kwargs)`
Given `field_name` as returned by `parse()` (see above), convert it to an object to be formatted. Returns a tuple `(obj, used_key)`. The default version takes strings of the form defined in PEP 3101, such as “0[name]” or “label.title”. `args` and `kwargs` are as passed in to `vformat()`. The return value `used_key` has the same meaning as the `key` parameter to `get_value()`.

`get_value(key, args, kwargs)`
Retrieve a given field value. The `key` argument will be either an integer or a string. If it is an integer, it represents the index of the positional argument in `args`; if it is a string, then it represents a named argument in `kwargs`.

The `args` parameter is set to the list of positional arguments to `vformat()`, and the `kwargs` parameter is set to the dictionary of keyword arguments.

For compound field names, these functions are only called for the first component of the field name; Subsequent components are handled through normal attribute and indexing operations.

So for example, the field expression ‘0.name’ would cause
get_value() to be called with a key argument of 0. The name attribute will be looked up after get_value() returns by calling the built-in getattr() function.

If the index or keyword refers to an item that does not exist, then an IndexError or KeyError should be raised.

checkUnusedArgs(used_args, args, kwargs)
Implement checking for unused arguments if desired. The arguments to this function is the set of all argument keys that were actually referred to in the format string (integers for positional arguments, and strings for named arguments), and a reference to the args and kwargs that was passed to vformat. The set of unused args can be calculated from these parameters. checkUnusedArgs() is assumed to throw an exception if the check fails.

formatField(value, format_spec)
formatField() simply calls the global format() built-in. The method is provided so that subclasses can override it.

convertField(value, conversion)
Converts the value (returned by getField()) given a conversion type (as in the tuple returned by the parse() method.) The default version understands ‘r’ (repr) and ‘s’ (str) conversion types.
Format String Syntax

The `str.format()` method and the `Formatter` class share the same syntax for format strings (although in the case of `Formatter`, subclasses can define their own format string syntax.)

Format strings contain “replacement fields” surrounded by curly braces `{}`. Anything that is not contained in braces is considered literal text, which is copied unchanged to the output. If you need to include a brace character in the literal text, it can be escaped by doubling: `{{` and `}}`.

The grammar for a replacement field is as follows:

```
replacement_field ::= "{" field_name ["!" conversion] [":"  
field_name ::= (identifier | integer) ("." attribute_name
attribute_name ::= identifier
element_index ::= integer
conversion ::= "r" | "s"
format_spec ::= <described in the next section>
```

In less formal terms, the replacement field starts with a `field_name`, which can either be a number (for a positional argument), or an identifier (for keyword arguments). Following this is an optional `conversion` field, which is preceded by an exclamation point `!'`, and a `format_spec`, which is preceded by a colon `:'`.

The `field_name` itself begins with either a number or a keyword. If it’s a number, it refers to a positional argument, and if it’s a keyword it refers to a named keyword argument. This can be followed by any number of index or attribute expressions. An expression of the form `'.name'` selects the named attribute using `getattr()`, while an expression of the form `'[index]'` does an index lookup using `__getitem__()`. 
Some simple format string examples:

```
"First, thou shalt count to {0}"     # References first positional
"My quest is {name}"                # References keyword argument
"Weight in tons {0.weight}"         # 'weight' attribute of first
"Units destroyed: {players[0]}"     # First element of keyword arg
```

The conversion field causes a type coercion before formatting. Normally, the job of formatting a value is done by the `__format__()` method of the value itself. However, in some cases it is desirable to force a type to be formatted as a string, overriding its own definition of formatting. By converting the value to a string before calling `__format__()`, the normal formatting logic is bypassed.

Two conversion flags are currently supported: `!s` which calls `str()` on the value, and `!r` which calls `repr()`.

Some examples:

```
"Harold's a clever {0!s}"          # Calls str() on the argument
"Bring out the holy {name!r}"      # Calls repr() on the argument
```

The format_spec field contains a specification of how the value should be presented, including such details as field width, alignment, padding, decimal precision and so on. Each value type can define its own “formatting mini-language” or interpretation of the format_spec.

Most built-in types support a common formatting mini-language, which is described in the next section.

A format_spec field can also include nested replacement fields within it. These nested replacement fields can contain only a field name; conversion flags and format specifications are not allowed. The replacement fields within the format_spec are substituted before the
*format_spec* string is interpreted. This allows the formatting of a value to be dynamically specified.

For example, suppose you wanted to have a replacement field whose field width is determined by another variable:

```python
"A man with two {0:{1}}".format("noses", 10)
```

This would first evaluate the inner replacement field, making the format string effectively:

```
"A man with two {0:10}"
```

Then the outer replacement field would be evaluated, producing:

```
"noses   "
```

Which is substituted into the string, yielding:

```
"A man with two noses   "
```

(The extra space is because we specified a field width of 10, and because left alignment is the default for strings.)

**Format Specification Mini-Language**

“Format specifications” are used within replacement fields contained within a format string to define how individual values are presented (see *Format String Syntax*.) They can also be passed directly to the builtin `format()` function. Each formattable type may define how the format specification is to be interpreted.

Most built-in types implement the following options for format specifications, although some of the formatting options are only supported by the numeric types.
A general convention is that an empty format string ("") produces the same result as if you had called str() on the value.

The general form of a standard format specifier is:

```
format_spec ::= [[fill]align][sign][#][0][width][.precision][type]
fill ::= <a character other than '{'}>
align ::= "<" | ">" | ":" | "^"
sign ::= "+" | "-" | "" 
width ::= integer
precision ::= integer
type ::= "b" | "c" | "d" | "e" | "E" | "f" | "F" | "g"
```

The fill character can be any character other than ‘{’ (which signifies the end of the field). The presence of a fill character is signaled by the next character, which must be one of the alignment options. If the second character of format_spec is not a valid alignment option, then it is assumed that both the fill character and the alignment option are absent.

The meaning of the various alignment options is as follows:

<table>
<thead>
<tr>
<th>Option</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>'&lt;'</td>
<td>Forces the field to be left-aligned within the available space (This is the default.)</td>
</tr>
<tr>
<td>'&gt;'</td>
<td>Forces the field to be right-aligned within the available space.</td>
</tr>
<tr>
<td>'='</td>
<td>Forces the padding to be placed after the sign (if any) but before the digits. This is used for printing fields in the form ‘+000000120’. This alignment option is only valid for numeric types.</td>
</tr>
<tr>
<td>'^'</td>
<td>Forces the field to be centered within the available space.</td>
</tr>
</tbody>
</table>

Note that unless a minimum field width is defined, the field width will always be the same size as the data to fill it, so that the alignment option has no meaning in this case.
The *sign* option is only valid for number types, and can be one of the following:

<table>
<thead>
<tr>
<th>Option</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>'+'</td>
<td>indicates that a sign should be used for both positive as well as negative numbers.</td>
</tr>
<tr>
<td>'-'</td>
<td>indicates that a sign should be used only for negative numbers (this is the default behavior).</td>
</tr>
<tr>
<td>space</td>
<td>indicates that a leading space should be used on positive numbers, and a minus sign on negative numbers.</td>
</tr>
</tbody>
</table>

The `'#'` option is only valid for integers, and only for binary, octal, or hexadecimal output. If present, it specifies that the output will be prefixed by `'0b'`, `'0o'`, or `'0x'`, respectively.

*width* is a decimal integer defining the minimum field width. If not specified, then the field width will be determined by the content.

If the width field is preceded by a zero (`'0'`) character, this enables zero-padding. This is equivalent to an *alignment* type of `='` and a *fill* character of `'0'`.

The *precision* is a decimal number indicating how many digits should be displayed after the decimal point for a floating point value formatted with `'f'` and `'F'`, or before and after the decimal point for a floating point value formatted with `'g'` or `'G'`. For non-number types the field indicates the maximum field size - in other words, how many characters will be used from the field content. The *precision* is ignored for integer values.

Finally, the *type* determines how the data should be presented.

The available integer presentation types are:
<table>
<thead>
<tr>
<th>Type</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>'b'</td>
<td>Binary format. Outputs the number in base 2.</td>
</tr>
<tr>
<td>'c'</td>
<td>Character. Converts the integer to the corresponding unicode character before printing.</td>
</tr>
<tr>
<td>'d'</td>
<td>Decimal Integer. Outputs the number in base 10.</td>
</tr>
<tr>
<td>'o'</td>
<td>Octal format. Outputs the number in base 8.</td>
</tr>
<tr>
<td>'x'</td>
<td>Hex format. Outputs the number in base 16, using lower-case letters for the digits above 9.</td>
</tr>
<tr>
<td>'X'</td>
<td>Hex format. Outputs the number in base 16, using upper-case letters for the digits above 9.</td>
</tr>
<tr>
<td>'n'</td>
<td>Number. This is the same as 'd', except that it uses the current locale setting to insert the appropriate number separator characters.</td>

</table>
Template strings

Templates provide simpler string substitutions as described in PEP 292. Instead of the normal `%`-based substitutions, Templates support `$`-based substitutions, using the following rules:

- `$$` is an escape; it is replaced with a single `$`
- `$identifier` names a substitution placeholder matching a mapping key of `"identifier"`. By default, `"identifier"` must spell a Python identifier. The first non-identifier character after the `$` character terminates this placeholder specification.
- `_${identifier}_` is equivalent to $identifier. It is required when valid identifier characters follow the placeholder but are not part of the placeholder, such as `"${noun}ification"`.

Any other appearance of `$` in the string will result in a `ValueError` being raised.

*New in version 2.4.*

The `string` module provides a `Template` class that implements these rules. The methods of `Template` are:

```python
class string.Template(template)

    The constructor takes a single argument which is the template string.

    substitute(mapping[, **kws])

    Performs the template substitution, returning a new string. `mapping` is any dictionary-like object with keys that match the placeholders in the template. Alternatively, you can provide keyword arguments, where the keywords are the
placeholders. When both `mapping` and `kws` are given and there are duplicates, the placeholders from `kws` take precedence.

```python
safe_substitute(mapping[, **kws])
```

Like `substitute()`, except that if placeholders are missing from `mapping` and `kws`, instead of raising a `KeyError` exception, the original placeholder will appear in the resulting string intact. Also, unlike with `substitute()`, any other appearances of the `$` will simply return `$` instead of raising `ValueError`.

While other exceptions may still occur, this method is called "safe" because substitutions always tries to return a usable string instead of raising an exception. In another sense, `safe_substitute()` may be anything other than safe, since it will silently ignore malformed templates containing dangling delimiters, unmatched braces, or placeholders that are not valid Python identifiers.

`Template` instances also provide one public data attribute:

```
string.template
```

This is the object passed to the constructor’s `template` argument. In general, you shouldn’t change it, but read-only access is not enforced.

Here is an example of how to use a Template:

```python
>>> from string import Template
>>> s = Template('$who likes $what')
'who likes what'
>>> s.substitute(who='tim', what='kung pao')
'tim likes kung pao'
>>> d = dict(who='tim')
>>> Template('Give $who $100').substitute(d)
Traceback (most recent call last):
 [...]
```
Advanced usage: you can derive subclasses of \texttt{Template} to customize the placeholder syntax, delimiter character, or the entire regular expression used to parse template strings. To do this, you can override these class attributes:

- \texttt{delimiter} – This is the literal string describing a placeholder introducing delimiter. The default value \texttt{$.} Note that this should \textit{not} be a regular expression, as the implementation will call \texttt{re.escape()} on this string as needed.
- \texttt{idpattern} – This is the regular expression describing the pattern for non-braced placeholders (the braces will be added automatically as appropriate). The default value is the regular expression \texttt{[_a-z][_a-z0-9]*}.

Alternatively, you can provide the entire regular expression pattern by overriding the class attribute \texttt{pattern}. If you do this, the value must be a regular expression object with four named capturing groups. The capturing groups correspond to the rules given above, along with the invalid placeholder rule:

- \texttt{escaped} – This group matches the escape sequence, e.g. \texttt{$$}, in the default pattern.
- \texttt{named} – This group matches the unbraced placeholder name; it should not include the delimiter in capturing group.
- \texttt{braced} – This group matches the brace enclosed placeholder name; it should not include either the delimiter or braces in the capturing group.
- \texttt{invalid} – This group matches any other delimiter pattern (usually
a single delimiter), and it should appear last in the regular expression.
String functions

The following functions are available to operate on string and Unicode objects. They are not available as string methods.

string. **capwords(s)**

Split the argument into words using `split()`, capitalize each word using `capitalize()`, and join the capitalized words using `join()`. Note that this replaces runs of whitespace characters by a single space, and removes leading and trailing whitespace.

string. **maketrans(from, to)**

Return a translation table suitable for passing to `translate()`, that will map each character in `from` into the character at the same position in `to`; `from` and `to` must have the same length.

**Warning:** Don't use strings derived from `lowercase` and `uppercase` as arguments; in some locales, these don't have the same length. For case conversions, always use `lower()` and `upper()`.
Deprecated string functions

The following list of functions are also defined as methods of string and Unicode objects; see section String Methods for more information on those. You should consider these functions as deprecated, although they will not be removed until Python 3.0. The functions defined in this module are:

string.atof(s)

*Deprecated since version 2.0:* Use the float() built-in function.

Convert a string to a floating point number. The string must have the standard syntax for a floating point literal in Python, optionally preceded by a sign (+ or -). Note that this behaves identically to the built-in function float() when passed a string.

**Note:** When passing in a string, values for NaN and Infinity may be returned, depending on the underlying C library. The specific set of strings accepted which cause these values to be returned depends entirely on the C library and is known to vary.

string.atoi(s[, base])

*Deprecated since version 2.0:* Use the int() built-in function.

Convert string s to an integer in the given base. The string must consist of one or more digits, optionally preceded by a sign (+ or -). The base defaults to 10. If it is 0, a default base is chosen depending on the leading characters of the string (after stripping the sign): 0x or 0X means 16, 0 means 8, anything else means 10. If base is 16, a leading 0x or 0X is always accepted, though not required. This behaves identically to the built-in function int() when passed a string. (Also note: for a more flexible
interpretation of numeric literals, use the built-in function `eval()`.

```python
string.atol(s[, base])
```

*Deprecated since version 2.0:* Use the `long()` built-in function.

Convert string `s` to a long integer in the given `base`. The string must consist of one or more digits, optionally preceded by a sign (`+` or `-`). The `base` argument has the same meaning as for `atoi()`. A trailing 1 or L is not allowed, except if the base is 0. Note that when invoked without `base` or with `base` set to 10, this behaves identical to the built-in function `long()` when passed a string.

```python
string.capitalize(word)
```

Return a copy of `word` with only its first character capitalized.

```python
string.expandtabs(s[, tabsize])
```

Expand tabs in a string replacing them by one or more spaces, depending on the current column and the given tab size. The column number is reset to zero after each newline occurring in the string. This doesn’t understand other non-printing characters or escape sequences. The tab size defaults to 8.

```python
string.find(s, sub[, start[, end]])
```

Return the lowest index in `s` where the substring `sub` is found such that `sub` is wholly contained in `s[start:end]`. Return -1 on failure. Defaults for `start` and `end` and interpretation of negative values is the same as for slices.

```python
string.rfind(s, sub[, start[, end]])
```

Like `find()` but find the highest index.

```python
string.index(s, sub[, start[, end]])
```
Like `find()` but raise `ValueError` when the substring is not found.

```
string.rindex(s, sub[, start[, end]])
```

Like `rfind()` but raise `ValueError` when the substring is not found.

```
string.count(s, sub[, start[, end]])
```

Return the number of (non-overlapping) occurrences of substring `sub` in string `s[start:end]`. Defaults for `start` and `end` and interpretation of negative values are the same as for slices.

```
string.lower(s)
```

Return a copy of `s`, but with upper case letters converted to lower case.

```
string.split(s[, sep[, maxsplit]])
```

Return a list of the words of the string `s`. If the optional second argument `sep` is absent or `None`, the words are separated by arbitrary strings of whitespace characters (space, tab, newline, return, formfeed). If the second argument `sep` is present and not `None`, it specifies a string to be used as the word separator. The returned list will then have one more item than the number of non-overlapping occurrences of the separator in the string. The optional third argument `maxsplit` defaults to 0. If it is nonzero, at most `maxsplit` number of splits occur, and the remainder of the string is returned as the final element of the list (thus, the list will have at most `maxsplit+1` elements).

The behavior of split on an empty string depends on the value of `sep`. If `sep` is not specified, or specified as `None`, the result will be an empty list. If `sep` is specified as any string, the result will be a list containing one element which is an empty string.
string. **rsplit**(s, sep[, maxsplit])

Return a list of the words of the string s, scanning s from the end. To all intents and purposes, the resulting list of words is the same as returned by **split()**, except when the optional third argument **maxsplit** is explicitly specified and nonzero. When **maxsplit** is nonzero, at most **maxsplit** number of splits – the **rightmost** ones – occur, and the remainder of the string is returned as the first element of the list (thus, the list will have at most **maxsplit**+1 elements).

*New in version 2.4.*

string. **splitfields**(s, sep[, maxsplit])

This function behaves identically to **split()**. (In the past, **split()** was only used with one argument, while **splitfields()** was only used with two arguments.)

string. **join**(words, sep)

Concatenate a list or tuple of words with intervening occurrences of **sep**. The default value for **sep** is a single space character. It is always true that string.join(string.split(s, sep), sep) equals s.

string. **joinfields**(words, sep)

This function behaves identically to **join()**. (In the past, **join()** was only used with one argument, while **joinfields()** was only used with two arguments.) Note that there is no **joinfields()** method on string objects; use the **join()** method instead.

string. **lstrip**(s, chars)

Return a copy of the string with leading characters removed. If **chars** is omitted or **None**, whitespace characters are removed. If
given and not None, chars must be a string; the characters in the string will be stripped from the beginning of the string this method is called on.

*Changed in version 2.2.3:* The chars parameter was added. The chars parameter cannot be passed in earlier 2.2 versions.

```
stringrstrip(s[, chars])
```
Return a copy of the string with trailing characters removed. If chars is omitted or None, whitespace characters are removed. If given and not None, chars must be a string; the characters in the string will be stripped from the end of the string this method is called on.

*Changed in version 2.2.3:* The chars parameter was added. The chars parameter cannot be passed in earlier 2.2 versions.

```
stringstrip(s[, chars])
```
Return a copy of the string with leading and trailing characters removed. If chars is omitted or None, whitespace characters are removed. If given and not None, chars must be a string; the characters in the string will be stripped from the both ends of the string this method is called on.

*Changed in version 2.2.3:* The chars parameter was added. The chars parameter cannot be passed in earlier 2.2 versions.

```
stringswapcase(s)
```
Return a copy of s, but with lower case letters converted to upper case and vice versa.

```
stringtranslate(s, table[, deletechars])
```
Delete all characters from s that are in deletechars (if present), and then translate the characters using table, which must be a
256-character string giving the translation for each character value, indexed by its ordinal. If `table` is `None`, then only the character deletion step is performed.

```
string.upper(s)
```

Return a copy of `s`, but with lower case letters converted to upper case.

```
string.ljust(s, width)
string.rjust(s, width)
string.center(s, width)
```

These functions respectively left-justify, right-justify and center a string in a field of given width. They return a string that is at least `width` characters wide, created by padding the string `s` with spaces until the given width on the right, left or both sides. The string is never truncated.

```
string.zfill(s, width)
```

Pad a numeric string on the left with zero digits until the given width is reached. Strings starting with a sign are handled correctly.

```
string.replace(str, old, new[, maxreplace])
```

Return a copy of string `str` with all occurrences of substring `old` replaced by `new`. If the optional argument `maxreplace` is given, the first `maxreplace` occurrences are replaced.
This module provides regular expression matching operations similar to those found in Perl. Both patterns and strings to be searched can be Unicode strings as well as 8-bit strings. The re module is always available.

Regular expressions use the backslash character (backslash) to indicate special forms or to allow special characters to be used without invoking their special meaning. This collides with Python's usage of the same character for the same purpose in string literals; for example, to match a literal backslash, one might have to write as the pattern string, because the regular expression must be inside a regular Python string literal.

The solution is to use Python's raw string notation for regular expression patterns; backslashes are not handled in any special way in a string literal prefixed with . So is a two-character string containing and , while is a one-character string containing a newline. Usually patterns will be expressed in Python code using this raw string notation.

It is important to note that most regular expression operations are available as module-level functions and RegexObject methods. The functions are shortcuts that don't require you to compile a regex object first, but miss some fine-tuning parameters.

See also:

Mastering Regular Expressions
Book on regular expressions by Jeffrey Friedl, published by O’Reilly. The second edition of the book no longer covers Python at all, but the first edition covered writing good regular expression patterns in great detail.

**Kodos**

is a graphical regular expression debugger written in Python.
A regular expression (or RE) specifies a set of strings that matches it; the functions in this module let you check if a particular string matches a given regular expression (or if a given regular expression matches a particular string, which comes down to the same thing).

Regular expressions can be concatenated to form new regular expressions; if \( A \) and \( B \) are both regular expressions, then \( AB \) is also a regular expression. In general, if a string \( p \) matches \( A \) and another string \( q \) matches \( B \), the string \( pq \) will match \( AB \). This holds unless \( A \) or \( B \) contain low precedence operations; boundary conditions between \( A \) and \( B \); or have numbered group references. Thus, complex expressions can easily be constructed from simpler primitive expressions like the ones described here. For details of the theory and implementation of regular expressions, consult the Friedl book referenced above, or almost any textbook about compiler construction.

A brief explanation of the format of regular expressions follows. For further information and a gentler presentation, consult the Regular Expression HOWTO.

Regular expressions can contain both special and ordinary characters. Most ordinary characters, like 'A', 'a', or '0', are the simplest regular expressions; they simply match themselves. You can concatenate ordinary characters, so \texttt{last} matches the string \texttt{'last'}. (In the rest of this section, we'll write RE's in this special style, usually without quotes, and strings to be matched \texttt{'in single quotes'}.)

Some characters, like '|' or '(', are special. Special characters either stand for classes of ordinary characters, or affect how the
regular expressions around them are interpreted. Regular expression pattern strings may not contain null bytes, but can specify the null byte using the \number notation, e.g., '\x00'.

The special characters are:

`.'
(Dot.) In the default mode, this matches any character except a newline. If the DOTALL flag has been specified, this matches any character including a newline.

`\A`
(Caret.) Matches the start of the string, and in MULTILINE mode also matches immediately after each newline.

`\$`
Matches the end of the string or just before the newline at the end of the string, and in MULTILINE mode also matches before a newline. foo matches both ‘foo’ and ‘foobar’, while the regular expression foo$ matches only ‘foo’. More interestingly, searching for foo.$ in 'foo1
foo2
' matches ‘foo2’ normally, but ‘foo1’ in MULTILINE mode; searching for a single $ in foo
 will find two (empty) matches: one just before the newline, and one at the end of the string.

`\*`
Causes the resulting RE to match 0 or more repetitions of the preceding RE, as many repetitions as are possible. ab* will match ‘a’, ‘ab’, or ‘a’ followed by any number of ‘b’s.

`\+`
Causes the resulting RE to match 1 or more repetitions of the preceding RE. ab+ will match ‘a’ followed by any non-zero number of ‘b’s; it will not match just ‘a’.

`\?`
Causes the resulting RE to match 0 or 1 repetitions of the preceding RE. ab? will match either ‘a’ or ‘ab’.
*?, +?, ??

The '*'`, `'+',` and '?' qualifiers are all greedy; they match as much text as possible. Sometimes this behaviour isn't desired; if the RE `<.*>` is matched against `<H1>title</H1>'`, it will match the entire string, and not just `<H1>'`. Adding '?' after the qualifier makes it perform the match in non-greedy or minimal fashion; as few characters as possible will be matched. Using `.*?` in the previous expression will match only `<H1>'`.

{m}

Specifies that exactly m copies of the previous RE should be matched; fewer matches cause the entire RE not to match. For example, a{6} will match exactly six 'a' characters, but not five.

{m,n}

Causes the resulting RE to match from m to n repetitions of the preceding RE, attempting to match as many repetitions as possible. For example, a{3,5} will match from 3 to 5 'a' characters. Omitting m specifies a lower bound of zero, and omitting n specifies an infinite upper bound. As an example, a{4,}b will match aaaaa or a thousand 'a' characters followed by a b, but not aaab. The comma may not be omitted or the modifier would be confused with the previously described form.

{m,n}?

Causes the resulting RE to match from m to n repetitions of the preceding RE, attempting to match as few repetitions as possible. This is the non-greedy version of the previous qualifier. For example, on the 6-character string 'aaaaaa', a{3,5} will match 5 'a' characters, while a{3,5}? will only match 3 characters.

'\'

Either escapes special characters (permitting you to match characters like '*', '?', and so forth), or signals a special sequence; special sequences are discussed below.
If you’re not using a raw string to express the pattern, remember that Python also uses the backslash as an escape sequence in string literals; if the escape sequence isn’t recognized by Python’s parser, the backslash and subsequent character are included in the resulting string. However, if Python would recognize the resulting sequence, the backslash should be repeated twice. This is complicated and hard to understand, so it’s highly recommended that you use raw strings for all but the simplest expressions.

[]

Used to indicate a set of characters. Characters can be listed individually, or a range of characters can be indicated by giving two characters and separating them by a '-'. Special characters are not active inside sets. For example, [akm$] will match any of the characters 'a', 'k', 'm', or '$'; [a-z] will match any lowercase letter, and [a-zA-Z0-9] matches any letter or digit. Character classes such as \w or \s (defined below) are also acceptable inside a range, although the characters they match depends on whether LOCALE or UNICODE mode is in force. If you want to include a ']' or a '-' inside a set, precede it with a backslash, or place it as the first character. The pattern [[]] will match '[]', for example.

You can match the characters not within a range by complementing the set. This is indicated by including a '^' as the first character of the set; '^' elsewhere will simply match the '^' character. For example, [^5] will match any character except '5', and [^] will match any character except '^'.

Note that inside [] the special forms and special characters lose their meanings and only the syntaxes described here are valid. For example, +, *, (, ), and so on are treated as literals inside
[], and backreferences cannot be used inside [].

A|B, where A and B can be arbitrary REs, creates a regular expression that will match either A or B. An arbitrary number of REs can be separated by the ' ' in this way. This can be used inside groups (see below) as well. As the target string is scanned, REs separated by ' ' are tried from left to right. When one pattern completely matches, that branch is accepted. This means that once A matches, B will not be tested further, even if it would produce a longer overall match. In other words, the ' ' operator is never greedy. To match a literal ' ', use \|, or enclose it inside a character class, as in [\|].

(...)
Matches whatever regular expression is inside the parentheses, and indicates the start and end of a group; the contents of a group can be retrieved after a match has been performed, and can be matched later in the string with the \number special sequence, described below. To match the literals '()' or ')', use \( or \), or enclose them inside a character class: [[()]].

(?...)
This is an extension notation (a '?' following a '(' is not meaningful otherwise). The first character after the '?' determines what the meaning and further syntax of the construct is. Extensions usually do not create a new group; (?P<name>...) is the only exception to this rule. Following are the currently supported extensions.

(?iLmsux)
(One or more letters from the set 'i', 'L', 'm', 's', 'u', 'x'.) The group matches the empty string; the letters set the corresponding flags: re.I (ignore case), re.L (locale dependent), re.M (multi-line), re.S (dot matches all), re.U (Unicode
dependent), and \texttt{re.x} (verbose), for the entire regular expression. (The flags are described in \textit{Module Contents}.) This is useful if you wish to include the flags as part of the regular expression, instead of passing a \textit{flag} argument to the \textit{compile()} function.

Note that the \texttt{(?x)} flag changes how the expression is parsed. It should be used first in the expression string, or after one or more whitespace characters. If there are non-whitespace characters before the flag, the results are undefined.

\texttt{(?::...)}

A non-grouping version of regular parentheses. Matches whatever regular expression is inside the parentheses, but the substring matched by the group \textit{cannot} be retrieved after performing a match or referenced later in the pattern.

\texttt{(?P<name>...)}

Similar to regular parentheses, but the substring matched by the group is accessible via the symbolic group name \texttt{name}. Group names must be valid Python identifiers, and each group name must be defined only once within a regular expression. A symbolic group is also a numbered group, just as if the group were not named. So the group named ‘id’ in the example below can also be referenced as the numbered group 1.

For example, if the pattern is \texttt{(??P<id>[a-zA-Z_][\w]*)}, the group can be referenced by its name in arguments to methods of match objects, such as \texttt{m.group('id')} or \texttt{m.end('id')}, and also by name in pattern text (for example, \texttt{(??P=id)}) and replacement text (such as \texttt{\g<id>}).

\texttt{(?P=name)}

Matches whatever text was matched by the earlier group named \texttt{name}. 
A comment; the contents of the parentheses are simply ignored.

Matches if ... matches next, but doesn’t consume any of the string. This is called a lookahead assertion. For example, Isaac (?=Asimov) will match 'Isaac ' only if it's followed by 'Asimov'.

Matches if ... doesn’t match next. This is a negative lookahead assertion. For example, Isaac (?!Asimov) will match 'Isaac ' only if it's not followed by 'Asimov'.

Matches if the current position in the string is preceded by a match for ... that ends at the current position. This is called a positive lookbehind assertion. (<?=abc)def will find a match in abcdef, since the lookbehind will back up 3 characters and check if the contained pattern matches. The contained pattern must only match strings of some fixed length, meaning that abc or a|b are allowed, but a* and a{3,4} are not. Note that patterns which start with positive lookbehind assertions will never match at the beginning of the string being searched; you will most likely want to use the search() function rather than the match() function:

```python
>>> import re
>>> m = re.search('(?<=abc)def', 'abcdef')
>>> m.group(0)
'def'
```

This example looks for a word following a hyphen:

```python
>>> m = re.search('(?<=\-)\w+', 'spam-egg')
>>> m.group(0)
'egg'
```
(?<!...)  
Matches if the current position in the string is not preceded by a match for .... This is called a negative lookbehind assertion. Similar to positive lookbehind assertions, the contained pattern must only match strings of some fixed length. Patterns which start with negative lookbehind assertions may match at the beginning of the string being searched.

(?<id/name)yes-pattern|no-pattern
Will try to match with yes-pattern if the group with given id or name exists, and with no-pattern if it doesn’t. no-pattern is optional and can be omitted. For example, (<)?(\w+@\w+(?:\.:\w+)+)?(1)> is a poor email matching pattern, which will match with '<user@host.com>' as well as user@host.com', but not with '<user@host.com'.

New in version 2.4.

The special sequences consist of \ and a character from the list below. If the ordinary character is not on the list, then the resulting RE will match the second character. For example, \$ matches the character '$'.

\number
Matches the contents of the group of the same number. Groups are numbered starting from 1. For example, (.+)\1 matches 'the the' or '55 55', but not 'the end' (note the space after the group). This special sequence can only be used to match one of the first 99 groups. If the first digit of number is 0, or number is 3 octal digits long, it will not be interpreted as a group match, but as the character with octal value number. Inside the '[' and ']' of a character class, all numeric escapes are treated as characters.

\A
Matches only at the start of the string.
\b
Matches the empty string, but only at the beginning or end of a word. A word is defined as a sequence of alphanumeric or underscore characters, so the end of a word is indicated by whitespace or a non-alphanumeric, non-underscore character. Note that \b is defined as the boundary between \w and \W, so the precise set of characters deemed to be alphanumeric depends on the values of the \texttt{UNICODE} and \texttt{LOCALE} flags. Inside a character range, \b represents the backspace character, for compatibility with Python’s string literals.

\B
Matches the empty string, but only when it is \textit{not} at the beginning or end of a word. This is just the opposite of \b, so is also subject to the settings of \texttt{LOCALE} and \texttt{UNICODE}.

\d
When the \texttt{UNICODE} flag is not specified, matches any decimal digit; this is equivalent to the set \texttt{[0-9]}. With \texttt{UNICODE}, it will match whatever is classified as a digit in the Unicode character properties database.

\D
When the \texttt{UNICODE} flag is not specified, matches any non-digit character; this is equivalent to the set \texttt{[^0-9]}. With \texttt{UNICODE}, it will match anything other than character marked as digits in the Unicode character properties database.

\s
When the \texttt{LOCALE} and \texttt{UNICODE} flags are not specified, matches any whitespace character; this is equivalent to the set \texttt{[	

\f\v]}. With \texttt{LOCALE}, it will match this set plus whatever characters are defined as space for the current locale. If \texttt{UNICODE} is set, this will match the characters \texttt{[	
\n\r\f\v]} plus whatever is classified as space in the Unicode character properties database.
When the **locale** and **unicode** flags are not specified, matches any non-whitespace character; this is equivalent to the set `[^\t\n\r\f\v]` With **locale**, it will match any character not in this set, and not defined as space in the current locale. If **unicode** is set, this will match anything other than `[^\t\n\r\f\v]` and characters marked as space in the Unicode character properties database.

When the **locale** and **unicode** flags are not specified, matches any alphanumeric character and the underscore; this is equivalent to the set `[a-zA-Z0-9_]`. With **locale**, it will match the set `[0-9_]` plus whatever characters are defined as alphanumeric for the current locale. If **unicode** is set, this will match the characters `[0-9_]` plus whatever is classified as alphanumeric in the Unicode character properties database.

When the **locale** and **unicode** flags are not specified, matches any non-alphanumeric character; this is equivalent to the set `[^a-zA-Z0-9_]`. With **locale**, it will match any character not in the set `[0-9_]`, and not defined as alphanumeric for the current locale. If **unicode** is set, this will match anything other than `[0-9_]` and characters marked as alphanumeric in the Unicode character properties database.

Matches only at the end of the string.

Most of the standard escapes supported by Python string literals are also accepted by the regular expression parser:

```
\a  \b  \f  \n
\r  \t  \v  \x
```
Octal escapes are included in a limited form: If the first digit is a 0, or if there are three octal digits, it is considered an octal escape. Otherwise, it is a group reference. As for string literals, octal escapes are always at most three digits in length.
Matching vs Searching

Python offers two different primitive operations based on regular expressions: **match** checks for a match only at the beginning of the string, while **search** checks for a match anywhere in the string (this is what Perl does by default).

Note that match may differ from search even when using a regular expression beginning with `'^'`: `'^'` matches only at the start of the string, or in **MULTILINE** mode also immediately following a newline. The “match” operation succeeds only if the pattern matches at the start of the string regardless of mode, or at the starting position given by the optional `pos` argument regardless of whether a newline precedes it.

```python
>>> re.match("c", "abcdef")  # No match
>>> re.search("c", "abcdef")  # Match
<_sre.SRE_Match object at ...>
```
Module Contents

The module defines several functions, constants, and an exception. Some of the functions are simplified versions of the full featured methods for compiled regular expressions. Most non-trivial applications always use the compiled form.

`re.compile(pattern[, flags])`

Compile a regular expression pattern into a regular expression object, which can be used for matching using its `match()` and `search()` methods, described below.

The expression's behaviour can be modified by specifying a `flags` value. Values can be any of the following variables, combined using bitwise OR (the `|` operator).

The sequence

```python
prog = re.compile(pat)
result = prog.match(str)
```

is equivalent to

```python
result = re.match(pat, str)
```

but the version using `compile()` is more efficient when the expression will be used several times in a single program.

`re.IGNORECASE`

Perform case-insensitive matching; expressions like `[A-Z]` will match lowercase letters, too. This is not affected by the current locale.
re. **L**
re. **LOCALE**
    Make \w, \W, \b, \B, \s and \S dependent on the current locale.

re. **M**
re. **MULTILINE**
    When specified, the pattern character '^' matches at the beginning of the string and at the beginning of each line (immediately following each newline); and the pattern character '$' matches at the end of the string and at the end of each line (immediately preceding each newline). By default, '^' matches only at the beginning of the string, and '$' only at the end of the string and immediately before the newline (if any) at the end of the string.

re. **S**
re. **DOTALL**
    Make the '.' special character match any character at all, including a newline; without this flag, '.' will match anything except a newline.

re. **U**
re. **UNICODE**
    Make \w, \W, \b, \B, \d, \D, \s and \S dependent on the Unicode character properties database.

    *New in version 2.0.*

re. **X**
re. **VERBOUSE**
    This flag allows you to write regular expressions that look nicer. Whitespace within the pattern is ignored, except when in a character class or preceded by an unescaped backslash, and, when a line contains a '#' neither in a character class or preceded by an unescaped backslash, all characters from the
leftmost such "#' through the end of the line are ignored.

That means that the two following regular expression objects that match a decimal number are functionally equal:

```python
a = re.compile(r"\d + # the integral part
 \. # the decimal point
 \d * # some fractional digits"", re.X)
b = re.compile(r"\d+\.\d*
```

**re.search(pattern, string[, flags])**

Scan through string looking for a location where the regular expression pattern produces a match, and return a corresponding MatchObject instance. Return None if no position in the string matches the pattern; note that this is different from finding a zero-length match at some point in the string.

**re.match(pattern, string[, flags])**

If zero or more characters at the beginning of string match the regular expression pattern, return a corresponding MatchObject instance. Return None if the string does not match the pattern; note that this is different from a zero-length match.

**Note:** If you want to locate a match anywhere in string, use search() instead.

**re.split(pattern, string[, maxsplit=0])**

Split string by the occurrences of pattern. If capturing parentheses are used in pattern, then the text of all groups in the pattern are also returned as part of the resulting list. If maxsplit is nonzero, at most maxsplit splits occur, and the remainder of the string is returned as the final element of the list. (Incompatibility note: in the original Python 1.5 release, maxsplit was ignored.)
This has been fixed in later releases.)

```python
>>> re.split(r'\W+', 'Words, words, words.')
['Words', 'words', 'words', '']
```

```python
>>> re.split(r'(\W+)', 'Words, words, words.')
['Words', '', '', 'words', '', '', 'words', '.', '']
```

```python
>>> re.split(r'\W+', 'Words, words, words.', 1)
['Words', 'words, words.']
```

If there are capturing groups in the separator and it matches at the start of the string, the result will start with an empty string. The same holds for the end of the string:

```python
>>> re.split(r'(\W+) ', '...words, words...')
[', '...', 'words', '', '', 'words', '...', '']
```

That way, separator components are always found at the same relative indices within the result list (e.g., if there's one capturing group in the separator, the 0th, the 2nd and so forth).

Note that `split` will never split a string on an empty pattern match. For example:

```python
>>> re.split('x*', 'foo')
['foo']
```

```python
>>> re.split("(?m)^$", "foo\n\nbar\n")
['foo\n\nbar\n']
```

`re.findall(pattern, string[, flags])`
Return all non-overlapping matches of `pattern` in `string`, as a list of strings. The `string` is scanned left-to-right, and matches are returned in the order found. If one or more groups are present in the pattern, return a list of groups; this will be a list of tuples if the pattern has more than one group. Empty matches are included in
the result unless they touch the beginning of another match.

New in version 1.5.2.

Changed in version 2.4: Added the optional flags argument.

```
re.finditer(pattern, string[, flags])
```
Return an iterator yielding MatchObject instances over all non-overlapping matches for the RE pattern in string. The string is scanned left-to-right, and matches are returned in the order found. Empty matches are included in the result unless they touch the beginning of another match.

New in version 2.2.

Changed in version 2.4: Added the optional flags argument.

```
re.sub(pattern, repl, string[, count])
```
Return the string obtained by replacing the leftmost non-overlapping occurrences of pattern in string by the replacement repl. If the pattern isn’t found, string is returned unchanged. repl can be a string or a function; if it is a string, any backslash escapes in it are processed. That is, \n is converted to a single newline character, \r is converted to a linefeed, and so forth. Unknown escapes such as \j are left alone. Backreferences, such as \6, are replaced with the substring matched by group 6 in the pattern. For example:

```python
>>> re.sub(r'def\s+([a-zA-Z_][a-zA-Z_0-9]*)\s*\(\s*\):',
          ...           r'static PyObject*\npy_\1(void)\n{',
          ...           'def myfunc():'
          ...           'static PyObject*\npy_myfunc(void)\n{',
```

If repl is a function, it is called for every non-overlapping
occurrence of \textit{pattern}. The function takes a single match object argument, and returns the replacement string. For example:

\begin{verbatim}
>>> def dashrepl(matchobj):
...    if matchobj.group(0) == '-': return ''
...    else: return '-'

>>> re.sub('-\{1,2}\', dashrepl, 'pro-\---gram-files')
'pro--gram files'
\end{verbatim}

The pattern may be a string or an RE object; if you need to specify regular expression flags, you must use a RE object, or use embedded modifiers in a pattern; for example, \texttt{sub("(?i)b+", \texttt{"x"}, \texttt{"bbbb BBBBB"}) returns \texttt{\textbackslash x \textbackslash x"}}.

The optional argument \textit{count} is the maximum number of pattern occurrences to be replaced; \textit{count} must be a non-negative integer. If omitted or zero, all occurrences will be replaced. Empty matches for the pattern are replaced only when not adjacent to a previous match, so \texttt{sub('x*', '-', 'abc')} returns \texttt{'-a-b-c-'}.

In addition to character escapes and backreferences as described above, \texttt{\g<name>} will use the substring matched by the group named \texttt{name}, as defined by the \texttt{(?P<name>...)} syntax. \texttt{\g<number>} uses the corresponding group number; \texttt{\g<2>} is therefore equivalent to \texttt{\2}, but isn't ambiguous in a replacement such as \texttt{\g<2>0}. \texttt{\20} would be interpreted as a reference to group 20, not a reference to group 2 followed by the literal character \texttt{0}. The backreference \texttt{\g<0>} substitutes in the entire substring matched by the RE.

\begin{verbatim}
re.subn(pattern, repl, string[, count])
Perform the same operation as \texttt{sub()}, but return a tuple
(new_string, number_of_subs_made).
\end{verbatim}
re. **escape**(string)
Return string with all non-alphanumerics backslashed; this is useful if you want to match an arbitrary literal string that may have regular expression metacharacters in it.

**exception re.error**
Exception raised when a string passed to one of the functions here is not a valid regular expression (for example, it might contain unmatched parentheses) or when some other error occurs during compilation or matching. It is never an error if a string contains no match for a pattern.
Compiled regular expression objects support the following methods and attributes:

```
RegexpObject.match(string[, pos[, endpos]])
```

If zero or more characters at the beginning of `string` match this regular expression, return a corresponding `MatchObject` instance. Return `None` if the string does not match the pattern; note that this is different from a zero-length match.

**Note:** If you want to locate a match anywhere in `string`, use `search()` instead.

The optional second parameter `pos` gives an index in the string where the search is to start; it defaults to 0. This is not completely equivalent to slicing the string; the `'^'` pattern character matches at the real beginning of the string and at positions just after a newline, but not necessarily at the index where the search is to start.

The optional parameter `endpos` limits how far the string will be searched; it will be as if the string is `endpos` characters long, so only the characters from `pos` to `endpos - 1` will be searched for a match. If `endpos` is less than `pos`, no match will be found, otherwise, if `rx` is a compiled regular expression object, `rx.match(string, 0, 50)` is equivalent to `rx.match(string[:50], 0)`.

```
>>> pattern = re.compile("o")
>>> pattern.match("dog")    # No match as "o" is not at the start
>>> pattern.match("dog", 1)  # Match as "o" is the 2nd character
```
RegexObject. `search(string[, pos[, endpos]])`
Scan through `string` looking for a location where this regular expression produces a match, and return a corresponding `MatchObject` instance. Return `None` if no position in the string matches the pattern; note that this is different from finding a zero-length match at some point in the string.

The optional `pos` and `endpos` parameters have the same meaning as for the `match()` method.

RegexObject. `split(string[, maxsplit=0])`
Identical to the `split()` function, using the compiled pattern.

RegexObject. `findall(string[, pos[, endpos]])`
Identical to the `findall()` function, using the compiled pattern.

RegexObject. `finditer(string[, pos[, endpos]])`
Identical to the `finditer()` function, using the compiled pattern.

RegexObject. `sub(repl, string[, count=0])`
Identical to the `sub()` function, using the compiled pattern.

RegexObject. `subn(repl, string[, count=0])`
Identical to the `subn()` function, using the compiled pattern.

RegexObject. `flags`
The flags argument used when the RE object was compiled, or `0` if no flags were provided.

RegexObject. `groupindex`
A dictionary mapping any symbolic group names defined by (?<id>) to group numbers. The dictionary is empty if no symbolic groups were used in the pattern.

**RegexObject**. **pattern**

The pattern string from which the RE object was compiled.
Match Objects

Match objects always have a boolean value of True, so that you can test whether e.g. `match()` resulted in a match with a simple if statement. They support the following methods and attributes:

**MatchObject.**`expand`(template)

Return the string obtained by doing backslash substitution on the template string `template`, as done by the `sub()` method. Escapes such as \n are converted to the appropriate characters, and numeric backreferences (\1, \2) and named backreferences (\g<1>, \g<name>) are replaced by the contents of the corresponding group.

**MatchObject.**`group`([group1,...])

Returns one or more subgroups of the match. If there is a single argument, the result is a single string; if there are multiple arguments, the result is a tuple with one item per argument. Without arguments, `group1` defaults to zero (the whole match is returned). If a `groupN` argument is zero, the corresponding return value is the entire matching string; if it is in the inclusive range [1..99], it is the string matching the corresponding parenthesized group. If a group number is negative or larger than the number of groups defined in the pattern, an `IndexError` exception is raised. If a group is contained in a part of the pattern that did not match, the corresponding result is `None`. If a group is contained in a part of the pattern that matched multiple times, the last match is returned.

```python
>>> m = re.match(r"(\w+) (\w+)", "Isaac Newton, physicist")
>>> m.group(0)    # The entire match
'Ignat Newton'
```
If the regular expression uses the \texttt{(?P<name>...)} syntax, the \texttt{groupN} arguments may also be strings identifying groups by their group name. If a string argument is not used as a group name in the pattern, an \texttt{IndexError} exception is raised.

A moderately complicated example:

```python
>>> m = re.match(r"(?P<first_name>\w+) (?P<last_name>\w+)", "Malcom Reynolds")
>>> m.group('first_name')
'Malcom'
>>> m.group('last_name')
'Reynolds'
```

Named groups can also be referred to by their index:

```python
>>> m.group(1)
'Malcom'
>>> m.group(2)
'Reynolds'
```

If a group matches multiple times, only the last match is accessible:

```python
>>> m = re.match(r"(.+)", "a1b2c3")  # Matches 3 times.
>>> m.group(1)  # Returns only the last match
'c3'
```
MatchObject.\texttt{groups}([\texttt{default}])

Return a tuple containing all the subgroups of the match, from 1 up to however many groups are in the pattern. The \texttt{default} argument is used for groups that did not participate in the match; it defaults to \texttt{None}. (Incompatibility note: in the original Python 1.5 release, if the tuple was one element long, a string would be returned instead. In later versions (from 1.5.1 on), a singleton tuple is returned in such cases.)

For example:

```python
>>> m = re.match(r"(\d+)\.(\d+)", "24.1632")
>>> m.groups()
('24', '1632')
```

If we make the decimal place and everything after it optional, not all groups might participate in the match. These groups will default to \texttt{None} unless the \texttt{default} argument is given:

```python
>>> m = re.match(r"(\d+)\.(?:(\d+)?", "24")
>>> m.groups()                      # Second group defaults to None.
('24', None)
>>> m.groups('0')                  # Now, the second group defaults to '0'.
('24', '0')
```

MatchObject.\texttt{groupdict}([\texttt{default}])

Return a dictionary containing all the named subgroups of the match, keyed by the subgroup name. The \texttt{default} argument is used for groups that did not participate in the match; it defaults to \texttt{None}. For example:

```python
>>> m = re.match(r"(?P<first_name>\w+) (?P<last_name>\w+) ",
>>> m.groupdict()
```
MatchObject.start([group])

MatchObject.end([group])

Return the indices of the start and end of the substring matched by group; group defaults to zero (meaning the whole matched substring). Return -1 if group exists but did not contribute to the match. For a match object m, and a group g that did contribute to the match, the substring matched by group g (equivalent to m.group(g)) is

m.string[m.start(g):m.end(g)]

Note that m.start(group) will equal m.end(group) if group matched a null string. For example, after m = re.search('b(c?)', 'cba'), m.start(0) is 1, m.end(0) is 2, m.start(1) and m.end(1) are both 2, and m.start(2) raises an IndexError exception.

An example that will remove remove_this from email addresses:

```python
>>> email = "tony@tiremove_thisger.net"
>>> m = re.search("remove_this", email)
>>> email[:m.start()] + email[m.end():]
'tony@tiger.net'
```

MatchObject.span([group])

For MatchObject m, return the 2-tuple (m.start(group), m.end(group)). Note that if group did not contribute to the match, this is (-1, -1). group defaults to zero, the entire match.

MatchObject.pos

The value of pos which was passed to the search() or match()
method of the RegexObject. This is the index into the string at which the RE engine started looking for a match.

**MatchObject. endpos**  
The value of `endpos` which was passed to the `search()` or `match()` method of the RegexObject. This is the index into the string beyond which the RE engine will not go.

**MatchObject. lastindex**  
The integer index of the last matched capturing group, or `None` if no group was matched at all. For example, the expressions `(a)b`, `((a)(b))`, and `((ab))` will have `lastindex == 1` if applied to the string `'ab'`, while the expression `(a)(b)` will have `lastindex == 2`, if applied to the same string.

**MatchObject. lastgroup**  
The name of the last matched capturing group, or `None` if the group didn’t have a name, or if no group was matched at all.

**MatchObject. re**  
The regular expression object whose `match()` or `search()` method produced this MatchObject instance.

**MatchObject. string**  
The string passed to `match()` or `search()`. 
Examples

Checking For a Pair

In this example, we'll use the following helper function to display match objects a little more gracefully:

```python
def displaymatch(match):
    if match is None:
        return None
    return '<Match: %r, groups=%r>' % (match.group(), match.groups())
```

Suppose you are writing a poker program where a player's hand is represented as a 5-character string with each character representing a card, “a” for ace, “k” for king, “q” for queen, j for jack, “0” for 10, and “1” through “9” representing the card with that value.

To see if a given string is a valid hand, one could do the following:

```python
>>> valid = re.compile(r"[0-9akqj]{5}$")
>>> displaymatch(valid.match("ak05q"))  # Valid.
"<Match: 'ak05q', groups=()>
>>> displaymatch(valid.match("ak05e"))  # Invalid.
>>> displaymatch(valid.match("ak0"))    # Invalid.
>>> displaymatch(valid.match("727ak"))  # Valid.
"<Match: '727ak', groups=()>
```

That last hand, "727ak", contained a pair, or two of the same valued cards. To match this with a regular expression, one could use backreferences as such:

```python
>>> pair = re.compile(r".*(.).*\1")  # Pair of 7s.
"<Match: '717', groups=('7',)>"
>>> displaymatch(pair.match("718ak"))  # No pairs.
>>> displaymatch(pair.match("354aa"))  # Pair of aces.
"<Match: '354aa', groups=('a',)>"
```
To find out what card the pair consists of, one could use the `group()` method of `MatchObject` in the following manner:

```python
>>> pair.match("717ak").group(1)
'7'
```

# Error because re.match() returns None, which doesn't have a group

```python
>>> pair.match("718ak").group(1)
Traceback (most recent call last):
  File "<pyshell#23>", line 1, in <module>
    re.match(r".*(.*).*\1", "718ak").group(1)
AttributeError: 'NoneType' object has no attribute 'group'
```

```python
>>> pair.match("354aa").group(1)
'a'
```

## Simulating scanf()

Python does not currently have an equivalent to `scanf`. Regular expressions are generally more powerful, though also more verbose, than `scanf` format strings. The table below offers some more-or-less equivalent mappings between `scanf` format tokens and regular expressions.

<table>
<thead>
<tr>
<th>scanf Token</th>
<th>Regular Expression</th>
</tr>
</thead>
<tbody>
<tr>
<td>%c</td>
<td>.</td>
</tr>
<tr>
<td>%5c</td>
<td>.{5}</td>
</tr>
<tr>
<td>%d</td>
<td>[-+]?\d+</td>
</tr>
<tr>
<td>%e, %E, %f, %g</td>
<td>[-+]?(\d+(.\d*)?</td>
</tr>
<tr>
<td>%i</td>
<td>[-+]?(0[xX][\dA-Fa-f]+</td>
</tr>
<tr>
<td>%o</td>
<td>0[0-7]*</td>
</tr>
<tr>
<td>%s</td>
<td>\S+</td>
</tr>
<tr>
<td>%u</td>
<td>\d+</td>
</tr>
<tr>
<td>%x, %X</td>
<td>0[xX][\dA-Fa-f]+</td>
</tr>
</tbody>
</table>

To extract the filename and numbers from a string like
you would use a `scanf` format like

```c
%s - %d errors, %d warnings
```

The equivalent regular expression would be

```regex
(S+) - (d+) errors, (d+) warnings
```

### Avoiding recursion

If you create regular expressions that require the engine to perform a lot of recursion, you may encounter a `RuntimeError` exception with the message `maximum recursion limit exceeded`. For example,

```python
>>> s = 'Begin ' + 1000*'a very long string ' + 'end'
>>> re.match('Begin (\w| )*? end', s).end()
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
  File "/usr/local/lib/python2.5/re.py", line 132, in match
    return _compile(pattern, flags).match(string)
RuntimeError: maximum recursion limit exceeded
```

You can often restructure your regular expression to avoid recursion.

Starting with Python 2.3, simple uses of the `*?` pattern are special-cased to avoid recursion. Thus, the above regular expression can avoid recursion by being recast as `Begin [a-zA-Z0-9_]*?end`. As a further benefit, such regular expressions will run faster than their recursive equivalents.

### search() vs. match()

In a nutshell, `match()` only attempts to match a pattern at the beginning of a string where `search()` will match a pattern anywhere
in a string. For example:

```python
>>> re.match("o", "dog")  # No match as "o" is not the first letter
>>> re.search("o", "dog") # Match as search() looks everywhere.
<_sre.SRE_Match object at ...>"
```

**Note:** The following applies only to regular expression objects like those created with `re.compile("pattern")`, not the primitives `re.match(pattern, string)` or `re.search(pattern, string)`.

`match()` has an optional second parameter that gives an index in the string where the search is to start:

```python
>>> pattern = re.compile("o")
>>> pattern.match("dog")  # No match as "o" is not at the start

# Equivalent to the above expression as 0 is the default starting index: >>> pattern.match("dog", 0)

# Match as "o" is the 2nd character of "dog" (index 0 is the first):
>>> pattern.match("dog", 1) <_sre.SRE_Match object at ...> >>>
>>> pattern.match("dog", 2) # No match as "o" is not the 3rd character of "dog."
```

**Making a Phonebook**

`split()` splits a string into a list delimited by the passed pattern. The method is invaluable for converting textual data into data structures that can be easily read and modified by Python as demonstrated in the following example that creates a phonebook.

First, here is the input. Normally it may come from a file, here we are using triple-quoted string syntax:
The entries are separated by one or more newlines. Now we convert the string into a list with each nonempty line having its own entry:

```python
>>> input = """Ross McFluff: 834.345.1254 155 Elm Street ... Ronal...""
... Ronald Heathmore: 892.345.3428 436 Finley Avenue ... Frank Burger: 925.541.7625 662 South Dogwood Way ... ... Heather Albrecht: 548.326.4584 919 Park Place""
```

The entries are separated by one or more newlines. Now we convert the string into a list with each nonempty line having its own entry:

```python
>>> entries = re.split("\n+", input)
```

Finally, split each entry into a list with first name, last name, telephone number, and address. We use the `maxsplit` parameter of `split()` because the address has spaces, our splitting pattern, in it:

```python
>>> [re.split(":?:", entry, 3) for entry in entries]
[['Ross', 'McFluff', '834.345.1254', '155 Elm Street'], ['Ronald', 'Heathmore', '892.345.3428', '436 Finley Avenue'], ['Frank', 'Burger', '925.541.7625', '662 South Dogwood Way'], ['Heather', 'Albrecht', '548.326.4584', '919 Park Place']]
```

The `:?:` pattern matches the colon after the last name, so that it does not occur in the result list. With a `maxsplit` of 4, we could separate the house number from the street name:

```python
>>> [re.split(":?:", entry, 4) for entry in entries]
[['Ross', 'McFluff', '834.345.1254', '155', 'Elm Street'], ['Ronald', 'Heathmore', '892.345.3428', '436', 'Finley Avenue'], ['Frank', 'Burger', '925.541.7625', '662', 'South Dogwood Way'], ['Heather', 'Albrecht', '548.326.4584', '919', 'Park Place']]
```

Text Munging
sub() replaces every occurrence of a pattern with a string or the result of a function. This example demonstrates using sub() with a function to “munge” text, or randomize the order of all the characters in each word of a sentence except for the first and last characters:

```python
>>> def repl(m):
...     inner_word = list(m.group(2))
...     random.shuffle(inner_word)
...     return m.group(1) + ''.join(inner_word) + m.group(3)

>>> text = "Professor Abdolmalek, please report your absences promptly.

>>> re.sub("(^\w+)(\w+)(\w)+", repl, text)
'Poefsroser Aealmlobdk, pslaee reorpt your abnseces plmrptoy.'

Finding all Adverbs

findall() matches all occurrences of a pattern, not just the first one as search() does. For example, if one was a writer and wanted to find all of the adverbs in some text, he or she might use findall() in the following manner:

```python
>>> text = "He was carefully disguised but captured quickly by police."

>>> re.findall(r"\w+ly", text)
['carefully', 'quickly']
```

```Finding all Adverbs and their Positions

If one wants more information about all matches of a pattern than the matched text, finditer() is useful as it provides instances of MatchObject instead of strings. Continuing with the previous example, if one was a writer who wanted to find all of the adverbs and their positions in some text, he or she would use finditer() in the following manner:

```python
>>> text = "Professor Abdolmalek, please report your absences promptly.

>>> re.finditer(r"\w+ly", text)
< iterator object at 0x12345678 >
```
Raw String Notation

Raw string notation (r"text") keeps regular expressions sane. Without it, every backslash (\') in a regular expression would have to be prefixed with another one to escape it. For example, the two following lines of code are functionally identical:

```python
>>> re.match(r'\W(.)\1\W', " ff ")
<_sre.SRE_Match object at ...>  
```

When one wants to match a literal backslash, it must be escaped in the regular expression. With raw string notation, this means r"\". Without raw string notation, one must use "\\", making the following lines of code functionally identical:

```python
>>> re.match(r"\\", r"\\")
<_sre.SRE_Match object at ...>  
```
struct — Interpret strings as packed binary data

This module performs conversions between Python values and C structs represented as Python strings. It uses format strings (explained below) as compact descriptions of the lay-out of the C structs and the intended conversion to/from Python values. This can be used in handling binary data stored in files or from network connections, among other sources.

The module defines the following exception and functions:

exception struct.error
   Exception raised on various occasions; argument is a string describing what is wrong.

struct.pack(fmt, v1, v2, ...)
   Return a string containing the values \(v_1, v_2, \ldots\) packed according to the given format. The arguments must match the values required by the format exactly.

struct.pack_into(fmt, buffer, offset, v1, v2, ...)
   Pack the values \(v_1, v_2, \ldots\) according to the given format, write the packed bytes into the writable buffer starting at offset. Note that the offset is a required argument.

   New in version 2.5.

struct.unpack(fmt, string)
   Unpack the string (presumably packed by `pack(fmt, ...)`) according to the given format. The result is a tuple even if it contains exactly one item. The string must contain exactly the amount of data required by the format (\(\text{len(string)}\) must equal
calcsize(fmt)).

struct.unpack_from(fmt, buffer[, offset=0])

Unpack the buffer according to the given format. The result is a tuple even if it contains exactly one item. The buffer must contain at least the amount of data required by the format (len(buffer[offset:])) must be at least calcsize(fmt)).

New in version 2.5.

struct.calcsize(fmt)

Return the size of the struct (and hence of the string) corresponding to the given format.

Format characters have the following meaning; the conversion between C and Python values should be obvious given their types:

<table>
<thead>
<tr>
<th>Format</th>
<th>C Type</th>
<th>Python</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>x</td>
<td>pad byte</td>
<td>no value</td>
<td></td>
</tr>
<tr>
<td>c</td>
<td>char</td>
<td>string</td>
<td></td>
</tr>
<tr>
<td>b</td>
<td>signed char</td>
<td>integer</td>
<td></td>
</tr>
<tr>
<td>B</td>
<td>unsigned char</td>

</tr>
<tr>
<td>f</td>
<td>float</td>
<td>float</td>
<td></td>
</tr>
<tr>
<td>d</td>
<td>double</td>
<td>float</td>
<td></td>
</tr>
</tbody>
</table>
Notes:

1. The '??' conversion code corresponds to the _Bool type defined by C99. If this type is not available, it is simulated using a char. In standard mode, it is always represented by one byte.

   New in version 2.6.

2. The 'q' and 'Q' conversion codes are available in native mode only if the platform C compiler supports C long long, or, on Windows, __int64. They are always available in standard modes.

   New in version 2.2.

A format character may be preceded by an integral repeat count. For example, the format string '4h' means exactly the same as 'hhhh'.

Whitespace characters between formats are ignored; a count and its format must not contain whitespace though.

For the 's' format character, the count is interpreted as the size of the string, not a repeat count like for the other format characters; for example, '10s' means a single 10-byte string, while '10c' means 10 characters. For packing, the string is truncated or padded with null bytes as appropriate to make it fit. For unpacking, the resulting string always has exactly the specified number of bytes. As a special case, '0s' means a single, empty string (while '0c' means 0 characters).

The 'p' format character encodes a “Pascal string”, meaning a short variable-length string stored in a fixed number of bytes. The count is
the total number of bytes stored. The first byte stored is the length of the string, or 255, whichever is smaller. The bytes of the string follow. If the string passed in to \texttt{pack()} is too long (longer than the count minus 1), only the leading count-1 bytes of the string are stored. If the string is shorter than count-1, it is padded with null bytes so that exactly count bytes in all are used. Note that for \texttt{unpack()}, the 'p' format character consumes count bytes, but that the string returned can never contain more than 255 characters.

For the 'I', 'L', 'q' and 'Q' format characters, the return value is a Python long integer.

For the 'P' format character, the return value is a Python integer or long integer, depending on the size needed to hold a pointer when it has been cast to an integer type. A \texttt{NULL} pointer will always be returned as the Python integer 0. When packing pointer-sized values, Python integer or long integer objects may be used. For example, the Alpha and Merced processors use 64-bit pointer values, meaning a Python long integer will be used to hold the pointer; other platforms use 32-bit pointers and will use a Python integer.

For the '?' format character, the return value is either \texttt{True} or \texttt{False}. When packing, the truth value of the argument object is used. Either 0 or 1 in the native or standard \texttt{bool} representation will be packed, and any non-zero value will be \texttt{True} when unpacking.

By default, C numbers are represented in the machine's native format and byte order, and properly aligned by skipping pad bytes if necessary (according to the rules used by the C compiler).

Alternatively, the first character of the format string can be used to indicate the byte order, size and alignment of the packed data, according to the following table:
<table>
<thead>
<tr>
<th>Character</th>
<th>Byte order</th>
<th>Size and alignment</th>
</tr>
</thead>
<tbody>
<tr>
<td>@</td>
<td>native</td>
<td>native</td>
</tr>
<tr>
<td>=</td>
<td>native</td>
<td>standard</td>
</tr>
<tr>
<td>&lt;</td>
<td>little-endian</td>
<td>standard</td>
</tr>
<tr>
<td>&gt;</td>
<td>big-endian</td>
<td>standard</td>
</tr>
<tr>
<td>!</td>
<td>network (= big-endian)</td>
<td>standard</td>
</tr>
</tbody>
</table>

If the first character is not one of these, '@' is assumed.

Native byte order is big-endian or little-endian, depending on the host system. For example, Motorola and Sun processors are big-endian; Intel and DEC processors are little-endian.

Native size and alignment are determined using the C compiler's `sizeof` expression. This is always combined with native byte order.

Standard size and alignment are as follows: no alignment is required for any type (so you have to use pad bytes); `short` is 2 bytes; `int` and `long` are 4 bytes; `long long` (`__int64` on Windows) is 8 bytes; `float` and `double` are 32-bit and 64-bit IEEE floating point numbers, respectively. `_Bool` is 1 byte.

Note the difference between '@' and '=': both use native byte order, but the size and alignment of the latter is standardized.

The form '!' is available for those poor souls who claim they can’t remember whether network byte order is big-endian or little-endian.

There is no way to indicate non-native byte order (force byte-swapping); use the appropriate choice of '<' or '>'.

The 'P' format character is only available for the native byte ordering (selected as the default or with the '@' byte order character). The byte order character '=' chooses to use little- or big-
endian ordering based on the host system. The struct module does not interpret this as native ordering, so the `'P'` format is not available.

Examples (all using native byte order, size and alignment, on a big-endian machine):

```python
>>> from struct import *
>>> pack('hhhl', 1, 2, 3)
'\x00\x01\x00\x02\x00\x00\x00\x03'
>>> unpack('hhhl', '\x00\x01\x00\x02\x00\x00\x00\x03')
(1, 2, 3)
>>> calcsize('hhhl')
8
```

Hint: to align the end of a structure to the alignment requirement of a particular type, end the format with the code for that type with a repeat count of zero. For example, the format `'llh0l'` specifies two pad bytes at the end, assuming longs are aligned on 4-byte boundaries. This only works when native size and alignment are in effect; standard size and alignment does not enforce any alignment.

Unpacked fields can be named by assigning them to variables or by wrapping the result in a named tuple:

```python
>>> record = 'raymond \x32\x12\x08\x01\x08'
>>> name, serialnum, school, gradelevel = unpack('<10sHHb', rec
>>> from collections import namedtuple
>>> Student = namedtuple('Student', 'name serialnum school gradelevel')
>>> Student._make(unpack('<10sHHb', s))
Student(name='raymond', serialnum=4658, school=264, gradelevel=8)
```

See also:

- **Module array**
  Packed binary storage of homogeneous data.
- **Module xdrlib**
Packing and unpacking of XDR data.
Struct Objects

The `struct` module also defines the following type:

```python
class struct.Struct(format)
```

Return a new `Struct` object which writes and reads binary data according to the format string `format`. Creating a `Struct` object once and calling its methods is more efficient than calling the `struct` functions with the same format since the format string only needs to be compiled once.

*New in version 2.5.*

Compiled `Struct` objects support the following methods and attributes:

- `pack(v1, v2, ...)`
  Identical to the `pack()` function, using the compiled format. `(len(result) will equal self.size.)`

- `pack_into(buffer, offset, v1, v2, ...)`
  Identical to the `pack_into()` function, using the compiled format.

- `unpack(string)`
  Identical to the `unpack()` function, using the compiled format. `(len(string) must equal self.size).`

- `unpack_from(buffer[, offset=0])`
  Identical to the `unpack_from()` function, using the compiled format. `(len(buffer[offset:]) must be at least self.size).`
The format string used to construct this Struct object.

**size**

The calculated size of the struct (and hence of the string) corresponding to *format*.
difflib — Helpers for computing deltas

New in version 2.1.

This module provides classes and functions for comparing sequences. It can be used for example, for comparing files, and can produce difference information in various formats, including HTML and context and unified diffs. For comparing directories and files, see also, the filecmp module.

class difflib.SequenceMatcher

This is a flexible class for comparing pairs of sequences of any type, so long as the sequence elements are hashable. The basic algorithm predates, and is a little fancier than, an algorithm published in the late 1980’s by Ratcliff and Obershlp under the hyperbolic name “gestalt pattern matching.” The idea is to find the longest contiguous matching subsequence that contains no “junk” elements (the Ratcliff and Obershlp algorithm doesn't address junk). The same idea is then applied recursively to the pieces of the sequences to the left and to the right of the matching subsequence. This does not yield minimal edit sequences, but does tend to yield matches that “look right” to people.

**Timing:** The basic Ratcliff-Obershlp algorithm is cubic time in the worst case and quadratic time in the expected case. SequenceMatcher is quadratic time for the worst case and has expected-case behavior dependent in a complicated way on how many elements the sequences have in common; best case time is linear.

class difflib.Differ
This is a class for comparing sequences of lines of text, and producing human-readable differences or deltas. Differ uses SequenceMatcher both to compare sequences of lines, and to compare sequences of characters within similar (near-matching) lines.

Each line of a Differ delta begins with a two-letter code:

<table>
<thead>
<tr>
<th>Code</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>'-'</td>
<td>line unique to sequence 1</td>
</tr>
<tr>
<td>'+'</td>
<td>line unique to sequence 2</td>
</tr>
<tr>
<td>' '</td>
<td>line common to both sequences</td>
</tr>
<tr>
<td>'?'</td>
<td>line not present in either input sequence</td>
</tr>
</tbody>
</table>

Lines beginning with '?' attempt to guide the eye to intraline differences, and were not present in either input sequence. These lines can be confusing if the sequences contain tab characters.

class difflib.HtmlDiff

This class can be used to create an HTML table (or a complete HTML file containing the table) showing a side by side, line by line comparison of text with inter-line and intra-line change highlights. The table can be generated in either full or contextual difference mode.

The constructor for this class is:

```
__init__(tabsize[, wrapcolumn][, linejunk][, charjunk])
```

Initializes instance of HtmlDiff.

`tabsize` is an optional keyword argument to specify tab stop spacing and defaults to 8.
`wrapcolumn` is an optional keyword to specify column number where lines are broken and wrapped, defaults to `None` where lines are not wrapped.

`linejunk` and `charjunk` are optional keyword arguments passed into `ndiff()` (used by `HtmlDiff` to generate the side by side HTML differences). See `ndiff()` documentation for argument default values and descriptions.

The following methods are public:

```python
make_file(fromlines, tolines[, fromdesc][, todesc][, context][, numlines])
```

Compares `fromlines` and `tolines` (lists of strings) and returns a string which is a complete HTML file containing a table showing line by line differences with inter-line and intra-line changes highlighted.

`fromdesc` and `todesc` are optional keyword arguments to specify from/to file column header strings (both default to an empty string).

`context` and `numlines` are both optional keyword arguments. Set `context` to `True` when contextual differences are to be shown, else the default is `False` to show the full files. `numlines` defaults to 5. When `context` is `True` `numlines` controls the number of context lines which surround the difference highlights. When `context` is `False` `numlines` controls the number of lines which are shown before a difference highlight when using the “next” hyperlinks (setting to zero would cause the “next” hyperlinks to place the next difference highlight at the top of the browser without any leading context).
make_table(fromlines, tolines[, fromdesc][, todesc][, context][, numlines])

Compares fromlines and tolines (lists of strings) and returns a string which is a complete HTML table showing line by line differences with inter-line and intra-line changes highlighted.

The arguments for this method are the same as those for the make_file() method.

Tools/scripts/diff.py is a command-line front-end to this class and contains a good example of its use.

New in version 2.4.

difflib.context_diff(a, b[, fromfile][, tofile][, fromfiledate][, tofiledate][, n][, lineterm])

Compare a and b (lists of strings); return a delta (a generator generating the delta lines) in context diff format.

Context diffs are a compact way of showing just the lines that have changed plus a few lines of context. The changes are shown in a before/after style. The number of context lines is set by n which defaults to three.

By default, the diff control lines (those with *** or ---) are created with a trailing newline. This is helpful so that inputs created from file.readlines() result in diffs that are suitable for use with file.writelines() since both the inputs and outputs have trailing newlines.

For inputs that do not have trailing newlines, set the lineterm argument to "" so that the output will be uniformly newline free.

The context diff format normally has a header for filenames and
modification times. Any or all of these may be specified using strings for `fromfile`, `tofile`, `fromfiledate`, and `tofiledate`. The modification times are normally expressed in the format returned by `time.ctime()`. If not specified, the strings default to blanks.

```python
>>> s1 = ['bacon\n', 'eggs\n', 'ham\n', 'guido\n']
>>> s2 = ['python\n', 'eggy\n', 'hamster\n', 'guido\n']
>>> for line in context_diff(s1, s2, fromfile='before.py', tofile='after.py', fromfiledate='2008-08-08', tofiledate='2008-08-09', fromfiledate='2008-08-08', tofiledate='2008-08-09')
...    sys.stdout.write(line)  # doctest: +NORMALIZE_WHITESPACE
```

See *A command-line interface to difflib* for a more detailed example.

*New in version 2.3.*

`difflib.get_close_matches(word, possibilities[, n][, cutoff])`

Return a list of the best “good enough” matches. `word` is a sequence for which close matches are desired (typically a string), and `possibilities` is a list of sequences against which to match `word` (typically a list of strings).
Optional argument \( n \) (default 3) is the maximum number of close matches to return; \( n \) must be greater than 0.

Optional argument \( \text{cutoff} \) (default 0.6) is a float in the range [0, 1]. Possibilities that don't score at least that similar to \textit{word} are ignored.

The best (no more than \( n \)) matches among the possibilities are returned in a list, sorted by similarity score, most similar first.

```python
>>> get_close_matches('appel', ['ape', 'apple', 'peach', 'puppy', 'apple', 'ape'])
['apple', 'ape']
>>> import keyword
>>> get_close_matches('wheel', keyword.kwlist)
['while']
>>> get_close_matches('apple', keyword.kwlist)
[]
>>> get_close_matches('accept', keyword.kwlist)
['except']
```

\[ \texttt{difflib.\textbf{ndiff}(a, b[, \textit{linejunk}][, \textit{charjunk}])} \]

Compare \( a \) and \( b \) (lists of strings); return a \textbf{Differ}-style delta (a \textit{generator} generating the delta lines).

Optional keyword parameters \textit{linejunk} and \textit{charjunk} are for filter functions (or \texttt{None}):

\textit{linejunk}: A function that accepts a single string argument, and returns true if the string is junk, or false if not. The default is \texttt{(None)}, starting with Python 2.3. Before then, the default was the module-level function \texttt{IS\_LINE\_JUNK()}, which filters out lines without visible characters, except for at most one pound character ('#'). As of Python 2.3, the underlying \texttt{SequenceMatcher}
class does a dynamic analysis of which lines are so frequent as to constitute noise, and this usually works better than the pre-2.3 default.

charjunk: A function that accepts a character (a string of length 1), and returns if the character is junk, or false if not. The default is module-level function IS_CHARACTER_JUNK(), which filters out whitespace characters (a blank or tab; note: bad idea to include newline in this!).

Tools/scripts/ndiff.py is a command-line front-end to this function.

```python
>>> diff = ndiff('one\ntwo\nthree\n'.splitlines(1),
...              'ore\ntree\nemu\n'.splitlines(1))
>>> print ''.join(diff),
 - one
  ? ^
 + ore
  ? ^
 - two
 - three
? -
 + tree
 + emu
```

difflib.restore(sequence, which)

Return one of the two sequences that generated a delta.

Given a sequence produced by Differ.compare() or ndiff(), extract lines originating from file 1 or 2 (parameter which), stripping off line prefixes.

Example:
```python
diff = ndiff('one\ntwo\nthree\n'.splitlines(1),
...                 'ore\ntree\nemu\n'.splitlines(1))
diff = list(diff) # materialize the generated delta into
>>> print ''.join(restore(diff, 1)),
  one
two
  three
>>> print ''.join(restore(diff, 2)),
  ore
tree
  emu
```

`difflib.unified_diff(a, b[, fromfile][, tofile][, fromfiledate][, tofiledate][, n][, lineterm])`

Compare `a` and `b` (lists of strings); return a delta (a generator generating the delta lines) in unified diff format.

Unified diffs are a compact way of showing just the lines that have changed plus a few lines of context. The changes are shown in a inline style (instead of separate before/after blocks). The number of context lines is set by `n` which defaults to three.

By default, the diff control lines (those with `---`, `+++`, or `@@`) are created with a trailing newline. This is helpful so that inputs created from `file.readlines()` result in diffs that are suitable for use with `file.writelines()` since both the inputs and outputs have trailing newlines.

For inputs that do not have trailing newlines, set the `lineterm` argument to `""` so that the output will be uniformly newline free.

The context diff format normally has a header for filenames and modification times. Any or all of these may be specified using
strings for `fromfile`, `tofile`, `fromfiledate`, and `tofiledate`. The modification times are normally expressed in the format returned by `time.ctime()`. If not specified, the strings default to blanks.

```python
>>> s1 = ['bacon
', 'eggs
', 'ham
', 'guido
']
>>> s2 = ['python
', 'eggy
', 'hamster
', 'guido
']
>>> for line in unified_diff(s1, s2, fromfile='before.py', t...
...    sys.stdout.write(line)  # doctest: +NORMALIZE_WHITESPACE
--- before.py
+++ after.py
@@ -1,4 +1,4 @@
-bacon
-eggs
-ham
+python
+eggy
+hamster
-guido

See [A command-line interface to difflib](#) for a more detailed example.

*New in version 2.3.*

difflib.**IS_LINE_JUNK**(line)

Return true for ignorable lines. The line `line` is ignorable if `line` is blank or contains a single `'#'`, otherwise it is not ignorable. Used as a default for parameter `linejunk` in `ndiff()` before Python 2.3.

difflib.**IS_CHARACTER_JUNK**(ch)

Return true for ignorable characters. The character `ch` is ignorable if `ch` is a space or tab, otherwise it is not ignorable. Used as a default for parameter `charjunk` in `ndiff()`.
See also:

**Pattern Matching: The Gestalt Approach**
Discussion of a similar algorithm by John W. Ratcliff and D. E. Metzener. This was published in *Dr. Dobb's Journal* in July, 1988.
SequenceMatcher Objects

The `SequenceMatcher` class has this constructor:

class `difflib.SequenceMatcher([isjunk, a, b])`

Optional argument `isjunk` must be `None` (the default) or a one-argument function that takes a sequence element and returns true if and only if the element is “junk” and should be ignored. Passing `None` for `isjunk` is equivalent to passing `lambda x: 0`; in other words, no elements are ignored. For example, pass:

```python
lambda x: x in " \	"
```

if you’re comparing lines as sequences of characters, and don’t want to synch up on blanks or hard tabs.

The optional arguments `a` and `b` are sequences to be compared; both default to empty strings. The elements of both sequences must be `hashable`.

`SequenceMatcher` objects have the following methods:

`set_seqs(a, b)`
Set the two sequences to be compared.

`SequenceMatcher` computes and caches detailed information about the second sequence, so if you want to compare one sequence against many sequences, use `set_seq2()` to set the commonly used sequence once and call `set_seq1()` repeatedly, once for each of the other sequences.

`set_seq1(a)`
Set the first sequence to be compared. The second sequence
to be compared is not changed.

**set_seq2(b)**

Set the second sequence to be compared. The first sequence to be compared is not changed.

**find_longest_match(alo, ahi, blo, bhi)**

Find longest matching block in a[alo:ahi] and b[blo:bhi].

If *isjunk* was omitted or *None*, `find_longest_match()` returns \((i, j, k)\) such that \(a[i:i+k] = b[j:j+k]\), where \(alo \leq i \leq i+k \leq ahi\) and \(blo \leq j \leq j+k \leq bhi\). For all \((i', j', k')\) meeting those conditions, the additional conditions \(k \geq k', i \leq i', \text{and if } i = i', j \leq j'\) are also met. In other words, of all maximal matching blocks, return one that starts earliest in \(a\), and of all those maximal matching blocks that start earliest in \(a\), return the one that starts earliest in \(b\).

```python
>>> s = SequenceMatcher(None, "abcd", "abcd abcd")
>>> s.find_longest_match(0, 5, 0, 9)
Match(a=0, b=4, size=5)
```

If *isjunk* was provided, first the longest matching block is determined as above, but with the additional restriction that no junk element appears in the block. Then that block is extended as far as possible by matching (only) junk elements on both sides. So the resulting block never matches on junk except as identical junk happens to be adjacent to an interesting match.

Here's the same example as before, but considering blanks to be junk. That prevents `abcd` from matching the `abcd` at the tail end of the second sequence directly. Instead only the `abcd` can match, and matches the leftmost `abcd` in the
second sequence:

```python
g>>> s = SequenceMatcher(lambda x: x==" ", "abcd", "abcd
g>>> s.find_longest_match(0, 5, 0, 9)
Match(a=1, b=0, size=4)
```

If no blocks match, this returns (a0, b0, 0).

*Changed in version 2.6:* This method returns a *named tuple*
Match(a, b, size).

**get_matching_blocks()**

Return list of triples describing matching subsequences. Each triple is of the form (i, j, n), and means that a[i:i+n] == b[j:j+n]. The triples are monotonically increasing in i and j.

The last triple is a dummy, and has the value (len(a), len(b), 0). It is the only triple with n == 0. If (i, j, n) and (i', j', n') are adjacent triples in the list, and the second is not the last triple in the list, then i+n != i' or j+n != j'; in other words, adjacent triples always describe non-adjacent equal blocks.

*Changed in version 2.5:* The guarantee that adjacent triples always describe non-adjacent blocks was implemented.

```python
g>>> s = SequenceMatcher(None, "abxcd", "abcd")
g>>> s.get_matching_blocks()
[Match(a=0, b=0, size=2), Match(a=3, b=2, size=2), Match(a=5, b=4, size=0)]
```

**get_opcodes()**

Return list of 5-tuples describing how to turn a into b. Each tuple is of the form (tag, i1, i2, j1, j2). The first tuple has
\( i_1 = j_1 = 0 \), and remaining tuples have \( i_1 \) equal to the \( i_2 \) from the preceding tuple, and, likewise, \( j_1 \) equal to the previous \( j_2 \).

The *tag* values are strings, with these meanings:

<table>
<thead>
<tr>
<th>Value</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>'replace'</td>
<td>( a[i_1:i_2] ) should be replaced by ( b[j_1:j_2] ).</td>
</tr>
<tr>
<td>'delete'</td>
<td>( a[i_1:i_2] ) should be deleted. Note that ( j_1 = j_2 ) in this case.</td>
</tr>
<tr>
<td>'insert'</td>
<td>( b[j_1:j_2] ) should be inserted at ( a[i_1:i_1] ). Note that ( i_1 = i_2 ) in this case.</td>
</tr>
<tr>
<td>'equal'</td>
<td>( a[i_1:i_2] = b[j_1:j_2] ) (the sub-sequences are equal).</td>
</tr>
</tbody>
</table>

For example:

```python
>>> a = "qabxcd"
>>> b = "abycdf"
>>> s = SequenceMatcher(None, a, b)
>>> for tag, i1, i2, j1, j2 in s.get_opcodes():
...     print ("%7s a[%d:%d] (%s) b[%d:%d] (%s)" %
...     (tag, i1, i2, a[i1:i2], j1, j2, b[j1:j2]))

delete a[0:1] (q) b[0:0] ()
equal a[1:3] (ab) b[0:2] (ab)
replace a[3:4] (x) b[2:3] (y)
```

get_grouped_opcodes([\( n \)])

Return a *generator* of groups with up to \( n \) lines of context.

Starting with the groups returned by *get_opcodes()*, this method splits out smaller change clusters and eliminates intervening ranges which have no changes.
The groups are returned in the same format as `get_opcodes()`.

*New in version 2.3.*

**ratio()**

Return a measure of the sequences’ similarity as a float in the range [0, 1].

Where T is the total number of elements in both sequences, and M is the number of matches, this is \(2.0 \times M / T\). Note that this is 1.0 if the sequences are identical, and 0.0 if they have nothing in common.

This is expensive to compute if `get_matching_blocks()` or `get_opcodes()` hasn’t already been called, in which case you may want to try `quick_ratio()` or `real_quick_ratio()` first to get an upper bound.

**quick_ratio()**

Return an upper bound on `ratio()` relatively quickly.

This isn’t defined beyond that it is an upper bound on `ratio()`, and is faster to compute.

**real_quick_ratio()**

Return an upper bound on `ratio()` very quickly.

This isn’t defined beyond that it is an upper bound on `ratio()`, and is faster to compute than either `ratio()` or `quick_ratio()`.

The three methods that return the ratio of matching to total characters can give different results due to differing levels of approximation, although `quick_ratio()` and `real_quick_ratio()` are
always at least as large as `ratio()`:

```python
>>> s = SequenceMatcher(None, "abcd", "bcde")
>>> s.ratio()
0.75
>>> s.quick_ratio()
0.75
>>> s.real_quick_ratio()
1.0
```
This example compares two strings, considering blanks to be “junk:”

```python
>>> s = SequenceMatcher(lambda x: x == " ",
                      "private Thread currentThread;",
                      "private volatile Thread currentThread;")
```

`ratio()` returns a float in [0, 1], measuring the similarity of the sequences. As a rule of thumb, a `ratio()` value over 0.6 means the sequences are close matches:

```python
>>> print round(s.ratio(), 3)
0.866
```

If you’re only interested in where the sequences match, `get_matching_blocks()` is handy:

```python
>>> for block in s.get_matching_blocks():
    ...   print "a[%d] and b[%d] match for %d elements" % block
a[0] and b[0] match for 8 elements
a[8] and b[17] match for 21 elements
a[29] and b[38] match for 0 elements
```

Note that the last tuple returned by `get_matching_blocks()` is always a dummy, `(len(a), len(b), 0)`, and this is the only case in which the last tuple element (number of elements matched) is 0.

If you want to know how to change the first sequence into the second, use `get_opcodes()`:

```python
>>> for opcode in s.get_opcodes():
    ...    print "%6s a[%d:%d] b[%d:%d]" % opcode
    equal a[0:8] b[0:8]
    insert a[8:8] b[8:17]
    equal a[8:29] b[17:38]
```
See also the function `get_close_matches()` in this module, which shows how simple code building on `SequenceMatcher` can be used to do useful work.
Differ Objects

Note that **Differ**-generated deltas make no claim to be **minimal** diffs. To the contrary, minimal diffs are often counter-intuitive, because they synch up anywhere possible, sometimes accidental matches 100 pages apart. Restricting synch points to contiguous matches preserves some notion of locality, at the occasional cost of producing a longer diff.

The **Differ** class has this constructor:

```python
class difflib.Differ([linejunk[, charjunk]])
```

Optional keyword parameters `linejunk` and `charjunk` are for filter functions (or `None`):

- **linejunk**: A function that accepts a single string argument, and returns true if the string is junk. The default is `None`, meaning that no line is considered junk.

- **charjunk**: A function that accepts a single character argument (a string of length 1), and returns true if the character is junk. The default is `None`, meaning that no character is considered junk.

**Differ** objects are used (deltas generated) via a single method:

```python
cmpare(a, b)
```

Compare two sequences of lines, and generate the delta (a sequence of lines).

Each sequence must contain individual single-line strings ending with newlines. Such sequences can be obtained from the `readlines()` method of file-like objects. The delta generated also consists of newline-terminated strings, ready
to be printed as-is via the `writelines()` method of a file-like object.
Differ Example

This example compares two texts. First we set up the texts, sequences of individual single-line strings ending with newlines (such sequences can also be obtained from the `readlines()` method of file-like objects):

```python
>>> text1 = '''  1. Beautiful is better than ugly.
...    2. Explicit is better than implicit.
...    3. Simple is better than complex.
...    4. Complex is better than complicated.
...  '''.splitlines(1)
>>> len(text1)
4
>>> text1[0][-1]
'\n'
```

```python
>>> text2 = '''  1. Beautiful is better than ugly.
...    3. Simple is better than complex.
...    4. Complicated is better than complex.
...    5. Flat is better than nested.
...  '''.splitlines(1)
```

Next we instantiate a Differ object:

```python
>>> d = Differ()
```

Note that when instantiating a `Differ` object we may pass functions to filter out line and character “junk.” See the `Differ()` constructor for details.

Finally, we compare the two:

```python
>>> result = list(d.compare(text1, text2))
```

`result` is a list of strings, so let’s pretty-print it:

```python
>>> from pprint import pprint
>>> pprint(result)
```
As a single multi-line string it looks like this:

```python
>>> import sys
>>> sys.stdout.writelines(result)
1. Beautiful is better than ugly.
- 2. Explicit is better than implicit.
- 3. Simple is better than complex.
+ 3. Simple is better than complex.
? ++
- 4. Complex is better than complicated.
? ^ ---- ^
+ 4. Complicated is better than complex.
? ++++ ^
+ 5. Flat is better than nested.
```
A command-line interface to difflib

This example shows how to use difflib to create a diff-like utility. It is also contained in the Python source distribution, as Tools/scripts/diff.py.

""" Command line interface to difflib.py providing diffs in four formats:
* ndiff: lists every line and highlights interline changes.
* context: highlights clusters of changes in a before/after format.
* unified: highlights clusters of changes in an inline format.
* html: generates side by side comparison with change highlights.
"""

import sys, os, time, difflib, optparse

def main():
    # Configure the option parser
    usage = "usage: %prog [options] fromfile tofile"
    parser = optparse.OptionParser(usage)
    parser.add_option("-c", action="store_true", default=False,
                      help='Produce a context format diff (default)
                      parser.add_option("-u", action="store_true", default=False,
                      help='Produce a unified format diff')
    hlp = 'Produce HTML side by side diff (can use -c and -l in
    parser.add_option("-m", action="store_true", default=False,
    parser.add_option("-n", action="store_true", default=False,
    help='Produce a ndiff format diff')
    parser.add_option("-1", "--lines", type="int", default=3,
                      help='Set number of context lines (default)
      (options, args) = parser.parse_args()

      if len(args) == 0:
          parser.print_help()
          sys.exit(1)
      if len(args) != 2:
          parser.error("need to specify both a fromfile and tofile")

      n = options.lines
      fromfile, tofile = args # as specified in the usage string

      # we're passing these as arguments to the diff function
      fromdate = time.ctime(os.stat(fromfile).st_mtime)
      todate = time.ctime(os.stat(tofile).st_mtime)
fromlines = open(fromfile, 'U').readlines()
tolines = open(tofile, 'U').readlines()

if options.u:
    diff = difflib.unified_diff(fromlines, tolines, fromfile, tofile, fromdate, todate, n=n)
elif options.n:
    diff = difflib.ndiff(fromlines, tolines)
elif options.m:
    diff = difflib.HtmlDiff().make_file(fromlines, tolines, tofile, context=opt
numlines=n)
else:
    diff = difflib.context_diff(fromlines, tolines, fromfile, tofile, fromdate, todate, n=n)

    # we're using writelines because diff is a generator
sys.stdout.writelines(diff)

if __name__ == '__main__':
    main()
This module implements a file-like class, `StringIO`, that reads and writes a string buffer (also known as memory files). See the description of file objects for operations (section File Objects). (For standard strings, see `str` and `unicode`.)

```python
class StringIO:

    When a `StringIO` object is created, it can be initialized to an existing string by passing the string to the constructor. If no string is given, the `StringIO` will start empty. In both cases, the initial file position starts at zero.

    The `StringIO` object can accept either Unicode or 8-bit strings, but mixing the two may take some care. If both are used, 8-bit strings that cannot be interpreted as 7-bit ASCII (that use the 8th bit) will cause a `UnicodeError` to be raised when `getvalue()` is called.

The following methods of `StringIO` objects require special mention:

`StringIO.getvalue()` Retrieve the entire contents of the “file” at any time before the `StringIO` object’s `close()` method is called. See the note above for information about mixing Unicode and 8-bit strings; such mixing can cause this method to raise `UnicodeError`.

`StringIO.close()` Free the memory buffer.
```

Example usage:
import StringIO

output = StringIO.StringIO()
output.write('First line.
')
print >>output, 'Second line.'

# Retrieve file contents -- this will be
# 'First line.
Second line.
'
contents = output.getvalue()

# Close object and discard memory buffer --
# .getvalue() will now raise an exception.
output.close()
The module `cStringIO` provides an interface similar to that of the `StringIO` module. Heavy use of `StringIO.StringIO` objects can be made more efficient by using the function `StringIO()` from this module instead.

Since this module provides a factory function which returns objects of built-in types, there's no way to build your own version using subclassing. Use the original `StringIO` module in that case.

Unlike the memory files implemented by the `StringIO` module, those provided by this module are not able to accept Unicode strings that cannot be encoded as plain ASCII strings.

Calling `StringIO()` with a Unicode string parameter populates the object with the buffer representation of the Unicode string, instead of encoding the string.

Another difference from the `StringIO` module is that calling `StringIO()` with a string parameter creates a read-only object. Unlike an object created without a string parameter, it does not have write methods. These objects are not generally visible. They turn up in tracebacks as `StringI` and `StringO`.

The following data objects are provided as well:

- `cStringIO.InputType`  
  The type object of the objects created by calling `StringIO()` with a string parameter.

- `cStringIO.OutputType`
The type object of the objects returned by calling `StringIO()` with no parameters.

There is a C API to the module as well; refer to the module source for more information.

Example usage:

```python
import cStringIO

output = cStringIO.StringIO()
output.write('First line.
')
print >>output, 'Second line.'

# Retrieve file contents -- this will be
# 'First line.
Second line.
' contents = output.getvalue()

# Close object and discard memory buffer --
# .getvalue() will now raise an exception.
output.close()
```
**textwrap — Text wrapping and filling**

*New in version 2.3.*

The `textwrap` module provides two convenience functions, `wrap()` and `fill()`, as well as `TextWrapper`, the class that does all the work, and a utility function `dedent()`. If you're just wrapping or filling one or two text strings, the convenience functions should be good enough; otherwise, you should use an instance of `TextWrapper` for efficiency.

```
wrap(text[, width[, ...]])
```

Wraps the single paragraph in `text` (a string) so every line is at most `width` characters long. Returns a list of output lines, without final newlines.

Optional keyword arguments correspond to the instance attributes of `TextWrapper`, documented below. `width` defaults to 70.

```
fill(text[, width[, ...]])
```

Wraps the single paragraph in `text`, and returns a single string containing the wrapped paragraph. `fill()` is shorthand for

```
"\n".join(wrap(text, ...))
```

In particular, `fill()` accepts exactly the same keyword arguments as `wrap()`.

Both `wrap()` and `fill()` work by creating a `TextWrapper` instance and calling a single method on it. That instance is not reused, so for applications that wrap/fill many text strings, it will be more efficient for you to create your own `TextWrapper` object.
Text is preferably wrapped on whitespaces and right after the hyphens in hyphenated words; only then will long words be broken if necessary, unless `TextWrapper.break_long_words` is set to false.

An additional utility function, `dedent()`, is provided to remove indentation from strings that have unwanted whitespace to the left of the text.

```python
def test():
    # end first line with \ to avoid the empty line!
    s = '  
    hello
    world
    
    print repr(s)  # prints '  hello
    print repr(dedent(s))  # prints 'hello

```

Note that tabs and spaces are both treated as whitespace, but they are not equal: the lines "  hello" and "\thello" are considered to have no common leading whitespace. (This behaviour is new in Python 2.5; older versions of this module incorrectly expanded tabs before searching for common leading whitespace.)

For example:
The `TextWrapper` constructor accepts a number of optional keyword arguments. Each argument corresponds to one instance attribute, so for example

```python
wrapper = TextWrapper(initial_indent="* ")
```

is the same as

```python
wrapper = TextWrapper()
wrapper.initial_indent = "* "
```

You can re-use the same `TextWrapper` object many times, and you can change any of its options through direct assignment to instance attributes between uses.

The `TextWrapper` instance attributes (and keyword arguments to the constructor) are as follows:

- **width**
  (default: 70) The maximum length of wrapped lines. As long as there are no individual words in the input text longer than `width`, `TextWrapper` guarantees that no output line will be longer than `width` characters.

- **expand_tabs**
  (default: True) If true, then all tab characters in `text` will be expanded to spaces using the `expandtabs()` method of `text`.

- **replace_whitespace**
  (default: True) If true, each whitespace character (as defined by `string.whitespace`) remaining after tab expansion will be replaced by a single space.

**Note:** If `expand_tabs` is false and `replace_whitespace` is true, each tab character will be replaced by a single space,
which is not the same as tab expansion.

**drop_whitespace**
(default: True) If true, whitespace that, after wrapping, happens to end up at the beginning or end of a line is dropped (leading whitespace in the first line is always preserved, though).

*New in version 2.6:* Whitespace was always dropped in earlier versions.

**initial_indent**
(default: '') String that will be prepended to the first line of wrapped output. Counts towards the length of the first line.

**subsequent_indent**
(default: '') String that will be prepended to all lines of wrapped output except the first. Counts towards the length of each line except the first.

**fix_sentence_endings**
(default: False) If true, TextWrapper attempts to detect sentence endings and ensure that sentences are always separated by exactly two spaces. This is generally desired for text in a monospaced font. However, the sentence detection algorithm is imperfect: it assumes that a sentence ending consists of a lowercase letter followed by one of '.', '!', or '?', possibly followed by one of '”' or '‘', followed by a space. One problem with this algorithm is that it is unable to detect the difference between “Dr.” in

... Dr. Frankenstein's monster ...

and “Spot.” in
See Spot. See Spot run ...

**fix_sentence_endings** is false by default.

Since the sentence detection algorithm relies on **string.lowercase** for the definition of “lowercase letter,” and a convention of using two spaces after a period to separate sentences on the same line, it is specific to English-language texts.

**break_long_words**

(default: True) If true, then words longer than **width** will be broken in order to ensure that no lines are longer than **width**. If it is false, long words will not be broken, and some lines may be longer than **width**. (Long words will be put on a line by themselves, in order to minimize the amount by which **width** is exceeded.)

**break_on_hyphens**

(default: True) If true, wrapping will occur preferably on whitespaces and right after hyphens in compound words, as it is customary in English. If false, only whitespaces will be considered as potentially good places for line breaks, but you need to set **break_long_words** to false if you want truly inseparable words. Default behaviour in previous versions was to always allow breaking hyphenated words.

*New in version 2.6.*

**TextWrapper** also provides two public methods, analogous to the module-level convenience functions:

**wrap(text)**

Wraps the single paragraph in **text** (a string) so every line is at
most **width** characters long. All wrapping options are taken from instance attributes of the `TextWrapper` instance. Returns a list of output lines, without final newlines.

**fill**(text)

Wraps the single paragraph in `text`, and returns a single string containing the wrapped paragraph.
This module defines base classes for standard Python codecs (encoders and decoders) and provides access to the internal Python codec registry which manages the codec and error handling lookup process.

It defines the following functions:

```python
codecs.register(search_function)
```

Register a codec search function. Search functions are expected to take one argument, the encoding name in all lower case letters, and return a `CodecInfo` object having the following attributes:

- `name` The name of the encoding;
- `encoder` The stateless encoding function;
- `decoder` The stateless decoding function;
- `incrementalencoder` An incremental encoder class or factory function;
- `incrementaldecoder` An incremental decoder class or factory function;
- `streamwriter` A stream writer class or factory function;
- `streamreader` A stream reader class or factory function.

The various functions or classes take the following arguments:

- `encoder` and `decoder`: These must be functions or methods which have the same interface as the `encode()`/`decode()` methods of Codec instances (see Codec Interface). The functions/methods are expected to work in a stateless mode.
incrementalencoder and incrementaldecoder: These have to be factory functions providing the following interface:

```
factory(errors='strict')
```

The factory functions must return objects providing the interfaces defined by the base classes IncrementalEncoder and IncrementalDecoder, respectively. Incremental codecs can maintain state.

streamreader and streamwriter: These have to be factory functions providing the following interface:

```
factory(stream, errors='strict')
```

The factory functions must return objects providing the interfaces defined by the base classes StreamWriter and StreamReader, respectively. Stream codecs can maintain state.

Possible values for errors are 'strict' (raise an exception in case of an encoding error), 'replace' (replace malformed data with a suitable replacement marker, such as '?'), 'ignore' (ignore malformed data and continue without further notice), 'xmlcharrefreplace' (replace with the appropriate XML character reference (for encoding only)) and 'backslashreplace' (replace with backslashed escape sequences (for encoding only)) as well as any other error handling name defined via register_error().

In case a search function cannot find a given encoding, it should return None.

codecs. lookup(encoding)

Looks up the codec info in the Python codec registry and returns a CodecInfo object as defined above.
Encodings are first looked up in the registry’s cache. If not found, the list of registered search functions is scanned. If no CodecInfo object is found, a LookupError is raised. Otherwise, the CodecInfo object is stored in the cache and returned to the caller.

To simplify access to the various codecs, the module provides these additional functions which use lookup() for the codec lookup:

```python
codecs.getencoder(encoding)
```

Look up the codec for the given encoding and return its encoder function.

Raises a LookupError in case the encoding cannot be found.

```python
codecs.getdecoder(encoding)
```

Look up the codec for the given encoding and return its decoder function.

Raises a LookupError in case the encoding cannot be found.

```python
codecs.getincrementalencoder(encoding)
```

Look up the codec for the given encoding and return its incremental encoder class or factory function.

Raises a LookupError in case the encoding cannot be found or the codec doesn’t support an incremental encoder.

*New in version 2.5.*

```python
codecs.getincrementaldecoder(encoding)
```

Look up the codec for the given encoding and return its incremental decoder class or factory function.

Raises a LookupError in case the encoding cannot be found or the codec doesn’t support an incremental decoder.
New in version 2.5.

codecs.getreader(encoding)
Look up the codec for the given encoding and return its StreamReader class or factory function.

Raises a LookupError in case the encoding cannot be found.

codecs.getWriter(encoding)
Look up the codec for the given encoding and return its StreamWriter class or factory function.

Raises a LookupError in case the encoding cannot be found.

codecs.register_error(name, error_handler)
Register the error handling function error_handler under the name name. error_handler will be called during encoding and decoding in case of an error, when name is specified as the errors parameter.

For encoding error_handler will be called with a UnicodeEncodeError instance, which contains information about the location of the error. The error handler must either raise this or a different exception or return a tuple with a replacement for the unencodable part of the input and a position where encoding should continue. The encoder will encode the replacement and continue encoding the original input at the specified position. Negative position values will be treated as being relative to the end of the input string. If the resulting position is out of bound an IndexError will be raised.

Decoding and translating works similar, except UnicodeDecodeError or UnicodeTranslateError will be passed to the handler and that the replacement from the error handler will be put into the output directly.
codecs. **lookup_error**(name)

Return the error handler previously registered under the name name.

Raises a LookupError in case the handler cannot be found.

codecs. **strict_errors**(exception)

Implements the strict error handling.

codecs. **replace_errors**(exception)

Implements the replace error handling.

codecs. **ignore_errors**(exception)

Implements the ignore error handling.

codecs. **xmlcharrefreplace_errors**(exception)

Implements the xmlcharrefreplace error handling.

codecs. **backslashreplace_errors**(exception)

Implements the backslashreplace error handling.

To simplify working with encoded files or stream, the module also defines these utility functions:

codecs. **open**(filename, mode[, encoding[, errors[, buffering]]])

Open an encoded file using the given mode and return a wrapped version providing transparent encoding/decoding. The default file mode is 'r' meaning to open the file in read mode.

**Note:** The wrapped version will only accept the object format defined by the codecs, i.e. Unicode objects for most built-in codecs. Output is also codec-dependent and will usually be Unicode as well.
**Note:** Files are always opened in binary mode, even if no binary mode was specified. This is done to avoid data loss due to encodings using 8-bit values. This means that no automatic conversion of '\n' is done on reading and writing.

*encoding* specifies the encoding which is to be used for the file.

*errors* may be given to define the error handling. It defaults to *strict* which causes a *ValueError* to be raised in case an encoding error occurs.

*buffering* has the same meaning as for the built-in *open()* function. It defaults to line buffered.

codecs.*EncodedFile*(file, input[, output[, errors]])

Return a wrapped version of file which provides transparent encoding translation.

Strings written to the wrapped file are interpreted according to the given *input* encoding and then written to the original file as strings using the *output* encoding. The intermediate encoding will usually be Unicode but depends on the specified codecs.

If *output* is not given, it defaults to *input*.

*errors* may be given to define the error handling. It defaults to *strict*, which causes *ValueError* to be raised in case an encoding error occurs.

codecs.*iterencode*(iterable[, encoding[, errors]])

Uses an incremental encoder to iteratively encode the input provided by *iterable*. This function is a *generator*. *errors* (as well as any other keyword argument) is passed through to the incremental encoder.
**New in version 2.5.**

codecs.iterdecode(iterable, encoding[, errors])

Uses an incremental decoder to iteratively decode the input provided by iterable. This function is a generator. errors (as well as any other keyword argument) is passed through to the incremental decoder.

**New in version 2.5.**

The module also provides the following constants which are useful for reading and writing to platform dependent files:

```python
codecs.BOM
 codecs.BOM_BE
 codecs.BOM_LE
 codecs.BOM_UTF8
 codecs.BOM_UTF16
 codecs.BOM_UTF16_BE
 codecs.BOM_UTF16_LE
 codecs.BOM_UTF32
 codecs.BOM_UTF32_BE
 codecs.BOM_UTF32_LE
```

These constants define various encodings of the Unicode byte order mark (BOM) used in UTF-16 and UTF-32 data streams to indicate the byte order used in the stream or file and in UTF-8 as a Unicode signature. BOM_UTF16 is either BOM_UTF16_BE or BOM_UTF16_LE depending on the platform's native byte order, BOM is an alias for BOM_UTF16, BOM_LE for BOM_UTF16_LE and BOM_BE for BOM_UTF16_BE. The others represent the BOM in UTF-8 and UTF-32 encodings.
Codec Base Classes

The **codecs** module defines a set of base classes which define the interface and can also be used to easily write your own codecs for use in Python.

Each codec has to define four interfaces to make it usable as codec in Python: stateless encoder, stateless decoder, stream reader and stream writer. The stream reader and writers typically reuse the stateless encoder/decoder to implement the file protocols.

The **Codec** class defines the interface for stateless encoders/decoders.

To simplify and standardize error handling, the **encode()** and **decode()** methods may implement different error handling schemes by providing the **errors** string argument. The following string values are defined and implemented by all standard Python codecs:

<table>
<thead>
<tr>
<th>Value</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>'strict'</td>
<td>Raise <strong>UnicodeError</strong> (or a subclass); this is the default.</td>
</tr>
<tr>
<td>'ignore'</td>
<td>Ignore the character and continue with the next.</td>
</tr>
<tr>
<td>'replace'</td>
<td>Replace with a suitable replacement character; Python will use the official U+FFFD REPLACEMENT CHARACTER for the built-in Unicode codecs on decoding and ‘?’ on encoding.</td>
</tr>
<tr>
<td>'xmlcharrefreplace'</td>
<td>Replace with the appropriate XML character reference (only for encoding).</td>
</tr>
<tr>
<td>'backslashreplace'</td>
<td>Replace with backslashed escape sequences (only for encoding).</td>
</tr>
</tbody>
</table>
Codec Objects

The `Codec` class defines these methods which also define the function interfaces of the stateless encoder and decoder:

```python
Codec.encode(input[, errors])
```

Encodes the object `input` and returns a tuple (output object, length consumed). While codecs are not restricted to use with Unicode, in a Unicode context, encoding converts a Unicode object to a plain string using a particular character set encoding (e.g., `cp1252` or `iso-8859-1`).

`errors` defines the error handling to apply. It defaults to `'strict'` handling.

The method may not store state in the `Codec` instance. Use `StreamCodec` for codecs which have to keep state in order to make encoding/decoding efficient.

The encoder must be able to handle zero length input and return an empty object of the output object type in this situation.

```python
Codec.decode(input[, errors])
```

Decodes the object `input` and returns a tuple (output object, length consumed). In a Unicode context, decoding converts a plain string encoded using a particular character set encoding to a Unicode object.

`input` must be an object which provides the `bf_getreadbuf` buffer slot. Python strings, buffer objects and memory mapped files are examples of objects providing this slot.
errors defines the error handling to apply. It defaults to 'strict' handling.

The method may not store state in the Codec instance. Use StreamCodec for codecs which have to keep state in order to make encoding/decoding efficient.

The decoder must be able to handle zero length input and return an empty object of the output object type in this situation.

The IncrementalEncoder and IncrementalDecoder classes provide the basic interface for incremental encoding and decoding. Encoding/decoding the input isn't done with one call to the stateless encoder/decoder function, but with multiple calls to the encode()/decode() method of the incremental encoder/decoder. The incremental encoder/decoder keeps track of the encoding/decoding process during method calls.

The joined output of calls to the encode()/decode() method is the same as if all the single inputs were joined into one, and this input was encoded/decoded with the stateless encoder/decoder.

### IncrementalEncoder Objects

*New in version 2.5.*

The IncrementalEncoder class is used for encoding an input in multiple steps. It defines the following methods which every incremental encoder must define in order to be compatible with the Python codec registry.

```python
class codecs.IncrementalEncoder([errors])
    Constructor for an IncrementalEncoder instance.
```
All incremental encoders must provide this constructor interface. They are free to add additional keyword arguments, but only the ones defined here are used by the Python codec registry.

The **IncrementalEncoder** may implement different error handling schemes by providing the `errors` keyword argument. These parameters are predefined:

- 'strict' Raise `ValueError` (or a subclass); this is the default.
- 'ignore' Ignore the character and continue with the next.
- 'replace' Replace with a suitable replacement character
- 'xmlcharrefreplace' Replace with the appropriate XML character reference
- 'backslashreplace' Replace with backslashed escape sequences.

The `errors` argument will be assigned to an attribute of the same name. Assigning to this attribute makes it possible to switch between different error handling strategies during the lifetime of the **IncrementalEncoder** object.

The set of allowed values for the `errors` argument can be extended with `register_error()`.

```python
encode(object[, final])
```

Encodes `object` (taking the current state of the encoder into account) and returns the resulting encoded object. If this is the last call to `encode()` `final` must be true (the default is false).

```python
reset()
```

Reset the encoder to the initial state.
The **IncrementalDecoder** class is used for decoding an input in multiple steps. It defines the following methods which every incremental decoder must define in order to be compatible with the Python codec registry.

```python
class codecs.IncrementalDecoder([errors])
    Constructor for an IncrementalDecoder instance.
```

All incremental decoders must provide this constructor interface. They are free to add additional keyword arguments, but only the ones defined here are used by the Python codec registry.

The **IncrementalDecoder** may implement different error handling schemes by providing the `errors` keyword argument. These parameters are predefined:

- **'strict'** Raise `ValueError` (or a subclass); this is the default.
- **'ignore'** Ignore the character and continue with the next.
- **'replace'** Replace with a suitable replacement character.

The `errors` argument will be assigned to an attribute of the same name. Assigning to this attribute makes it possible to switch between different error handling strategies during the lifetime of the **IncrementalDecoder** object.

The set of allowed values for the `errors` argument can be extended with `register_error()`.

```python
decode(object[, final])
    Decodes `object` (taking the current state of the decoder into account) and returns the resulting decoded object. If this is
the last call to `decode()` `final` must be true (the default is false). If `final` is true the decoder must decode the input completely and must flush all buffers. If this isn’t possible (e.g. because of incomplete byte sequences at the end of the input) it must initiate error handling just like in the stateless case (which might raise an exception).

```python
reset()
```

Reset the decoder to the initial state.

The `StreamWriter` and `StreamReader` classes provide generic working interfaces which can be used to implement new encoding submodules very easily. See `encodings.utf_8` for an example of how this is done.

## StreamWriter Objects

The `StreamWriter` class is a subclass of `codec` and defines the following methods which every stream writer must define in order to be compatible with the Python codec registry.

```python
class codecs.StreamWriter(stream[, errors])

Constructor for a `StreamWriter` instance.
```

All stream writers must provide this constructor interface. They are free to add additional keyword arguments, but only the ones defined here are used by the Python codec registry.

- `stream` must be a file-like object open for writing binary data.

The `StreamWriter` may implement different error handling schemes by providing the `errors` keyword argument. These parameters are predefined:

- `'strict'` Raise `ValueError` (or a subclass); this is the
default.

- `'ignore'` Ignore the character and continue with the next.
- `'replace'` Replace with a suitable replacement character
- `'xmlcharrefreplace'` Replace with the appropriate XML character reference
- `'backslashreplace'` Replace with backslashed escape sequences.

The *errors* argument will be assigned to an attribute of the same name. Assigning to this attribute makes it possible to switch between different error handling strategies during the lifetime of the `StreamWriter` object.

The set of allowed values for the *errors* argument can be extended with `register_error()`.

**write**(object)

Writes the object's contents encoded to the stream.

**writelines**(list)

Writes the concatenated list of strings to the stream (possibly by reusing the `write()` method).

**reset()**

Flushes and resets the codec buffers used for keeping state.

Calling this method should ensure that the data on the output is put into a clean state that allows appending of new fresh data without having to rescan the whole stream to recover state.

In addition to the above methods, the `StreamWriter` must also inherit all other methods and attributes from the underlying stream.

StreamReader Objects
The `StreamReader` class is a subclass of `codec` and defines the following methods which every stream reader must define in order to be compatible with the Python codec registry.

```python
class codecs.StreamReader(stream[, errors])
```
Constructor for a `StreamReader` instance.

All stream readers must provide this constructor interface. They are free to add additional keyword arguments, but only the ones defined here are used by the Python codec registry.

`stream` must be a file-like object open for reading (binary) data.

The `StreamReader` may implement different error handling schemes by providing the `errors` keyword argument. These parameters are defined:

- `'strict'` Raise `ValueError` (or a subclass); this is the default.
- `'ignore'` Ignore the character and continue with the next.
- `'replace'` Replace with a suitable replacement character.

The `errors` argument will be assigned to an attribute of the same name. Assigning to this attribute makes it possible to switch between different error handling strategies during the lifetime of the `StreamReader` object.

The set of allowed values for the `errors` argument can be extended with `register_error()`.

```python
read([size[, chars[, firstline]]])
```
Decodes data from the stream and returns the resulting object.

`chars` indicates the number of characters to read from the
stream. **read()** will never return more than *chars* characters, but it might return less, if there are not enough characters available.

*size* indicates the approximate maximum number of bytes to read from the stream for decoding purposes. The decoder can modify this setting as appropriate. The default value -1 indicates to read and decode as much as possible. *size* is intended to prevent having to decode huge files in one step.

*firstline* indicates that it would be sufficient to only return the first line, if there are decoding errors on later lines.

The method should use a greedy read strategy meaning that it should read as much data as is allowed within the definition of the encoding and the given size, e.g. if optional encoding endings or state markers are available on the stream, these should be read too.

*Changed in version 2.4: chars argument added.*

*Changed in version 2.4.2: firstline argument added.*

**readline((**[size[, keepends]])**

Read one line from the input stream and return the decoded data.

*size*, if given, is passed as size argument to the stream’s **readline()** method.

If *keepends* is false line-endings will be stripped from the lines returned.

*Changed in version 2.4: keepends argument added.*

**readlines([**[sizehint[, keepends]]**})**
Read all lines available on the input stream and return them as a list of lines.

Line-endings are implemented using the codec's decoder method and are included in the list entries if keepends is true.

sizehint, if given, is passed as the size argument to the stream's read() method.

reset()
Resets the codec buffers used for keeping state.

Note that no stream repositioning should take place. This method is primarily intended to be able to recover from decoding errors.

In addition to the above methods, the StreamReader must also inherit all other methods and attributes from the underlying stream.

The next two base classes are included for convenience. They are not needed by the codec registry, but may provide useful in practice.

**StreamReaderWriter Objects**

The StreamReaderWriter allows wrapping streams which work in both read and write modes.

The design is such that one can use the factory functions returned by the lookup() function to construct the instance.

class codecs.StreamReaderWriter(stream, Reader, Writer, errors)

Creates a StreamReaderWriter instance. stream must be a file-like object. Reader and Writer must be factory functions or classes providing the StreamReader and StreamWriter interface resp. Error handling is done in the same way as defined for the stream
StreamWriter instances define the combined interfaces of StreamReader and StreamWriter classes. They inherit all other methods and attributes from the underlying stream.

StreamRecoder Objects

The StreamRecoder provide a frontend - backend view of encoding data which is sometimes useful when dealing with different encoding environments.

The design is such that one can use the factory functions returned by the lookup() function to construct the instance.

class codecs.StreamRecoder(stream, encode, decode, Reader, Writer, errors)

Creates a StreamRecoder instance which implements a two-way conversion: encode and decode work on the frontend (the input to read() and output of write()) while Reader and Writer work on the backend (reading and writing to the stream).

You can use these objects to do transparent direct recodings from e.g. Latin-1 to UTF-8 and back.

stream must be a file-like object.

encode, decode must adhere to the Codec interface. Reader, Writer must be factory functions or classes providing objects of the StreamReader and StreamWriter interface respectively.

encode and decode are needed for the frontend translation, Reader and Writer for the backend translation. The intermediate format used is determined by the two sets of codecs, e.g. the Unicode codecs will use Unicode as the intermediate encoding.
Error handling is done in the same way as defined for the stream readers and writers.

StreamRecorder instances define the combined interfaces of StreamReader and StreamWriter classes. They inherit all other methods and attributes from the underlying stream.
Encodings and Unicode

Unicode strings are stored internally as sequences of codepoints (to be precise as `Py_UNICODE` arrays). Depending on the way Python is compiled (either via `--enable-unicode=ucs2` or `--enable-unicode=ucs4`, with the former being the default) `Py_UNICODE` is either a 16-bit or 32-bit data type. Once a Unicode object is used outside of CPU and memory, CPU endianness and how these arrays are stored as bytes become an issue. Transforming a unicode object into a sequence of bytes is called encoding and recreating the unicode object from the sequence of bytes is known as decoding. There are many different methods for how this transformation can be done (these methods are also called encodings). The simplest method is to map the codepoints 0-255 to the bytes `\x00-\xff`. This means that a unicode object that contains codepoints above `U+00FF` can’t be encoded with this method (which is called 'latin-1' or 'iso-8859-1'). `unicode.encode()` will raise a `UnicodeEncodeError` that looks like this: `UnicodeEncodeError: 'latin-1' codec can't encode character u'\u1234' in position 3: ordinal not in range(256).

There’s another group of encodings (the so called charmap encodings) that choose a different subset of all unicode code points and how these codepoints are mapped to the bytes `\x00-\xff`. To see how this is done simply open e.g. `encodings/cp1252.py` (which is an encoding that is used primarily on Windows). There’s a string constant with 256 characters that shows you which character is mapped to which byte value.

All of these encodings can only encode 256 of the 65536 (or 1114111) codepoints defined in unicode. A simple and straightforward way that can store each Unicode code point, is to store each codepoint as two consecutive bytes. There are two
possibilities: Store the bytes in big endian or in little endian order. These two encodings are called UTF-16-BE and UTF-16-LE respectively. Their disadvantage is that if e.g. you use UTF-16-BE on a little endian machine you will always have to swap bytes on encoding and decoding. UTF-16 avoids this problem: Bytes will always be in natural endianness. When these bytes are read by a CPU with a different endianness, then bytes have to be swapped though. To be able to detect the endianness of a UTF-16 byte sequence, there's the so called BOM (the “Byte Order Mark”). This is the Unicode character \texttt{U+FEFF}. This character will be prepended to every UTF-16 byte sequence. The byte swapped version of this character (\texttt{0xFFFE}) is an illegal character that may not appear in a Unicode text. So when the first character in an UTF-16 byte sequence appears to be a \texttt{U+FFFE} the bytes have to be swapped on decoding. Unfortunately upto Unicode 4.0 the character \texttt{U+FEFF} had a second purpose as a \texttt{ZERO WIDTH NO-BREAK SPACE}: A character that has no width and doesn’t allow a word to be split. It can e.g. be used to give hints to a ligature algorithm. With Unicode 4.0 using \texttt{U+FEFF} as a \texttt{ZERO WIDTH NO-BREAK SPACE} has been deprecated (with \texttt{U+2060} (\texttt{WORD JOINER}) assuming this role). Nevertheless Unicode software still must be able to handle \texttt{U+FEFF} in both roles: As a BOM it’s a device to determine the storage layout of the encoded bytes, and vanishes once the byte sequence has been decoded into a Unicode string; as a \texttt{ZERO WIDTH NO-BREAK SPACE} it’s a normal character that will be decoded like any other.

There's another encoding that is able to encoding the full range of Unicode characters: UTF-8. UTF-8 is an 8-bit encoding, which means there are no issues with byte order in UTF-8. Each byte in a UTF-8 byte sequence consists of two parts: Marker bits (the most significant bits) and payload bits. The marker bits are a sequence of zero to six 1 bits followed by a 0 bit. Unicode characters are encoded like this (with \texttt{x} being payload bits, which when concatenated give
the Unicode character):

<table>
<thead>
<tr>
<th>Range</th>
<th>Encoding</th>
</tr>
</thead>
<tbody>
<tr>
<td>U-00000000 ... U-0000007F</td>
<td>0xxxxxxx</td>
</tr>
<tr>
<td>U-00000080 ... U-000007FF</td>
<td>110xxxxx 10xxxxxx</td>
</tr>
<tr>
<td>U-00000800 ... U-0000FFFF</td>
<td>1110xxx 10xxxxxx 10xxxxxx</td>
</tr>
<tr>
<td>U-00010000 ... U-001FFFFF</td>
<td>11110xxx 10xxxxxx 10xxxxxx 10xxxxxx</td>
</tr>
<tr>
<td>U-00200000 ... U-03FFFFFF</td>
<td>111110xx 10xxxxxx 10xxxxxx 10xxxxxx</td>
</tr>
<tr>
<td>U-04000000 ... U-7FFFFFFF</td>
<td>1111110x 10xxxxxx 10xxxxxx 10xxxxxx 10xxxxxx</td>
</tr>
</tbody>
</table>

The least significant bit of the Unicode character is the rightmost x bit.

As UTF-8 is an 8-bit encoding no BOM is required and any U+FEFF character in the decoded Unicode string (even if it's the first character) is treated as a ZERO WIDTH NO-BREAK SPACE.

Without external information it's impossible to reliably determine which encoding was used for encoding a Unicode string. Each charmap encoding can decode any random byte sequence. However that's not possible with UTF-8, as UTF-8 byte sequences have a structure that doesn't allow arbitrary byte sequences. To increase the reliability with which a UTF-8 encoding can be detected, Microsoft invented a variant of UTF-8 (that Python 2.5 calls "utf-8-sig") for its Notepad program: Before any of the Unicode characters is written to the file, a UTF-8 encoded BOM (which looks like this as a byte sequence: \x0e, \xbb, \xbf) is written. As it's rather improbable that any charmap encoded file starts with these byte values (which would e.g. map to

LATIN SMALL LETTER I WITH DIAERESIS
RIGHT-POINTING DOUBLE ANGLE QUOTATION MARK
in iso-8859-1), this increases the probability that a utf-8-sig encoding can be correctly guessed from the byte sequence. So here the BOM is not used to be able to determine the byte order used for generating the byte sequence, but as a signature that helps in guessing the encoding. On encoding the utf-8-sig codec will write \(0xef, 0xbb, 0xbf\) as the first three bytes to the file. On decoding utf-8-sig will skip those three bytes if they appear as the first three bytes in the file.
Standard Encodings

Python comes with a number of codecs built-in, either implemented as C functions or with dictionaries as mapping tables. The following table lists the codecs by name, together with a few common aliases, and the languages for which the encoding is likely used. Neither the list of aliases nor the list of languages is meant to be exhaustive. Notice that spelling alternatives that only differ in case or use a hyphen instead of an underscore are also valid aliases.

Many of the character sets support the same languages. They vary in individual characters (e.g. whether the EURO SIGN is supported or not), and in the assignment of characters to code positions. For the European languages in particular, the following variants typically exist:

- an ISO 8859 codeset
- a Microsoft Windows code page, which is typically derived from a 8859 codeset, but replaces control characters with additional graphic characters
- an IBM EBCDIC code page
- an IBM PC code page, which is ASCII compatible

</table>

A number of codecs are specific to Python, so their codec names have no meaning outside Python. Some of them don’t convert from Unicode strings to byte strings, but instead use the property of the Python codecs machinery that any bijective function with one argument can be considered as an encoding.

For the codecs listed below, the result in the “encoding” direction is always a byte string. The result of the “decoding” direction is listed as operand type in the table.

New in version 2.3: The idna and punycode encodings.
encodings.idna — Internationalized Domain Names in Applications

New in version 2.3.

This module implements RFC 3490 (Internationalized Domain Names in Applications) and RFC 3492 (Nameprep: A Stringprep Profile for Internationalized Domain Names (IDN)). It builds upon the punycode encoding and stringprep.

These RFCs together define a protocol to support non-ASCII characters in domain names. A domain name containing non-ASCII characters (such as `www.Alliancefrançaise.nu`) is converted into an ASCII-compatible encoding (ACE, such as `www.xn--alliancefranaise-npb.nu`). The ACE form of the domain name is then used in all places where arbitrary characters are not allowed by the protocol, such as DNS queries, HTTP Host fields, and so on. This conversion is carried out in the application; if possible invisible to the user: The application should transparently convert Unicode domain labels to IDNA on the wire, and convert back ACE labels to Unicode before presenting them to the user.

Python supports this conversion in several ways: The idna codec allows to convert between Unicode and the ACE. Furthermore, the socket module transparently converts Unicode host names to ACE, so that applications need not be concerned about converting host names themselves when they pass them to the socket module. On top of that, modules that have host names as function parameters, such as `httplib` and `ftplib`, accept Unicode host names (`httplib` then also transparently sends an IDNA hostname in the `Host` field if it sends that field at all).
When receiving host names from the wire (such as in reverse name lookup), no automatic conversion to Unicode is performed: Applications wishing to present such host names to the user should decode them to Unicode.

The module `encodings.idna` also implements the nameprep procedure, which performs certain normalizations on host names, to achieve case-insensitivity of international domain names, and to unify similar characters. The nameprep functions can be used directly if desired.

`encodings.idna.nameprep(label)`

Return the nameprepped version of `label`. The implementation currently assumes query strings, so `AllowUnassigned` is true.

`encodings.idna.ToASCII(label)`

Convert a label to ASCII, as specified in RFC 3490. `UseSTD3ASCII Rue` is assumed to be false.

`encodings.idna.ToUnicode(label)`

Convert a label to Unicode, as specified in RFC 3490.
encodings.utf_8_sig — UTF-8 codec with BOM signature

New in version 2.5.

This module implements a variant of the UTF-8 codec: On encoding a UTF-8 encoded BOM will be prepended to the UTF-8 encoded bytes. For the stateful encoder this is only done once (on the first write to the byte stream). For decoding an optional UTF-8 encoded BOM at the start of the data will be skipped.
This module provides access to the Unicode Character Database which defines character properties for all Unicode characters. The data in this database is based on the UnicodeData.txt file version 5.1.0 which is publicly available from ftp://ftp.unicode.org/.

The module uses the same names and symbols as defined by the UnicodeData File Format 5.1.0 (see http://www.unicode.org/Public/5.1.0/ucd/UCD.html). It defines the following functions:

**unicodedata.** `lookup(name)`
Look up character by name. If a character with the given name is found, return the corresponding Unicode character. If not found, `KeyError` is raised.

**unicodedata.** `name(unichr[, default])`
Returns the name assigned to the Unicode character `unichr` as a string. If no name is defined, `default` is returned, or, if not given, `ValueError` is raised.

**unicodedata.** `decimal(unichr[, default])`
Returns the decimal value assigned to the Unicode character `unichr` as integer. If no such value is defined, `default` is returned, or, if not given, `ValueError` is raised.

**unicodedata.** `digit(unichr[, default])`
Returns the digit value assigned to the Unicode character `unichr` as integer. If no such value is defined, `default` is returned, or, if not given, `ValueError` is raised.
unicodedata.\texttt{numeric}(\texttt{unichr}[\texttt{, default}])

Returns the numeric value assigned to the Unicode character \texttt{unichr} as float. If no such value is defined, \texttt{default} is returned, or, if not given, \texttt{ValueError} is raised.

unicodedata.\texttt{category}(\texttt{unichr})

Returns the general category assigned to the Unicode character \texttt{unichr} as string.

unicodedata.\texttt{bidirectional}(\texttt{unichr})

Returns the bidirectional category assigned to the Unicode character \texttt{unichr} as string. If no such value is defined, an empty string is returned.

unicodedata.\texttt{combining}(\texttt{unichr})

Returns the canonical combining class assigned to the Unicode character \texttt{unichr} as integer. Returns $\emptyset$ if no combining class is defined.

unicodedata.\texttt{east_asian_width}(\texttt{unichr})

Returns the east asian width assigned to the Unicode character \texttt{unichr} as string.

\textit{New in version 2.4.}

unicodedata.\texttt{mirrored}(\texttt{unichr})

Returns the mirrored property assigned to the Unicode character \texttt{unichr} as integer. Returns 1 if the character has been identified as a “mirrored” character in bidirectional text, 0 otherwise.

unicodedata.\texttt{decomposition}(\texttt{unichr})

Returns the character decomposition mapping assigned to the Unicode character \texttt{unichr} as string. An empty string is returned in case no such mapping is defined.
unicodedata.normalize(form, unistr)

Return the normal form form for the Unicode string unistr. Valid values for form are ‘NFC’, ‘NFKC’, ‘NFD’, and ‘NFKD’.

The Unicode standard defines various normalization forms of a Unicode string, based on the definition of canonical equivalence and compatibility equivalence. In Unicode, several characters can be expressed in various way. For example, the character U+00C7 (LATIN CAPITAL LETTER C WITH CEDILLA) can also be expressed as the sequence U+0327 (COMBINING CEDILLA) U+0043 (LATIN CAPITAL LETTER C).

For each character, there are two normal forms: normal form C and normal form D. Normal form D (NFD) is also known as canonical decomposition, and translates each character into its decomposed form. Normal form C (NFC) first applies a canonical decomposition, then composes pre-combined characters again.

In addition to these two forms, there are two additional normal forms based on compatibility equivalence. In Unicode, certain characters are supported which normally would be unified with other characters. For example, U+2160 (ROMAN NUMERAL ONE) is really the same thing as U+0049 (LATIN CAPITAL LETTER I). However, it is supported in Unicode for compatibility with existing character sets (e.g. gb2312).

The normal form KD (NFKD) will apply the compatibility decomposition, i.e. replace all compatibility characters with their equivalents. The normal form KC (NFKC) first applies the compatibility decomposition, followed by the canonical composition.

Even if two unicode strings are normalized and look the same to a human reader, if one has combining characters and the other doesn’t, they may not compare equal.
New in version 2.3.

In addition, the module exposes the following constant:

```
unicodedata.unidata_version
```

The version of the Unicode database used in this module.

New in version 2.3.

```
unicodedata.ucd_3_2_0
```

This is an object that has the same methods as the entire module, but uses the Unicode database version 3.2 instead, for applications that require this specific version of the Unicode database (such as IDNA).

New in version 2.5.

Examples:

```python
>>> import unicodedata
>>> unicodedata.lookup('LEFT CURLY BRACKET')
'{'
>>> unicodedata.name(u'/')  # 'SOLIDUS'
'SOLIDUS'
>>> unicodedata.decimal(u'9')
9
>>> unicodedata.decimal(u'a')  # not a decimal
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
ValueError: not a decimal
>>> unicodedata.category(u'A')  # 'L'etter, 'u'ppercase
'Lu'
>>> unicodedata.bidirectional(u'٠')  # 'A'rabic, 'N'umber
'AN'
```
When identifying things (such as host names) in the internet, it is often necessary to compare such identifications for “equality”. Exactly how this comparison is executed may depend on the application domain, e.g. whether it should be case-insensitive or not. It may be also necessary to restrict the possible identifications, to allow only identifications consisting of “printable” characters.

**RFC 3454** defines a procedure for “preparing” Unicode strings in internet protocols. Before passing strings onto the wire, they are processed with the preparation procedure, after which they have a certain normalized form. The RFC defines a set of tables, which can be combined into profiles. Each profile must define which tables it uses, and what other optional parts of the **stringprep** procedure are part of the profile. One example of a **stringprep** profile is **nameprep**, which is used for internationalized domain names.

The module **stringprep** only exposes the tables from RFC 3454. As these tables would be very large to represent them as dictionaries or lists, the module uses the Unicode character database internally. The module source code itself was generated using the **mkstringprep.py** utility.

As a result, these tables are exposed as functions, not as data structures. There are two kinds of tables in the RFC: sets and mappings. For a set, **stringprep** provides the “characteristic function”, i.e. a function that returns true if the parameter is part of the set. For mappings, it provides the mapping function: given the key, it returns the associated value. Below is a list of all functions
available in the module.

stringprep.in_table_a1(code)
   Determine whether code is in tableA.1 (Unassigned code points in Unicode 3.2).

stringprep.in_table_b1(code)
   Determine whether code is in tableB.1 (Commonly mapped to nothing).

stringprep.map_table_b2(code)
   Return the mapped value for code according to tableB.2 (Mapping for case-folding used with NFKC).

stringprep.map_table_b3(code)
   Return the mapped value for code according to tableB.3 (Mapping for case-folding used with no normalization).

stringprep.in_table_c11(code)
   Determine whether code is in tableC.1.1 (ASCII space characters).

stringprep.in_table_c12(code)
   Determine whether code is in tableC.1.2 (Non-ASCII space characters).

stringprep.in_table_c11_c12(code)
   Determine whether code is in tableC.1 (Space characters, union of C.1.1 and C.1.2).

stringprep.in_table_c21(code)
   Determine whether code is in tableC.2.1 (ASCII control characters).

stringprep.in_table_c22(code)
Determine whether code is in table C.2.2 (Non-ASCII control characters).

stringprep.in_table_c21_c22(code)
Determine whether code is in table C.2 (Control characters, union of C.2.1 and C.2.2).

stringprep.in_table_c3(code)
Determine whether code is in table C.3 (Private use).

stringprep.in_table_c4(code)
Determine whether code is in table C.4 (Non-character code points).

stringprep.in_table_c5(code)
Determine whether code is in table C.5 (Surrogate codes).

stringprep.in_table_c6(code)
Determine whether code is in table C.6 (Inappropriate for plain text).

stringprep.in_table_c7(code)
Determine whether code is in table C.7 (Inappropriate for canonical representation).

stringprep.in_table_c8(code)
Determine whether code is in table C.8 (Change display properties or are deprecated).

stringprep.in_table_c9(code)
Determine whether code is in table C.9 (Tagging characters).

stringprep.in_table_d1(code)
Determine whether code is in table D.1 (Characters with bidirectional property “R” or “AL”).
stringprep.in_table_d2(code)
Determine whether code is in tableD.2 (Characters with bidirectional property “L”).
Floating point conversions

*Deprecated since version 2.6:* The `fpformat` module has been removed in Python 3.0.

The `fpformat` module defines functions for dealing with floating point numbers representations in 100% pure Python.

**Note:** This module is unnecessary: everything here can be done using the `%` string interpolation operator described in the *String Formatting Operations* section.

The `fpformat` module defines the following functions and an exception:

**fpformat.fix(x, digs)**

Format `x` as `[-]ddd.ddd` with `digs` digits after the point and at least one digit before. If `digs <= 0`, the decimal point is suppressed.

- `x` can be either a number or a string that looks like one. `digs` is an integer.

  Return value is a string.

**fpformat.sci(x, digs)**

Format `x` as `[-]d.dddE[+-]ddd` with `digs` digits after the point and exactly one digit before. If `digs <= 0`, one digit is kept and the point is suppressed.

- `x` can be either a real number, or a string that looks like one. `digs`
is an integer.

Return value is a string.

exception fpformat. NotANumber
   Exception raised when a string passed to fix() or sci() as the x parameter does not look like a number. This is a subclass of ValueError when the standard exceptions are strings. The exception value is the improperly formatted string that caused the exception to be raised.

Example:

```python
>>> import fpformat
>>> fpformat.fix(1.23, 1)
'1.2'
```
The modules described in this chapter provide a variety of specialized data types such as dates and times, fixed-type arrays, heap queues, synchronized queues, and sets.

Python also provides some built-in data types, in particular, `dict`, `list`, `set` (which along with `frozenset`, replaces the deprecated `sets` module), and `tuple`. The `str` class can be used to handle binary data and 8-bit text, and the `unicode` class to handle Unicode text.

The following modules are documented in this chapter:

- **datetime** — Basic date and time types
  - Available Types
  - `timedelta` Objects
  - `date` Objects
  - `datetime` Objects
  - `time` Objects
  - `tzinfo` Objects
  - `strftime` Behavior

- **calendar** — General calendar-related functions

- **collections** — High-performance container datatypes
  - ABCs - abstract base classes
  - `deque` objects
    - `deque` Recipes
  - `defaultdict` objects
    - `defaultdict` Examples
  - `namedtuple` Factory Function for Tuples with Named Fields
- **heapq** — Heap queue algorithm
  - Theory

- **bisect** — Array bisection algorithm
  - Examples

- **array** — Efficient arrays of numeric values

- **sets** — Unordered collections of unique elements
  - Set Objects
  - Example
    - Protocol for automatic conversion to immutable
    - Comparison to the built-in `set` types

- **sched** — Event scheduler
  - Scheduler Objects

- **mutex** — Mutual exclusion support
  - Mutex Objects

- **queue** — A synchronized queue class
  - Queue Objects

- **weakref** — Weak references
  - Weak Reference Objects
  - Example

- **UserDict** — Class wrapper for dictionary objects
- **UserList** — Class wrapper for list objects
- **UserString** — Class wrapper for string objects

- **types** — Names for built-in types

- **new** — Creation of runtime internal objects
- **copy** — Shallow and deep copy operations

- **pprint** — Data pretty printer
  - PrettyPrinter Objects
  - pprint Example

- **repr** — Alternate `repr` implementation
  - Repr Objects
  - Subclassing Repr Objects
datetime — Basic date and time types

New in version 2.3.

The datetime module supplies classes for manipulating dates and times in both simple and complex ways. While date and time arithmetic is supported, the focus of the implementation is on efficient member extraction for output formatting and manipulation. For related functionality, see also the time and calendar modules.

There are two kinds of date and time objects: “naive” and “aware”. This distinction refers to whether the object has any notion of time zone, daylight saving time, or other kind of algorithmic or political time adjustment. Whether a naive datetime object represents Coordinated Universal Time (UTC), local time, or time in some other timezone is purely up to the program, just like it's up to the program whether a particular number represents metres, miles, or mass. Naive datetime objects are easy to understand and to work with, at the cost of ignoring some aspects of reality.

For applications requiring more, datetime and time objects have an optional time zone information member, tzinfo, that can contain an instance of a subclass of the abstract tzinfo class. These tzinfo objects capture information about the offset from UTC time, the time zone name, and whether Daylight Saving Time is in effect. Note that no concrete tzinfo classes are supplied by the datetime module. Supporting timezones at whatever level of detail is required is up to the application. The rules for time adjustment across the world are more political than rational, and there is no standard suitable for every application.
The `datetime` module exports the following constants:

`datetime.MINYEAR`

The smallest year number allowed in a `date` or `datetime` object. `MINYEAR` is 1.

`datetime.MAXYEAR`

The largest year number allowed in a `date` or `datetime` object. `MAXYEAR` is 9999.

See also:

**Module** `calendar`

General calendar related functions.

**Module** `time`

Time access and conversions.
Available Types

class datetime.date
    An idealized naive date, assuming the current Gregorian calendar always was, and always will be, in effect. Attributes: year, month, and day.

class datetime.time
    An idealized time, independent of any particular day, assuming that every day has exactly 24*60*60 seconds (there is no notion of “leap seconds” here). Attributes: hour, minute, second, microsecond, and tzinfo.

class datetime.datetime
    A combination of a date and a time. Attributes: year, month, day, hour, minute, second, microsecond, and tzinfo.

class datetime.timedelta
    A duration expressing the difference between two date, time, or datetime instances to microsecond resolution.

class datetime.tzinfo
    An abstract base class for time zone information objects. These are used by the datetime and time classes to provide a customizable notion of time adjustment (for example, to account for time zone and/or daylight saving time).

Objects of these types are immutable.

Objects of the date type are always naive.

An object d of type time or datetime may be naive or aware. d is aware if d.tzinfo is not None and d.tzinfo.utcoffset(d) does not
return None. If \texttt{d.tzinfo} is \texttt{None}, or if \texttt{d.tzinfo} is not \texttt{None} but \texttt{d.tzinfo.utcoffset(d)} returns \texttt{None}, \texttt{d} is naive.

The distinction between naive and aware doesn't apply to \texttt{timedelta} objects.

Subclass relationships:

\begin{verbatim}
object
timedelta
tzinfo
time
date
datetime
\end{verbatim}
timedelta Objects

A timedelta object represents a duration, the difference between two
dates or times.

class datetime.timedelta([days[, seconds[, microseconds[, milliseconds[, minutes[, hours[, weeks]]]]]]])

All arguments are optional and default to 0. Arguments may be
ints, longs, or floats, and may be positive or negative.

Only days, seconds and microseconds are stored internally. Arguments are converted to those units:

- A millisecond is converted to 1000 microseconds.
- A minute is converted to 60 seconds.
- An hour is converted to 3600 seconds.
- A week is converted to 7 days.

and days, seconds and microseconds are then normalized so
that the representation is unique, with

- 0 <= microseconds < 1000000
- 0 <= seconds < 3600*24 (the number of seconds in one day)
- -999999999 <= days <= 999999999

If any argument is a float and there are fractional microseconds,
the fractional microseconds left over from all arguments are
combined and their sum is rounded to the nearest microsecond.
If no argument is a float, the conversion and normalization
processes are exact (no information is lost).

If the normalized value of days lies outside the indicated range,
OverflowError is raised.
Note that normalization of negative values may be surprising at first. For example,

```python
>>> from datetime import timedelta
>>> d = timedelta(microseconds=-1)
>>> (d.days, d.seconds, d.microseconds)
(-1, 86399, 999999)
```

Class attributes are:

`timmedelta.min`

The most negative `timedelta` object, `timedelta(-999999999)`.

`timmedelta.max`

The most positive `timedelta` object, `timedelta(days=999999999, hours=23, minutes=59, seconds=59, microseconds=999999)`.

`timmedelta.resolution`

The smallest possible difference between non-equal `timedelta` objects, `timedelta(microseconds=1)`.

Note that, because of normalization, `timedelta.max > -timedelta.min`. `-timedelta.max` is not representable as a `timedelta` object.

Instance attributes (read-only):

<table>
<thead>
<tr>
<th>Attribute</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>days</td>
<td>Between -999999999 and 999999999 inclusive</td>
</tr>
<tr>
<td>seconds</td>
<td>Between 0 and 86399 inclusive</td>
</tr>
<tr>
<td>microseconds</td>
<td>Between 0 and 999999 inclusive</td>
</tr>
</tbody>
</table>

Supported operations:
### Operation Result

<table>
<thead>
<tr>
<th>Operation</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td>( t_1 = t_2 + t_3 )</td>
<td>Sum of ( t_2 ) and ( t_3 ). Afterwards ( t_1-t_2 ) == ( t_3 ) and ( t_1-t_3 ) == ( t_2 ) are true. (1)</td>
</tr>
<tr>
<td>( t_1 = t_2 - t_3 )</td>
<td>Difference of ( t_2 ) and ( t_3 ). Afterwards ( t_1 ) == ( t_2 - t_3 ) and ( t_2 ) == ( t_1 + t_3 ) are true. (1)</td>
</tr>
<tr>
<td>( t_1 = t_2 \times i ) or ( t_1 = i \times t_2 )</td>
<td>Delta multiplied by an integer or long. Afterwards ( t_1 // i ) == ( t_2 ) is true, provided ( i \neq 0 ). In general, ( t_1 \times i == t_1 \times (i-1) + t_1 ) is true. (1)</td>
</tr>
<tr>
<td>( t_1 = t_2 // i )</td>
<td>The floor is computed and the remainder (if any) is thrown away. (3)</td>
</tr>
<tr>
<td>(+t_1)</td>
<td>Returns a \texttt{timedelta} object with the same value. (2)</td>
</tr>
<tr>
<td>(-t_1)</td>
<td>equivalent to \texttt{timedelta}(-( t_1 ).days, -( t_1 ).seconds, -( t_1 ).microseconds), and to ( t_1 \times -1 ). (1)(4)</td>
</tr>
<tr>
<td>( \text{abs}(t))</td>
<td>equivalent to (+<em>t</em>) when ( t ).days ( \geq 0 ), and to (-t) when ( t ).days ( &lt; 0 ). (2)</td>
</tr>
</tbody>
</table>

**Notes:**

1. This is exact, but may overflow.
2. This is exact, and cannot overflow.
3. Division by 0 raises \texttt{ZeroDivisionError}.
4. \texttt{-timedelta.max} is not representable as a \texttt{timedelta} object.

In addition to the operations listed above \texttt{timedelta} objects support certain additions and subtractions with \texttt{date} and \texttt{datetime} objects (see below).

Comparisons of \texttt{timedelta} objects are supported with the \texttt{timedelta} object representing the smaller duration considered to be the smaller \texttt{timedelta}. In order to stop mixed-type comparisons from falling back to the default comparison by object address, when a \texttt{timedelta}
object is compared to an object of a different type, ValueError is raised unless the comparison is \( \texttt{==} \) or \( \texttt{!=} \). The latter cases return False or True, respectively.

timedelta objects are hashable (usable as dictionary keys), support efficient pickling, and in Boolean contexts, a timedelta object is considered to be true if and only if it isn’t equal to timedelta(0).

Example usage:

```python
>>> from datetime import timedelta
>>> year = timedelta(days=365)
>>> another_year = timedelta(weeks=40, days=84, hours=23,
... minutes=50, seconds=600)  # adds up to 365 days
>>> year == another_year
True
>>> ten_years = 10 * year
>>> ten_years, ten_years.days // 365
(datetime.timedelta(3650), 10)
>>> nine_years = ten_years - year
>>> nine_years, nine_years.days // 365
(datetime.timedelta(3285), 9)
>>> three_years = nine_years // 3;
>>> three_years, three_years.days // 365
(datetime.timedelta(1095), 3)
>>> abs(three_years - ten_years) == 2 * three_years + year
True
```
date Objects

A date object represents a date (year, month and day) in an idealized calendar, the current Gregorian calendar indefinitely extended in both directions. January 1 of year 1 is called day number 1, January 2 of year 1 is called day number 2, and so on. This matches the definition of the “proleptic Gregorian” calendar in Dershowitz and Reingold’s book Calendrical Calculations, where it’s the base calendar for all computations. See the book for algorithms for converting between proleptic Gregorian ordinals and many other calendar systems.

class datetime.date(year, month, day)

All arguments are required. Arguments may be ints or longs, in the following ranges:

- MINYEAR <= year <= MAXYEAR
- 1 <= month <= 12
- 1 <= day <= number of days in the given month and year

If an argument outside those ranges is given, ValueError is raised.

Other constructors, all class methods:

date.today()

Return the current local date. This is equivalent to
date.fromtimestamp(time.time()).

date.fromtimestamp(timestamp)

Return the local date corresponding to the POSIX timestamp, such as is returned by time.time(). This may raise ValueError, if the timestamp is out of the range of values supported by the
platform C `localtime` function. It's common for this to be restricted to years from 1970 through 2038. Note that on non-POSIX systems that include leap seconds in their notion of a timestamp, leap seconds are ignored by `fromtimestamp()`.

date. `fromordinal(ordinal)`
Return the date corresponding to the proleptic Gregorian ordinal, where January 1 of year 1 has ordinal 1. `ValueError` is raised unless \(1 \leq \text{ordinal} \leq \text{date.max.toordinal()}\). For any date \(d\), `date.fromordinal(d.toordinal()) == d`.

Class attributes:

date. `min`
The earliest representable date, `date(MINYEAR, 1, 1)`.

date. `max`
The latest representable date, `date(MAXYEAR, 12, 31)`.

date. `resolution`
The smallest possible difference between non-equal date objects, `timedelta(days=1)`.

Instance attributes (read-only):

date. `year`
Between \(\text{MINYEAR}\) and \(\text{MAXYEAR}\) inclusive.

date. `month`
Between 1 and 12 inclusive.

date. `day`
Between 1 and the number of days in the given month of the given year.

Supported operations:
<table>

<tr>
<td>timedelta = date1 - date2</td>
<td>(3)</td>
</tr>
<tr>
<td>date1 &lt; date2</td>
<td><em>date1</em> is considered less than <em>date2</em> when <em>date1</em> precedes <em>date2</em> in time. (4)</td>
</tr>
</tbody>
</table>

Notes:

1. *date2* is moved forward in time if *timedelta*.days > 0, or backward if *timedelta*.days < 0. Afterward *date2* - *date1* == *timedelta*.days, *timedelta*.seconds and *timedelta*.microseconds are ignored. *OverflowError* is raised if *date2*.year would be smaller than *MINYEAR* or larger than *MAXYEAR*.
2. This isn’t quite equivalent to *date1* + (-*timedelta*), because -*timedelta* in isolation can overflow in cases where *date1* - *timedelta* does not. *timedelta*.seconds and *timedelta*.microseconds are ignored.
3. This is exact, and cannot overflow. *timedelta*.seconds and *timedelta*.microseconds are 0, and *date2* + *timedelta* == *date1* after.
4. In other words, *date1* < *date2* if and only if *date1*.toordinal() < *date2*.toordinal(). In order to stop comparison from falling back to the default scheme of comparing object addresses, date comparison normally raises *TypeError* if the other comparand isn’t also a *date* object. However, *NotImplemented* is returned instead if the other comparand has a *timetuple* attribute. This hook gives other kinds of date objects a chance at implementing mixed-type comparison. If not, when a *date* object is compared to an object of a different type, *TypeError* is raised unless the
comparison is == or !=. The latter cases return False or True, respectively.

Dates can be used as dictionary keys. In Boolean contexts, all date objects are considered to be true.

Instance methods:

date.replace(year, month, day)

Return a date with the same value, except for those members given new values by whichever keyword arguments are specified. For example, if d == date(2002, 12, 31), then d.replace(day=26) == date(2002, 12, 26).

date.timetuple()

Return a time.struct_time such as returned by time.localtime(). The hours, minutes and seconds are 0, and the DST flag is -1. d.timetuple() is equivalent to

time.struct_time((d.year, d.month, d.day, 0, 0, 0, d.weekday(), d.toordinal() - date(d.year, 1, 1).toordinal() + 1, -1))

date.toordinal()

Return the proleptic Gregorian ordinal of the date, where January 1 of year 1 has ordinal 1. For any date object d, date.fromordinal(d.toordinal()) == d.

date.weekday()

Return the day of the week as an integer, where Monday is 0 and Sunday is 6. For example, date(2002, 12, 4).weekday() == 2, a Wednesday. See also isoweekday().

date.isoweekday()

Return the day of the week as an integer, where Monday is 1 and
Sunday is 7. For example, \(\text{date}(2002, 12, 4).\text{isoweekday}() == 3\), a Wednesday. See also \text{weekday()}, \text{isocalendar()}.

date.\text{isocalendar}()

Return a 3-tuple, (ISO year, ISO week number, ISO weekday).

The ISO calendar is a widely used variant of the Gregorian calendar. See http://www.phys.uu.nl/vgent/calendar/isocalendar.htm for a good explanation.

The ISO year consists of 52 or 53 full weeks, and where a week starts on a Monday and ends on a Sunday. The first week of an ISO year is the first (Gregorian) calendar week of a year containing a Thursday. This is called week number 1, and the ISO year of that Thursday is the same as its Gregorian year.

For example, 2004 begins on a Thursday, so the first week of ISO year 2004 begins on Monday, 29 Dec 2003 and ends on Sunday, 4 Jan 2004, so that \(\text{date}(2003, 12, 29).\text{isocalendar}() == (2004, 1, 1)\) and \(\text{date}(2004, 1, 4).\text{isocalendar}() == (2004, 1, 7)\).

date.\text{isoformat}()

Return a string representing the date in ISO 8601 format, ‘YYYY-MM-DD’. For example, \(\text{date}(2002, 12, 4).\text{isoformat}() == \text{'2002-12-04'}\).

date.\text{__str__}()

For a date \(d\), \text{str}(d)\) is equivalent to \(d.\text{isoformat}()\).

date.\text{ctime}()

Return a string representing the date, for example \(\text{date}(2002, 12, 4).\text{ctime}() == \text{'Wed Dec 4 00:00:00 2002'}\). \(d.\text{ctime}()\) is equivalent to \(\text{time.ctime(time.mktime(d.timetuple()))}\) on
platforms where the native C `ctime` function (which `time.ctime()` invokes, but which `date.ctime()` does not invoke) conforms to the C standard.

date. `strftime(format)`

Return a string representing the date, controlled by an explicit format string. Format codes referring to hours, minutes or seconds will see 0 values. See section `strftime() Behavior`.

Example of counting days to an event:

```python
>>> import time
>>> from datetime import date
>>> today = date.today()
>>> today = date(2007, 12, 5)
>>> today == date.fromtimestamp(time.time())
True
>>> my_birthday = date(today.year, 6, 24)
>>> if my_birthday < today:
...     my_birthday = my_birthday.replace(year=today.year + 1)
>>> my_birthday
datetime.date(2008, 6, 24)
>>> time_to_birthday = abs(my_birthday - today)
>>> time_to_birthday.days
202
```

Example of working with `date`:

```python
>>> from datetime import date
>>> d = date.fromordinal(730920) # 730920th day after 1. 1. 000
>>> d
datetime.date(2002, 3, 11)
>>> t = d.timetuple()
>>> for i in t:
...     print i
2002 # year
3 # month
11 # day
0
0
0
0 # weekday (0 = Monday)
```
70  # 70th day in the year
-1
>>> ic = d.isocalendar()
>>> for i in ic:
...     print i
 2002  # ISO year
 11  # ISO week number
 1  # ISO day number (1 = Monday)
>>> d.isoformat()
'2002-03-11'
>>> d.strftime("%d/%m/%y")
'11/03/02'
>>> d.strftime("%A %d. %B %Y")
'Monday 11. March 2002'
datetime Objects

A datetime object is a single object containing all the information from a date object and a time object. Like a date object, datetime assumes the current Gregorian calendar extended in both directions; like a time object, datetime assumes there are exactly 3600*24 seconds in every day.

Constructor:

```python
class datetime.datetime(year, month, day[, hour[, minute[, second[, microsecond[, tzinfo]]]]])
```

The year, month and day arguments are required. tzinfo may be None, or an instance of a tzinfo subclass. The remaining arguments may be ints or longs, in the following ranges:

- MINYEAR <= year <= MAXYEAR
- 1 <= month <= 12
- 1 <= day <= number of days in the given month and year
- 0 <= hour < 24
- 0 <= minute < 60
- 0 <= second < 60
- 0 <= microsecond < 1000000

If an argument outside those ranges is given, ValueError is raised.

Other constructors, all class methods:

```python
datetime.today()
```

Return the current local datetime, with tzinfo None. This is equivalent to `datetime.fromtimestamp(time.time())`. See also
now(), fromtimestamp().

datetime.now([tz])
Return the current local date and time. If optional argument tz is None or not specified, this is like today(), but, if possible, supplies more precision than can be gotten from going through a time.time() timestamp (for example, this may be possible on platforms supplying the C gettimeofday function).

Else tz must be an instance of a class tzinfo subclass, and the current date and time are converted to tz’s time zone. In this case the result is equivalent to tz.fromutc(datetime.utcnow().replace(tzinfo=tz)). See also today(), utcnow().

datetime.utcnow()
Return the current UTC date and time, with tzinfo None. This is like now(), but returns the current UTC date and time, as a naive datetime object. See also now().

datetime.fromtimestamp(timestamp[, tz])
Return the local date and time corresponding to the POSIX timestamp, such as is returned by time.time(). If optional argument tz is None or not specified, the timestamp is converted to the platform’s local date and time, and the returned datetime object is naive.

Else tz must be an instance of a class tzinfo subclass, and the timestamp is converted to tz’s time zone. In this case the result is equivalent to tz.fromutc(datetime.utcfromtimestamp(timestamp).replace(tzinfo=tzinfo).replace(tzinfo=tzinfo)).

fromtimestamp() may raise ValueError, if the timestamp is out of
the range of values supported by the platform C \texttt{localtime} or \texttt{gmtime} functions. It's common for this to be restricted to years in 1970 through 2038. Note that on non-POSIX systems that include leap seconds in their notion of a timestamp, leap seconds are ignored by \texttt{fromtimestamp()}, and then it's possible to have two timestamps differing by a second that yield identical \texttt{datetime} objects. See also \texttt{utcfromtimestamp()}.

\texttt{datetime.utcfromtimestamp(timestamp)}

Return the UTC \texttt{datetime} corresponding to the POSIX timestamp, with \texttt{tzinfo None}. This may raise \texttt{ValueError}, if the timestamp is out of the range of values supported by the platform C \texttt{gmtime} function. It's common for this to be restricted to years in 1970 through 2038. See also \texttt{fromtimestamp()}.

\texttt{datetime.fromordinal(ordinal)}

Return the \texttt{datetime} corresponding to the proleptic Gregorian ordinal, where January 1 of year 1 has ordinal 1. \texttt{ValueError} is raised unless \(1 \leq \text{ordinal} \leq \text{datetime.max.toordinal}()\). The hour, minute, second and microsecond of the result are all 0, and \texttt{tzinfo} is \texttt{None}.

\texttt{datetime.combine(date, time)}

Return a new \texttt{datetime} object whose date members are equal to the given \texttt{date} object's, and whose time and \texttt{tzinfo} members are equal to the given \texttt{time} object's. For any \texttt{datetime} object \(d\), \(d == \text{datetime.combine}(d.date(), d.timetz())\). If \texttt{date} is a \texttt{datetime} object, its time and \texttt{tzinfo} members are ignored.

\texttt{datetime.strptime(date_string, format)}

Return a \texttt{datetime} corresponding to \texttt{date_string}, parsed according to \texttt{format}. This is equivalent to \texttt{datetime(*}
(time.strptime(date_string, format)[0:6]). **ValueError** is raised if the date_string and format can't be parsed by `time.strptime()` or if it returns a value which isn't a time tuple.

*New in version 2.5.*

Class attributes:

```python
datetime.min
The earliest representable `datetime`, `datetime`(MINYEAR, 1, 1, tzinfo=None).
datetime.max
The latest representable `datetime`, `datetime`(MAXYEAR, 12, 31, 23, 59, 59, 999999, tzinfo=None).
datetime.resolution
The smallest possible difference between non-equal `datetime` objects, `timedelta`(microseconds=1).
```

Instance attributes (read-only):

```python
datetime.year
Between MINYEAR and MAXYEAR inclusive.
datetime.month
Between 1 and 12 inclusive.
datetime.day
Between 1 and the number of days in the given month of the given year.
datetime.hour
In range(24).
datetime.minute
```
```python
In range(60).
datetime.second
In range(60).
datetime.microsecond
In range(1000000).
datetime.tzinfo
    The object passed as the tzinfo argument to the datetime constructor, or None if none was passed.
```

**Supported operations:**

<table>
<thead>
<tr>
<th>Operation</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>datetime2 = datetime1 + timedelta</code></td>
<td>(1)</td>
</tr>
<tr>
<td><code>datetime2 = datetime1 - timedelta</code></td>
<td>(2)</td>
</tr>
<tr>
<td><code>timedelta = datetime1 - datetime2</code></td>
<td>(3)</td>
</tr>
<tr>
<td><code>datetime1 &lt; datetime2</code></td>
<td>Compares <code>datetime</code> to <code>datetime</code>. (4)</td>
</tr>
</tbody>
</table>

1. `datetime2` is a duration of `timedelta` removed from `datetime1`, moving forward in time if `timedelta.days > 0`, or backward if `timedelta.days < 0`. The result has the same tzinfo member as the input datetime, and `datetime2 - datetime1 == timedelta` after. `OverflowError` is raised if `datetime2.year` would be smaller than `MINYEAR` or larger than `MAXYEAR`. Note that no time zone adjustments are done even if the input is an aware object.

2. Computes the `datetime2` such that `datetime2 + timedelta == datetime1`. As for addition, the result has the same tzinfo member as the input datetime, and no time zone adjustments are done even if the input is aware. This isn’t quite equivalent to `datetime1 + (-timedelta)`, because -timedelta in isolation can
overflow in cases where datetime1 - timedelta does not.

3. Subtraction of a `datetime` from a `datetime` is defined only if both operands are naive, or if both are aware. If one is aware and the other is naive, `TypeError` is raised.

   If both are naive, or both are aware and have the same `tzinfo` member, the `tzinfo` members are ignored, and the result is a `timedelta` object $t$ such that $\text{datetime2} + t = \text{datetime1}$. No time zone adjustments are done in this case.

   If both are aware and have different `tzinfo` members, $a-b$ acts as if $a$ and $b$ were first converted to naive UTC datetimes first. The result is $(a.\text{replace(tzinfo=None)} - a.\text{utcoffset()}) - (b.\text{replace(tzinfo=None)} - b.\text{utcoffset()})$ except that the implementation never overflows.

4. `datetime1` is considered less than `datetime2` when `datetime1` precedes `datetime2` in time.

   If one comparand is naive and the other is aware, `TypeError` is raised. If both comparands are aware, and have the same `tzinfo` member, the common `tzinfo` member is ignored and the base datetimes are compared. If both comparands are aware and have different `tzinfo` members, the comparands are first adjusted by subtracting their UTC offsets (obtained from `self.\text{utcoffset()}`).

   **Note:** In order to stop comparison from falling back to the default scheme of comparing object addresses, `datetime` comparison normally raises `TypeError` if the other comparand isn’t also a `datetime` object. However, `NotImplemented` is returned instead if the other comparand has a `timetuple()`
attribute. This hook gives other kinds of date objects a chance at implementing mixed-type comparison. If not, when a `datetime` object is compared to an object of a different type, `TypeError` is raised unless the comparison is `==` or `!=`. The latter cases return `False` or `True`, respectively.

`datetime` objects can be used as dictionary keys. In Boolean contexts, all `datetime` objects are considered to be true.

Instance methods:

`datetime.date()`
Return `date` object with same year, month and day.

`datetime.time()`
Return `time` object with same hour, minute, second and microsecond. `tzinfo` is `None`. See also method `timetz()`.

`datetime.timetz()`
Return `time` object with same hour, minute, second, microsecond, and `tzinfo` members. See also method `time()`.

`datetime.replace([year[, month[, day[, hour[, minute[, second[, microsecond[, tzinfo]]]]]]]])`
Return a datetime with the same members, except for those members given new values by whichever keyword arguments are specified. Note that `tzinfo=None` can be specified to create a naive datetime from an aware datetime with no conversion of date and time members.

`datetime.astimezone(tz)`
Return a `datetime` object with new `tzinfo` member `tz`, adjusting the date and time members so the result is the same UTC time
as \textit{self}, but in \textit{tz}'s local time.

tz must be an instance of a \texttt{tzinfo} subclass, and its \texttt{utcoffset()} and \texttt{dst()} methods must not return \texttt{None}. \textit{self} must be aware (\texttt{self.tzinfo} must not be \texttt{None}, and \texttt{self.utcoffset()} must not return \texttt{None}).

If \texttt{self.tzinfo} is \texttt{tz}, \texttt{self.astimezone(tz)} is equal to \texttt{self}: no adjustment of date or time members is performed. Else the result is local time in time zone \texttt{tz}, representing the same UTC time as \texttt{self}: after \texttt{astz = dt.astimezone(tz)}, \texttt{astz - astz.utcoffset()} will usually have the same date and time members as \texttt{dt - dt.utcoffset()}. The discussion of class \texttt{tzinfo} explains the cases at Daylight Saving Time transition boundaries where this cannot be achieved (an issue only if \texttt{tz} models both standard and daylight time).

If you merely want to attach a time zone object \texttt{tz} to a \texttt{datetime} \texttt{dt} without adjustment of date and time members, use \texttt{dt.replace(tzinfo=tz)}. If you merely want to remove the time zone object from an aware \texttt{datetime} \texttt{dt} without conversion of date and time members, use \texttt{dt.replace(tzinfo=None)}.

Note that the default \texttt{tzinfo.fromutc()} method can be overridden in a \texttt{tzinfo} subclass to affect the result returned by \texttt{astimezone()}. Ignoring error cases, \texttt{astimezone()} acts like:

```python
def astimezone(self, tz):
    if self.tzinfo is tz:
        return self
    # Convert self to UTC, and attach the new time zone object
    utc = (self - self.utcoffset()).replace(tzinfo=tz)
    # Convert from UTC to tz's local time.
    return tz.fromutc(utc)
```
datetime.**utcoffset()**
If **tzinfo** is **None**, returns **None**, else returns `self.tzinfo.utcoffset(self)`, and raises an exception if the latter doesn't return **None**, or a `timedelta` object representing a whole number of minutes with magnitude less than one day.

datetime.**dst()**
If **tzinfo** is **None**, returns **None**, else returns `self.tzinfo.dst(self)`, and raises an exception if the latter doesn't return **None**, or a `timedelta` object representing a whole number of minutes with magnitude less than one day.

datetime.**tzname()**
If **tzinfo** is **None**, returns **None**, else returns `self.tzinfo.tzname(self)`, raises an exception if the latter doesn't return **None** or a string object,

datetime.**timetuple()**
Return a `time.struct_time` such as returned by `time.localtime()`. d.timetuple() is equivalent to `time.struct_time((d.year, d.month, d.day, d.hour, d.minute, d.second, d.weekday(), d.toordinal() - date(d.year, 1, 1).toordinal() + 1, dst))` The **tm_isdst** flag of the result is set according to the **dst()** method: **tzinfo** is **None** or **dst()** returns **None**, **tm_isdst** is set to `-1`; else if **dst()** returns a non-zero value, **tm_isdst** is set to `1`; else **tm_isdst** is set to `0`.

datetime.**utctimetuple()**
If datetime instance **d** is naive, this is the same as d.timetuple() except that **tm_isdst** is forced to `0` regardless of what d.dst() returns. DST is never in effect for a UTC time.
If \( d \) is aware, \( d \) is normalized to UTC time, by subtracting \( d.utcoffset() \), and a \texttt{time.struct_time} for the normalized time is returned. \texttt{tm.isdst} is forced to 0. Note that the result's \texttt{tm.year} member may be \texttt{MINYEAR-1} or \texttt{MAXYEAR+1}, if \( d.year \) was \texttt{MINYEAR} or \texttt{MAXYEAR} and UTC adjustment spills over a year boundary.

\texttt{datetime.toordinal()}  
Return the proleptic Gregorian ordinal of the date. The same as \texttt{self.date().toordinal()}.

\texttt{datetime.weekday()}  
Return the day of the week as an integer, where Monday is 0 and Sunday is 6. The same as \texttt{self.date().weekday()}. See also \texttt{isoweekday()}.

\texttt{datetime.isoweekday()}  
Return the day of the week as an integer, where Monday is 1 and Sunday is 7. The same as \texttt{self.date().isoweekday()}. See also \texttt{weekday()}, \texttt{isocalendar()}.

\texttt{datetime.isocalendar()}  
Return a 3-tuple, (ISO year, ISO week number, ISO weekday). The same as \texttt{self.date().isocalendar()}.

\texttt{datetime.isoformat([sep])}  
Return a string representing the date and time in ISO 8601 format, YYYY-MM-DDTHH:MM:SS.mmmmmm or, if \texttt{microsecond} is 0, YYYY-MM-DDTHH:MM:SS

If \texttt{utcoffset()} does not return \texttt{None}, a 6-character string is appended, giving the UTC offset in (signed) hours and minutes: YYYY-MM-DDTHH:MM:SS.mmmmmm+HH:MM or, if \texttt{microsecond} is 0 YYYY-MM-DDTHH:MM:SS+HH:MM
The optional argument `sep` (default 'T') is a one-character separator, placed between the date and time portions of the result. For example,

```python
>>> from datetime import tzinfo, timedelta, datetime
class TZ(tzinfo):
    def utcoffset(self, dt): return timedelta(minutes=-3)

>>> datetime(2002, 12, 25, tzinfo=TZ()).isoformat(' T')
'2002-12-25 00:00:00-06:39'
```

`datetime.__str__()`

For a `datetime` instance `d`, `str(d)` is equivalent to `d.isoformat(' ')`.

`datetime.ctime()`

Return a string representing the date and time, for example `datetime(2002, 12, 4, 20, 30, 40).ctime() == 'Wed Dec 4 20:30:40 2002'`. `d.ctime()` is equivalent to `time.ctime(time.mktime(d.timetuple()))` on platforms where the native C `ctime` function (which `time.ctime()` invokes, but which `datetime.ctime()` does not invoke) conforms to the C standard.

`datetime.strftime(format)`

Return a string representing the date and time, controlled by an explicit format string. See section `strftime() Behavior`.

Examples of working with datetime objects:

```python
>>> from datetime import datetime, date, time
>>> # Using datetime.combine()
d = date(2005, 7, 14)
t = time(12, 30)
datetime.combine(d, t)
datetime.datetime(2005, 7, 14, 12, 30)
```
Using datetime with tzinfo:

```python
>>> # Using datetime.now() or datetime.utcnow()
>>> datetime.now()
datetime.datetime(2007, 12, 6, 16, 29, 43, 79043)  # GMT +1
>>> datetime.utcnow()
datetime.datetime(2007, 12, 6, 15, 29, 43, 79060)

>>> # Using datetime.strptime()
>>> dt = datetime.strptime("21/11/06 16:30", "%d/%m/%y %H:%M")
>>> dt
datetime.datetime(2006, 11, 21, 16, 30)

>>> # Using datetime.timetuple() to get tuple of all attributes
>>> tt = dt.timetuple()

>>> for it in tt:
...     print it
...
2006  # year
11   # month
21   # day
16   # hour
30   # minute
0    # second
1    # weekday (0 = Monday)
325  # number of days since 1st January
-1   # dst - method tzinfo.dst() returned None

>>> # Date in ISO format
>>> ic = dt.isocalendar()

>>> for it in ic:
...     print it
...
2006  # ISO year
47    # ISO week
2     # ISO weekday

>>> # Formatting datetime
>>> dt.strftime("%A, %d. %B %Y %I:%M%p")
'Tuesday, 21. November 2006 04:30PM'

>>> # Using datetime with tzinfo:
>>> from datetime import timedelta, datetime, tzinfo
>>> class GMT1(tzinfo):
...     def __init__(self):
...         # DST starts last Sunday in March
...         d = datetime(dt.year, 4, 1)    # ends last Sunday in October
...         self.dston = d - timedelta(days=d.weekday() + 1)
...         d = datetime(dt.year, 11, 1)
...         self.dstoff = d - timedelta(days=d.weekday() + 1)
...     def utcoffset(self, dt):
...         return timedelta(hours=1) + self.dst(dt)
...     def dst(self, dt):
```

... if self.dston <= dt.replace(tzinfo=None) < self.dstoff:
    return timedelta(hours=1)
else:
    return timedelta(0)
def tzname(self, dt):
    return "GMT +1"

>>> class GMT2(tzinfo):
...     def __init__(self):
...         d = datetime(dt.year, 4, 1)
...         self.dston = d - timedelta(days=d.weekday() + 1)
...         d = datetime(dt.year, 11, 1)
...         self.dstoff = d - timedelta(days=d.weekday() + 1)
...     def utcoffset(self, dt):
...         return timedelta(hours=1) + self.dst(dt)
...     def dst(self, dt):
...         if self.dston <= dt.replace(tzinfo=None) < self.dstoff:
...             return timedelta(hours=2)
...         else:
...             return timedelta(0)
...     def tzname(self, dt):
...         return "GMT +2"

>>> gmt1 = GMT1()
>>> # Daylight Saving Time
>>> dt1 = datetime(2006, 11, 21, 16, 30, tzinfo=gmt1)
>>> dt1.dst() #datetime.timedelta(0)
>>> dt1.utcoffset() #datetime.timedelta(0, 3600)
>>> dt2 = datetime(2006, 6, 14, 13, 0, tzinfo=gmt1)
>>> dt2.dst() #datetime.timedelta(0, 3600)
>>> dt2.utcoffset() #datetime.timedelta(0, 7200)
>>> # Convert datetime to another time zone
>>> dt3 = dt2.astimezone(GMT2())
>>> dt3 # doctest: +ELLIPSIS
datetime.datetime(2006, 6, 14, 13, 0, tzinfo=<GMT2 object at 0x...>)
>>> dt2 # doctest: +ELLIPSIS
datetime.datetime(2006, 6, 14, 14, 0, tzinfo=<GMT1 object at 0x...>)
>>> dt2.utctimetuple() == dt3.utctimetuple()
True
A time object represents a (local) time of day, independent of any particular day, and subject to adjustment via a `tzinfo` object.

```python
class datetime.time(hour[, minute[, second[, microsecond[, tzinfo]]]])
```

All arguments are optional. `tzinfo` may be `None`, or an instance of a `tzinfo` subclass. The remaining arguments may be ints or longs, in the following ranges:

- $0 \leq \text{hour} < 24$
- $0 \leq \text{minute} < 60$
- $0 \leq \text{second} < 60$
- $0 \leq \text{microsecond} < 1000000$

If an argument outside those ranges is given, `ValueError` is raised. All default to 0 except `tzinfo`, which defaults to `None`.

### Class attributes:

- `time.min`  
  The earliest representable time, `time(0, 0, 0, 0)`.

- `time.max`  
  The latest representable time, `time(23, 59, 59, 999999)`.

- `time.resolution`  
  The smallest possible difference between non-equal time objects, `timedelta(microseconds=1)`, although note that arithmetic on time objects is not supported.

### Instance attributes (read-only):
The `time` module provides several operations:

- `time.hour` should be an integer in the range `0 <= hour < 24`.
- `time.minute` should be an integer in the range `0 <= minute < 60`.
- `time.second` should be an integer in the range `0 <= second < 60`.
- `time.microsecond` should be an integer in the range `0 <= microsecond < 1000000`.

The `time.tzinfo` attribute is used to specify the time zone where a given time is relative to UTC. The object passed as the `tzinfo` argument to the `time` constructor, or `None` if none was passed.

Supported operations:

- Comparison of `time` to `time`, where `a` is considered less than `b` when `a` precedes `b` in time. If one comparand is naive and the other is aware, `TypeError` is raised. If both comparands are aware, and have the same `tzinfo` member, the common `tzinfo` member is ignored and the base times are compared. If both comparands are aware and have different `tzinfo` members, the comparands are first adjusted by subtracting their UTC offsets (obtained from `self.utcoffset()`). In order to stop mixed-type comparisons from falling back to the default comparison by object address, when a `time` object is compared to an object of a different type, `TypeError` is raised unless the comparison is `==` or `!=`. The latter cases return `False` or `True`, respectively.
- `hash`, use as dict key
- Efficient pickling
- In Boolean contexts, a `time` object is considered to be true if and only if, after converting it to minutes and subtracting `utcoffset()`
(or 0 if that's None), the result is non-zero.

Instance methods:

```python
time.replace([hour[, minute[, second[, microsecond[, tzinfo]]]]])
```
Return a `time` with the same value, except for those members given new values by whichever keyword arguments are specified. Note that `tzinfo=None` can be specified to create a naive `time` from an aware `time`, without conversion of the time members.

```python
time.isoformat()
```
Return a string representing the time in ISO 8601 format, HH:MM:SS.mmmmmm or, if self.microsecond is 0, HH:MM:SS If `utcoffset()` does not return `None`, a 6-character string is appended, giving the UTC offset in (signed) hours and minutes: HH:MM:SS.mmmmmm+HH:MM or, if self.microsecond is 0, HH:MM:SS+HH:MM

```python
time.__str__()
```
For a time `t`, `str(t)` is equivalent to `t.isoformat()`.

```python
time.strftime(format)
```
Return a string representing the time, controlled by an explicit format string. See section `strftime()` Behavior.

```python
time.utcoffset()
```
If `tzinfo` is `None`, returns `None`, else returns `self.tzinfo.utcoffset(None)`, and raises an exception if the latter doesn't return `None` or a `timedelta` object representing a whole number of minutes with magnitude less than one day.

```python
time.dst()
```
If `tzinfo` is `None`, returns `None`, else returns
self.tzinfo.dst(None), and raises an exception if the latter doesn't return None, or a timedelta object representing a whole number of minutes with magnitude less than one day.

time.tzname()
If tzinfo is None, returns None, else returns self.tzinfo.tzname(None), or raises an exception if the latter doesn't return None or a string object.

Example:

```python
>>> from datetime import time, tzinfo
>>> class GMT1(tzinfo):
...     def utcoffset(self, dt):
...         return timedelta(hours=1)
...     def dst(self, dt):
...         return timedelta(0)
...     def tzname(self, dt):
...         return "Europe/Prague"
...>>> t = time(12, 10, 30, tzinfo=GMT1())
>>> t # doctest: +ELLIPSIS
datetime.time(12, 10, 30, tzinfo=<GMT1 object at 0x...>)
>>> gmt = GMT1()
>>> t.isoformat()
'12:10:30+01:00'
>>> t.dst()
datetime.timedelta(0)
>>> t.tzname()
'Europe/Prague'
>>> t.strftime("%H:%M:%S %Z")
'12:10:30 Europe/Prague'
```
**tzinfo Objects**

*tzinfo* is an abstract base class, meaning that this class should not be instantiated directly. You need to derive a concrete subclass, and (at least) supply implementations of the standard *tzinfo* methods needed by the *datetime* methods you use. The *datetime* module does not supply any concrete subclasses of *tzinfo*.

An instance of (a concrete subclass of) *tzinfo* can be passed to the constructors for *datetime* and *time* objects. The latter objects view their members as being in local time, and the *tzinfo* object supports methods revealing offset of local time from UTC, the name of the time zone, and DST offset, all relative to a date or time object passed to them.

Special requirement for pickling: A *tzinfo* subclass must have an *__init__()* method that can be called with no arguments, else it can be pickled but possibly not unpickled again. This is a technical requirement that may be relaxed in the future.

A concrete subclass of *tzinfo* may need to implement the following methods. Exactly which methods are needed depends on the uses made of aware *datetime* objects. If in doubt, simply implement all of them.

*tzinfo.* **utcoffset**(self, dt)

Return offset of local time from UTC, in minutes east of UTC. If local time is west of UTC, this should be negative. Note that this is intended to be the total offset from UTC; for example, if a *tzinfo* object represents both time zone and DST adjustments, *utcoffset()* should return their sum. If the UTC offset isn’t known, return *None*. Else the value returned must be a *timedelta*.
object specifying a whole number of minutes in the range -1439 to 1439 inclusive (1440 = 24*60; the magnitude of the offset must be less than one day). Most implementations of utcoffset() will probably look like one of these two:

```
return CONSTANT            # fixed-offset class
return CONSTANT + self.dst(dt)  # daylight-aware class
```

If utcoffset() does not return None, dst() should not return None either.

The default implementation of utcoffset() raises NotImplemented.

tzinfo. dst(self, dt)

Return the daylight saving time (DST) adjustment, in minutes east of UTC, or None if DST information isn’t known. Return timedelta(0) if DST is not in effect. If DST is in effect, return the offset as a timedelta object (see utcoffset() for details). Note that DST offset, if applicable, has already been added to the UTC offset returned by utcoffset(), so there’s no need to consult dst() unless you’re interested in obtaining DST info separately. For example, datetime.timetuple() calls its tzinfo member’s dst() method to determine how the tm_isdst flag should be set, and tzinfo.fromutc() calls dst() to account for DST changes when crossing time zones.

An instance tz of a tzinfo subclass that models both standard and daylight times must be consistent in this sense:

```
tz.utcoffset(dt) - tz.dst(dt)
```

must return the same result for every datetime dt with dt.tzinfo == tz For sane tzinfo subclasses, this expression yields the
time zone's "standard offset", which should not depend on the date or the time, but only on geographic location. The implementation of `datetime.astimezone()` relies on this, but cannot detect violations; it's the programmer's responsibility to ensure it. If a `tzinfo` subclass cannot guarantee this, it may be able to override the default implementation of `tzinfo.fromutc()` to work correctly with `astimezone()` regardless.

Most implementations of `dst()` will probably look like one of these two:

```python
def dst(self):
    # a fixed-offset class: doesn't account for DST
    return timedelta(0)
```

or

```python
def dst(self):
    # Code to set dston and dstoff to the time zone's DST
    # transition times based on the input dt.year, and expre
    # in standard local time. Then

    if dston <= dt.replace(tzinfo=None) < dstoff:
        return timedelta(hours=1)
    else:
        return timedelta(0)
```

The default implementation of `dst()` raises `NotImplementedError`.

`tzinfo.tzname(self, dt)`

Return the time zone name corresponding to the `datetime` object `dt`, as a string. Nothing about string names is defined by the `datetime` module, and there's no requirement that it mean
anything in particular. For example, “GMT”, “UTC”, “-500”, “-5:00”, “EDT”, “US/Eastern”, “America/New York” are all valid replies. Return None if a string name isn’t known. Note that this is a method rather than a fixed string primarily because some tzinfo subclasses will wish to return different names depending on the specific value of dt passed, especially if the tzinfo class is accounting for daylight time.

The default implementation of tzname() raises NotImplementedError.

These methods are called by a datetime or time object, in response to their methods of the same names. A datetime object passes itself as the argument, and a time object passes None as the argument. A tzinfo subclass’s methods should therefore be prepared to accept a dt argument of None, or of class datetime.

When None is passed, it’s up to the class designer to decide the best response. For example, returning None is appropriate if the class wishes to say that time objects don’t participate in the tzinfo protocols. It may be more useful for utcoffset(None) to return the standard UTC offset, as there is no other convention for discovering the standard offset.

When a datetime object is passed in response to a datetime method, dt.tzinfo is the same object as self. tzinfo methods can rely on this, unless user code calls tzinfo methods directly. The intent is that the tzinfo methods interpret dt as being in local time, and not need worry about objects in other timezones.

There is one more tzinfo method that a subclass may wish to override:
tzinfo.fromutc(self, dt)

This is called from the default datetime.astimezone() implementation. When called from that, dt.tzinfo is self, and dt's date and time members are to be viewed as expressing a UTC time. The purpose of fromutc() is to adjust the date and time members, returning an equivalent datetime in self's local time.

Most tzinfo subclasses should be able to inherit the default fromutc() implementation without problems. It's strong enough to handle fixed-offset time zones, and time zones accounting for both standard and daylight time, and the latter even if the DST transition times differ in different years. An example of a time zone the default fromutc() implementation may not handle correctly in all cases is one where the standard offset (from UTC) depends on the specific date and time passed, which can happen for political reasons. The default implementations of astimezone() and fromutc() may not produce the result you want if the result is one of the hours straddling the moment the standard offset changes.

Skipping code for error cases, the default fromutc() implementation acts like:

```python
def fromutc(self, dt):
    # raise ValueError error if dt.tzinfo is not self
dtoff = dt.utcoffset()
dtdst = dt.dst()
    # raise ValueError if dtoff is None or dtdst is None
delta = dtoff - dtdst  # this is self's standard offset
    if delta:
        dt += delta  # convert to standard local time
        dtdst = dt.dst()
        # raise ValueError if dtdst is None
```
if dtdst:
    return dt + dtdst
else:
    return dt

Example tzinfo classes:

from datetime import tzinfo, timedelta, datetime
ZERO = timedelta(0)
HOUR = timedelta(hours=1)

# A UTC class.
class UTC(tzinfo):
    """UTC""
    def utcoffset(self, dt):
        return ZERO
    def tzname(self, dt):
        return "UTC"
    def dst(self, dt):
        return ZERO

utc = UTC()

# A class building tzinfo objects for fixed-offset time zones.
# Note that FixedOffset(0, "UTC") is a different way to build a
# UTC tzinfo object.
class FixedOffset(tzinfo):
    """Fixed offset in minutes east from UTC.""
    def __init__(self, offset, name):
        self.__offset = timedelta(minutes = offset)
        self.__name = name
    def utcoffset(self, dt):
        return self.__offset
    def tzname(self, dt):
        return self.__name
    def dst(self, dt):
# A class capturing the platform's idea of local time.

```python
import time as _time

STDOFFSET = timedelta(seconds = -_time.timezone)
if _time.daylight:
    DSTOFFSET = timedelta(seconds = -_time.altzone)
else:
    DSTOFFSET = STDOFFSET

DSTDIFF = DSTOFFSET - STDOFFSET

class LocalTimezone(tzinfo):
    def utcoffset(self, dt):
        if self._isdst(dt):
            return DSTOFFSET
        else:
            return STDOFFSET

    def dst(self, dt):
        if self._isdst(dt):
            return DSTDIFF
        else:
            return ZERO

    def tzname(self, dt):
        return _time.tzname[self._isdst(dt)]

    def _isdst(self, dt):
        tt = (dt.year, dt.month, dt.day,
              dt.hour, dt.minute, dt.second,
              dt.weekday(), 0, -1)
        stamp = _time.mktime(tt)
        tt = _time.localtime(stamp)
        return tt.tm_isdst > 0

Local = LocalTimezone()
```

# A complete implementation of current DST rules for major US t

```python
def first_sunday_on_or_after(dt):
    days_to_go = 6 - dt.weekday()
    if days_to_go:
        dt += timedelta(days_to_go)
    return dt
```
# US DST Rules
#

    def dst(self, dt):
        if dt is None or dt.tzinfo is None:
            # An exception may be sensible here, in one or both cases.
            # It depends on how you want to treat them. The default

from utc() implementation (called by the default astimezone() implementation) passes a datetime with dt.tzinfo
return ZERO
assert dt.tzinfo is self

# Find start and end times for US DST. For years before # ZERO for no DST.
if 2006 < dt.year:
    dststart, dstend = DSTSTART_2007, DSTEND_2007
elif 1986 < dt.year < 2007:
elif 1966 < dt.year < 1987:
else:
    return ZERO

start = first_sunday_on_or_after(dststart.replace(year=dt.year))
end = first_sunday_on_or_after(dstend.replace(year=dt.year))

# Can't compare naive to aware objects, so strip the timezone # dt first.
if start <= dt.replace(tzinfo=None) < end:
    return HOUR
else:
    return ZERO

Eastern = USTimeZone(-5, "Eastern", "EST", "EDT")
Central = USTimeZone(-6, "Central", "CST", "CDT")
Mountain = USTimeZone(-7, "Mountain", "MST", "MDT")
Pacific = USTimeZone(-8, "Pacific", "PST", "PDT")

Note that there are unavoidable subtleties twice per year in a tzinfo subclass accounting for both standard and daylight time, at the DST transition points. For concreteness, consider US Eastern (UTC -0500), where EDT begins the minute after 1:59 (EST) on the first Sunday in April, and ends the minute after 1:59 (EDT) on the last Sunday in October:

<table>
<thead>
<tr>
<th>time</th>
<th>UTC</th>
<th>EST</th>
<th>EDT</th>
<th>Pacific</th>
</tr>
</thead>
<tbody>
<tr>
<td>start</td>
<td>22:MM</td>
<td>23:MM</td>
<td>0:MM</td>
<td>3:MM</td>
</tr>
<tr>
<td>end</td>
<td>23:MM</td>
<td>0:MM</td>
<td>1:MM</td>
<td>3:MM</td>
</tr>
</tbody>
</table>
When DST starts (the “start” line), the local wall clock leaps from 1:59 to 3:00. A wall time of the form 2:MM doesn’t really make sense on that day, so `astimezone(Eastern)` won’t deliver a result with `hour == 2` on the day DST begins. In order for `astimezone()` to make this guarantee, the `tzinfo.dst()` method must consider times in the “missing hour” (2:MM for Eastern) to be in daylight time.

When DST ends (the “end” line), there’s a potentially worse problem: there’s an hour that can’t be spelled unambiguously in local wall time: the last hour of daylight time. In Eastern, that’s times of the form 5:MM UTC on the day daylight time ends. The local wall clock leaps from 1:59 (daylight time) back to 1:00 (standard time) again. Local times of the form 1:MM are ambiguous. `astimezone()` mimics the local clock’s behavior by mapping two adjacent UTC hours into the same local hour then. In the Eastern example, UTC times of the form 5:MM and 6:MM both map to 1:MM when converted to Eastern. In order for `astimezone()` to make this guarantee, the `tzinfo.dst()` method must consider times in the “repeated hour” to be in standard time. This is easily arranged, as in the example, by expressing DST switch times in the time zone’s standard local time.

Applications that can’t bear such ambiguities should avoid using hybrid `tzinfo` subclasses; there are no ambiguities when using UTC, or any other fixed-offset `tzinfo` subclass (such as a class representing only EST (fixed offset -5 hours), or only EDT (fixed offset -4 hours)).
strftime() Behavior

date, datetime, and time objects all support a `strftime(format)` method, to create a string representing the time under the control of an explicit format string. Broadly speaking, `d.strftime(fmt)` acts like the `time` module's `time.strftime(fmt, d.timetuple())` although not all objects support a `timetuple()` method.

For time objects, the format codes for year, month, and day should not be used, as time objects have no such values. If they're used anyway, 1900 is substituted for the year, and 0 for the month and day.

For date objects, the format codes for hours, minutes, seconds, and microseconds should not be used, as date objects have no such values. If they're used anyway, 0 is substituted for them.

time and datetime objects support a `%f` format code which expands to the number of microseconds in the object, zero-padded on the left to six places.

*New in version 2.6.*

For a naive object, the `%z` and `%Z` format codes are replaced by empty strings.

For an aware object:

```
%z
```

`utcoffset()` is transformed into a 5-character string of the form +HHMM or -HHMM, where HH is a 2-digit string giving the number of UTC offset hours, and MM is a 2-digit string giving the number of UTC offset minutes. For example, if `utcoffset()`
returns `timedelta(hours=-3, minutes=-30)`, `%z` is replaced with the string '0330'.

If `tzname()` returns `None`, `%Z` is replaced by an empty string. Otherwise `%Z` is replaced by the returned value, which must be a string.

The full set of format codes supported varies across platforms, because Python calls the platform C library's `strftime()` function, and platform variations are common.

The following is a list of all the format codes that the C standard (1989 version) requires, and these work on all platforms with a standard C implementation. Note that the 1999 version of the C standard added additional format codes.

The exact range of years for which `strftime()` works also varies across platforms. Regardless of platform, years before 1900 cannot be used.

Notes:

1. When used with the `strptime()` function, the `%f` directive accepts from one to six digits and zero pads on the right. `%f` is
an extension to the set of format characters in the C standard.

2. When used with the strftime() function, the %p directive only affects the output hour field if the %I directive is used to parse the hour.

3. The range really is 0 to 61; this accounts for leap seconds and the (very rare) double leap seconds.

4. When used with the strftime() function, %U and %W are only used in calculations when the day of the week and the year are specified.

5. For example, if utcoffset() returns timedelta(hours=-3, minutes=-30), %z is replaced with the string '-0330'.
This module allows you to output calendars like the Unix `cal` program, and provides additional useful functions related to the calendar. By default, these calendars have Monday as the first day of the week, and Sunday as the last (the European convention). Use `setfirstweekday()` to set the first day of the week to Sunday (6) or to any other weekday. Parameters that specify dates are given as integers. For related functionality, see also the `datetime` and `time` modules.

Most of these functions and classes rely on the `datetime` module which uses an idealized calendar, the current Gregorian calendar indefinitely extended in both directions. This matches the definition of the “proleptic Gregorian” calendar in Dershowitz and Reingold’s book “Calendrical Calculations”, where it’s the base calendar for all computations.

```python
class calendar.Calendar([firstweekday])

Creates a Calendar object. firstweekday is an integer specifying the first day of the week. 0 is Monday (the default), 6 is Sunday.

A Calendar object provides several methods that can be used for preparing the calendar data for formatting. This class doesn’t do any formatting itself. This is the job of subclasses.

New in version 2.5.

Calendar instances have the following methods:

iterweekdays()```
Return an iterator for the week day numbers that will be used for one week. The first value from the iterator will be the same as the value of the firstweekday property.

`itermonthdates(year, month)`
Return an iterator for the month `month` (1-12) in the year `year`. This iterator will return all days (as `datetime.date` objects) for the month and all days before the start of the month or after the end of the month that are required to get a complete week.

`itermonthdays2(year, month)`
Return an iterator for the month `month` in the year `year` similar to `itermonthdates()`. Days returned will be tuples consisting of a day number and a week day number.

`itermonthdays(year, month)`
Return an iterator for the month `month` in the year `year` similar to `itermonthdates()`. Days returned will simply be day numbers.

`monthdatescalendar(year, month)`
Return a list of the weeks in the month `month` of the `year` as full weeks. Weeks are lists of seven `datetime.date` objects.

`monthdays2calendar(year, month)`
Return a list of the weeks in the month `month` of the `year` as full weeks. Weeks are lists of seven tuples of day numbers and weekday numbers.

`monthdayscalendar(year, month)`
Return a list of the weeks in the month `month` of the `year` as full weeks. Weeks are lists of seven day numbers.

`yeardatescalendar(year[, width])`
Return the data for the specified year ready for formatting. The return value is a list of month rows. Each month row contains up to \textit{width} months (defaulting to 3). Each month contains between 4 and 6 weeks and each week contains 1–7 days. Days are \texttt{datetime.date} objects.

\texttt{yeardays2calendar(year[, width])}

Return the data for the specified year ready for formatting (similar to \texttt{yeardatescalendar()}). Entries in the week lists are tuples of day numbers and weekday numbers. Day numbers outside this month are zero.

\texttt{yeardayscalendar(year[, width])}

Return the data for the specified year ready for formatting (similar to \texttt{yeardatescalendar()}). Entries in the week lists are day numbers. Day numbers outside this month are zero.

\texttt{class calendar.TextCalendar([firstweekday])}

This class can be used to generate plain text calendars.

\textit{New in version 2.5}.

\texttt{TextCalendar} instances have the following methods:

\texttt{formatmonth(theyear, themonth[, w[, l]])}

Return a month’s calendar in a multi-line string. If \textit{w} is provided, it specifies the width of the date columns, which are centered. If \textit{l} is given, it specifies the number of lines that each week will use. Depends on the first weekday as specified in the constructor or set by the \texttt{setfirstweekday()} method.

\texttt{prmonth(theyear, themonth[, w[, l]])}

Print a month’s calendar as returned by \texttt{formatmonth()}. 
formatyear\( (\text{theyear}, \text{themonth}[, \ w[, \ l[, \ c[, \ m]]]]) \)

Return a \( m \)-column calendar for an entire year as a multi-line string. Optional parameters \( w \), \( l \), and \( c \) are for date column width, lines per week, and number of spaces between month columns, respectively. Depends on the first weekday as specified in the constructor or set by the \texttt{setfirstweekday()} method. The earliest year for which a calendar can be generated is platform-dependent.

\( \text{pryear}(\text{theyear}[, \ w[, \ l[, \ c[, \ m]]]]) \)

Print the calendar for an entire year as returned by \texttt{formatyear()}.  

\begin{verbatim}
class calendar.HTMLCalendar([\texttt{firstweekday}])
This class can be used to generate HTML calendars.

\textit{New in version 2.5.}
\end{verbatim}

\texttt{HTMLCalendar} instances have the following methods:

formatmonth\( (\text{theyear}, \text{themonth}[, \text{withyear}]) \)

Return a month’s calendar as an HTML table. If \texttt{withyear} is true the year will be included in the header, otherwise just the month name will be used.

formatyear\( (\text{theyear}, \text{themonth}[, \text{width}]) \)

Return a year’s calendar as an HTML table. \texttt{width} (defaulting to 3) specifies the number of months per row.

formatyearpage\( (\text{theyear}[, \text{width}[, \text{css}[, \text{encoding}]]]) \)

Return a year’s calendar as a complete HTML page. \texttt{width} (defaulting to 3) specifies the number of months per row. \texttt{css} is the name for the cascading style sheet to be used. \texttt{None} can be passed if no style sheet should be used. \texttt{encoding}
specifies the encoding to be used for the output (defaulting to the system default encoding).

class calendar. **LocaleTextCalendar**([firstweekday[, locale]])

This subclass of TextCalendar can be passed a locale name in the constructor and will return month and weekday names in the specified locale. If this locale includes an encoding all strings containing month and weekday names will be returned as unicode.

*New in version 2.5.*

class calendar. **LocaleHTMLCalendar**([firstweekday[, locale]])

This subclass of HTMLCalendar can be passed a locale name in the constructor and will return month and weekday names in the specified locale. If this locale includes an encoding all strings containing month and weekday names will be returned as unicode.

*New in version 2.5.*

For simple text calendars this module provides the following functions.

calendar. **setfirstweekday**(weekday)

Sets the weekday (0 is Monday, 6 is Sunday) to start each week. The values **MONDAY**, **TUESDAY**, **WEDNESDAY**, **THURSDAY**, **FRIDAY**, **SATURDAY**, and **SUNDAY** are provided for convenience. For example, to set the first weekday to Sunday:

```python
import calendar
calendar.setfirstweekday(calendar.SUNDAY)
```

*New in version 2.0.*
calendar.**firstweekday()**
Returns the current setting for the weekday to start each week.

*New in version 2.0.*

calendar.**isleap(year)**
Returns **True** if `year` is a leap year, otherwise **False**.

calendar.**leapdays(y1, y2)**
Returns the number of leap years in the range from `y1` to `y2` (exclusive), where `y1` and `y2` are years.

*Changed in version 2.0:* This function didn’t work for ranges spanning a century change in Python 1.5.2.

calendar.**weekday(year, month, day)**
Returns the day of the week (0 is Monday) for `year` (1970–...), `month` (1–12), `day` (1–31).

calendar.**weekheader(n)**
Return a header containing abbreviated weekday names. `n` specifies the width in characters for one weekday.

calendar.**monthrange(year, month)**
Returns weekday of first day of the month and number of days in month, for the specified `year` and `month`.

calendar.**monthcalendar(year, month)**
Returns a matrix representing a month’s calendar. Each row represents a week; days outside of the month a represented by zeros. Each week begins with Monday unless set by `setfirstweekday()`.

calendar.**prmonth(theyear, themonth[, w[, l]])**
Prints a month’s calendar as returned by `month()`.

```python
calendar.month(theyear, themonth[, w[, l]])
```

Returns a month’s calendar in a multi-line string using the `formatmonth()` of the `TextCalendar` class.

*New in version 2.0.*

```python
calendar.prcal(year[, w[, l[, c]]])
```

Prints the calendar for an entire year as returned by `calendar()`.

```python
calendar.calendar(year[, w[, l[, c]]])
```

Returns a 3-column calendar for an entire year as a multi-line string using the `formatyear()` of the `TextCalendar` class.

*New in version 2.0.*

```python
calendar.timegm(tuple)
```

An unrelated but handy function that takes a time tuple such as returned by the `gmtime()` function in the `time` module, and returns the corresponding Unix timestamp value, assuming an epoch of 1970, and the POSIX encoding. In fact, `time.gmtime()` and `timegm()` are each others’ inverse.

*New in version 2.0.*

The `calendar` module exports the following data attributes:

```python
calendar.day_name
```

An array that represents the days of the week in the current locale.

```python
calendar.day_abbr
```

An array that represents the abbreviated days of the week in the
current locale.

**calendar.month_name**

An array that represents the months of the year in the current locale. This follows normal convention of January being month number 1, so it has a length of 13 and `month_name[0]` is the empty string.

**calendar.month_abbr**

An array that represents the abbreviated months of the year in the current locale. This follows normal convention of January being month number 1, so it has a length of 13 and `month_abbr[0]` is the empty string.

**See also:**

**Module datetime**

Object-oriented interface to dates and times with similar functionality to the time module.

**Module time**

Low-level time related functions.
New in version 2.4.

This module implements high-performance container datatypes. Currently, there are two datatypes, deque and defaultdict, and one datatype factory function, namedtuple().

Changed in version 2.5: Added defaultdict.

Changed in version 2.6: Added namedtuple().

The specialized containers provided in this module provide alternatives to Python’s general purpose built-in containers, dict, list, set, and tuple.

Besides the containers provided here, the optional bsddb module offers the ability to create in-memory or file based ordered dictionaries with string keys using the bsddb.btopen() method.

In addition to containers, the collections module provides some ABCs (abstract base classes) that can be used to test whether a class provides a particular interface, for example, is it hashable or a mapping.

Changed in version 2.6: Added abstract base classes.
ABCs - abstract base classes

The collections module offers the following ABCs:

<table>
<thead>
<tr>
<th>ABC</th>
<th>Inherits</th>
<th>Abstract Methods</th>
<th>Mixin Methods</th>
</tr>
</thead>
<tbody>
<tr>
<td>Container</td>
<td></td>
<td><strong>contains</strong></td>

</tr>
<tr>
<td>Mapping</td>
<td>Sized, Iterable, Container</td>
<td><strong>getitem</strong>, <strong>len</strong>, <strong>iter</strong></td>
<td><strong>contains</strong>, keys, items, values, get, <strong>eq</strong>, and <strong>ne</strong></td>
</tr>
</tbody>
</table>

|                          |                           | __getitem__      |                        |
|                          |                           |                  |                        |
MutableMapping Mapping

__setitem__,
__delitem__,
__iter__,
and __len__

Inherited Mapping methods and pop, popitem, clear, update, and setdefault

MappingView Sized

__len__

KeysView MappingView, Set

__contains__,
__iter__

ItemsView MappingView, Set

__contains__,
__iter__

ValuesView MappingView

__contains__,
__iter__

These ABCs allow us to ask classes or instances if they provide particular functionality, for example:

```python
size = None
if isinstance(myvar, collections.Sized):
    size = len(myvar)
```

Several of the ABCs are also useful as mixins that make it easier to develop classes supporting container APIs. For example, to write a class supporting the full set API, it only necessary to supply the three underlying abstract methods: __contains__(), __iter__(), and __len__(). The ABC supplies the remaining methods such as __and__() and isdisjoint()
return len(self.elements)

s1 = ListBasedSet('abcdef')
s2 = ListBasedSet('defghi')
overlap = s1 & s2  # The __and__() method is supported

Notes on using Set and MutableSet as a mixin:

1. Since some set operations create new sets, the default mixin methods need a way to create new instances from an iterable. The class constructor is assumed to have a signature in the form ClassName(iterable). That assumption is factored-out to an internal classmethod called _from_iterable() which calls cls(iterable) to produce a new set. If the set mixin is being used in a class with a different constructor signature, you will need to override from_iterable() with a classmethod that can construct new instances from an iterable argument.

2. To override the comparisons (presumably for speed, as the semantics are fixed), redefine __le__() and then the other operations will automatically follow suit.

3. The set mixin provides a _hash() method to compute a hash value for the set; however, __hash__() is not defined because not all sets are hashable or immutable. To add set hashabilty using mixins, inherit from both Set() and Hashable(), then define __hash__ = Set._hash.

(For more about ABCs, see the abc module and PEP 3119.)
**deque objects**

class collections.deque([iterable[, maxlen]])

Returns a new deque object initialized left-to-right (using append()) with data from iterable. If iterable is not specified, the new deque is empty.

Deques are a generalization of stacks and queues (the name is pronounced “deck” and is short for “double-ended queue”). Deques support thread-safe, memory efficient appends and pops from either side of the deque with approximately the same O(1) performance in either direction.

Though list objects support similar operations, they are optimized for fast fixed-length operations and incur O(n) memory movement costs for pop(0) and insert(0, v) operations which change both the size and position of the underlying data representation.

*New in version 2.4.*

If maxlen is not specified or is None, deques may grow to an arbitrary length. Otherwise, the deque is bounded to the specified maximum length. Once a bounded length deque is full, when new items are added, a corresponding number of items are discarded from the opposite end. Bounded length deques provide functionality similar to the tail filter in Unix. They are also useful for tracking transactions and other pools of data where only the most recent activity is of interest.

*Changed in version 2.6: Added maxlen parameter.*

Deque objects support the following methods:
**append(x)**
Add x to the right side of the deque.

**appendleft(x)**
Add x to the left side of the deque.

**clear()**
Remove all elements from the deque leaving it with length 0.

**extend(iterable)**
Extend the right side of the deque by appending elements from the iterable argument.

**extendleft(iterable)**
Extend the left side of the deque by appending elements from iterable. Note, the series of left appends results in reversing the order of elements in the iterable argument.

**pop()**
Remove and return an element from the right side of the deque. If no elements are present, raises an `IndexError`.

**popleft()**
Remove and return an element from the left side of the deque. If no elements are present, raises an `IndexError`.

**remove(value)**
Removed the first occurrence of value. If not found, raises a `ValueError`.

*New in version 2.5.*

**rotate(n)**
Rotate the deque n steps to the right. If n is negative, rotate to the left. Rotating one step to the right is equivalent to:
\[d.appendleft(d.pop())).\]
In addition to the above, deques support iteration, pickling, \texttt{len(d)}, \texttt{reversed(d)}, \texttt{copy.copy(d)}, \texttt{copy.deepcopy(d)}, membership testing with the \texttt{in} operator, and subscript references such as \texttt{d[-1]}.

Example:

```python
>>> from collections import deque
>>> d = deque('ghi')  # make a new deque with three items
>>> for elem in d:    # iterate over the deque's elements
...     print elem.upper()
G
H
I

>>> d.append('j')    # add a new entry to the right side
>>> d.appendleft('f')  # add a new entry to the left side
>>> d               # show the representation
deque(['f', 'g', 'h', 'i', 'j'])

>>> d.pop()          # return and remove the rightmost item
'j'
>>> d.popleft()      # return and remove the leftmost item
'f'

>>> list(d)          # list the contents of the deque
['g', 'h', 'i']

>>> d[0]             # peek at leftmost item
'g'

>>> d[-1]            # peek at rightmost item
'i'

>>> list(reversed(d))  # list the contents of a deque in reverse
['i', 'h', 'g']

>>> 'h' in d          # search the deque
True

>>> d.extend('jkl')  # add multiple elements at once
>>> d                # return the deque
deque(['g', 'h', 'i', 'j', 'k', 'l'])

>>> d.rotate(1)       # right rotation
>>> d                # return the deque
deque(['j', 'g', 'h', 'i', 'k', 'l'])

>>> d.rotate(-1)     # left rotation
>>> d                # return the deque
deque(['g', 'h', 'i', 'j', 'k', 'l'])

>>> deque(reversed(d))  # make a new deque in reverse
deque(['l', 'k', 'j', 'i', 'h', 'g'])

>>> d.clear()         # empty the deque
```
deque Recipes

This section shows various approaches to working with deques.

The rotate() method provides a way to implement deque slicing and deletion. For example, a pure python implementation of `del d[n]` relies on the rotate() method to position elements to be popped:

```python
def delete_nth(d, n):
    d.rotate(-n)
    d.popleft()
    d.rotate(n)
```

To implement deque slicing, use a similar approach applying rotate() to bring a target element to the left side of the deque. Remove old entries with `popleft()`, add new entries with `extend()`, and then reverse the rotation. With minor variations on that approach, it is easy to implement Forth style stack manipulations such as `dup`, `drop`, `swap`, `over`, `pick`, `rot`, and `roll`.

Multi-pass data reduction algorithms can be succinctly expressed and efficiently coded by extracting elements with multiple calls to `popleft()`, applying a reduction function, and calling `append()` to add the result back to the deque.

For example, building a balanced binary tree of nested lists entails reducing two adjacent nodes into one by grouping them in a list:
```python
>>> def maketree(iterable):
...     d = deque(iterable)
...     while len(d) > 1:
...         pair = [d.popleft(), d.popleft()]
...         d.append(pair)
...     return list(d)
...
>>> print maketree('abcdefgh')
[[[['a', 'b'], ['c', 'd']], [['e', 'f'], ['g', 'h']]]]
```

Bounded length deques provide functionality similar to the `tail` filter in Unix:

```python
def tail(filename, n=10):
    'Return the last n lines of a file'
    return deque(open(filename, n))
```
**defaultdict objects**

class collections.defaultdict([default_factory[, ...]])

Returns a new dictionary-like object. defaultdict is a subclass of the builtin dict class. It overrides one method and adds one writable instance variable. The remaining functionality is the same as for the dict class and is not documented here.

The first argument provides the initial value for the default_factory attribute; it defaults to None. All remaining arguments are treated the same as if they were passed to the dict constructor, including keyword arguments.

*New in version 2.5.*

defaultdict objects support the following method in addition to the standard dict operations:

__missing__(key)

If the default_factory attribute is None, this raises a KeyError exception with the key as argument.

If default_factory is not None, it is called without arguments to provide a default value for the given key, this value is inserted in the dictionary for the key, and returned.

If calling default_factory raises an exception this exception is propagated unchanged.

This method is called by the __getitem__() method of the dict class when the requested key is not found; whatever it returns or raises is then returned or raised by __getitem__().
**defaultdict** objects support the following instance variable:

**default_factory**

This attribute is used by the **__missing__()** method; it is initialized from the first argument to the constructor, if present, or to **None**, if absent.

### defaultdict Examples

Using **list** as the **default_factory**, it is easy to group a sequence of key-value pairs into a dictionary of lists:

```python
>>> s = [('yellow', 1), ('blue', 2), ('yellow', 3), ('blue', 4)]
>>> d = defaultdict(list)
>>> for k, v in s:
...     d[k].append(v)
... >>> d.items()
[('blue', [2, 4]), ('red', [1]), ('yellow', [1, 3])]
```

When each key is encountered for the first time, it is not already in the mapping; so an entry is automatically created using the **default_factory** function which returns an empty **list**. The **list.append()** operation then attaches the value to the new list. When keys are encountered again, the look-up proceeds normally (returning the list for that key) and the **list.append()** operation adds another value to the list. This technique is simpler and faster than an equivalent technique using **dict.setdefault()**:

```python
>>> d = {}
>>> for k, v in s:
...     d.setdefault(k, []).append(v)
... >>> d.items()
[('blue', [2, 4]), ('red', [1]), ('yellow', [1, 3])]
```

Setting the **default_factory** to **int** makes the **defaultdict** useful for
counting (like a bag or multiset in other languages):

```python
>>> s = 'mississippi'
>>> d = defaultdict(int)
>>> for k in s:
...     d[k] += 1
...  
>>> d.items()
[('i', 4), ('p', 2), ('s', 4), ('m', 1)]
```

When a letter is first encountered, it is missing from the mapping, so the `default_factory` function calls `int()` to supply a default count of zero. The increment operation then builds up the count for each letter.

The function `int()` which always returns zero is just a special case of constant functions. A faster and more flexible way to create constant functions is to use `itertools.repeat()` which can supply any constant value (not just zero):

```python
>>> def constant_factory(value):
...     return itertools.repeat(value).next

>>> d = defaultdict(constant_factory('<missing>'))

>>> d.update(name='John', action='ran')
>>> '%%(name)s %%(action)s to %%(object)s' % d
'John ran to <missing>'
```

Setting the `default_factory` to `set` makes the `defaultdict` useful for building a dictionary of sets:

```python
>>> s = [('red', 1), ('blue', 2), ('red', 3), ('blue', 4), ('red', 5), ('blue', 6)]
>>> d = defaultdict(set)

>>> for k, v in s:
...     d[k].add(v)
...

>>> d.items()
[['blue', set([2, 4])], ('red', set([1, 3]))]
```
Named tuples assign meaning to each position in a tuple and allow for more readable, self-documenting code. They can be used wherever regular tuples are used, and they add the ability to access fields by name instead of position index.

```
collections.namedtuple(typename, fieldnames[, verbose])
```

Returns a new tuple subclass named `typename`. The new subclass is used to create tuple-like objects that have fields accessible by attribute lookup as well as being indexable and iterable. Instances of the subclass also have a helpful docstring (with typename and fieldnames) and a helpful `__repr__()` method which lists the tuple contents in a `name=value` format.

The `fieldnames` are a single string with each fieldname separated by whitespace and/or commas, for example 'x y' or 'x, y'. Alternatively, `fieldnames` can be a sequence of strings such as `['x', 'y']`.

Any valid Python identifier may be used for a fieldname except for names starting with an underscore. Valid identifiers consist of letters, digits, and underscores but do not start with a digit or underscore and cannot be a keyword such as `class`, `for`, `return`, `global`, `pass`, `print`, or `raise`.

If `verbose` is true, the class definition is printed just before being built.

Named tuple instances do not have per-instance dictionaries, so they are lightweight and require no more memory than regular tuples.
New in version 2.6.

Example:

```python
def Point(x, y):
    return tuple.__new__(cls, (x, y))

@classmethod
def _make(cls, iterable, new=tuple.__new__, len=len):
    result = new(cls, iterable)
    if len(result) != 2:
        raise TypeError('Expected 2 arguments, got %d' % len(result))
    return result

def _asdict(t):
    return {'x': t[0], 'y': t[1]}

def _replace(self, **kwds):
    result = self._make(map(kwds.pop, ('x', 'y'), self))
    if kwds:
        raise ValueError('Got unexpected field names: %r' % kwds.keys())
    return result

x = property(itemgetter(0))
y = property(itemgetter(1))
```

```python
>>> p = Point(11, y=22)  # instantiate with positional or keyword arguments
>>> p[0] + p[1]          # indexable like the plain tuple (11, 22)
33
>>> x, y = p              # unpack like a regular tuple
```
Named tuples are especially useful for assigning field names to result tuples returned by the `csv` or `sqlite3` modules:

```python
import csv
for emp in map(EmployeeRecord._make, csv.reader(open("employees.csv"))):
  print emp.name, emp.title
```

```python
import sqlite3
conn = sqlite3.connect('/companydata')
cursor = conn.cursor()
cursor.execute('SELECT name, age, title, department, paygrade FROM employees')
for emp in map(EmployeeRecord._make, cursor.fetchall()):
  print emp.name, emp.title
```

In addition to the methods inherited from tuples, named tuples support three additional methods and one attribute. To prevent conflicts with field names, the method and attribute names start with an underscore.

```python
somenamedtuple._make(iterable)
```
Class method that makes a new instance from an existing sequence or iterable.

```python
>>> t = [11, 22]
>>> Point._make(t)
Point(x=11, y=22)
```

```python
somenamedtuple._asdict()
```
Return a new dict which maps field names to their corresponding values:
>>> p._asdict()
{'x': 11, 'y': 22}

somenamedtuple._replace(**kwargs)

Return a new instance of the named tuple replacing specified fields with new values:

```python
>>> p = Point(x=11, y=22)
>>> p._replace(x=33)
Point(x=33, y=22)
```

```python
>>> for partnum, record in inventory.items():
...    inventory[partnum] = record._replace(price=newprices[partnum])
```

somenamedtuple._fields

Tuple of strings listing the field names. Useful for introspection and for creating new named tuple types from existing named tuples.

```python
>>> p._fields                      # view the field names
('x', 'y')
>>> Color = namedtuple('Color', 'red green blue')
>>> Pixel = namedtuple('Pixel', Point._fields + Color._fields)
>>> Pixel(11, 22, 128, 255, 0)
Pixel(x=11, y=22, red=128, green=255, blue=0)
```

To retrieve a field whose name is stored in a string, use the `getattr()` function:

```python
>>> getattr(p, 'x')
11
```

To convert a dictionary to a named tuple, use the double-star-operator [1]:

```python
>>> d = {'x': 11, 'y': 22}
>>> Point(**d)
Point(x=11, y=22)
Since a named tuple is a regular Python class, it is easy to add or change functionality with a subclass. Here is how to add a calculated field and a fixed-width print format:

```python
>>> class Point(namedtuple('Point', 'x y')):
...     __slots__ = ()
...     @property
...     def hypot(self):
...         return (self.x ** 2 + self.y ** 2) ** 0.5
...     def __str__(self):
...         return 'Point: x=%6.3f y=%6.3f hypot=%6.3f'

>>> for p in Point(3, 4), Point(14, 5/7):
...     print p
Point: x= 3.000 y= 4.000 hypot= 5.000
Point: x=14.000 y= 0.714 hypot=14.018
```

The subclass shown above sets `__slots__` to an empty tuple. This keeps memory requirements low by preventing the creation of instance dictionaries.

Subclassing is not useful for adding new, stored fields. Instead, simply create a new named tuple type from the `_fields` attribute:

```python
>>> Point3D = namedtuple('Point3D', Point._fields + ('z',))
```

Default values can be implemented by using `__replace()` to customize a prototype instance:

```python
>>> Account = namedtuple('Account', 'owner balance transaction_count')
>>> default_account = Account('<owner name>', 0.0, 0)
>>> johns_account = default_account._replace(owner='John')
```

Enumerated constants can be implemented with named tuples, but it is simpler and more efficient to use a simple class declaration:

```python
>>> Status = namedtuple('Status', 'open pending closed')._make(Status.open, Status.pending, Status.closed)
```
(0, 1, 2)

```python
>>> class Status:
...     open, pending, closed = range(3)
```

Footnotes

[1] For information on the double-star-operator see *Unpacking Argument Lists* and *Calls*.
New in version 2.3.

This module provides an implementation of the heap queue algorithm, also known as the priority queue algorithm.

Heaps are arrays for which \( \text{heap}[k] \leq \text{heap}[2 \times k+1] \) and \( \text{heap}[k] \leq \text{heap}[2 \times k+2] \) for all \( k \), counting elements from zero. For the sake of comparison, non-existing elements are considered to be infinite. The interesting property of a heap is that \( \text{heap}[0] \) is always its smallest element.

The API below differs from textbook heap algorithms in two aspects: (a) We use zero-based indexing. This makes the relationship between the index for a node and the indexes for its children slightly less obvious, but is more suitable since Python uses zero-based indexing. (b) Our pop method returns the smallest item, not the largest (called a “min heap” in textbooks; a “max heap” is more common in texts because of its suitability for in-place sorting).

These two make it possible to view the heap as a regular Python list without surprises: \( \text{heap}[0] \) is the smallest item, and \( \text{heap}.\text{sort()} \) maintains the heap invariant!

To create a heap, use a list initialized to [], or you can transform a populated list into a heap via function \( \text{heapify()} \).

The following functions are provided:

```
heapq.\textbf{heappush}(heap, item)
```

Push the value \( item \) onto the \( heap \), maintaining the heap invariant.
heapq. **heappop**(heap)
Pop and return the smallest item from the heap, maintaining the heap invariant. If the heap is empty, *IndexError* is raised.

heapq. **heappushpop**(heap, item)
Push *item* on the heap, then pop and return the smallest item from the heap. The combined action runs more efficiently than **heappush()** followed by a separate call to **heappop()**.

*New in version 2.6.*

heapq. **heapify**(x)
Transform list *x* into a heap, in-place, in linear time.

heapq. **heappreplace**(heap, item)
Pop and return the smallest item from the heap, and also push the new *item*. The heap size doesn't change. If the heap is empty, *IndexError* is raised. This is more efficient than **heappop()** followed by **heappush()**, and can be more appropriate when using a fixed-size heap. Note that the value returned may be larger than *item*! That constrains reasonable uses of this routine unless written as part of a conditional replacement:

```python
if item > heap[0]:
    item = heappreplace(heap, item)
```

Example of use:

```python
>>> from heapq import heappush, heappop
>>> heap = []
>>> data = [1, 3, 5, 7, 9, 2, 4, 6, 8, 0]
>>> for item in data:
...    heappush(heap, item)
...
>>> ordered = []
>>> while heap:
...    ordered.append(heappop(heap))
```
The module also offers three general purpose functions based on heaps.

heapq.merge(*iterables)
Merge multiple sorted inputs into a single sorted output (for example, merge timestamped entries from multiple log files). Returns an iterator over over the sorted values.

Similar to sorted(itertools.chain(*iterables)) but returns an iterable, does not pull the data into memory all at once, and assumes that each of the input streams is already sorted (smallest to largest).

New in version 2.6.

heapq.nlargest(n, iterable[, key])
Return a list with the n largest elements from the dataset defined by iterable. key, if provided, specifies a function of one argument that is used to extract a comparison key from each element in the iterable: key=str.lower  Equivalent to: sorted(iterable, key=key, reverse=True)[:n]

New in version 2.4.

Changed in version 2.5: Added the optional key argument.

heapq.nsmallest(n, iterable[, key])
Return a list with the n smallest elements from the dataset defined by iterable. key, if provided, specifies a function of one
argument that is used to extract a comparison key from each element in the iterable:  

```python
key=str.lower
esorted(iterable, key=key)[n]
```

New in version 2.4.

*Changed in version 2.5:* Added the optional `key` argument.

The latter two functions perform best for smaller values of `n`. For larger values, it is more efficient to use the `sorted()` function. Also, when `n=1`, it is more efficient to use the builtin `min()` and `max()` functions.
Theory

(This explanation is due to François Pinard. The Python code for this module was contributed by Kevin O’Connor.)

Heaps are arrays for which $a[k] \leq a[2*k+1]$ and $a[k] \leq a[2*k+2]$ for all $k$, counting elements from 0. For the sake of comparison, non-existing elements are considered to be infinite. The interesting property of a heap is that $a[0]$ is always its smallest element.

The strange invariant above is meant to be an efficient memory representation for a tournament. The numbers below are $k$, not $a[k]$:

<p>| | | | |</p>
<table>
<thead>
<tr>
<th></th>
<th></th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>1</td>
<td>2</td>
<td></td>
</tr>
<tr>
<td>3</td>
<td>4</td>
<td>5</td>
<td>6</td>
</tr>
<tr>
<td>7</td>
<td>8</td>
<td>9</td>
<td>10</td>
</tr>
<tr>
<td>11</td>
<td>12</td>
<td>13</td>
<td>14</td>
</tr>
<tr>
<td>15</td>
<td>16</td>
<td>17</td>
<td>18</td>
</tr>
<tr>
<td>19</td>
<td>20</td>
<td>21</td>
<td>22</td>
</tr>
<tr>
<td>23</td>
<td>24</td>
<td>25</td>
<td>26</td>
</tr>
<tr>
<td>27</td>
<td>28</td>
<td>29</td>
<td>30</td>
</tr>
</tbody>
</table>

In the tree above, each cell $k$ is topping $2*k+1$ and $2*k+2$. In an usual binary tournament we see in sports, each cell is the winner over the two cells it tops, and we can trace the winner down the tree to see all opponents s/he had. However, in many computer applications of such tournaments, we do not need to trace the history of a winner. To be more memory efficient, when a winner is promoted, we try to replace it by something else at a lower level, and the rule becomes that a cell and the two cells it tops contain three different items, but the top cell “wins” over the two topped cells.

If this heap invariant is protected at all time, index 0 is clearly the overall winner. The simplest algorithmic way to remove it and find the “next” winner is to move some loser (let’s say cell 30 in the diagram...
above) into the 0 position, and then percolate this new 0 down the
tree, exchanging values, until the invariant is re-established. This is
clearly logarithmic on the total number of items in the tree. By
iterating over all items, you get an \(O(n \log n)\) sort.

A nice feature of this sort is that you can efficiently insert new items
while the sort is going on, provided that the inserted items are not
“better” than the last 0’th element you extracted. This is especially
useful in simulation contexts, where the tree holds all incoming
events, and the “win” condition means the smallest scheduled time.
When an event schedule other events for execution, they are
scheduled into the future, so they can easily go into the heap. So, a
heap is a good structure for implementing schedulers (this is what I
used for my MIDI sequencer :-).

Various structures for implementing schedulers have been
extensively studied, and heaps are good for this, as they are
reasonably speedy, the speed is almost constant, and the worst case
is not much different than the average case. However, there are
other representations which are more efficient overall, yet the worst
cases might be terrible.

Heaps are also very useful in big disk sorts. You most probably all
know that a big sort implies producing “runs” (which are pre-sorted
sequences, which size is usually related to the amount of CPU
memory), followed by a merging passes for these runs, which
merging is often very cleverly organised [1]. It is very important that
the initial sort produces the longest runs possible. Tournaments are a
good way to that. If, using all the memory available to hold a
tournament, you replace and percolate items that happen to fit the
current run, you’ll produce runs which are twice the size of the
memory for random input, and much better for input fuzzily ordered.

Moreover, if you output the 0'th item on disk and get an input which
may not fit in the current tournament (because the value “wins” over
the last output value), it cannot fit in the heap, so the size of the heap decreases. The freed memory could be cleverly reused immediately for progressively building a second heap, which grows at exactly the same rate the first heap is melting. When the first heap completely vanishes, you switch heaps and start a new run. Clever and quite effective!

In a word, heaps are useful memory structures to know. I use them in a few applications, and I think it is good to keep a ‘heap’ module around. :-)

Footnotes

The disk balancing algorithms which are current, nowadays, are more annoying than clever, and this is a consequence of the seeking capabilities of the disks. On devices which cannot seek, like big tape drives, the story was quite different, and one had to be very clever to ensure (far in advance) that each tape movement will be the most effective possible (that is, will best participate at “progressing” the merge). Some tapes were even able to read backwards, and this was also used to avoid the rewinding time. Believe me, real good tape sorts were quite spectacular to watch! From all times, sorting has always been a Great Art! :-)

[1]
This module provides support for maintaining a list in sorted order without having to sort the list after each insertion. For long lists of items with expensive comparison operations, this can be an improvement over the more common approach. The module is called `bisect` because it uses a basic bisection algorithm to do its work. The source code may be most useful as a working example of the algorithm (the boundary conditions are already right!).

The following functions are provided:

```
bisect.bisect_left(list, item[, lo[, hi]])
```

Locate the proper insertion point for `item` in `list` to maintain sorted order. The parameters `lo` and `hi` may be used to specify a subset of the list which should be considered; by default the entire list is used. If `item` is already present in `list`, the insertion point will be before (to the left of) any existing entries. The return value is suitable for use as the first parameter to `list.insert()`. This assumes that `list` is already sorted.

*New in version 2.1.*

```
bisect.bisect_right(list, item[, lo[, hi]])
```

Similar to `bisect_left()`, but returns an insertion point which comes after (to the right of) any existing entries of `item` in `list`.

*New in version 2.1.*

```
bisect(...)
```

Alias for `bisect_right()`.

```
bisect.insert_left(list, item[, lo[, hi]])
```

Insert *item* in *list* in sorted order. This is equivalent to

```python
list.insert(bisect.bisect_left(list, item, lo, hi), item).
```

This assumes that *list* is already sorted.

*New in version 2.1.*

```python
bisect.insort_right(list, item[, lo[, hi]])
```

Similar to `insort_left()`, but inserting *item* in *list* after any existing entries of *item*.

*New in version 2.1.*

```python
bisect.insort(...)  
```

Alias for `insort_right()`.
Examples

The `bisect()` function is generally useful for categorizing numeric data. This example uses `bisect()` to look up a letter grade for an exam total (say) based on a set of ordered numeric breakpoints: 85 and up is an ‘A’, 75..84 is a ‘B’, etc.

```python
>>> grades = "FEDCBA"
>>> breakpoints = [30, 44, 66, 75, 85]
>>> from bisect import bisect
>>> def grade(total):
...     return grades[bisect(breakpoints, total)]
...
>>> grade(66)
'C'
'C'
>>> map(grade, [33, 99, 77, 44, 12, 88])
['E', 'A', 'B', 'D', 'F', 'A']
```
This module defines an object type which can compactly represent an array of basic values: characters, integers, floating point numbers. Arrays are sequence types and behave very much like lists, except that the type of objects stored in them is constrained. The type is specified at object creation time by using a *type code*, which is a single character. The following type codes are defined:

<table>
<thead>
<tr>
<th>Type code</th>
<th>C Type</th>
<th>Python Type</th>
<th>Minimum size in bytes</th>
</tr>
</thead>
<tbody>
<tr>
<td>'c'</td>
<td>char</td>
<td>character</td>
<td>1</td>
</tr>
<tr>
<td>'b'</td>
<td>signed char</td>
<td>int</td>
<td>1</td>
</tr>
<tr>
<td>'B'</td>
<td>unsigned char</td>
<td>int</td>
<td>1</td>
</tr>
<tr>
<td>'u'</td>
<td>Py_UNICODE</td>
<td>Unicode character</td>
<td>2</td>
</tr>
<tr>
<td>'h'</td>
<td>signed short</td>
<td>int</td>
<td>2</td>
</tr>
<tr>
<td>'H'</td>
<td>unsigned short</td>
<td>int</td>
<td>2</td>
</tr>
<tr>
<td>'i'</td>
<td>signed int</td>
<td>int</td>
<td>2</td>
</tr>
<tr>
<td>'I'</td>
<td>unsigned int</td>
<td>long</td>
<td>2</td>
</tr>
<tr>
<td>'l'</td>
<td>signed long</td>
<td>int</td>
<td>4</td>
</tr>
<tr>
<td>'L'</td>
<td>unsigned long</td>
<td>long</td>
<td>4</td>
</tr>
<tr>
<td>'f'</td>
<td>float</td>
<td>float</td>
<td>4</td>
</tr>
<tr>
<td>'d'</td>
<td>double</td>
<td>float</td>
<td>8</td>
</tr>
</tbody>
</table>

The actual representation of values is determined by the machine architecture (strictly speaking, by the C implementation). The actual size can be accessed through the *itemsize* attribute. The values stored for 'L' and 'I' items will be represented as Python long integers when retrieved, because Python's plain integer type cannot
represent the full range of C’s unsigned (long) integers.

The module defines the following type:

```python
array.array(typecode[, initializer])
```

Return a new array whose items are restricted by `typecode`, and initialized from the optional `initializer` value, which must be a list, string, or iterable over elements of the appropriate type.

*Changed in version 2.4:* Formerly, only lists or strings were accepted.

If given a list or string, the initializer is passed to the new array’s `fromlist()`, `fromstring()`, or `fromunicode()` method (see below) to add initial items to the array. Otherwise, the iterable initializer is passed to the `extend()` method.

```python
arrayArrayType
```

Obsolete alias for `array()`.

Array objects support the ordinary sequence operations of indexing, slicing, concatenation, and multiplication. When using slice assignment, the assigned value must be an array object with the same type code; in all other cases, `TypeError` is raised. Array objects also implement the buffer interface, and may be used wherever buffer objects are supported.

The following data items and methods are also supported:

```python
array.typecode
```

The typecode character used to create the array.

```python
array.itemsize
```

The length in bytes of one array item in the internal representation.
array.append(x)

Append a new item with value x to the end of the array.

def array.buffer_info()

Return a tuple (address, length) giving the current memory address and the length in elements of the buffer used to hold array’s contents. The size of the memory buffer in bytes can be computed as array.buffer_info()[1] * array.itemsize. This is occasionally useful when working with low-level (and inherently unsafe) I/O interfaces that require memory addresses, such as certain ioctl operations. The returned numbers are valid as long as the array exists and no length-changing operations are applied to it.

**Note:** When using array objects from code written in C or C++ (the only way to effectively make use of this information), it makes more sense to use the buffer interface supported by array objects. This method is maintained for backward compatibility and should be avoided in new code. The buffer interface is documented in Buffer Objects.

array.byteswap()

“Byteswap” all items of the array. This is only supported for values which are 1, 2, 4, or 8 bytes in size; for other types of values, **RuntimeError** is raised. It is useful when reading data from a file written on a machine with a different byte order.

def array.count(x)

Return the number of occurrences of x in the array.

def array.extend(iterable)

Append items from iterable to the end of the array. If iterable is another array, it must have exactly the same type code; if not,
**TypeError** will be raised. If *iterable* is not an array, it must be iterable and its elements must be the right type to be appended to the array.

*Changed in version 2.4:* Formerly, the argument could only be another array.

`array.fromfile(f, n)`
Read *n* items (as machine values) from the file object *f* and append them to the end of the array. If less than *n* items are available, **EOFError** is raised, but the items that were available are still inserted into the array. *f* must be a real built-in file object; something else with a `read()` method won’t do.

`array.fromlist(list)`
Append items from the list. This is equivalent to `for x in list: a.append(x)` except that if there is a type error, the array is unchanged.

`array.fromstring(s)`
Appends items from the string, interpreting the string as an array of machine values (as if it had been read from a file using the `fromfile()` method).

`array.fromunicode(s)`
Extends this array with data from the given unicode string. The array must be a type `u` array; otherwise a **ValueError** is raised. Use `array.fromstring(unicodestring.encode(enc))` to append Unicode data to an array of some other type.

`array.index(x)`
Return the smallest *i* such that *i* is the index of the first occurrence of *x* in the array.
array.**insert**(i, x)

Insert a new item with value x in the array before position i. Negative values are treated as being relative to the end of the array.

array.**pop**([i])

Removes the item with the index i from the array and returns it. The optional argument defaults to -1, so that by default the last item is removed and returned.

array.**read**(f, n)

*Deprecated since version 1.5.1:* Use the fromfile() method.

Read n items (as machine values) from the file object f and append them to the end of the array. If less than n items are available, EOFError is raised, but the items that were available are still inserted into the array. f must be a real built-in file object; something else with a read() method won’t do.

array.**remove**(x)

Remove the first occurrence of x from the array.

array.**reverse**()

Reverse the order of the items in the array.

array.**tofile**(f)

Write all items (as machine values) to the file object f.

array.**tolist**()

Convert the array to an ordinary list with the same items.

array.**tostring**()

Convert the array to an array of machine values and return the string representation (the same sequence of bytes that would be
written to a file by the tofile() method.

array.tounicode()
Convert the array to a unicode string. The array must be a type 'u' array; otherwise a ValueError is raised. Use array.tostring().decode(enc) to obtain a unicode string from an array of some other type.

array.write(f)
Deprecated since version 1.5.1: Use the tofile() method.

Write all items (as machine values) to the file object f.

When an array object is printed or converted to a string, it is represented as array(typecode, initializer). The initializer is omitted if the array is empty, otherwise it is a string if the typecode is 'c', otherwise it is a list of numbers. The string is guaranteed to be able to be converted back to an array with the same type and value using eval(), so long as the array() function has been imported using from array import array. Examples:

array('l')
array('c', 'hello world')
array('u', u'hello ♁')
array('l', [1, 2, 3, 4, 5])
array('d', [1.0, 2.0, 3.14])

sets — Unordered collections of unique elements

New in version 2.3.

Deprecated since version 2.6: The built-in set/frozenset types replace this module.

The sets module provides classes for constructing and manipulating unordered collections of unique elements. Common uses include membership testing, removing duplicates from a sequence, and computing standard math operations on sets such as intersection, union, difference, and symmetric difference.

Like other collections, sets support `x in set`, `len(set)`, and `for x in set`. Being an unordered collection, sets do not record element position or order of insertion. Accordingly, sets do not support indexing, slicing, or other sequence-like behavior.

Most set applications use the Set class which provides every set method except for `__hash__()`. For advanced applications requiring a hash method, the ImmutableSet class adds a `__hash__()` method but omits methods which alter the contents of the set. Both Set and ImmutableSet derive from BaseSet, an abstract class useful for determining whether something is a set: `isinstance(obj, BaseSet)`.

The set classes are implemented using dictionaries. Accordingly, the requirements for set elements are the same as those for dictionary keys; namely, that the element defines both `__eq__()` and `__hash__()`. As a result, sets cannot contain mutable elements such as lists or dictionaries. However, they can contain immutable collections such as tuples or instances of ImmutableSet. For
convenience in implementing sets of sets, inner sets are automatically converted to immutable form, for example, 
\[
\text{Set([Set([\{'dog\']])])}
\]
is transformed to 
\[
\text{Set([ImmutableSet([\{'dog\']])])}.
\]

class sets.Set([iterable])

Constructs a new empty set object. If the optional iterable parameter is supplied, updates the set with elements obtained from iteration. All of the elements in iterable should be immutable or be transformable to an immutable using the protocol described in section Protocol for automatic conversion to immutable.

class sets.ImmutableSet([iterable])

Constructs a new empty ImmutableSet object. If the optional iterable parameter is supplied, updates the set with elements obtained from iteration. All of the elements in iterable should be immutable or be transformable to an immutable using the protocol described in section Protocol for automatic conversion to immutable.

Because ImmutableSet objects provide a __hash__() method, they can be used as set elements or as dictionary keys. ImmutableSet objects do not have methods for adding or removing elements, so all of the elements must be known when the constructor is called.
## Set Objects

Instances of *Set* and *ImmutableSet* both provide the following operations:

<table>
<thead>
<tr>
<th>Operation</th>
<th>Equivalent</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td>len(s)</td>
<td></td>
<td>cardinality of set s</td>
</tr>
<tr>
<td>x in s</td>
<td></td>
<td>test x for membership in s</td>
</tr>
<tr>
<td>x not in s</td>
<td></td>
<td>test x for non-membership in s</td>
</tr>
<tr>
<td>s.issubset(t)</td>
<td>s &lt;= t</td>
<td>test whether every element in s is in t</td>
</tr>
<tr>
<td>s.issuperset(t)</td>
<td>s &gt;= t</td>
<td>test whether every element in t is in s</td>
</tr>
<tr>
<td>s.union(t)</td>
<td>s</td>
<td>t</td>
</tr>
<tr>
<td>s.intersection(t)</td>
<td>s &amp; t</td>
<td>new set with elements common to s and t</td>
</tr>
<tr>
<td>s.difference(t)</td>
<td>s - t</td>
<td>new set with elements in s but not in t</td>
</tr>
<tr>
<td>s.symmetric_difference(t)</td>
<td>s ^ t</td>
<td>new set with elements in either s or t but not both</td>
</tr>
<tr>
<td>s.copy()</td>
<td></td>
<td>new set with a shallow copy of s</td>
</tr>
</tbody>
</table>

Note, the non-operator versions of `union()`, `intersection()`, `difference()`, and `symmetric_difference()` will accept any iterable as an argument. In contrast, their operator based counterparts require their arguments to be sets. This precludes error-prone constructions like `Set('abc') & 'cbs'` in favor of the more readable `Set('abc').intersection('cbs')`.

*Changed in version 2.3.1:* Formerly all arguments were required to
be sets.

In addition, both `Set` and `ImmutableSet` support set to set comparisons. Two sets are equal if and only if every element of each set is contained in the other (each is a subset of the other). A set is less than another set if and only if the first set is a proper subset of the second set (is a subset, but is not equal). A set is greater than another set if and only if the first set is a proper superset of the second set (is a superset, but is not equal).

The subset and equality comparisons do not generalize to a complete ordering function. For example, any two disjoint sets are not equal and are not subsets of each other, so all of the following return `False`: `a<b`, `a==b`, or `a>b`. Accordingly, sets do not implement the `__cmp__()` method.

Since sets only define partial ordering (subset relationships), the output of the `list.sort()` method is undefined for lists of sets.

The following table lists operations available in `ImmutableSet` but not found in `Set`:

<table>
<thead>
<tr>
<th>Operation</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>hash(s)</code></td>
<td>returns a hash value for <code>s</code></td>
</tr>
</tbody>
</table>

The following table lists operations available in `Set` but not found in `ImmutableSet`:

<table>
<thead>
<tr>
<th>Operation</th>
<th>Equivalent</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>s.update(t)</code></td>
<td>`s</td>
<td>= t`</td>
</tr>
<tr>
<td><code>s.intersection_update(t)</code></td>
<td><code>s &amp;= t</code></td>
<td>return set <code>s</code> keeping only elements also</td>
</tr>
<tr>
<td>Method</td>
<td>Description</td>
<td></td>
</tr>
<tr>
<td>------------------------------------</td>
<td>-----------------------------------------------------------------------------</td>
<td></td>
</tr>
<tr>
<td><code>s.difference_update(t)</code></td>
<td><code>s - t</code> return set <code>s</code> after removing elements found in <code>t</code></td>
<td></td>
</tr>
<tr>
<td><code>s.symmetric_difference_update(t)</code></td>
<td><code>s ^= t</code> return set <code>s</code> with elements from <code>s</code> or <code>t</code> but not both</td>
<td></td>
</tr>
<tr>
<td><code>s.add(x)</code></td>
<td>add element <code>x</code> to set <code>s</code></td>
<td></td>
</tr>
<tr>
<td><code>s.remove(x)</code></td>
<td>remove <code>x</code> from set <code>s</code>; raises <code>KeyError</code> if not present</td>
<td></td>
</tr>
<tr>
<td><code>s.discard(x)</code></td>
<td>removes <code>x</code> from set <code>s</code> if present</td>
<td></td>
</tr>
<tr>
<td><code>s.pop()</code></td>
<td>remove and return an arbitrary element from <code>s</code>; raises <code>KeyError</code> if empty</td>
<td></td>
</tr>
<tr>
<td><code>s.clear()</code></td>
<td>remove all elements from set <code>s</code></td>
<td></td>
</tr>
</tbody>
</table>

Note, the non-operator versions of `update()`, `intersection_update()`, `difference_update()`, and `symmetric_difference_update()` will accept any iterable as an argument.

*Changed in version 2.3.1:* Formerly all arguments were required to be sets.

Also note, the module also includes a `union_update()` method which is an alias for `update()`. The method is included for backwards compatibility. Programmers should prefer the `update()` method because it is supported by the builtin `set()` and `frozenset()` types.
Example

```python
>>> from sets import Set
>>> engineers = Set(['John', 'Jane', 'Jack', 'Janice'])
>>> programmers = Set(['Jack', 'Sam', 'Susan', 'Janice'])
>>> managers = Set(['Jane', 'Jack', 'Susan', 'Zack'])
>>> employees = engineers | programmers | managers  #
>>> engineering_management = engineers & managers  #
>>> fulltime_management = managers - engineers - programmers #
>>> engineers.add('Marvin')  #
>>> print engineers  # doctest: +SKIP
Set(['Jane', 'Marvin', 'Janice', 'John', 'Jack'])
>>> employees.issuperset(employees)  # superset test
False
>>> employees.update(engineers)  # update from another set
>>> employees.issuperset(employees)
True
>>> for group in [engineers, programmers, managers, employees]:
...    group.discard('Susan')  # unconditionally remove
...    print group
...  ...
Set(['Jane', 'Marvin', 'Janice', 'John', 'Jack'])
Set(['Janice', 'Jack', 'Sam'])
Set(['Jane', 'Zack', 'Jack'])
Set(['Jack', 'Sam', 'Jane', 'Marvin', 'Janice', 'John', 'Zack'])
```
Protocol for automatic conversion to immutable

Sets can only contain immutable elements. For convenience, mutable `Set` objects are automatically copied to an `ImmutableSet` before being added as a set element.

The mechanism is to always add a *hashable* element, or if it is not hashable, the element is checked to see if it has an `__as_immutable__()` method which returns an immutable equivalent.

Since `Set` objects have a `__as_immutable__()` method returning an instance of `ImmutableSet`, it is possible to construct sets of sets.

A similar mechanism is needed by the `__contains__()` and `remove()` methods which need to hash an element to check for membership in a set. Those methods check an element for hashability and, if not, check for a `__as_temporarily_immutable__()` method which returns the element wrapped by a class that provides temporary methods for `__hash__()`, `__eq__()`, and `__ne__()`.  

The alternate mechanism spares the need to build a separate copy of the original mutable object.

`Set` objects implement the `__as_temporarily_immutable__()` method which returns the `Set` object wrapped by a new class `_TemporarilyImmutableSet`.

The two mechanisms for adding hashability are normally invisible to the user; however, a conflict can arise in a multi-threaded environment where one thread is updating a set while another has temporarily wrapped it in `_TemporarilyImmutableSet`. In other words,
sets of mutable sets are not thread-safe.
Comparison to the built-in set types

The built-in `set` and `frozenset` types were designed based on lessons learned from the `sets` module. The key differences are:

- `Set` and `ImmutableSet` were renamed to `set` and `frozenset`.
- There is no equivalent to `BaseSet`. Instead, use `isinstance(x, (set, frozenset))`.
- The hash algorithm for the built-ins performs significantly better (fewer collisions) for most datasets.
- The built-in versions have more space efficient pickles.
- The built-in versions do not have a `union_update()` method. Instead, use the `update()` method which is equivalent.
- The built-in versions do not have a `_repr(sorted=True)` method. Instead, use the built-in `repr()` and `sorted()` functions: `repr(sorted(s))`.
- The built-in version does not have a protocol for automatic conversion to immutable. Many found this feature to be confusing and no one in the community reported having found real uses for it.
The `sched` module defines a class which implements a general purpose event scheduler:

```python
class sched.scheduler(timefunc, delayfunc)
```

The `scheduler` class defines a generic interface to scheduling events. It needs two functions to actually deal with the “outside world” — `timefunc` should be callable without arguments, and return a number (the “time”, in any units whatsoever). The `delayfunc` function should be callable with one argument, compatible with the output of `timefunc`, and should delay that many time units. `delayfunc` will also be called with the argument 0 after each event is run to allow other threads an opportunity to run in multi-threaded applications.

Example:

```python
>>> import sched, time
>>> s = sched.scheduler(time.time, time.sleep)
>>> def print_time():
...    print "From print_time", time.time()
...    ...
>>> def print_some_times():
...    print time.time()
...    s.enter(5, 1, print_time, ())
...    s.enter(10, 1, print_time, ())
...    s.run()
...    print time.time()
...    ...
>>> print_some_times()
930343690.257
From print_time 930343695.274
From print_time 930343700.273
930343700.276
```

In multi-threaded environments, the `scheduler` class has limitations with respect to thread-safety, inability to insert a new task before the one currently pending in a running scheduler, and holding up the
main thread until the event queue is empty. Instead, the preferred approach is to use the `threading.Timer` class instead.

Example:

```python
g>>> import time
g>>> from threading import Timer
g>>> def print_time():
...    print "From print_time", time.time()
...

g>>> def print_some_times():
...    print time.time()
...    Timer(5, print_time, ()).start()  
...    Timer(10, print_time, ()).start() 
...    time.sleep(11)  # sleep while time-delay events exe
...    print time.time()
...

g>>> print_some_times()
930343690.257
From print_time 930343695.274
From print_time 930343700.273
930343701.301
```
Scheduler Objects

**scheduler** instances have the following methods and attributes:

**scheduler.**`enterabs(time, priority, action, argument)`: Schedule a new event. The *time* argument should be a numeric type compatible with the return value of the *timefunc* function passed to the constructor. Events scheduled for the same *time* will be executed in the order of their *priority*.

 Executing the event means executing `action(*argument)`. *argument* must be a sequence holding the parameters for *action*.

 Return value is an event which may be used for later cancellation of the event (see `cancel()`).

**scheduler.**`enter(delay, priority, action, argument)`: Schedule an event for *delay* more time units. Other then the relative time, the other arguments, the effect and the return value are the same as those for `enterabs()`.

**scheduler.**`cancel(event)`: Remove the event from the queue. If *event* is not an event currently in the queue, this method will raise a `RuntimeError`.

**scheduler.**`empty()`: Return true if the event queue is empty.

**scheduler.**`run()`: Run all scheduled events. This function will wait (using the `delayfunc()` function passed to the constructor) for the next event, then execute it and so on until there are no more scheduled events.
Either `action` or `delayfunc` can raise an exception. In either case, the scheduler will maintain a consistent state and propagate the exception. If an exception is raised by `action`, the event will not be attempted in future calls to `run()`.

If a sequence of events takes longer to run than the time available before the next event, the scheduler will simply fall behind. No events will be dropped; the calling code is responsible for canceling events which are no longer pertinent.

**scheduler.queue**

Read-only attribute returning a list of upcoming events in the order they will be run. Each event is shown as a `named tuple` with the following fields: time, priority, action, argument.

*New in version 2.6.*
**mutex — Mutual exclusion support**

*Deprecated since version The:* The `mutex` module has been removed in Python 3.0.

The `mutex` module defines a class that allows mutual-exclusion via acquiring and releasing locks. It does not require (or imply) `threading` or multi-tasking, though it could be useful for those purposes.

The `mutex` module defines the following class:

```python
class mutex:
    # Create a new (unlocked) mutex.

    # A mutex has two pieces of state — a “locked” bit and a queue. When the mutex is not locked, the queue is empty. Otherwise, the queue contains zero or more (function, argument) pairs representing functions (or methods) waiting to acquire the lock. When the mutex is unlocked while the queue is not empty, the first queue entry is removed and its function(argument) pair called, implying it now has the lock.

    # Of course, no multi-threading is implied – hence the funny interface for lock(), where a function is called once the lock is acquired.
```
Mutex Objects

`mutex` objects have following methods:

\[\text{mutex.test()}\]
Check whether the mutex is locked.

\[\text{mutex.testandset()}\]
“Atomic” test-and-set, grab the lock if it is not set, and return \text{True}, otherwise, return \text{False}.

\[\text{mutex.lock(function, argument)}\]
Execute \text{function(argument)}, unless the mutex is locked. In the case it is locked, place the function and argument on the queue. See \text{unlock()} for explanation of when \text{function(argument)} is executed in that case.

\[\text{mutex.unlock()}\]
Unlock the mutex if queue is empty, otherwise execute the first element in the queue.
queue — A synchronized queue class

Note: The queue module has been renamed to queue in Python 3.0. The 2to3 tool will automatically adapt imports when converting your sources to 3.0.

The Queue module implements multi-producer, multi-consumer queues. It is especially useful in threaded programming when information must be exchanged safely between multiple threads. The Queue class in this module implements all the required locking semantics. It depends on the availability of thread support in Python; see the threading module.

Implements three types of queue whose only difference is the order that the entries are retrieved. In a FIFO queue, the first tasks added are the first retrieved. In a LIFO queue, the most recently added entry is the first retrieved (operating like a stack). With a priority queue, the entries are kept sorted (using the heapq module) and the lowest valued entry is retrieved first.

The Queue module defines the following classes and exceptions:

class Queue. Queue(maxsize)

Constructor for a FIFO queue. maxsize is an integer that sets the upperbound limit on the number of items that can be placed in the queue. Insertion will block once this size has been reached, until queue items are consumed. If maxsize is less than or equal to zero, the queue size is infinite.

class Queue. LifoQueue(maxsize)

Constructor for a LIFO queue. maxsize is an integer that sets the
upperbound limit on the number of items that can be placed in the queue. Insertion will block once this size has been reached, until queue items are consumed. If \textit{maxsize} is less than or equal to zero, the queue size is infinite.

\textit{New in version 2.6.}

class Queue. \textbf{PriorityQueue}(\textit{maxsize})
Constructor for a priority queue. \textit{maxsize} is an integer that sets the upperbound limit on the number of items that can be placed in the queue. Insertion will block once this size has been reached, until queue items are consumed. If \textit{maxsize} is less than or equal to zero, the queue size is infinite.

The lowest valued entries are retrieved first (the lowest valued entry is the one returned by \texttt{sorted(list(entries))}[0]). A typical pattern for entries is a tuple in the form: \texttt{(priority_number, data)}.

\textit{New in version 2.6.}

exception Queue. \textbf{Empty}
Exception raised when non-blocking \texttt{get()} (or \texttt{get_nowait()}) is called on a \texttt{Queue} object which is empty.

exception Queue. \textbf{Full}
Exception raised when non-blocking \texttt{put()} (or \texttt{put_nowait()}) is called on a \texttt{Queue} object which is full.
Queue objects (*Queue*, *LifoQueue*, or *PriorityQueue*) provide the public methods described below.

Queue.*qsize()*  
Return the approximate size of the queue. Note, *qsize()* > 0 doesn't guarantee that a subsequent *get()* will not block, nor will *qsize()* < *maxsize* guarantee that *put()* will not block.

Queue.*empty()*  
Return *True* if the queue is empty, *False* otherwise. If *empty()* returns *True* it doesn’t guarantee that a subsequent call to *put()* will not block. Similarly, if *empty()* returns *False* it doesn’t guarantee that a subsequent call to *get()* will not block.

Queue.*full()*  
Return *True* if the queue is full, *False* otherwise. If *full()* returns *True* it doesn’t guarantee that a subsequent call to *get()* will not block. Similarly, if *full()* returns *False* it doesn’t guarantee that a subsequent call to *put()* will not block.

Queue.*put(item[, block[, timeout]])*  
Put *item* into the queue. If optional args *block* is true and *timeout* is None (the default), block if necessary until a free slot is available. If *timeout* is a positive number, it blocks at most *timeout* seconds and raises the *Full* exception if no free slot was available within that time. Otherwise (*block* is false), put an item on the queue if a free slot is immediately available, else raise the *Full* exception (*timeout* is ignored in that case).

*New in version 2.3:* The *timeout* parameter.
Queue. `put_nowait(item)`  
Equivalent to `put(item, False)`.

Queue. `get([block[, timeout]])`  
Remove and return an item from the queue. If optional args `block` is true and `timeout` is None (the default), block if necessary until an item is available. If `timeout` is a positive number, it blocks at most `timeout` seconds and raises the `Empty` exception if no item was available within that time. Otherwise (`block` is false), return an item if one is immediately available, else raise the `Empty` exception (`timeout` is ignored in that case).

*New in version 2.3:* The `timeout` parameter.

Queue. `get_nowait()`  
Equivalent to `get(False)`.

Two methods are offered to support tracking whether enqueued tasks have been fully processed by daemon consumer threads.

Queue. `task_done()`  
Indicate that a formerly enqueued task is complete. Used by queue consumer threads. For each `get()` used to fetch a task, a subsequent call to `task_done()` tells the queue that the processing on the task is complete.

If a `join()` is currently blocking, it will resume when all items have been processed (meaning that a `task_done()` call was received for every item that had been `put()` into the queue).

 Raises a `ValueError` if called more times than there were items placed in the queue.

*New in version 2.5.*
Queue.join()

Blocks until all items in the queue have been gotten and processed.

The count of unfinished tasks goes up whenever an item is added to the queue. The count goes down whenever a consumer thread calls task_done() to indicate that the item was retrieved and all work on it is complete. When the count of unfinished tasks drops to zero, join() unblocks.

New in version 2.5.

Example of how to wait for enqueued tasks to be completed:

```python
def worker():
    while True:
        item = q.get()
        do_work(item)
        q.task_done()

q = Queue()
for i in range(num_worker_threads):
    t = Thread(target=worker)
    t.setDaemon(True)
    t.start()

for item in source():
    q.put(item)

q.join()  # block until all tasks are done
```
The `weakref` module allows the Python programmer to create *weak references* to objects.

In the following, the term *referent* means the object which is referred to by a weak reference.

A weak reference to an object is not enough to keep the object alive: when the only remaining references to a referent are weak references, *garbage collection* is free to destroy the referent and reuse its memory for something else. A primary use for weak references is to implement caches or mappings holding large objects, where it's desired that a large object not be kept alive solely because it appears in a cache or mapping.

For example, if you have a number of large binary image objects, you may wish to associate a name with each. If you used a Python dictionary to map names to images, or images to names, the image objects would remain alive just because they appeared as values or keys in the dictionaries. The `WeakKeyDictionary` and `WeakValueDictionary` classes supplied by the `weakref` module are an alternative, using weak references to construct mappings that don't keep objects alive solely because they appear in the mapping objects. If, for example, an image object is a value in a `WeakValueDictionary`, then when the last remaining references to that image object are the weak references held by weak mappings, garbage collection can reclaim the object, and its corresponding entries in weak mappings are simply deleted.

`WeakKeyDictionary` and `WeakValueDictionary` use weak references in their implementation, setting up callback functions on the weak
references that notify the weak dictionaries when a key or value has been reclaimed by garbage collection. Most programs should find that using one of these weak dictionary types is all they need – it’s not usually necessary to create your own weak references directly. The low-level machinery used by the weak dictionary implementations is exposed by the `weakref` module for the benefit of advanced uses.

**Note:** Weak references to an object are cleared before the object’s `__del__()` is called, to ensure that the weak reference callback (if any) finds the object still alive.

Not all objects can be weakly referenced; those objects which can include class instances, functions written in Python (but not in C), methods (both bound and unbound), sets, frozensets, file objects, `generators`, `type` objects, `DBcursor` objects from the `bsddb` module, sockets, arrays, deques, and regular expression pattern objects.

*Changed in version 2.4:* Added support for files, sockets, arrays, and patterns.

Several builtin types such as `list` and `dict` do not directly support weak references but can add support through subclassing:

```python
class Dict(dict):
    pass

obj = Dict(red=1, green=2, blue=3)  # this object is weak referenceable
```

Extension types can easily be made to support weak references; see `Weak Reference Support`.

```python
class weakref.ref(object[, callback])
```

Return a weak reference to `object`. The original object can be
retrieved by calling the reference object if the referent is still alive; if the referent is no longer alive, calling the reference object will cause `None` to be returned. If `callback` is provided and not `None`, and the returned weakref object is still alive, the callback will be called when the object is about to be finalized; the weak reference object will be passed as the only parameter to the callback; the referent will no longer be available.

It is allowable for many weak references to be constructed for the same object. Callbacks registered for each weak reference will be called from the most recently registered callback to the oldest registered callback.

Exceptions raised by the callback will be noted on the standard error output, but cannot be propagated; they are handled in exactly the same way as exceptions raised from an object's `__del__()` method.

Weak references are `hashable` if the `object` is hashable. They will maintain their hash value even after the `object` was deleted. If `hash()` is called the first time only after the `object` was deleted, the call will raise `TypeError`.

Weak references support tests for equality, but not ordering. If the referents are still alive, two references have the same equality relationship as their referents (regardless of the `callback`). If either referent has been deleted, the references are equal only if the reference objects are the same object.

*Changed in version 2.4:* This is now a subclassable type rather than a factory function; it derives from `object`.

```python
weakref.proxy(object[, callback])
```

Return a proxy to `object` which uses a weak reference. This supports use of the proxy in most contexts instead of requiring
the explicit dereferencing used with weak reference objects. The returned object will have a type of either ProxyType or CallableProxyType, depending on whether object is callable. Proxy objects are not hashable regardless of the referent; this avoids a number of problems related to their fundamentally mutable nature, and prevent their use as dictionary keys. callback is the same as the parameter of the same name to the ref() function.

weakref.getweakrefcount(object)
Return the number of weak references and proxies which refer to object.

weakref.getweakrefs(object)
Return a list of all weak reference and proxy objects which refer to object.

class weakref.WeakKeyDictionary(dict)
Mapping class that references keys weakly. Entries in the dictionary will be discarded when there is no longer a strong reference to the key. This can be used to associate additional data with an object owned by other parts of an application without adding attributes to those objects. This can be especially useful with objects that override attribute accesses.

Note: Caution: Because a WeakKeyDictionary is built on top of a Python dictionary, it must not change size when iterating over it. This can be difficult to ensure for a WeakKeyDictionary because actions performed by the program during iteration may cause items in the dictionary to vanish “by magic” (as a side effect of garbage collection).

WeakKeyDictionary objects have the following additional methods.
These expose the internal references directly. The references are not guaranteed to be “live” at the time they are used, so the result of calling the references needs to be checked before being used. This can be used to avoid creating references that will cause the garbage collector to keep the keys around longer than needed.

`WeakKeyDictionary.iterkeyrefs()`

Return an *iterator* that yields the weak references to the keys.

*New in version 2.5.*

`WeakKeyDictionary.keyrefs()`

Return a list of weak references to the keys.

*New in version 2.5.*

```python
class weakref.WeakValueDictionary([dict])
```

Mapping class that references values weakly. Entries in the dictionary will be discarded when no strong reference to the value exists any more.

**Note:** Caution: Because a `WeakValueDictionary` is built on top of a Python dictionary, it must not change size when iterating over it. This can be difficult to ensure for a `WeakValueDictionary` because actions performed by the program during iteration may cause items in the dictionary to vanish “by magic” (as a side effect of garbage collection).

`WeakValueDictionary` objects have the following additional methods. These method have the same issues as the `iterkeyrefs()` and `keyrefs()` methods of `WeakKeyDictionary` objects.

`WeakValueDictionary.itervaluerefs()`

Return an *iterator* that yields the weak references to the values.
New in version 2.5.

WeakValueDictionary.valuerefs()
    Return a list of weak references to the values.

New in version 2.5.

weakref.ReferenceType
    The type object for weak references objects.

weakref.ProxyType
    The type object for proxies of objects which are not callable.

weakref.CallableProxyType
    The type object for proxies of callable objects.

weakref.ProxyTypes
    Sequence containing all the type objects for proxies. This can make it simpler to test if an object is a proxy without being dependent on naming both proxy types.

exception weakref.ReferenceError
    Exception raised when a proxy object is used but the underlying object has been collected. This is the same as the standard ReferenceError exception.

See also:

PEP 0205 - Weak References
    The proposal and rationale for this feature, including links to earlier implementations and information about similar features in other languages.
Weak Reference Objects

Weak reference objects have no attributes or methods, but do allow the referent to be obtained, if it still exists, by calling it:

```python
>>> import weakref
>>> class Object:
...    pass
...>>> o = Object()
>>> r = weakref.ref(o)
>>> o2 = r()
>>> o is o2
True
```

If the referent no longer exists, calling the reference object returns `None`:

```python
>>> del o, o2
>>> print r()
None
```

Testing that a weak reference object is still live should be done using the expression `ref() is not None`. Normally, application code that needs to use a reference object should follow this pattern:

```python
# r is a weak reference object
o = r()
if o is None:
    # referent has been garbage collected
    print "Object has been deallocated; can't frobnicate."
else:
    print "Object is still live!"
    o.do_something_useful()
```

Using a separate test for “liveness” creates race conditions in threaded applications; another thread can cause a weak reference to become invalidated before the weak reference is called; the idiom shown above is safe in threaded applications as well as single-
threaded applications.

Specialized versions of \texttt{ref} objects can be created through subclassing. This is used in the implementation of the \texttt{WeakValueDictionary} to reduce the memory overhead for each entry in the mapping. This may be most useful to associate additional information with a reference, but could also be used to insert additional processing on calls to retrieve the referent.

This example shows how a subclass of \texttt{ref} can be used to store additional information about an object and affect the value that's returned when the referent is accessed:

```python
import weakref

class ExtendedRef(weakref.ref):
    def __init__(self, ob, callback=None, **annotations):
        super(ExtendedRef, self).__init__(ob, callback)
        self.__counter = 0
        for k, v in annotations.iteritems():
            setattr(self, k, v)

    def __call__(self):
        """Return a pair containing the referent and the number
        times the reference has been called."
        ob = super(ExtendedRef, self).__call__()
        if ob is not None:
            self.__counter += 1
            ob = (ob, self.__counter)
        return ob
```
This simple example shows how an application can use objects IDs to retrieve objects that it has seen before. The IDs of the objects can then be used in other data structures without forcing the objects to remain alive, but the objects can still be retrieved by ID if they do.

```python
import weakref

_id2obj_dict = weakref.WeakValueDictionary()

def remember(obj):
    oid = id(obj)
    _id2obj_dict[oid] = obj
    return oid

def id2obj(oid):
    return _id2obj_dict[oid]
```
UserDict — Class wrapper for dictionary objects

The module defines a mixin, `DictMixin`, defining all dictionary methods for classes that already have a minimum mapping interface. This greatly simplifies writing classes that need to be substitutable for dictionaries (such as the shelve module).

This module also defines a class, `UserDict`, that acts as a wrapper around dictionary objects. The need for this class has been largely supplanted by the ability to subclass directly from `dict` (a feature that became available starting with Python version 2.2). Prior to the introduction of `dict`, the `UserDict` class was used to create dictionary-like sub-classes that obtained new behaviors by overriding existing methods or adding new ones.

The `UserDict` module defines the `UserDict` class and `DictMixin`:

class UserDict:
    `UserDict`([`initialdata`])

    Class that simulates a dictionary. The instance's contents are kept in a regular dictionary, which is accessible via the `data` attribute of `UserDict` instances. If `initialdata` is provided, `data` is initialized with its contents; note that a reference to `initialdata` will not be kept, allowing it be used for other purposes.

    **Note:** For backward compatibility, instances of `UserDict` are not iterable.

class UserDict:
    `IterableUserDict`([`initialdata`])

    Subclass of `UserDict` that supports direct iteration (e.g. `for key in myDict`).
In addition to supporting the methods and operations of mappings (see section *Mapping Types — dict*), *UserDict* and *IterableUserDict* instances provide the following attribute:

**IterableUserDict**. **data**

A real dictionary used to store the contents of the *UserDict* class.

**class UserDict**. **DictMixin**

Mixin defining all dictionary methods for classes that already have a minimum dictionary interface including *__getitem__()*, *__setitem__()*, *__delitem__()*, and **keys()**.

This mixin should be used as a superclass. Adding each of the above methods adds progressively more functionality. For instance, defining all but *__delitem__()* will preclude only __pop__() and __popitem__() from the full interface.

In addition to the four base methods, progressively more efficiency comes with defining *__contains__()*, *__iter__()*, and **iteritems()**.

Since the mixin has no knowledge of the subclass constructor, it does not define __init__() or copy().

Starting with Python version 2.6, it is recommended to use collections.MutableMapping instead of DictMixin.
**UserList — Class wrapper for list objects**

**Note:** This module is available for backward compatibility only. If you are writing code that does not need to work with versions of Python earlier than Python 2.2, please consider subclassing directly from the built-in `list` type.

This module defines a class that acts as a wrapper around list objects. It is a useful base class for your own list-like classes, which can inherit from them and override existing methods or add new ones. In this way one can add new behaviors to lists.

The `UserList` module defines the `UserList` class:

```python
class UserList.UserList([list])
    Class that simulates a list. The instance's contents are kept in a regular list, which is accessible via the `data` attribute of `UserList` instances. The instance's contents are initially set to a copy of `list`, defaulting to the empty list `[]`. `list` can be any iterable, e.g. a real Python list or a `UserList` object.
```

**Note:** The `UserList` class has been moved to the `collections` module in Python 3.0. The `2to3` tool will automatically adapt imports when converting your sources to 3.0.

In addition to supporting the methods and operations of mutable sequences (see section *Sequence Types — str, unicode, list, tuple, buffer, xrange*), `UserList` instances provide the following attribute:

```python
UserList.data
    A real Python list object used to store the contents of the
```
**UserList** class.

**Subclassing requirements:** Subclasses of **UserList** are expect to offer a constructor which can be called with either no arguments or one argument. List operations which return a new sequence attempt to create an instance of the actual implementation class. To do so, it assumes that the constructor can be called with a single parameter, which is a sequence object used as a data source.

If a derived class does not wish to comply with this requirement, all of the special methods supported by this class will need to be overridden; please consult the sources for information about the methods which need to be provided in that case.

*Changed in version 2.0:* Python versions 1.5.2 and 1.6 also required that the constructor be callable with no parameters, and offer a mutable **data** attribute. Earlier versions of Python did not attempt to create instances of the derived class.
UserString — Class wrapper for string objects

Note: This UserString class from this module is available for backward compatibility only. If you are writing code that does not need to work with versions of Python earlier than Python 2.2, please consider subclassing directly from the built-in str type instead of using UserString (there is no built-in equivalent to MutableString).

This module defines a class that acts as a wrapper around string objects. It is a useful base class for your own string-like classes, which can inherit from them and override existing methods or add new ones. In this way one can add new behaviors to strings.

It should be noted that these classes are highly inefficient compared to real string or Unicode objects; this is especially the case for MutableString.

The UserString module defines the following classes:

class UserString. UserString([sequence])

Class that simulates a string or a Unicode string object. The instance's content is kept in a regular string or Unicode string object, which is accessible via the data attribute of UserString instances. The instance's contents are initially set to a copy of sequence. sequence can be either a regular Python string or Unicode string, an instance of UserString (or a subclass) or an arbitrary sequence which can be converted into a string using the built-in str() function.
Note: The `UserString` class has been moved to the `collections` module in Python 3.0. The `2to3` tool will automatically adapt imports when converting your sources to 3.0.

class `UserString`. `MutableString([sequence])`

This class is derived from the `UserString` above and redefines strings to be *mutable*. Mutable strings can't be used as dictionary keys, because dictionaries require *immutable* objects as keys. The main intention of this class is to serve as an educational example for inheritance and necessity to remove (override) the `__hash__()` method in order to trap attempts to use a mutable object as dictionary key, which would be otherwise very error prone and hard to track down.

_Deprecated since version 2.6:_ The `MutableString` class has been removed in Python 3.0.

In addition to supporting the methods and operations of string and Unicode objects (see section `String Methods`), `UserString` instances provide the following attribute:

`MutableString.data`

A real Python string or Unicode object used to store the content of the `UserString` class.
This module defines names for some object types that are used by the standard Python interpreter, but not for the types defined by various extension modules. Also, it does not include some of the types that arise during processing such as the listiterator type. It is safe to use `from types import *` — the module does not export any names besides the ones listed here. New names exported by future versions of this module will all end in `Type`.

Typical use is for functions that do different things depending on their argument types, like the following:

```python
from types import *
def delete(mylist, item):
    if type(item) is IntType:
        del mylist[item]
    else:
        mylist.remove(item)
```

Starting in Python 2.2, built-in factory functions such as `int()` and `str()` are also names for the corresponding types. This is now the preferred way to access the type instead of using the `types` module. Accordingly, the example above should be written as follows:

```python
def delete(mylist, item):
    if isinstance(item, int):
        del mylist[item]
    else:
        mylist.remove(item)
```

The module defines the following names:

- `types.NoneType`: The type of `None`.
- `types.TypeType`
The type of type objects (such as returned by `type()`); alias of the built-in `type`.

types. **BooleanType**
The type of the `bool` values `True` and `False`; alias of the built-in `bool`.

*New in version 2.3.*

types. **IntType**
The type of integers (e.g. `1`); alias of the built-in `int`.

types. **LongType**
The type of long integers (e.g. `1L`); alias of the built-in `long`.

types. **FloatType**
The type of floating point numbers (e.g. `1.0`); alias of the built-in `float`.

types. **ComplexType**
The type of complex numbers (e.g. `1.0j`). This is not defined if Python was built without complex number support.

types. **StringType**
The type of character strings (e.g. `'Spam'`); alias of the built-in `str`.

types. **UnicodeType**
The type of Unicode character strings (e.g. `u'Spam'`). This is not defined if Python was built without Unicode support. It's an alias of the built-in `unicode`.

types. **TupleType**
The type of tuples (e.g. `(1, 2, 3, 'Spam')`); alias of the built-in `tuple`. 
types:\texttt{ListType}

The type of lists (e.g. $[0, 1, 2, 3]$); alias of the built-in \texttt{list}.

types:\texttt{DictType}

The type of dictionaries (e.g. \{'Bacon': 1, 'Ham': 0\}); alias of the built-in \texttt{dict}.

types:\texttt{DictionaryType}

An alternate name for \texttt{DictType}.

types:\texttt{FunctionType}

types:\texttt{LambdaType}

The type of user-defined functions and functions created by \texttt{lambda} expressions.

types:\texttt{GeneratorType}

The type of \texttt{generator}-iterator objects, produced by calling a generator function.

\textit{New in version 2.2.}

types:\texttt{CodeType}

The type for code objects such as returned by \texttt{compile}().

types:\texttt{ClassType}

The type of user-defined old-style classes.

types:\texttt{InstanceType}

The type of instances of user-defined classes.

types:\texttt{MethodType}

The type of methods of user-defined class instances.

types:\texttt{UnboundMethodType}

An alternate name for \texttt{MethodType}.

types:\texttt{BuiltInFunctionType}
types. `BuiltInMethodType`
The type of built-in functions like `len()` or `sys.exit()`, and methods of built-in classes. (Here, the term “built-in” means “written in C”.)

types. `ModuleType`
The type of modules.

types. `FileType`
The type of open file objects such as `sys.stdout`; alias of the built-in `file`.

types. `XRangeType`
The type of range objects returned by `xrange()`; alias of the built-in `xrange`.

types. `SliceType`
The type of objects returned by `slice()`; alias of the built-in `slice`.

types. `EllipsisType`
The type of `Ellipsis`.

types. `TracebackType`
The type of traceback objects such as found in `sys.exc_traceback`.

types. `FrameType`
The type of frame objects such as found in `tb.tb_frame` if `tb` is a traceback object.

types. `BufferType`
The type of buffer objects created by the `buffer()` function.

types. `DictProxyType`
The type of dict proxies, such as `TypeType.__dict__`. 
types. **NotImplementedType**

The type of `NotImplemented`

---

types. **GetSetDescriptorType**

The type of objects defined in extension modules with `PyGetSetDef`, such as `FrameType.f_locals` or `array.array.typecode`. This type is used as descriptor for object attributes; it has the same purpose as the `property` type, but for classes defined in extension modules.

*New in version 2.5.*

---

types. **MemberDescriptorType**

The type of objects defined in extension modules with `PyMemberDef`, such as `datetime.timedelta.days`. This type is used as descriptor for simple C data members which use standard conversion functions; it has the same purpose as the `property` type, but for classes defined in extension modules. In other implementations of Python, this type may be identical to `GetSetDescriptorType`.

*New in version 2.5.*

---

types. **StringTypes**

A sequence containing `StringType` and `UnicodeType` used to facilitate easier checking for any string object. Using this is more portable than using a sequence of the two string types constructed elsewhere since it only contains `UnicodeType` if it has been built in the running version of Python. For example: `isinstance(s, types.StringTypes)`.

*New in version 2.2.*
new — Creation of runtime internal objects

Deprecated since version 2.6: The new module has been removed in Python 3.0.

The new module allows an interface to the interpreter object creation functions. This is for use primarily in marshal-type functions, when a new object needs to be created “magically” and not by using the regular creation functions. This module provides a low-level interface to the interpreter, so care must be exercised when using this module. It is possible to supply non-sensical arguments which crash the interpreter when the object is used.

The new module defines the following functions:

new.**instance**(class[, dict])

This function creates an instance of class with dictionary dict without calling the __init__() constructor. If dict is omitted or None, a new, empty dictionary is created for the new instance. Note that there are no guarantees that the object will be in a consistent state.

new.**instancemethod**(function, instance, class)

This function will return a method object, bound to instance, or unbound if instance is None. function must be callable.

new.**function**(code, globals[, name[, argdefs[, closure]]]])

Returns a (Python) function with the given code and globals. If name is given, it must be a string or None. If it is a string, the function will have the given name, otherwise the function name will be taken from code.co_name. If argdefs is given, it must be a
tuple and will be used to determine the default values of parameters. If closure is given, it must be None or a tuple of cell objects containing objects to bind to the names in code.co_freevars.

```
new. code(argcount, nlocals, stacksize, flags, codestring, constants, names, varnames, filename, name, firstlineno, lnotab)
```

This function is an interface to the PyCode_New C function.

```
new. module(name[, doc])
```

This function returns a new module object with name name. name must be a string. The optional doc argument can have any type.

```
new. classobj(name, baseclasses, dict)
```

This function returns a new class object, with name name, derived from baseclasses (which should be a tuple of classes) and with namespace dict.
copy — Shallow and deep copy operations

This module provides generic (shallow and deep) copying operations.

Interface summary:

```python
import copy
x = copy.copy(y)       # make a shallow copy of y
x = copy.deepcopy(y)   # make a deep copy of y
```

For module specific errors, `copy.error` is raised.

The difference between shallow and deep copying is only relevant for compound objects (objects that contain other objects, like lists or class instances):

- A *shallow copy* constructs a new compound object and then (to the extent possible) inserts *references* into it to the objects found in the original.
- A *deep copy* constructs a new compound object and then, recursively, inserts *copies* into it of the objects found in the original.

Two problems often exist with deep copy operations that don’t exist with shallow copy operations:

- Recursive objects (compound objects that, directly or indirectly, contain a reference to themselves) may cause a recursive loop.
- Because deep copy copies *everything* it may copy too much, e.g., administrative data structures that should be shared even between copies.
The `deepcopy()` function avoids these problems by:

- keeping a “memo” dictionary of objects already copied during the current copying pass; and
- letting user-defined classes override the copying operation or the set of components copied.

This module does not copy types like module, method, stack trace, stack frame, file, socket, window, array, or any similar types. It does “copy” functions and classes (shallow and deeply), by returning the original object unchanged; this is compatible with the way these are treated by the `pickle` module.

Shallow copies of dictionaries can be made using `dict.copy()`, and of lists by assigning a slice of the entire list, for example, `copied_list = original_list[:]`.

*Changed in version 2.5*: Added copying functions.

Classes can use the same interfaces to control copying that they use to control pickling. See the description of module `pickle` for information on these methods. The `copy` module does not use the `copy_reg` registration module.

In order for a class to define its own copy implementation, it can define special methods `__copy__()` and `__deepcopy__()`. The former is called to implement the shallow copy operation; no additional arguments are passed. The latter is called to implement the deep copy operation; it is passed one argument, the memo dictionary. If the `__deepcopy__()` implementation needs to make a deep copy of a component, it should call the `deepcopy()` function with the component as first argument and the memo dictionary as second argument.

**Module pickle**
Discussion of the special methods used to support object state retrieval and restoration.
The `pprint` module provides a capability to “pretty-print” arbitrary Python data structures in a form which can be used as input to the interpreter. If the formatted structures include objects which are not fundamental Python types, the representation may not be loadable. This may be the case if objects such as files, sockets, classes, or instances are included, as well as many other built-in objects which are not representable as Python constants.

The formatted representation keeps objects on a single line if it can, and breaks them onto multiple lines if they don’t fit within the allowed width. Construct `PrettyPrinter` objects explicitly if you need to adjust the width constraint.

*Changed in version 2.5:* Dictionaries are sorted by key before the display is computed; before 2.5, a dictionary was sorted only if its display required more than one line, although that wasn’t documented.

*Changed in version 2.6:* Added support for `set` and `frozenset`.

The `pprint` module defines one class:  

```python
class pprint.PrettyPrinter(...)
```

Construct a `PrettyPrinter` instance. This constructor understands several keyword parameters. An output stream may be set using the `stream` keyword; the only method used on the stream object is the file protocol’s `write()` method. If not specified, the `PrettyPrinter` adopts `sys.stdout`. Three additional parameters may be used to control the formatted representation. The keywords are `indent`, `depth`, and `width`. The amount of indentation added for each recursive level is specified by `indent`;
the default is one. Other values can cause output to look a little odd, but can make nesting easier to spot. The number of levels which may be printed is controlled by `depth`; if the data structure being printed is too deep, the next contained level is replaced by `...`. By default, there is no constraint on the depth of the objects being formatted. The desired output width is constrained using the `width` parameter; the default is 80 characters. If a structure cannot be formatted within the constrained width, a best effort will be made.

```python
>>> import pprint
>>> stuff = ['spam', 'eggs', 'lumberjack', 'knights', 'ni']
>>> stuff.insert(0, stuff[:])
>>> pp = pprint.PrettyPrinter(indent=4)
>>> pp.pprint(stuff)
['spam',
 'eggs',
 'lumberjack',
 'knights',
 'ni']
>>> tup = ('spam', ('eggs', ('lumberjack', ('knights', ('ni', ('dead', (...)))))))
>>> pp = pprint.PrettyPrinter(depth=6)
>>> pp.pprint(tup)
('spam', ('eggs', ('lumberjack', ('knights', ('ni', ('dead',

The `PrettyPrinter` class supports several derivative functions:

`pprint.pformat(object[, indent[, width[, depth]]])`

Return the formatted representation of `object` as a string. `indent`, `width` and `depth` will be passed to the `PrettyPrinter` constructor as formatting parameters.
Changed in version 2.4: The parameters `indent`, `width` and `depth` were added.

```
>>> import pprint
>>> stuff = ['spam', 'eggs', 'lumberjack', 'knights', 'ni']
>>> stuff.insert(0, stuff)
>>> pprint.pprint(stuff)
[<Recursion on list with id=...>,
 'spam',
 'eggs',
 'lumberjack',
 'knights',
 'ni']
```

Changed in version 2.4: The parameters `indent`, `width` and `depth` were added.

```
>>> pprint.isreadable(stuff)
False
```

```
>>> pprint.isrecursive(stuff)
```

Determine if *object* requires a recursive representation.

One more support function is also defined:

```python
>>> pprint.saferepr(stuff)
'[[<Recursion on list with id=...>, 'spam', 'eggs', 'lumberjack', 'ni']
```
PrettyPrinter Objects

PrettyPrinter instances have the following methods:

**PrettyPrinter.** `pformat(object)`

Return the formatted representation of `object`. This takes into account the options passed to the `PrettyPrinter` constructor.

**PrettyPrinter.** `pprint(object)`

Print the formatted representation of `object` on the configured stream, followed by a newline.

The following methods provide the implementations for the corresponding functions of the same names. Using these methods on an instance is slightly more efficient since new `PrettyPrinter` objects don’t need to be created.

**PrettyPrinter.** `isreadable(object)`

Determine if the formatted representation of the object is “readable,” or can be used to reconstruct the value using `eval()`. Note that this returns `False` for recursive objects. If the `depth` parameter of the `PrettyPrinter` is set and the object is deeper than allowed, this returns `False`.

**PrettyPrinter.** `isrecursive(object)`

Determine if the object requires a recursive representation.

This method is provided as a hook to allow subclasses to modify the way objects are converted to strings. The default implementation uses the internals of the `saferepr()` implementation.

**PrettyPrinter.** `format(object, context, maxlevels, level)`

Returns three values: the formatted version of `object` as a string,
a flag indicating whether the result is readable, and a flag indicating whether recursion was detected. The first argument is the object to be presented. The second is a dictionary which contains the \texttt{id()} of objects that are part of the current presentation context (direct and indirect containers for \textit{object} that are affecting the presentation) as the keys; if an object needs to be presented which is already represented in \textit{context}, the third return value should be \texttt{True}. Recursive calls to the \texttt{format()} method should add additional entries for containers to this dictionary. The third argument, \textit{maxlevels}, gives the requested limit to recursion; this will be \texttt{0} if there is no requested limit. This argument should be passed unmodified to recursive calls. The fourth argument, \textit{level}, gives the current level; recursive calls should be passed a value less than that of the current call.

\textit{New in version 2.3.}
This example demonstrates several uses of the `pprint()` function and its parameters.

```python
>>> import pprint
tup = ('spam', ('eggs', ('lumberjack', ('knights', ('ni', ('dead', ('parrot', ('fresh fruit',))))))))
>>> stuff = ['a' * 10, tup, ['a' * 30, 'b' * 30], ['c' * 20, 'd']
>>> pprint.pprint(stuff)
['aaaaaaaaaa',
 ('spam',
  ('eggs',
   ('lumberjack',
    ('knights', ('ni', ('dead', ('parrot', ('fresh fruit',))))))))
 ['aaaaaaaaaaaaaaaaaaaaaaaaaaaaa', 'bbbbbbbbbbbbbbbbbbbbbbbbbbbbbbb'
 ['cccccccccccccccccccccccc', 'dddddddddddddddddddddd']

>>> pprint.pprint(stuff, depth=3)
['aaaaaaaaaa',
 ('spam', ('eggs', (...)) ),
 ['aaaaaaaaaaaaaaaaaaaaaaaaaaaaa', 'bbbbbbbbbbbbbbbbbbbbbbbbbb
 ['ccccccccccccccccccccccccc', 'dddddddddddddddddddddd']

>>> pprint.pprint(stuff, width=60)
['aaaaaaaaaa',
 ('spam',
  ('eggs',
   ('lumberjack',
    ('knights',
     ('ni', ('dead', ('parrot', ('fresh fruit',)))))) ),
 ['aaaaaaaaaaaaaaaaaaaaaaaaaaaaa',
 bbbbbbbbbbbbbbbbbbbbbbbbbbbbbbb'],
 ['cccccccccccccccccccccc', 'ddddddddddddddddddd']
```
The `repr` module provides a means for producing object representations with limits on the size of the resulting strings. This is used in the Python debugger and may be useful in other contexts as well.

This module provides a class, an instance, and a function:

**class `repr.Repr`**

Class which provides formatting services useful in implementing functions similar to the built-in `repr()`; size limits for different object types are added to avoid the generation of representations which are excessively long.

**`repr.aRepr`**

This is an instance of `Repr` which is used to provide the `repr()` function described below. Changing the attributes of this object will affect the size limits used by `repr()` and the Python debugger.

**`repr.repr(obj)`**

This is the `repr()` method of `aRepr`. It returns a string similar to that returned by the built-in function of the same name, but with limits on most sizes.
Repr Objects

Repr instances provide several members which can be used to provide size limits for the representations of different object types, and methods which format specific object types.

Repr. **maxlevel**
Depth limit on the creation of recursive representations. The default is 6.

Repr. **maxdict**
Repr. **maxlist**
Repr. **maxtuple**
Repr. **maxset**
Repr. **maxfrozenset**
Repr. **maxdeque**
Repr. **maxarray**
Limits on the number of entries represented for the named object type. The default is 4 for **maxdict**, 5 for **maxarray**, and 6 for the others.

*New in version 2.4:* **maxset**, **maxfrozenset**, and **set**.

Repr. **maxlong**
Maximum number of characters in the representation for a long integer. Digits are dropped from the middle. The default is 40.

Repr. **maxstring**
Limit on the number of characters in the representation of the string. Note that the “normal” representation of the string is used as the character source: if escape sequences are needed in the representation, these may be mangled when the representation is shortened. The default is 30.

Repr. **maxother**
This limit is used to control the size of object types for which no specific formatting method is available on the `repr` object. It is applied in a similar manner as `maxstring`. The default is 20.

**Repr. `repr(obj)`**

The equivalent to the built-in `repr()` that uses the formatting imposed by the instance.

**Repr. `repr1(obj, level)`**

Recursive implementation used by `repr()`. This uses the type of `obj` to determine which formatting method to call, passing it `obj` and `level`. The type-specific methods should call `repr1()` to perform recursive formatting, with `level - 1` for the value of `level` in the recursive call.

**Repr. `repr_TYPE(obj, level)`**

Formatting methods for specific types are implemented as methods with a name based on the type name. In the method name, `TYPE` is replaced by `string.join(string.split(type(obj).__name__, '_'))`. Dispatch to these methods is handled by `repr1()`. Type-specific methods which need to recursively format a value should call `self.repr1(subobj, level - 1)`.
The use of dynamic dispatching by `Repr.repr1()` allows subclasses of `Repr` to add support for additional built-in object types or to modify the handling of types already supported. This example shows how special support for file objects could be added:

```python
import repr
import sys

class MyRepr(repr.Repr):
    def repr_file(self, obj, level):
        if obj.name in ['<stdin>', '<stdout>', '<stderr>']:
            return obj.name
        else:
            return `obj`

aRepr = MyRepr()
print aRepr.repr(sys.stdin)  # prints '<stdin>'
```
The modules described in this chapter provide numeric and math-related functions and data types. The `numbers` module defines an abstract hierarchy of numeric types. The `math` and `cmath` modules contain various mathematical functions for floating-point and complex numbers. For users more interested in decimal accuracy than in speed, the `decimal` module supports exact representations of decimal numbers.

The following modules are documented in this chapter:

- **numbers** — Numeric abstract base classes
  - The numeric tower
  - Notes for type implementors
    - Adding More Numeric ABCs
    - Implementing the arithmetic operations

- **math** — Mathematical functions

- **cmath** — Mathematical functions for complex numbers
  - Complex coordinates
  - cmath functions

- **decimal** — Decimal fixed point and floating point arithmetic
  - Quick-start Tutorial
  - Decimal objects
    - Logical operands
  - Context objects
  - Signals
  - Floating Point Notes
    - Mitigating round-off error with increased precision
    - Special values
  - Working with threads
- Recipes
- Decimal FAQ

- **fractions** — Rational numbers

- **random** — Generate pseudo-random numbers

- **itertools** — Functions creating iterators for efficient looping
  - Itertool functions
  - Examples
  - Recipes

- **functools** — Higher order functions and operations on callable objects
  - partial Objects

- **operator** — Standard operators as functions
  - Mapping Operators to Functions
New in version 2.6.

The numbers module (PEP 3141) defines a hierarchy of numeric abstract base classes which progressively define more operations. None of the types defined in this module can be instantiated.

class numbers.Number

The root of the numeric hierarchy. If you just want to check if an argument x is a number, without caring what kind, use isinstance(x, Number).
The numeric tower

```python
class numbers.Complex
    Subclasses of this type describe complex numbers and include the operations that work on the builtin complex type. These are: conversions to complex and bool, real, imag, +, -, *, /, abs(), conjugate(), ==, and !=. All except - and != are abstract.

    real
        Abstract. Retrieves the Real component of this number.

    imag
        Abstract. Retrieves the Real component of this number.

    conjugate()
        Abstract. Returns the complex conjugate. For example, (1+3j).conjugate() == (1-3j).
```

```python
class numbers.Real
    To Complex, Real adds the operations that work on real numbers.

    In short, those are: a conversion to float, trunc(), round(), math.floor(), math.ceil(), divmod(), //, %, <, <=, >, and >=.

    Real also provides defaults for complex(), Complex.real, Complex.imag, and Complex.conjugate().
```

```python
class numbers.Rational
    Subtypes Real and adds Rational.numerator and Rational.denominator properties, which should be in lowest terms. With these, it provides a default for float().

    numerator
```
Abstract.

denominator

Abstract.

class numbers. Integral
Subtypes Rational and adds a conversion to int. Provides defaults for float(), Rational.numerator, and Rational.denominator, and bit-string operations: <<, >>, &, ^, |, ~.
Implementors should be careful to make equal numbers equal and hash them to the same values. This may be subtle if there are two different extensions of the real numbers. For example, \texttt{fractions.Fraction} implements \texttt{hash()} as follows:

```python
def \_\_hash\_(self):
    if self.denominator == 1:
        # Get integers right.
        return hash(self.numerator)
    # Expensive check, but definitely correct.
    if self == float(self):
        return hash(float(self))
    else:
        # Use tuple's hash to avoid a high collision rate on
        # simple fractions.
        return hash((self.numerator, self.denominator))
```

Adding More Numeric ABCs

There are, of course, more possible ABCs for numbers, and this would be a poor hierarchy if it precluded the possibility of adding those. You can add \texttt{MyFoo} between \texttt{Complex} and \texttt{Real} with:

```python
class MyFoo(Complex): ...
MyFoo.register(Real)
```

Implementing the arithmetic operations

We want to implement the arithmetic operations so that mixed-mode operations either call an implementation whose author knew about the types of both arguments, or convert both to the nearest built in type and do the operation there. For subtypes of \texttt{Integral}, this means that \texttt{\_\_add\_()} and \texttt{\_\_radd\_()} should be defined as:
There are 5 different cases for a mixed-type operation on subclasses of `Complex`. I'll refer to all of the above code that doesn't refer to `MyIntegral` and `OtherTypeIKnowAbout` as “boilerplate”. `a` will be an instance of `A`, which is a subtype of `Complex` (`a : A <: Complex`), and `b : B <: Complex`. I'll consider `a + b`:

1. If `A` defines an `__add__()` which accepts `b`, all is well.
2. If `A` falls back to the boilerplate code, and it were to return a value from `__add__()`, we'd miss the possibility that `B` defines a more intelligent `__radd__()`, so the boilerplate should return `NotImplemented` from `__add__()`. (Or `A` may not implement `__add__()` at all.)
3. Then `B`'s `__radd__()` gets a chance. If it accepts `a`, all is well.
4. If it falls back to the boilerplate, there are no more possible methods to try, so this is where the default implementation...
should live.

5. If \( B <: A \), Python tries \( B.__radd__ \) before \( A.__add__ \). This is ok, because it was implemented with knowledge of \( A \), so it can handle those instances before delegating to \texttt{Complex}.

If \( A <: \texttt{Complex} \) and \( B <: \texttt{Real} \) without sharing any other knowledge, then the appropriate shared operation is the one involving the built in \texttt{complex}, and both \( \_\_radd\_\_() \) s land there, so \( a+b == b+a \).

Because most of the operations on any given type will be very similar, it can be useful to define a helper function which generates the forward and reverse instances of any given operator. For example, \texttt{fractions.Fraction} uses:

```python
def _operator_fallbacks(monomorphic_operator, fallback_operator):
    def forward(a, b):
        if isinstance(b, (int, long, Fraction)):
            return monomorphic_operator(a, b)
        elif isinstance(b, float):
            return fallback_operator(float(a), b)
        elif isinstance(b, complex):
            return fallback_operator(complex(a), b)
        else:
            return NotImplemented

    forward.__name__ = '__' + fallback_operator.__name__ + '__'
    forward.__doc__ = monomorphic_operator.__doc__

    def reverse(b, a):
        if isinstance(a, Rational):
            # Includes ints.
            return monomorphic_operator(a, b)
        elif monomorphic_operator(a, numbers.Real):
            return fallback_operator(float(a), float(b))
        elif monomorphic_operator(a, numbers.Complex):
            return fallback_operator(complex(a), complex(b))
        else:
            return NotImplemented

    reverse.__name__ = '__r' + fallback_operator.__name__ + '__'
    reverse.__doc__ = monomorphic_operator.__doc__

    return forward, reverse

def _add(a, b):
```

"""a + b"""

```python
return Fraction(a.numerator * b.denominator +
b.numerator * a.denominator,  
a.denominator * b.denominator)
```

```
__add__, __radd__ = _operator_fallbacks(_add, operator.add)
```
This module is always available. It provides access to the mathematical functions defined by the C standard.

These functions cannot be used with complex numbers; use the functions of the same name from the `cmath` module if you require support for complex numbers. The distinction between functions which support complex numbers and those which don’t is made since most users do not want to learn quite as much mathematics as required to understand complex numbers. Receiving an exception instead of a complex result allows earlier detection of the unexpected complex number used as a parameter, so that the programmer can determine how and why it was generated in the first place.

The following functions are provided by this module. Except when explicitly noted otherwise, all return values are floats.

Number-theoretic and representation functions:

- **math.ceil(x)**
  Return the ceiling of `x` as a float, the smallest integer value greater than or equal to `x`.

- **math.copysign(x, y)**
  Return `x` with the sign of `y`. `copysign` copies the sign bit of an IEEE 754 float, `copysign(1, -0.0)` returns `-1.0`.

  *New in version 2.6.*

- **math.fabs(x)**
  Return the absolute value of `x`. 
math.factorial(x)
    Return x factorial. Raises ValueError if x is not integral or is negative.

    New in version 2.6.

math.floor(x)
    Return the floor of x as a float, the largest integer value less than or equal to x.

    Changed in version 2.6: Added __floor__() delegation.

math.fmod(x, y)
    Return fmod(x, y), as defined by the platform C library. Note that the Python expression x % y may not return the same result. The intent of the C standard is that fmod(x, y) be exactly (mathematically; to infinite precision) equal to x - n*y for some integer n such that the result has the same sign as x and magnitude less than abs(y). Python’s x % y returns a result with the sign of y instead, and may not be exactly computable for float arguments. For example, fmod(-1e-100, 1e100) is -1e-100, but the result of Python’s -1e-100 % 1e100 is 1e100-1e-100, which cannot be represented exactly as a float, and rounds to the surprising 1e100. For this reason, function fmod() is generally preferred when working with floats, while Python’s x % y is preferred when working with integers.

math.frexp(x)
    Return the mantissa and exponent of x as the pair (m, e). m is a float and e is an integer such that x == m * 2**e exactly. If x is zero, returns (0.0, 0), otherwise 0.5 <= abs(m) < 1. This is used to “pick apart” the internal representation of a float in a portable way.
math. **fsum**(iterable)

Return an accurate floating point sum of values in the iterable. Avoids loss of precision by tracking multiple intermediate partial sums. The algorithm's accuracy depends on IEEE-754 arithmetic guarantees and the typical case where the rounding mode is half-even.

**Note:** The accuracy of fsum() may be impaired on builds that use extended precision addition and then double-round the results.

*New in version 2.6.*

math. **isinf**(x)

Checks if the float x is positive or negative infinite.

*New in version 2.6.*

math. **isnan**(x)

Checks if the float x is a NaN (not a number). NaNs are part of the IEEE 754 standards. Operation like but not limited to inf * 0, inf / inf or any operation involving a NaN, e.g. nan * 1, return a NaN.

*New in version 2.6.*

math. **ldexp**(x, i)

Return x * (2**i). This is essentially the inverse of function frexp().

math. **modf**(x)

Return the fractional and integer parts of x. Both results carry the sign of x, and both are floats.

math. **trunc**(x)
Return the **Real** value $x$ truncated to an **Integral** (usually a long integer). Delegates to `x.__trunc__()`.

*New in version 2.6.*

Note that `frexp()` and `modf()` have a different call/return pattern than their C equivalents: they take a single argument and return a pair of values, rather than returning their second return value through an 'output parameter' (there is no such thing in Python).

For the `ceil()`, `floor()`, and `modf()` functions, note that all floating-point numbers of sufficiently large magnitude are exact integers. Python floats typically carry no more than 53 bits of precision (the same as the platform C double type), in which case any float $x$ with $\text{abs}(x) \geq 2^{52}$ necessarily has no fractional bits.

**Power and logarithmic functions:**

```
math.exp(x)
```

Return $e^x$.

```
math.log(x[, base])
```

Return the logarithm of $x$ to the given `base`. If the `base` is not specified, return the natural logarithm of $x$ (that is, the logarithm to base $e$).

*Changed in version 2.3: base argument added.*

```
math.log1p(x)
```

Return the natural logarithm of $1+x$ (base $e$). The result is calculated in a way which is accurate for $x$ near zero.

*New in version 2.6.*

```
math.log10(x)
```
Return the base-10 logarithm of \( x \).

**math.\pow(x, y)**

Return \( x \) raised to the power \( y \). Exceptional cases follow Annex ‘F’ of the C99 standard as far as possible. In particular, \( \pow(1.0, x) \) and \( \pow(x, \ 0.0) \) always return 1.0, even when \( x \) is a zero or a NaN. If both \( x \) and \( y \) are finite, \( x \) is negative, and \( y \) is not an integer then \( \pow(x, y) \) is undefined, and raises `ValueError`.

*Changed in version 2.6:* The outcome of \( 1**\text{nan} \) and \( \text{nan}**\theta \) was undefined.

**math.\sqrt(x)**

Return the square root of \( x \).

Trigonometric functions:

**math.\acos(x)**

Return the arc cosine of \( x \), in radians.

**math.\asin(x)**

Return the arc sine of \( x \), in radians.

**math.\atan(x)**

Return the arc tangent of \( x \), in radians.

**math.\atan2(y, x)**

Return \( \atan(y / x) \), in radians. The result is between -\( \pi \) and \( \pi \). The vector in the plane from the origin to point \((x, y)\) makes this angle with the positive X axis. The point of \( \atan2() \) is that the signs of both inputs are known to it, so it can compute the correct quadrant for the angle. For example, \( \atan(1) \) and \( \atan2(1, 1) \) are both \( \pi/4 \), but \( \atan2(-1, -1) \) is \( -3\pi/4 \).
math.\texttt{cos}(x) \\
    Return the cosine of \(x\) radians.

math.\texttt{hypot}(x, y) \\
    Return the Euclidean norm, \(\sqrt{x^2 + y^2}\). This is the length of 
    the vector from the origin to point \((x, y)\).

math.\texttt{sin}(x) \\
    Return the sine of \(x\) radians.

math.\texttt{tan}(x) \\
    Return the tangent of \(x\) radians.

Angular conversion:

math.\texttt{degrees}(x) \\
    Converts angle \(x\) from radians to degrees.

math.\texttt{radians}(x) \\
    Converts angle \(x\) from degrees to radians.

Hyperbolic functions:

math.\texttt{acosh}(x) \\
    Return the inverse hyperbolic cosine of \(x\). \\
    \textit{New in version 2.6.}

math.\texttt{asinh}(x) \\
    Return the inverse hyperbolic sine of \(x\). \\
    \textit{New in version 2.6.}

math.\texttt{atanh}(x) \\
    Return the inverse hyperbolic tangent of \(x\).
New in version 2.6.

math.cosh(x)
    Return the hyperbolic cosine of x.

math.sinh(x)
    Return the hyperbolic sine of x.

math.tanh(x)
    Return the hyperbolic tangent of x.

The module also defines two mathematical constants:

math.pi
    The mathematical constant $\pi$.

math.e
    The mathematical constant $e$.

**Note:** The `math` module consists mostly of thin wrappers around the platform C math library functions. Behavior in exceptional cases is loosely specified by the C standards, and Python inherits much of its math-function error-reporting behavior from the platform C implementation. As a result, the specific exceptions raised in error cases (and even whether some arguments are considered to be exceptional at all) are not defined in any useful cross-platform or cross-release way. For example, whether `math.log(0)` returns `Inf` or raises `ValueError` or `OverflowError` isn't defined, and in cases where `math.log(0)` raises `OverflowError`, `math.log(0L)` may raise `ValueError` instead. All functions return a quiet `NaN` if at least one of the args is `NaN`. Signaling `NaNs` raise an exception. The exception type still depends on the platform and libm implementation. It’s usually `ValueError` for `EDOM` and `OverflowError` for errno `ERANGE`.

*Changed in version 2.6:* In earlier versions of Python the outcome
of an operation with NaN as input depended on platform and libm implementation.

See also:

**Module `cmath`**

Complex number versions of many of these functions.
This module is always available. It provides access to mathematical functions for complex numbers. The functions in this module accept integers, floating-point numbers or complex numbers as arguments. They will also accept any Python object that has either a \_\_complex\_() or a \_\_float\_() method: these methods are used to convert the object to a complex or floating-point number, respectively, and the function is then applied to the result of the conversion.

**Note:** On platforms with hardware and system-level support for signed zeros, functions involving branch cuts are continuous on both sides of the branch cut: the sign of the zero distinguishes one side of the branch cut from the other. On platforms that do not support signed zeros the continuity is as specified below.
Complex numbers can be expressed by two important coordinate systems. Python’s `complex` type uses rectangular coordinates where a number on the complex plain is defined by two floats, the real part and the imaginary part.

Definition:

\[
z = x + 1j * y
\]

\[
x := \text{real}(z)
\]

\[
y := \text{imag}(z)
\]

In engineering the polar coordinate system is popular for complex numbers. In polar coordinates a complex number is defined by the radius \( r \) and the phase angle \( \phi \). The radius \( r \) is the absolute value of the complex, which can be viewed as distance from \((0, 0)\). The radius \( r \) is always 0 or a positive float. The phase angle \( \phi \) is the counter clockwise angle from the positive \( x \) axis, e.g. \( 1 \) has the angle \( 0 \), \( 1j \) has the angle \( \pi/2 \) and \(-1\) the angle \(-\pi\).

**Note:** While `phase()` and `func:polar` return \(+\pi\) for a negative real they may return \(-\pi\) for a complex with a very small negative imaginary part, e.g. \(-1-1E-300j\).

Definition:

\[
z = r * \exp(1j * \phi)
\]

\[
z = r * \text{cis}(\phi)
\]

\[
r := \text{abs}(z) := \sqrt{\text{real}(z)^2 + \text{imag}(z)^2}
\]

\[
\phi := \text{phase}(z) := \text{atan2}(\text{imag}(z), \text{real}(z))
\]

\[
\text{cis}(\phi) := \cos(\phi) + 1j * \sin(\phi)
\]

`cmath.phase(x)`
Return phase, also known as the argument, of a complex.

*New in version 2.6.*

cmath.**polar**(*x*)

Convert a complex from rectangular coordinates to polar coordinates. The function returns a tuple with the two elements *r* and *phi*. *r* is the distance from 0 and *phi* the phase angle.

*New in version 2.6.*

cmath.**rect**(*r*, *phi*)

Convert from polar coordinates to rectangular coordinates and return a complex.

*New in version 2.6.*
cmath functions

cmath.\texttt{acos}(x)

Return the arc cosine of \(x\). There are two branch cuts: One extends right from 1 along the real axis to \(\infty\), continuous from below. The other extends left from -1 along the real axis to -\(\infty\), continuous from above.

cmath.\texttt{acosh}(x)

Return the hyperbolic arc cosine of \(x\). There is one branch cut, extending left from 1 along the real axis to -\(\infty\), continuous from above.

cmath.\texttt{asin}(x)

Return the arc sine of \(x\). This has the same branch cuts as \texttt{acos()}.

cmath.\texttt{asinh}(x)

Return the hyperbolic arc sine of \(x\). There are two branch cuts: One extends from \(1j\) along the imaginary axis to \(\infty j\), continuous from the right. The other extends from \(-1j\) along the imaginary axis to \(-\infty j\), continuous from the left.

\textit{Changed in version 2.6:} branch cuts moved to match those recommended by the C99 standard

cmath.\texttt{atan}(x)

Return the arc tangent of \(x\). There are two branch cuts: One extends from \(1j\) along the imaginary axis to \(\infty j\), continuous from the right. The other extends from \(-1j\) along the imaginary axis to \(-\infty j\), continuous from the left.

\textit{Changed in version 2.6:} direction of continuity of upper cut
cmath.\texttt{atanh}(x)
Return the hyperbolic arc tangent of \(x\). There are two branch cuts: One extends from \(1\) along the real axis to \(\infty\), continuous from below. The other extends from \(-1\) along the real axis to \(-\infty\), continuous from above.

\textit{Changed in version 2.6}: direction of continuity of right cut reversed

cmath.\texttt{cos}(x)
Return the cosine of \(x\).

cmath.\texttt{cosh}(x)
Return the hyperbolic cosine of \(x\).

cmath.\texttt{exp}(x)
Return the exponential value \(e^{**x}\).

cmath.\texttt{isinf}(x)
Return \texttt{True} if the real or the imaginary part of \(x\) is positive or negative infinity.

\textit{New in version 2.6.}

cmath.\texttt{isnan}(x)
Return \texttt{True} if the real or imaginary part of \(x\) is not a number (NaN).

\textit{New in version 2.6.}

cmath.\texttt{log}(x[, \texttt{base}])
Returns the logarithm of \(x\) to the given \texttt{base}. If the \texttt{base} is not specified, returns the natural logarithm of \(x\). There is one branch
cut, from 0 along the negative real axis to -∞, continuous from above.

*Changed in version 2.4: base argument added.*

cmath.\texttt{log10}(x)

Return the base-10 logarithm of \( x \). This has the same branch cut as \texttt{log()}.

cmath.\texttt{sin}(x)

Return the sine of \( x \).

cmath.\texttt{sinh}(x)

Return the hyperbolic sine of \( x \).

cmath.\texttt{sqrt}(x)

Return the square root of \( x \). This has the same branch cut as \texttt{log()}.

cmath.\texttt{tan}(x)

Return the tangent of \( x \).

cmath.\texttt{tanh}(x)

Return the hyperbolic tangent of \( x \).

The module also defines two mathematical constants:

cmath.\texttt{pi}

The mathematical constant \( \pi \), as a float.

cmath.\texttt{e}

The mathematical constant \( e \), as a float.

Note that the selection of functions is similar, but not identical, to that in module \texttt{math}. The reason for having two modules is that some users aren’t interested in complex numbers, and perhaps don’t even
know what they are. They would rather have \texttt{math.sqrt(-1)} raise an exception than return a complex number. Also note that the functions defined in \texttt{cmath} always return a complex number, even if the answer can be expressed as a real number (in which case the complex number has an imaginary part of zero).

A note on branch cuts: They are curves along which the given function fails to be continuous. They are a necessary feature of many complex functions. It is assumed that if you need to compute with complex functions, you will understand about branch cuts. Consult almost any (not too elementary) book on complex variables for enlightenment. For information of the proper choice of branch cuts for numerical purposes, a good reference should be the following:

\begin{quote}
\end{quote}
Decimal fixed point and floating point arithmetic

New in version 2.4.

The `decimal` module provides support for decimal floating point arithmetic. It offers several advantages over the `float` datatype:

- Decimal “is based on a floating-point model which was designed with people in mind, and necessarily has a paramount guiding principle – computers must provide an arithmetic that works in the same way as the arithmetic that people learn at school.” – excerpt from the decimal arithmetic specification.

- Decimal numbers can be represented exactly. In contrast, numbers like 1.1 do not have an exact representation in binary floating point. End users typically would not expect 1.1 to display as `1.1000000000000001` as it does with binary floating point.

- The exactness carries over into arithmetic. In decimal floating point, `0.1 + 0.1 + 0.1 - 0.3` is exactly equal to zero. In binary floating point, the result is `5.5511151231257827e-017`. While near to zero, the differences prevent reliable equality testing and differences can accumulate. For this reason, decimal is preferred in accounting applications which have strict equality invariants.

- The decimal module incorporates a notion of significant places so that `1.30 + 1.20` is `2.50`. The trailing zero is kept to indicate significance. This is the customary presentation for monetary applications. For multiplication, the “schoolbook” approach uses all the figures in the multiplicands. For instance, `1.3 * 1.2` gives
1.56 while 1.30 * 1.20 gives 1.5600.

- Unlike hardware based binary floating point, the decimal module has a user alterable precision (defaulting to 28 places) which can be as large as needed for a given problem:

```python
>>> getcontext().prec = 6
>>> Decimal(1) / Decimal(7)
Decimal('0.142857')
>>> getcontext().prec = 28
>>> Decimal(1) / Decimal(7)
Decimal('0.1428571428571428571428571429')
```

- Both binary and decimal floating point are implemented in terms of published standards. While the built-in float type exposes only a modest portion of its capabilities, the decimal module exposes all required parts of the standard. When needed, the programmer has full control over rounding and signal handling. This includes an option to enforce exact arithmetic by using exceptions to block any inexact operations.

- The decimal module was designed to support “without prejudice, both exact unrounded decimal arithmetic (sometimes called fixed-point arithmetic) and rounded floating-point arithmetic.” – excerpt from the decimal arithmetic specification.

The module design is centered around three concepts: the decimal number, the context for arithmetic, and signals.

A decimal number is immutable. It has a sign, coefficient digits, and an exponent. To preserve significance, the coefficient digits do not truncate trailing zeros. Decimals also include special values such as Infinity, -Infinity, and NaN. The standard also differentiates -0 from +0.
The context for arithmetic is an environment specifying precision, rounding rules, limits on exponents, flags indicating the results of operations, and trap enablers which determine whether signals are treated as exceptions. Rounding options include `ROUND_CEILING`, `ROUND_DOWN`, `ROUND_FLOOR`, `ROUND_HALF_DOWN`, `ROUND_HALF_EVEN`, `ROUND_HALF_UP`, `ROUND_UP`, and `ROUND_05UP`.

Signals are groups of exceptional conditions arising during the course of computation. Depending on the needs of the application, signals may be ignored, considered as informational, or treated as exceptions. The signals in the decimal module are: `Clamped`, `InvalidOperation`, `DivisionByZero`, `Inexact`, `Rounded`, `Subnormal`, `Overflow`, and `Underflow`.

For each signal there is a flag and a trap enabler. When a signal is encountered, its flag is set to one, then, if the trap enabler is set to one, an exception is raised. Flags are sticky, so the user needs to reset them before monitoring a calculation.

See also:

Quick-start Tutorial

The usual start to using decimals is importing the module, viewing the current context with `getcontext()` and, if necessary, setting new values for precision, rounding, or enabled traps:

```python
>>> from decimal import *
>>> getcontext()
Context(prec=28, rounding=ROUND_HALF_EVEN, Emin=-999999999, Emax=999999999, capitals=1, flags=[], traps=[Overflow, DivisionByZero, InvalidOperation])
>>> getcontext().prec = 7    # Set a new precision
```

Decimal instances can be constructed from integers, strings, or tuples. To create a Decimal from a `float`, first convert it to a string. This serves as an explicit reminder of the details of the conversion (including representation error). Decimal numbers include special values such as `NaN` which stands for “Not a number”, positive and negative `Infinity`, and `-0`.

```python
>>> getcontext().prec = 28
>>> Decimal('10')
Decimal('10')
>>> Decimal('3.14')
Decimal('3.14')
>>> Decimal((0, (3, 1, 4), -2))
Decimal('3.14')
>>> Decimal(str(2.0 ** 0.5))
Decimal('1.41421356237')
>>> Decimal(2) ** Decimal('0.5')
Decimal('1.414213562373095048801688724')
>>> Decimal('NaN')
Decimal('NaN')
>>> Decimal('-Infinity')
Decimal('-Infinity')
```

The significance of a new Decimal is determined solely by the number of digits input. Context precision and rounding only come
into play during arithmetic operations.

```python
>>> getcontext().prec = 6
>>> Decimal('3.0')
Decimal('3.0')
>>> Decimal('3.1415926535')
Decimal('3.1415926535')
>>> Decimal('3.1415926535') + Decimal('2.7182818285')
Decimal('5.85987')
>>> getcontext().rounding = ROUND_UP
>>> Decimal('3.1415926535') + Decimal('2.7182818285')
Decimal('5.85988')
```

Decimals interact well with much of the rest of Python. Here is a small decimal floating point flying circus:

```python
>>> data = map(Decimal, '1.34 1.87 3.45 2.35 1.00 0.03 9.25'.split)
>>> max(data)
Decimal('9.25')
>>> min(data)
Decimal('0.03')
>>> sorted(data)
[Decimal('0.03'), Decimal('1.00'), Decimal('1.34'), Decimal('1.35'), Decimal('2.35'), Decimal('3.45'), Decimal('9.25')]
>>> sum(data)
Decimal('19.29')
>>> a, b, c = data[:3]
>>> str(a)
'1.34'
>>> float(a)
1.3400000000000001
>>> round(a, 1)  # round() first converts to binary floating point
1.3
>>> int(a)
1
>>> a * 5
Decimal('6.70')
>>> a * b
Decimal('2.5058')
>>> c % a
Decimal('0.77')
```

And some mathematical functions are also available to Decimal:

```python
>>> getcontext().prec = 28
```
The `quantize()` method rounds a number to a fixed exponent. This method is useful for monetary applications that often round results to a fixed number of places:

```python
>>> Decimal('7.325').quantize(Decimal('.01'), rounding=ROUND_DOWN)
Decimal('7.32')
>>> Decimal('7.325').quantize(Decimal('1.'), rounding=ROUND_UP)
Decimal('8')
```

As shown above, the `getcontext()` function accesses the current context and allows the settings to be changed. This approach meets the needs of most applications.

For more advanced work, it may be useful to create alternate contexts using the `Context()` constructor. To make an alternate active, use the `setcontext()` function.

In accordance with the standard, the `Decimal` module provides two ready to use standard contexts, `BasicContext` and `ExtendedContext`. The former is especially useful for debugging because many of the traps are enabled:

```python
>>> myothercontext = Context(prec=60, rounding=ROUND_HALF_DOWN)
>>> setcontext(myothercontext)
>>> Decimal(1) / Decimal(7)
Decimal('0.142857142857142857142857142857142857142857142857142857142857')
>>> ExtendedContext
Context(prec=9, rounding=ROUND_HALF_EVEN, Emin=-999999999, Emax=999999999, capitals=1, flags=[], traps=[])
>>> setcontext(ExtendedContext)
```
Contexts also have signal flags for monitoring exceptional conditions encountered during computations. The flags remain set until explicitly cleared, so it is best to clear the flags before each set of monitored computations by using the `clear_flags()` method.

The flags entry shows that the rational approximation to \( \pi \) was rounded (digits beyond the context precision were thrown away) and that the result is inexact (some of the discarded digits were non-zero).

Individual traps are set using the dictionary in the traps field of a context:
Most programs adjust the current context only once, at the beginning of the program. And, in many applications, data is converted to **Decimal** with a single cast inside a loop. With context set and decimals created, the bulk of the program manipulates the data no differently than with other Python numeric types.
Decimal objects

class decimal.**Decimal**([*value*, *context]*)

Construct a new **Decimal** object based from *value*.

*value* can be an integer, string, tuple, or another **Decimal** object. If no *value* is given, returns **Decimal('0')**. If *value* is a string, it should conform to the decimal numeric string syntax after leading and trailing whitespace characters are removed:

```plaintext
sign ::= '+' | '-'
digit ::= '0' | '1' | '2' | '3' | '4' | '5' | '6'
indicator ::= 'e' | 'E'
digits ::= digit [digit]...
decimal-part ::= digits '.' [digits] | ['.'] digits
exponent-part ::= indicator [sign] digits
infinity ::= 'Infinity' | 'Inf'
nan ::= 'NaN' [digits] | 'sNaN' [digits]
numeric-value ::= decimal-part [exponent-part] | infinity
numeric-string ::= [sign] numeric-value | [sign] nan
```

If *value* is a **tuple**, it should have three components, a sign (0 for positive or 1 for negative), a **tuple** of digits, and an integer exponent. For example, **Decimal((0, (1, 4, 1, 4), -3))** returns **Decimal('1.414')**.

The *context* precision does not affect how many digits are stored. That is determined exclusively by the number of digits in *value*. For example, **Decimal('3.00000')** records all five zeros even if the context precision is only three.

The purpose of the *context* argument is determining what to do if
value is a malformed string. If the context traps \texttt{InvalidOperation}, an exception is raised; otherwise, the constructor returns a new \texttt{Decimal} with the value of \texttt{NaN}.

Once constructed, \texttt{Decimal} objects are immutable.

\textit{Changed in version 2.6}: leading and trailing whitespace characters are permitted when creating a \texttt{Decimal} instance from a string.

Decimal floating point objects share many properties with the other built-in numeric types such as \texttt{float} and \texttt{int}. All of the usual math operations and special methods apply. Likewise, decimal objects can be copied, pickled, printed, used as dictionary keys, used as set elements, compared, sorted, and coerced to another type (such as \texttt{float} or \texttt{long}).

In addition to the standard numeric properties, decimal floating point objects also have a number of specialized methods:

\begin{description}
  \item[\texttt{adjusted()}] Return the adjusted exponent after shifting out the coefficient’s rightmost digits until only the lead digit remains: \texttt{Decimal('321e+5').adjusted()} returns seven. Used for determining the position of the most significant digit with respect to the decimal point.
  \item[\texttt{as\_tuple()}] Return a \textit{named tuple} representation of the number: \texttt{DecimalTuple(sign, digits, exponent)}.
  \textit{Changed in version 2.6}: Use a named tuple.
  \item[\texttt{canonical()}] Return the canonical encoding of the argument. Currently, the
encoding of a `Decimal` instance is always canonical, so this operation returns its argument unchanged.

*New in version 2.6.*

**`compare(other[, context])`**

Compare the values of two Decimal instances. This operation behaves in the same way as the usual comparison method `__cmp__()`, except that `compare()` returns a Decimal instance rather than an integer, and if either operand is a NaN then the result is a NaN:

- `a or b is a NaN` ➞ `Decimal('NaN')`
- `a < b` ➞ `Decimal('-1')`
- `a == b` ➞ `Decimal('0')`
- `a > b` ➞ `Decimal('1')`

**`compare_signal(other[, context])`**

This operation is identical to the `compare()` method, except that all NaNs signal. That is, if neither operand is a signaling NaN then any quiet NaN operand is treated as though it were a signaling NaN.

*New in version 2.6.*

**`compare_total(other)`**

Compare two operands using their abstract representation rather than their numerical value. Similar to the `compare()` method, but the result gives a total ordering on `Decimal` instances. Two `Decimal` instances with the same numeric value but different representations compare unequal in this ordering:

```python
>>> Decimal('12.0').compare_total(Decimal('12'))
```
Quiet and signaling NaNs are also included in the total ordering. The result of this function is $\text{Decimal}'0'\text{'}$ if both operands have the same representation, $\text{Decimal}'-1'\text{'}$ if the first operand is lower in the total order than the second, and $\text{Decimal}'1'\text{'}$ if the first operand is higher in the total order than the second operand. See the specification for details of the total order.

*New in version 2.6.*

**compare_total_mag**(other)

Compare two operands using their abstract representation rather than their value as in `compare_total()`, but ignoring the sign of each operand. $x.\text{compare_total_mag}(y)$ is equivalent to $x.\text{copy_abs()}.\text{compare_total}(y.\text{copy_abs()})$.

*New in version 2.6.*

**conjugate()**

Just returns self, this method is only to comply with the Decimal Specification.

*New in version 2.6.*

**copy_abs()**

Return the absolute value of the argument. This operation is unaffected by the context and is quiet: no flags are changed and no rounding is performed.

*New in version 2.6.*

**copy_negate()**

Return the negation of the argument. This operation is
unaffected by the context and is quiet: no flags are changed and no rounding is performed.

*New in version 2.6.*

**copy_sign**(other)

Return a copy of the first operand with the sign set to be the same as the sign of the second operand. For example:

```python
>>> Decimal('2.3').copy_sign(Decimal('-1.5'))
Decimal('-2.3')
```

This operation is unaffected by the context and is quiet: no flags are changed and no rounding is performed.

*New in version 2.6.*

**exp**(context)

Return the value of the (natural) exponential function \( e^{**x} \) at the given number. The result is correctly rounded using the `ROUND_HALF_EVEN` rounding mode.

```python
>>> Decimal(1).exp()
Decimal('2.718281828459045235360287471')
>>> Decimal(321).exp()
Decimal('2.561702493119680037517373933E+139')
```

*New in version 2.6.*

**fma**(other, third[, context])

Fused multiply-add. Return self*other+third with no rounding of the intermediate product self*other.

```python
>>> Decimal(2).fma(3, 5)
```

```python
Decimal('11')
```
Decimal('11')

New in version 2.6.

is_canonical()
Return True if the argument is canonical and False otherwise. Currently, a Decimal instance is always canonical, so this operation always returns True.

New in version 2.6.

is_finite()
Return True if the argument is a finite number, and False if the argument is an infinity or a NaN.

New in version 2.6.

is_infinite()
Return True if the argument is either positive or negative infinity and False otherwise.

New in version 2.6.

is_nan()
Return True if the argument is a (quiet or signaling) NaN and False otherwise.

New in version 2.6.

is_normal()
Return True if the argument is a normal finite number. Return False if the argument is zero, subnormal, infinite or a NaN.

New in version 2.6.
is_qnan()
Return True if the argument is a quiet NaN, and False otherwise.

*New in version 2.6.*

is_signed()
Return True if the argument has a negative sign and False otherwise. Note that zeros and NaNs can both carry signs.

*New in version 2.6.*

is_snan()
Return True if the argument is a signaling NaN and False otherwise.

*New in version 2.6.*

is_subnormal()
Return True if the argument is subnormal, and False otherwise.

*New in version 2.6.*

is_zero()
Return True if the argument is a (positive or negative) zero and False otherwise.

*New in version 2.6.*

\ln([context])
Return the natural (base e) logarithm of the operand. The result is correctly rounded using the **ROUND_HALF_EVEN** rounding mode.
New in version 2.6.

\texttt{log10([\texttt{context}])}

Return the base ten logarithm of the operand. The result is correctly rounded using the \texttt{ROUND\_HALF\_EVEN} rounding mode.

New in version 2.6.

\texttt{logb([\texttt{context}])}

For a nonzero number, return the adjusted exponent of its operand as a \texttt{Decimal} instance. If the operand is a zero then \texttt{Decimal('\texttt{-}\texttt{Infinity}'\texttt{)}} is returned and the \texttt{DivisionByZero} flag is raised. If the operand is an infinity then \texttt{Decimal('\texttt{Infinity}'\texttt{)}} is returned.

New in version 2.6.

\texttt{logical\_and\(\texttt{other[, context]}\))}

\texttt{logical\_and()} is a logical operation which takes two \texttt{logical operands} (see \texttt{Logical operands}). The result is the digit-wise and of the two operands.

New in version 2.6.

\texttt{logical\_invert\(\texttt{other[, context]}\))}

\texttt{logical\_invert()} is a logical operation. The argument must be a \texttt{logical operand} (see \texttt{Logical operands}). The result is the digit-wise inversion of the operand.

New in version 2.6.

\texttt{logical\_or\(\texttt{other[, context]}\))}

\texttt{logical\_or()} is a logical operation which takes two \texttt{logical operands} (see \texttt{Logical operands}). The result is the digit-wise or of the two operands.
operands (see Logical operands). The result is the digit-wise or of the two operands.

*New in version 2.6.*

`logical_xor(other[, context])`

`logical_xor()` is a logical operation which takes two logical operands (see Logical operands). The result is the digit-wise exclusive or of the two operands.

*New in version 2.6.*

`max(other[, context])`

Like `max(self, other)` except that the context rounding rule is applied before returning and that NaN values are either signaled or ignored (depending on the context and whether they are signaling or quiet).

*New in version 2.6.*

`max_mag(other[, context])`

Similar to the `max()` method, but the comparison is done using the absolute values of the operands.

*New in version 2.6.*

`min(other[, context])`

Like `min(self, other)` except that the context rounding rule is applied before returning and that NaN values are either signaled or ignored (depending on the context and whether they are signaling or quiet).

`min_mag(other[, context])`

Similar to the `min()` method, but the comparison is done using the absolute values of the operands.
New in version 2.6.

next_minus([context])
Return the largest number representable in the given context (or in the current thread’s context if no context is given) that is smaller than the given operand.

New in version 2.6.

next_plus([context])
Return the smallest number representable in the given context (or in the current thread’s context if no context is given) that is larger than the given operand.

New in version 2.6.

next_toward(other[, context])
If the two operands are unequal, return the number closest to the first operand in the direction of the second operand. If both operands are numerically equal, return a copy of the first operand with the sign set to be the same as the sign of the second operand.

New in version 2.6.

normalize([context])
Normalize the number by stripping the rightmost trailing zeros and converting any result equal to Decimal('0') to Decimal('0e0'). Used for producing canonical values for members of an equivalence class. For example, Decimal('32.100') and Decimal('0.321000e+2') both normalize to the equivalent value Decimal('32.1').

number_class([context])
Return a string describing the class of the operand. The returned value is one of the following ten strings.

- **"-Infinity"**, indicating that the operand is negative infinity.
- **"-Normal"**, indicating that the operand is a negative normal number.
- **"-Subnormal"**, indicating that the operand is negative and subnormal.
- **"-Zero"**, indicating that the operand is a negative zero.
- **"+Zero"**, indicating that the operand is a positive zero.
- **"+Subnormal"**, indicating that the operand is positive and subnormal.
- **"+Normal"**, indicating that the operand is a positive normal number.
- **"+Infinity"**, indicating that the operand is positive infinity.
- **"NaN"**, indicating that the operand is a quiet NaN (Not a Number).
- **"sNaN"**, indicating that the operand is a signaling NaN.

*New in version 2.6.*

quantize\((\text{exp}[,\ \text{rounding}[,\ \text{context}[,\ \text{watchexp}]]])\)

Return a value equal to the first operand after rounding and having the exponent of the second operand.

```python
>>> Decimal('1.41421356').quantize(Decimal('1.000'))
Decimal('1.414')
```

Unlike other operations, if the length of the coefficient after the quantize operation would be greater than precision, then an **InvalidOperation** is signaled. This guarantees that, unless there is an error condition, the quantized exponent is always
equal to that of the right-hand operand.

Also unlike other operations, quantize never signals Underflow, even if the result is subnormal and inexact.

If the exponent of the second operand is larger than that of the first then rounding may be necessary. In this case, the rounding mode is determined by the rounding argument if given, else by the given context argument; if neither argument is given the rounding mode of the current thread’s context is used.

If watchexp is set (default), then an error is returned whenever the resulting exponent is greater than $E_{\text{max}}$ or less than $E_{\text{tiny}}$.

**radix()**

Return `Decimal(10)`, the radix (base) in which the `Decimal` class does all its arithmetic. Included for compatibility with the specification.

*New in version 2.6.*

**remainder_near(other[, context])**

Compute the modulo as either a positive or negative value depending on which is closest to zero. For instance, `Decimal(10).remainder_near(6)` returns `Decimal('-2')` which is closer to zero than `Decimal('4')`.

If both are equally close, the one chosen will have the same sign as `self`.

**rotate(other[, context])**

Return the result of rotating the digits of the first operand by an amount specified by the second operand. The second
operand must be an integer in the range -precision through precision. The absolute value of the second operand gives the number of places to rotate. If the second operand is positive then rotation is to the left; otherwise rotation is to the right. The coefficient of the first operand is padded on the left with zeros to length precision if necessary. The sign and exponent of the first operand are unchanged.

*New in version 2.6.*

**same_quantum**(other[, context])
Test whether self and other have the same exponent or whether both are NaN.

**scaleb**(other[, context])
Return the first operand with exponent adjusted by the second. Equivalently, return the first operand multiplied by \(10^{\text{other}}\). The second operand must be an integer.

*New in version 2.6.*

**shift**(other[, context])
Return the result of shifting the digits of the first operand by an amount specified by the second operand. The second operand must be an integer in the range -precision through precision. The absolute value of the second operand gives the number of places to shift. If the second operand is positive then the shift is to the left; otherwise the shift is to the right. Digits shifted into the coefficient are zeros. The sign and exponent of the first operand are unchanged.

*New in version 2.6.*

**sqrt**(context)

Return the square root of the argument to full precision.

**to_eng_string**([context])
Convert to an engineering-type string.

Engineering notation has an exponent which is a multiple of 3, so there are up to 3 digits left of the decimal place. For example, converts `Decimal('123E+1')` to `Decimal('1.23E+3')`.

**to_integral**([rounding[, context]])
Identical to the **to_integral_value**() method. The `to_integral` name has been kept for compatibility with older versions.

**to_integral_exact**([rounding[, context]])
Round to the nearest integer, signaling **Inexact** or **Rounded** as appropriate if rounding occurs. The rounding mode is determined by the **rounding** parameter if given, else by the given **context**. If neither parameter is given then the rounding mode of the current context is used.

*New in version 2.6.*

**to_integral_value**([rounding[, context]])
Round to the nearest integer without signaling **Inexact** or **Rounded**. If given, applies **rounding**; otherwise, uses the rounding method in either the supplied **context** or the current context.

*Changed in version 2.6:* renamed from `to_integral` to `to_integral_value`. The old name remains valid for compatibility.
**Logical operands**

The `logical_and()`, `logical_invert()`, `logical_or()`, and `logical_xor()` methods expect their arguments to be *logical operands*. A *logical operand* is a `Decimal` instance whose exponent and sign are both zero, and whose digits are all either 0 or 1.
Context objects

Contexts are environments for arithmetic operations. They govern precision, set rules for rounding, determine which signals are treated as exceptions, and limit the range for exponents.

Each thread has its own current context which is accessed or changed using the `getcontext()` and `setcontext()` functions:

```python
decimal.getcontext()
Return the current context for the active thread.
```

```python
decimal.setcontext(c)
Set the current context for the active thread to c.
```

Beginning with Python 2.5, you can also use the `with` statement and the `localcontext()` function to temporarily change the active context.

```python
decimal.localcontext([c])
Return a context manager that will set the current context for the active thread to a copy of c on entry to the with-statement and restore the previous context when exiting the with-statement. If no context is specified, a copy of the current context is used.
```

*New in version 2.5.*

For example, the following code sets the current decimal precision to 42 places, performs a calculation, and then automatically restores the previous context:

```python
from decimal import localcontext

with localcontext() as ctx:
```
ctx.prec = 42  # Perform a high precision calculation
s = calculate_something()

# Round the final result back to the default precision

New contexts can also be created using the `Context` constructor described below. In addition, the module provides three pre-made contexts:

class decimal.BasicContext
This is a standard context defined by the General Decimal Arithmetic Specification. Precision is set to nine. Rounding is set to `ROUND_HALF_UP`. All flags are cleared. All traps are enabled (treated as exceptions) except `Inexact`, `Rounded`, and `Subnormal`.

Because many of the traps are enabled, this context is useful for debugging.

class decimal.ExtendedContext
This is a standard context defined by the General Decimal Arithmetic Specification. Precision is set to nine. Rounding is set to `ROUND_HALF_EVEN`. All flags are cleared. No traps are enabled (so that exceptions are not raised during computations).

Because the traps are disabled, this context is useful for applications that prefer to have result value of `NaN` or `Infinity` instead of raising exceptions. This allows an application to complete a run in the presence of conditions that would otherwise halt the program.

class decimal.DefaultContext
This context is used by the `Context` constructor as a prototype for new contexts. Changing a field (such a precision) has the effect of changing the default for new contexts creating by the `Context` constructor.
This context is most useful in multi-threaded environments. Changing one of the fields before threads are started has the effect of setting system-wide defaults. Changing the fields after threads have started is not recommended as it would require thread synchronization to prevent race conditions.

In single threaded environments, it is preferable to not use this context at all. Instead, simply create contexts explicitly as described below.

The default values are precision=28, rounding=ROUND_HALF_EVEN, and enabled traps for Overflow, InvalidOperation, and DivisionByZero.

In addition to the three supplied contexts, new contexts can be created with the `Context` constructor.

```python
class decimal. Context (prec=None, rounding=None, traps=None, flags=None, Emin=None, Emax=None, capitals=1)
```

Creates a new context. If a field is not specified or is `None`, the default values are copied from the `DefaultContext`. If the `flags` field is not specified or is `None`, all flags are cleared.

The `prec` field is a positive integer that sets the precision for arithmetic operations in the context.

The `rounding` option is one of:

- `ROUND_CEILING` (towards Infinity),
- `ROUND_DOWN` (towards zero),
- `ROUND_FLOOR` (towards -Infinity),
- `ROUND_HALF_DOWN` (to nearest with ties going towards zero),
- `ROUND_HALF_EVEN` (to nearest with ties going to nearest even integer),
- **ROUND_HALF_UP** (to nearest with ties going away from zero), or
- **ROUND_UP** (away from zero).
- **ROUND_05UP** (away from zero if last digit after rounding towards zero would have been 0 or 5; otherwise towards zero)

The *traps* and *flags* fields list any signals to be set. Generally, new contexts should only set traps and leave the flags clear.

The *Emin* and *Emax* fields are integers specifying the outer limits allowable for exponents.

The *capitals* field is either 0 or 1 (the default). If set to 1, exponents are printed with a capital E; otherwise, a lowercase e is used: `Decimal('6.02e+23')`.

*Changed in version 2.6:* The **ROUND_05UP** rounding mode was added.

The Context class defines several general purpose methods as well as a large number of methods for doing arithmetic directly in a given context. In addition, for each of the Decimal methods described above (with the exception of the adjusted() and as_tuple() methods) there is a corresponding Context method. For example, `c.exp(x)` is equivalent to `x.exp(context=C)`.

**clear_flags()**

Resets all of the flags to 0.

**copy()**

Return a duplicate of the context.

**copy_decimal(num)**

Return a copy of the Decimal instance num.
**create_decimal(num)**

Creates a new Decimal instance from *num* but using *self* as context. Unlike the Decimal constructor, the context precision, rounding method, flags, and traps are applied to the conversion.

This is useful because constants are often given to a greater precision than is needed by the application. Another benefit is that rounding immediately eliminates unintended effects from digits beyond the current precision. In the following example, using unrounded inputs means that adding zero to a sum can change the result:

```python
>>> getcontext().prec = 3
>>> Decimal('3.4445') + Decimal('1.0023')
Decimal('4.45')
>>> Decimal('3.4445') + Decimal(0) + Decimal('1.0023')
Decimal('4.44')
```

This method implements the to-number operation of the IBM specification. If the argument is a string, no leading or trailing whitespace is permitted.

**Etiny()**

Returns a value equal to \( E_{\text{min}} - \text{prec} + 1 \) which is the minimum exponent value for subnormal results. When underflow occurs, the exponent is set to \( \text{Etiny} \).

**Etop()**

Returns a value equal to \( E_{\text{max}} - \text{prec} + 1 \).

The usual approach to working with decimals is to create Decimal instances and then apply arithmetic operations which take place within the current context for the active thread. An alternative approach is to use context methods for calculating within a
specific context. The methods are similar to those for the \texttt{Decimal} class and are only briefly recounted here.

\texttt{abs}(x)
  Returns the absolute value of \(x\).

\texttt{add}(x, y)
  Return the sum of \(x\) and \(y\).

\texttt{canonical}(x)
  Returns the same \texttt{Decimal} object \(x\).

\texttt{compare}(x, y)
  Compares \(x\) and \(y\) numerically.

\texttt{compare\_signal}(x, y)
  Compares the values of the two operands numerically.

\texttt{compare\_total}(x, y)
  Compares two operands using their abstract representation.

\texttt{compare\_total\_mag}(x, y)
  Compares two operands using their abstract representation, ignoring sign.

\texttt{copy\_abs}(x)
  Returns a copy of \(x\) with the sign set to 0.

\texttt{copy\_negate}(x)
  Returns a copy of \(x\) with the sign inverted.

\texttt{copy\_sign}(x, y)
  Copies the sign from \(y\) to \(x\).

\texttt{divide}(x, y)
  Return \(x\) divided by \(y\).
\texttt{divide\_int}(x, y) \\
Return \( x \) divided by \( y \), truncated to an integer.

\texttt{divmod}(x, y) \\
Divides two numbers and returns the integer part of the result.

\texttt{exp}(x) \\
Returns \( e \ ^\ x \).

\texttt{fma}(x, y, z) \\
Returns \( x \) multiplied by \( y \), plus \( z \).

\texttt{is\_canonical}(x) \\
Returns True if \( x \) is canonical; otherwise returns False.

\texttt{is\_finite}(x) \\
Returns True if \( x \) is finite; otherwise returns False.

\texttt{is\_infinite}(x) \\
Returns True if \( x \) is infinite; otherwise returns False.

\texttt{is\_nan}(x) \\
Returns True if \( x \) is a qNaN or sNaN; otherwise returns False.

\texttt{is\_normal}(x) \\
Returns True if \( x \) is a normal number; otherwise returns False.

\texttt{is\_qnan}(x) \\
Returns True if \( x \) is a quiet NaN; otherwise returns False.

\texttt{is\_signed}(x) \\
Returns True if \( x \) is negative; otherwise returns False.

\texttt{is\_snan}(x) \\
Returns True if \( x \) is a signaling NaN; otherwise returns False.

\texttt{is\_subnormal}(x)
Returns True if x is subnormal; otherwise returns False.

\( \text{is\_zero}(x) \)
Returns True if x is a zero; otherwise returns False.

\( \ln(x) \)
Returns the natural (base e) logarithm of x.

\( \log_{10}(x) \)
Returns the base 10 logarithm of x.

\( \logb(x) \)
Returns the exponent of the magnitude of the operand's MSD.

\( \text{logical\_and}(x, y) \)
Applies the logical operation and between each operand's digits.

\( \text{logical\_invert}(x) \)
Invert all the digits in x.

\( \text{logical\_or}(x, y) \)
Applies the logical operation or between each operand's digits.

\( \text{logical\_xor}(x, y) \)
Applies the logical operation xor between each operand's digits.

\( \max(x, y) \)
Compares two values numerically and returns the maximum.

\( \max\_\text{mag}(x, y) \)
Compares the values numerically with their sign ignored.

\( \min(x, y) \)
Compares two values numerically and returns the minimum.
\textbf{min\_mag}(x, y)

Compares the values numerically with their sign ignored.

\textbf{minus}(x)

Minus corresponds to the unary prefix minus operator in Python.

\textbf{multiply}(x, y)

Return the product of \( x \) and \( y \).

\textbf{next\_minus}(x)

Returns the largest representable number smaller than \( x \).

\textbf{next\_plus}(x)

Returns the smallest representable number larger than \( x \).

\textbf{next\_toward}(x, y)

Returns the number closest to \( x \), in direction towards \( y \).

\textbf{normalize}(x)

Reduces \( x \) to its simplest form.

\textbf{number\_class}(x)

Returns an indication of the class of \( x \).

\textbf{plus}(x)

Plus corresponds to the unary prefix plus operator in Python. This operation applies the context precision and rounding, so it is \textit{not} an identity operation.

\textbf{power}(x, y, [modulo])

Return \( x \) to the power of \( y \), reduced modulo modulo if given.

With two arguments, compute \( x^{\ast y} \). If \( x \) is negative then \( y \) must be integral. The result will be inexact unless \( y \) is integral and the result is finite and can be expressed exactly in
'precision' digits. The result should always be correctly rounded, using the rounding mode of the current thread's context.

With three arguments, compute \((x**y) \mod \text{modulo}\). For the three argument form, the following restrictions on the arguments hold:

- all three arguments must be integral
- \(y\) must be nonnegative
- at least one of \(x\) or \(y\) must be nonzero
- \(\text{modulo}\) must be nonzero and have at most 'precision' digits

The result of \(\text{Context.power}(x, y, \text{modulo})\) is identical to the result that would be obtained by computing \((x**y) \mod \text{modulo}\) with unbounded precision, but is computed more efficiently. It is always exact.

*Changed in version 2.6:* \(y\) may now be nonintegral in \(x**y\). Stricter requirements for the three-argument version.

**quantize\((x, y)\)**

Returns a value equal to \(x\) (rounded), having the exponent of \(y\).

**radix()**

Just returns 10, as this is Decimal, :)

**remainder\((x, y)\)**

Returns the remainder from integer division.

The sign of the result, if non-zero, is the same as that of the original dividend.
**remainder_near**(\(x, y\))
Returns \(x - y * n\), where \(n\) is the integer nearest the exact value of \(x / y\) (if the result is 0 then its sign will be the sign of \(x\)).

**rotate**(\(x, y\))
Returns a rotated copy of \(x, y\) times.

**same_quantum**(\(x, y\))
Returns True if the two operands have the same exponent.

**scaleb**(\(x, y\))
Returns the first operand after adding the second value its exp.

**shift**(\(x, y\))
Returns a shifted copy of \(x, y\) times.

**sqrt**(\(x\))
Square root of a non-negative number to context precision.

**subtract**(\(x, y\))
Return the difference between \(x\) and \(y\).

**to_eng_string**(\(x\))
Converts a number to a string, using scientific notation.

**to_integral_exact**(\(x\))
Rounds to an integer.

**to_sci_string**(\(x\))
Converts a number to a string using scientific notation.
Signals

Signals represent conditions that arise during computation. Each corresponds to one context flag and one context trap enabler.

The context flag is set whenever the condition is encountered. After the computation, flags may be checked for informational purposes (for instance, to determine whether a computation was exact). After checking the flags, be sure to clear all flags before starting the next computation.

If the context’s trap enabler is set for the signal, then the condition causes a Python exception to be raised. For example, if the DivisionByZero trap is set, then a DivisionByZero exception is raised upon encountering the condition.

class decimal.Clamped

    Altered an exponent to fit representation constraints.

    Typically, clamping occurs when an exponent falls outside the context’s Emin and Emax limits. If possible, the exponent is reduced to fit by adding zeros to the coefficient.

class decimal.DecimalException

    Base class for other signals and a subclass of ArithmeticError.

class decimal.DivisionByZero

    Signals the division of a non-infinite number by zero.

    Can occur with division, modulo division, or when raising a number to a negative power. If this signal is not trapped, returns Infinity or -Infinity with the sign determined by the inputs to the calculation.
class decimal. **Inexact**
Indicates that rounding occurred and the result is not exact.

Signals when non-zero digits were discarded during rounding. The rounded result is returned. The signal flag or trap is used to detect when results are inexact.

class decimal. **InvalidOperation**
An invalid operation was performed.

Indicates that an operation was requested that does not make sense. If not trapped, returns NaN. Possible causes include:

<table>
<thead>
<tr>
<th>Expression</th>
</tr>
</thead>
<tbody>
<tr>
<td>Infinity - Infinity</td>
</tr>
<tr>
<td>0 * Infinity</td>
</tr>
<tr>
<td>Infinity / Infinity</td>
</tr>
<tr>
<td>x % 0</td>
</tr>
<tr>
<td>Infinity % x</td>
</tr>
<tr>
<td>x._rescale( non-integer )</td>
</tr>
<tr>
<td>sqrt(-x) and x &gt; 0</td>
</tr>
<tr>
<td>0 ** 0</td>
</tr>
<tr>
<td>x ** (non-integer)</td>
</tr>
<tr>
<td>x ** Infinity</td>
</tr>
</tbody>
</table>

class decimal. **Overflow**
Numerical overflow.

Indicates the exponent is larger than $E_{\text{max}}$ after rounding has occurred. If not trapped, the result depends on the rounding mode, either pulling inward to the largest representable finite number or rounding outward to Infinity. In either case, Inexact and Rounded are also signaled.

class decimal. **Rounded**
Rounding occurred though possibly no information was lost.
Signaled whenever rounding discards digits; even if those digits are zero (such as rounding 5.00 to 5.0). If not trapped, returns the result unchanged. This signal is used to detect loss of significant digits.

class decimal. **Subnormal**

Exponent was lower than $E_{\text{min}}$ prior to rounding.

Occurs when an operation result is subnormal (the exponent is too small). If not trapped, returns the result unchanged.

class decimal. **Underflow**

Numerical underflow with result rounded to zero.

Occurs when a subnormal result is pushed to zero by rounding. **Inexact** and **Subnormal** are also signaled.

The following table summarizes the hierarchy of signals:

```python
exceptions.ArithmeticError(exceptions.StandardError)
    DecimalException
        Clamped
        DivisionByZero(DecimalException, exceptions.ZeroDivisionError)
    Inexact
        Overflow(Inexact, Rounded)
        Underflow(Inexact, Rounded, Subnormal)
    InvalidOperation
    Rounded
    Rounded
    Subnormal
```
Floating Point Notes

Mitigating round-off error with increased precision

The use of decimal floating point eliminates decimal representation error (making it possible to represent 0.1 exactly); however, some operations can still incur round-off error when non-zero digits exceed the fixed precision.

The effects of round-off error can be amplified by the addition or subtraction of nearly offsetting quantities resulting in loss of significance. Knuth provides two instructive examples where rounded floating point arithmetic with insufficient precision causes the breakdown of the associative and distributive properties of addition:

```python
# Examples from Seminumerical Algorithms, Section 4.2.2.
>>> from decimal import Decimal, getcontext
>>> getcontext().prec = 8

>>> u, v, w = Decimal(11111113), Decimal(-11111111), Decimal('7.51111111')
>>> (u + v) + w
Decimal('9.5111111')
>>> u + (v + w)
Decimal('10')

>>> u, v, w = Decimal(20000), Decimal(-6), Decimal('6.0000003')
>>> (u*v) + (u*w)
Decimal('0.01')
>>> u * (v+w)
Decimal('0.0060000')
```

The `decimal` module makes it possible to restore the identities by expanding the precision sufficiently to avoid loss of significance:

```python
>>> getcontext().prec = 20
>>> u, v, w = Decimal(11111113), Decimal(-11111111), Decimal('7
```
Special values

The number system for the `decimal` module provides special values including `NaN`, `sNaN`, `-Infinity`, `Infinity`, and two zeros, `+0` and `-0`.

Infinities can be constructed directly with: `Decimal('Infinity')`. Also, they can arise from dividing by zero when the `DivisionByZero` signal is not trapped. Likewise, when the `Overflow` signal is not trapped, infinity can result from rounding beyond the limits of the largest representable number.

The infinities are signed (affine) and can be used in arithmetic operations where they get treated as very large, indeterminate numbers. For instance, adding a constant to infinity gives another infinite result.

Some operations are indeterminate and return `NaN`, or if the `InvalidOperation` signal is trapped, raise an exception. For example, `0/0` returns `NaN` which means “not a number”. This variety of `NaN` is quiet and, once created, will flow through other computations always resulting in another `NaN`. This behavior can be useful for a series of computations that occasionally have missing inputs — it allows the calculation to proceed while flagging specific results as invalid.

A variant is `sNaN` which signals rather than remaining quiet after
every operation. This is a useful return value when an invalid result needs to interrupt a calculation for special handling.

The behavior of Python’s comparison operators can be a little surprising where a NaN is involved. A test for equality where one of the operands is a quiet or signaling NaN always returns False (even when doing `Decimal('NaN')==Decimal('NaN')`), while a test for inequality always returns True. An attempt to compare two Decimals using any of the `<`, `<=`, `>`, or `>=` operators will raise the InvalidOperation signal if either operand is a NaN, and return False if this signal is not trapped. Note that the General Decimal Arithmetic specification does not specify the behavior of direct comparisons; these rules for comparisons involving a NaN were taken from the IEEE 854 standard (see Table 3 in section 5.7). To ensure strict standards-compliance, use the `compare()` and `compare-signal()` methods instead.

The signed zeros can result from calculations that underflow. They keep the sign that would have resulted if the calculation had been carried out to greater precision. Since their magnitude is zero, both positive and negative zeros are treated as equal and their sign is informational.

In addition to the two signed zeros which are distinct yet equal, there are various representations of zero with differing precisions yet equivalent in value. This takes a bit of getting used to. For an eye accustomed to normalized floating point representations, it is not immediately obvious that the following calculation returns a value equal to zero:

```plaintext
>>> 1 / Decimal('Infinity')
Decimal('0E-100000026')
```
Working with threads

The `getcontext()` function accesses a different `Context` object for each thread. Having separate thread contexts means that threads may make changes (such as `getcontext.prec=10`) without interfering with other threads.

Likewise, the `setcontext()` function automatically assigns its target to the current thread.

If `setcontext()` has not been called before `getcontext()`, then `getcontext()` will automatically create a new context for use in the current thread.

The new context is copied from a prototype context called `DefaultContext`. To control the defaults so that each thread will use the same values throughout the application, directly modify the `DefaultContext` object. This should be done before any threads are started so that there won’t be a race condition between threads calling `getcontext()`. For example:

```python
# Set application-wide defaults for all threads about to be launched
DefaultContext.prec = 12
DefaultContext.rounding = ROUND_DOWN
DefaultContext.traps = ExtendedContext.traps.copy()
DefaultContext.traps[InvalidOperation] = 1
setcontext(DefaultContext)

# Afterwards, the threads can be started
thread1.start()
thread2.start()
thread3.start()
...```

```
Recipes

Here are a few recipes that serve as utility functions and that demonstrate ways to work with the \texttt{Decimal} class:

\begin{verbatim}
def moneyfmt(value, places=2, curr='\', sep='\', dp='.',
pos='\', neg='-', trailneg=''):
    """Convert Decimal to a money formatted string."

    places: required number of places after the decimal point
    curr: optional currency symbol before the sign (may be blank)
    sep: optional grouping separator (comma, period, space)
    dp: decimal point indicator (comma or period)
     only specify as blank when places is zero
    pos: optional sign for positive numbers: '+', space or blank
    neg: optional sign for negative numbers: '-', '(', space
    trailneg:optional trailing minus indicator: '-', ')', space

    >>> d = Decimal('-1234567.8901')
    >>> moneyfmt(d, curr='$')
    '$1,234,567.89'
    >>> moneyfmt(d, places=0, sep='.', dp='', neg='', trailneg='')
    '1.234.568-
    >>> moneyfmt(d, curr='$', neg='(', trailneg=')')
    '($1,234,567.89)'
    >>> moneyfmt(Decimal(123456789), sep = ' ')
    '123 456 789.00'
    >>> moneyfmt(Decimal('-0.02'), neg='<', trailneg='>')
    '<0.02>'

    """

    q = Decimal(10) ** -places        # 2 places --> '0.01'
    sign, digits, exp = value.quantize(q).as_tuple()
    result = []
    digits = map(str, digits)
    build, next = result.append, digits.pop
    if sign:
        build(trailneg)
    for i in range(places):
        build(next() if digits else '0')
    build(dp)
    if not digits:
        build('0')
    i = 0
    while digits:
\end{verbatim}
build(next())
i += 1
if i == 3 and digits:
    i = 0
    build(sep)
build(curr)
build(neg if sign else pos)
return ''.join(reversed(result))

def pi():
    """Compute Pi to the current precision."
    >>> print pi()
    3.141592653589793238462643383
    ""
    getcontext().prec += 2  # extra digits for intermediate steps
    three = Decimal(3)       # substitute "three=3.0" for regular float
    lasts, t, s, n, na, d, da = 0, three, 3, 1, 0, 0, 24
    while s != lasts:
        lasts = s
        n, na = n+na, na+8
        d, da = d+da, da+32
        t = (t * n) / d
        s += t
    getcontext().prec -= 2  # unary plus applies the new precision
    return +s

def exp(x):
    """Return e raised to the power of x. Result type matches input type."
    >>> print exp(Decimal(1))
    2.718281828459045235360287471
    >>> print exp(Decimal(2))

    i, lasts, s, fact, num = 0, 0, 1, 1, 1
    while s != lasts:
        lasts = s
        i += 1
        fact *= i
        num *= x
        s += num / fact
    getcontext().prec -= 2
def cos(x):
    """Return the cosine of x as measured in radians."

    >>> print cos(Decimal('0.5'))
    0.8775825618903727161162815826
    >>> print cos(0.5)
    0.87758256189
    >>> print cos(0.5+0j)
    (0.87758256189+0j)

    """
    getcontext().prec += 2
    i, lasts, s, fact, num, sign = 0, 0, 1, 1, 1, 1
     while s != lasts:
        lasts = s
        i += 2
        fact *= i * (i-1)
        num *= x * x
        sign *= -1
        s += num / fact * sign
    getcontext().prec -= 2
    return +s

def sin(x):
    """Return the sine of x as measured in radians."

    >>> print sin(Decimal('0.5'))
    0.479425538604203002732879352
    >>> print sin(0.5)
    0.479425538604
    >>> print sin(0.5+0j)
    (0.479425538604+0j)

    """
    getcontext().prec += 2
    i, lasts, s, fact, num, sign = 1, 0, x, 1, x, 1
     while s != lasts:
        lasts = s
        i += 2
        fact *= i * (i-1)
        num *= x * x
        sign *= -1
        s += num / fact * sign
    getcontext().prec -= 2
    return +s
Decimal FAQ

Q. It is cumbersome to type `decimal.Decimal('1234.5')`. Is there a way to minimize typing when using the interactive interpreter?

A. Some users abbreviate the constructor to just a single letter:

```python
>>> D = decimal.Decimal
>>> D('1.23') + D('3.45')
Decimal('4.68')
```

Q. In a fixed-point application with two decimal places, some inputs have many places and need to be rounded. Others are not supposed to have excess digits and need to be validated. What methods should be used?

A. The `quantize()` method rounds to a fixed number of decimal places. If the `Inexact` trap is set, it is also useful for validation:

```python
>>> TWOPLACES = Decimal(10) ** -2  # same as Decimal('0.01')
>>> # Round to two places
>>> Decimal('3.214').quantize(TWOPLACES)
Decimal('3.21')

>>> # Validate that a number does not exceed two places
>>> Decimal('3.21').quantize(TWOPLACES, context=Context(traps=[Inexact]))
Decimal('3.21')

>>> Decimal('3.214').quantize(TWOPLACES, context=Context(traps=[Inexact]))
Traceback (most recent call last):
  ... Inexact
```

Q. Once I have valid two place inputs, how do I maintain that
invariant throughout an application?

A. Some operations like addition, subtraction, and multiplication by an integer will automatically preserve fixed point. Others operations, like division and non-integer multiplication, will change the number of decimal places and need to be followed-up with a quantize() step:

```python
>>> a = Decimal('102.72')  # Initial fixed-point value
>>> b = Decimal('3.17')    # Addition preserves fixed-
>>> a + b                  # So does integer multiplication
Decimal('105.89')
>>> a - b                  # Must quantize non-integer multiplication
Decimal('99.55')
>>> a * 42                 # And quantize division
Decimal('4314.24')
>>> (a * b).quantize(TWOPLACES)
Decimal('325.62')
>>> (b / a).quantize(TWOPLACES)
Decimal('0.03')
```

In developing fixed-point applications, it is convenient to define functions to handle the quantize() step:

```python
>>> def mul(x, y, fp=TWOPLACES):
...     return (x * y).quantize(fp)
>>> def div(x, y, fp=TWOPLACES):
...     return (x / y).quantize(fp)
```

Q. There are many ways to express the same value. The numbers 200, 200.000, 2E2, and 02E+4 all have the same value at various precisions. Is there a way to transform them to a single recognizable canonical value?

A. The normalize() method maps all equivalent values to a single
representative:

```python
>>> values = map(Decimal, '200 200.000 2E2 .02E+4'.split())
>>> [v.normalize() for v in values]
[Decimal('2E+2'), Decimal('2E+2'), Decimal('2E+2'), Decimal('2E+2')]
```

Q. Some decimal values always print with exponential notation. Is there a way to get a non-exponential representation?

A. For some values, exponential notation is the only way to express the number of significant places in the coefficient. For example, expressing 5.0E+3 as 5000 keeps the value constant but cannot show the original's two-place significance.

If an application does not care about tracking significance, it is easy to remove the exponent and trailing zeroes, losing significance, but keeping the value unchanged:

```python
>>> def remove_exponent(d):
...     return d.quantize(Decimal(1)) if d == d.to_integral

>>> remove_exponent(Decimal('5E+3'))
Decimal('5000')
```

Q. Is there a way to convert a regular float to a Decimal?

A. Yes, all binary floating point numbers can be exactly expressed as a Decimal. An exact conversion may take more precision than intuition would suggest, so we trap Inexact to signal a need for more precision:

```python
def float_to_decimal(f):
    "Convert a floating point number to a Decimal with no loss of info,"
    d = f.as_integer_ratio()
    with localcontext() as ctx:
        ctx.traps[Inexact] = True
        while True:
```
try:
    return Decimal(n) / Decimal(d)
except Inexact:
    ctx.prec += 1

>>> float_to_decimal(math.pi)
Decimal('3.141592653589793115997963468544185161590576171875')

Q. Why isn’t the float_to_decimal() routine included in the module?

A. There is some question about whether it is advisable to mix binary and decimal floating point. Also, its use requires some care to avoid the representation issues associated with binary floating point:

   >>> float_to_decimal(1.1)
Decimal('1.100000000000000088817841970012523233890533447265625')

Q. Within a complex calculation, how can I make sure that I haven’t gotten a spurious result because of insufficient precision or rounding anomalies.

A. The decimal module makes it easy to test results. A best practice is to re-run calculations using greater precision and with various rounding modes. Widely differing results indicate insufficient precision, rounding mode issues, ill-conditioned inputs, or a numerically unstable algorithm.

Q. I noticed that context precision is applied to the results of operations but not to the inputs. Is there anything to watch out for when mixing values of different precisions?

A. Yes. The principle is that all values are considered to be exact and so is the arithmetic on those values. Only the results are rounded. The advantage for inputs is that “what you type is what you get”. A disadvantage is that the results can look odd if you forget that the inputs haven’t been rounded:
The solution is either to increase precision or to force rounding of inputs using the unary plus operation:

```python
>>> getcontext().prec = 3
>>> Decimal('3.104') + Decimal('2.104')
Decimal('5.21')
```

```python
>>> Decimal('3.104') + Decimal('0.000') + Decimal('2.104')
Decimal('5.20')
```

Alternatively, inputs can be rounded upon creation using the `Context.create_decimal()` method:

```python
>>> Context(prec=5, rounding=ROUND_DOWN).create_decimal('1.23456789')
Decimal('1.2345')
```
fractions — Rational numbers

New in version 2.6.

The fractions module provides support for rational number arithmetic.

A Fraction instance can be constructed from a pair of integers, from another rational number, or from a string.

class fractions.Fraction(numerator=0, denominator=1)
class fractions.Fraction(other_fraction)
class fractions.Fraction(string)

The first version requires that numerator and denominator are instances of numbers.Integral and returns a new Fraction instance with value numerator/denominator. If denominator is 0, it raises a ZeroDivisionError. The second version requires that other_fraction is an instance of numbers.Rational and returns an Fraction instance with the same value. The last version of the constructor expects a string or unicode instance in one of two possible forms. The first form is:

```
[sign] numerator ['/' denominator]
```

where the optional sign may be either '+' or '-' and numerator and denominator (if present) are strings of decimal digits. The second permitted form is that of a number containing a decimal point:

```
[sign] integer '.' [fraction] | [sign] '.' fraction
```

where integer and fraction are strings of digits. In either form the input string may also have leading and/or trailing whitespace. Here are some examples:
The `Fraction` class inherits from the abstract base class `numbers.Rational`, and implements all of the methods and operations from that class. `Fraction` instances are hashable, and should be treated as immutable. In addition, `Fraction` has the following methods:

**from_float(flt)**

This class method constructs a `Fraction` representing the exact value of `flt`, which must be a `float`. Beware that `Fraction.from_float(0.3)` is not the same value as `Fraction(3, 10)`.

**from_decimal(dec)**

This class method constructs a `Fraction` representing the exact value of `dec`, which must be a `decimal.Decimal`.

**limit_denominator(max_denominator=1000000)**
Finds and returns the closest \texttt{Fraction} to \texttt{self} that has denominator at most \texttt{max_denominator}. This method is useful for finding rational approximations to a given floating-point number:

```python
>>> from fractions import Fraction
>>> Fraction('3.1415926535897932').limit_denominator(1000)
Fraction(355, 113)
```

or for recovering a rational number that's represented as a float:

```python
>>> from math import pi, cos
>>> Fraction.from_float(cos(pi/3))
Fraction(4503599627370497, 9007199254740992)
>>> Fraction.from_float(cos(pi/3)).limit_denominator()
Fraction(1, 2)
```

\texttt{fractions.gcd(a, b)}

Return the greatest common divisor of the integers \texttt{a} and \texttt{b}. If either \texttt{a} or \texttt{b} is nonzero, then the absolute value of \texttt{gcd(a, b)} is the largest integer that divides both \texttt{a} and \texttt{b}. \texttt{gcd(a,b)} has the same sign as \texttt{b} if \texttt{b} is nonzero; otherwise it takes the sign of \texttt{a}. \texttt{gcd(0, 0)} returns 0.

\textbf{See also:}

\textbf{Module numbers}

The abstract base classes making up the numeric tower.
random — Generate pseudo-random numbers

This module implements pseudo-random number generators for various distributions.

For integers, uniform selection from a range. For sequences, uniform selection of a random element, a function to generate a random permutation of a list in-place, and a function for random sampling without replacement.

On the real line, there are functions to compute uniform, normal (Gaussian), lognormal, negative exponential, gamma, and beta distributions. For generating distributions of angles, the von Mises distribution is available.

Almost all module functions depend on the basic function `random()`, which generates a random float uniformly in the semi-open range \([0.0, 1.0)\). Python uses the Mersenne Twister as the core generator. It produces 53-bit precision floats and has a period of \(2^{19937}-1\). The underlying implementation in C is both fast and threadsafe. The Mersenne Twister is one of the most extensively tested random number generators in existence. However, being completely deterministic, it is not suitable for all purposes, and is completely unsuitable for cryptographic purposes.

The functions supplied by this module are actually bound methods of a hidden instance of the `random.Random` class. You can instantiate your own instances of `Random` to get generators that don't share state. This is especially useful for multi-threaded programs, creating a different instance of `Random` for each thread, and using the `jumpahead()` method to make it likely that the generated sequences seen by each thread don't overlap.
Class Random can also be subclassed if you want to use a different basic generator of your own devising: in that case, override the random(), seed(), getstate(), setstate() and jumpahead() methods. Optionally, a new generator can supply a getrandbits() method — this allows randrange() to produce selections over an arbitrarily large range.

*New in version 2.4:* the getrandbits() method.

As an example of subclassing, the random module provides the WichmannHill class that implements an alternative generator in pure Python. The class provides a backward compatible way to reproduce results from earlier versions of Python, which used the Wichmann-Hill algorithm as the core generator. Note that this Wichmann-Hill generator can no longer be recommended: its period is too short by contemporary standards, and the sequence generated is known to fail some stringent randomness tests. See the references below for a recent variant that repairs these flaws.

*Changed in version 2.3:* Substituted MersenneTwister for Wichmann-Hill.

Bookkeeping functions:

`random.seed([x])`

Initialize the basic random number generator. Optional argument x can be any hashable object. If x is omitted or None, current system time is used; current system time is also used to initialize the generator when the module is first imported. If randomness sources are provided by the operating system, they are used instead of the system time (see the os.urandom() function for details on availability).

*Changed in version 2.4:* formerly, operating system resources
were not used.

If \( x \) is not \texttt{None} or an \texttt{int} or \texttt{long}, \texttt{hash(x)} is used instead. If \( x \) is an \texttt{int} or \texttt{long}, \( x \) is used directly.

\texttt{random.getstate()}

Return an object capturing the current internal state of the generator. This object can be passed to \texttt{setstate()} to restore the state.

\textit{New in version 2.1.}

\textit{Changed in version 2.6}: State values produced in Python 2.6 cannot be loaded into earlier versions.

\texttt{random.setstate(state)}

\textit{state} should have been obtained from a previous call to \texttt{getstate()}, and \texttt{setstate()} restores the internal state of the generator to what it was at the time \texttt{setstate()} was called.

\textit{New in version 2.1.}

\texttt{random.jumpahead(n)}

Change the internal state to one different from and likely far away from the current state. \( n \) is a non-negative integer which is used to scramble the current state vector. This is most useful in multi-threaded programs, in conjunction with multiple instances of the \texttt{Random} class: \texttt{setstate()} or \texttt{seed()} can be used to force all instances into the same internal state, and then \texttt{jumpahead()} can be used to force the instances' states far apart.

\textit{New in version 2.1.}

\textit{Changed in version 2.3}: Instead of jumping to a specific state, \( n \) steps ahead, \texttt{jumpahead(n)} jumps to another state likely to be
separated by many steps.

random.getrandbits($k$

Returns a python `long` int with $k$ random bits. This method is supplied with the MersenneTwister generator and some other generators may also provide it as an optional part of the API. When available, `getrandbits()` enables `randrange()` to handle arbitrarily large ranges.

*New in version 2.4.*

Functions for integers:

random.randrange([`start`, `stop[, step]`])

Return a randomly selected element from `range(start, stop, step)`. This is equivalent to `choice(range(start, stop, step))`, but doesn’t actually build a range object.

*New in version 1.5.2.*

random.randint(a, b)

Return a random integer $N$ such that $a \leq N \leq b$.

Functions for sequences:

random.choice(seq)

Return a random element from the non-empty sequence `seq`. If `seq` is empty, raises `IndexError`.

random.shuffle(x[, random])

Shuffle the sequence `x` in place. The optional argument `random` is a 0-argument function returning a random float in $[0.0, 1.0)$; by default, this is the function `random()`.
Note that for even rather small \texttt{len(x)}, the total number of permutations of \texttt{x} is larger than the period of most random number generators; this implies that most permutations of a long sequence can never be generated.

\texttt{random.sample(population, k)}

Return a \textit{k} length list of unique elements chosen from the population sequence. Used for random sampling without replacement.

\textit{New in version 2.3.}

Returns a new list containing elements from the population while leaving the original population unchanged. The resulting list is in selection order so that all sub-slices will also be valid random samples. This allows raffle winners (the sample) to be partitioned into grand prize and second place winners (the subslices).

Members of the population need not be \textit{hashable} or unique. If the population contains repeats, then each occurrence is a possible selection in the sample.

To choose a sample from a range of integers, use an \texttt{xrange()} object as an argument. This is especially fast and space efficient for sampling from a large population: \texttt{sample(xrange(10000000), 60)}.

The following functions generate specific real-valued distributions. Function parameters are named after the corresponding variables in the distribution’s equation, as used in common mathematical practice; most of these equations can be found in any statistics text.

\texttt{random.randint()}  
Return the next random floating point number in the range \([0.0, 1.0]).\]
random. **uniform**(*a, b*)

Return a random floating point number *N* such that *a* <= *N* < *b* for *a* <= *b* and *b* <= *N* < *a* for *b* < *a*.

random. **triangular**(*low, high, mode*)

Return a random floating point number *N* such that *low* <= *N* < *high* and with the specified *mode* between those bounds. The *low* and *high* bounds default to zero and one. The *mode* argument defaults to the midpoint between the bounds, giving a symmetric distribution.

*New in version 2.6.*

random. **betavariate**(*alpha, beta*)

Beta distribution. Conditions on the parameters are *alpha* > 0 and *beta* > 0. Returned values range between 0 and 1.

random. **expovariate**(*lambda*)

Exponential distribution. *lambda* is 1.0 divided by the desired mean. (The parameter would be called “lambda”, but that is a reserved word in Python.) Returned values range from 0 to positive infinity.

random. **gammavariate**(*alpha, beta*)

Gamma distribution. *(Not the gamma function!)* Conditions on the parameters are *alpha* > 0 and *beta* > 0.

random. **gauss**(*mu, sigma*)

Gaussian distribution. *mu* is the mean, and *sigma* is the standard deviation. This is slightly faster than the **normalvariate()** function defined below.

random. **lognormvariate**(*mu, sigma*)

Log normal distribution. If you take the natural logarithm of this
distribution, you'll get a normal distribution with mean \( mu \) and standard deviation \( sigma \). \( mu \) can have any value, and \( sigma \) must be greater than zero.

```
random.normalvariate(mu, sigma)
```

Normal distribution. \( mu \) is the mean, and \( sigma \) is the standard deviation.

```
random.vonmisesvariate(mu, kappa)
```

\( mu \) is the mean angle, expressed in radians between 0 and 2*\( pi \), and \( kappa \) is the concentration parameter, which must be greater than or equal to zero. If \( kappa \) is equal to zero, this distribution reduces to a uniform random angle over the range 0 to 2*\( pi \).

```
random.paretovariate(alpha)
```

Pareto distribution. \( alpha \) is the shape parameter.

```
random.weibullvariate(alpha, beta)
```

Weibull distribution. \( alpha \) is the scale parameter and \( beta \) is the shape parameter.

Alternative Generators:

```
class random.WichmannHill([seed])
```

Class that implements the Wichmann-Hill algorithm as the core generator. Has all of the same methods as `Random` plus the `whseed()` method described below. Because this class is implemented in pure Python, it is not threadsafe and may require locks between calls. The period of the generator is 6,953,607,871,644 which is small enough to require care that two independent random sequences do not overlap.

```
random.whseed([x])
```

This is obsolete, supplied for bit-level compatibility with versions
of Python prior to 2.1. See `seed()` for details. `whseed()` does not
guarantee that distinct integer arguments yield distinct internal
states, and can yield no more than about $2^{24}$ distinct internal
states in all.

class random.SystemRandom([seed])
Class that uses the `os.urandom()` function for generating random
numbers from sources provided by the operating system. Not
available on all systems. Does not rely on software state and
sequences are not reproducible. Accordingly, the `seed()` and
`jumpahead()` methods have no effect and are ignored. The
`getstate()` and `setstate()` methods raise `NotImplementedError` if
called.

New in version 2.4.

Examples of basic usage:

```python
>>> random.random()  # Random float x, 0.0 <= x < 1.0
0.37444887175646646
>>> random.uniform(1, 10)  # Random float x, 1.0 <= x < 10.0
1.1800146073117523
>>> random.randint(1, 10)  # Integer from 1 to 10, endpoints included
7
>>> random.randrange(0, 101, 2)  # Even integer from 0 to 100
26
>>> random.choice('abcdefghij')  # Choose a random element 'c'
'c'
```

```python
>>> items = [1, 2, 3, 4, 5, 6, 7]
>>> random.shuffle(items)
>>> items
[7, 3, 2, 5, 6, 4, 1]
```

```python
>>> random.sample([1, 2, 3, 4, 5], 3)  # Choose 3 elements
[4, 1, 5]
```

**itertools — Functions creating iterators for efficient looping**

*New in version 2.3.*

This module implements a number of *iterator* building blocks inspired by constructs from the Haskell and SML programming languages. Each has been recast in a form suitable for Python.

The module standardizes a core set of fast, memory efficient tools that are useful by themselves or in combination. Standardization helps avoid the readability and reliability problems which arise when many different individuals create their own slightly varying implementations, each with their own quirks and naming conventions.

The tools are designed to combine readily with one another. This makes it easy to construct more specialized tools succinctly and efficiently in pure Python.

For instance, SML provides a tabulation tool: `tabulate(f)` which produces a sequence $f(0), f(1), \ldots$. This toolbox provides `imap()` and `count()` which can be combined to form `imap(f, count())` and produce an equivalent result.

Likewise, the functional tools are designed to work well with the high-speed functions provided by the `operator` module.

Whether cast in pure python form or compiled code, tools that use iterators are more memory efficient (and often faster) than their list based counterparts. Adopting the principles of just-in-time manufacturing, they create data when and where needed instead of consuming memory with the computer equivalent of “inventory”.
Itertool functions

The following module functions all construct and return iterators. Some provide streams of infinite length, so they should only be accessed by functions or loops that truncate the stream.

**itertools.**chain**(*iterables)**

Make an iterator that returns elements from the first iterable until it is exhausted, then proceeds to the next iterable, until all of the iterables are exhausted. Used for treating consecutive sequences as a single sequence. Equivalent to:

```python
def chain(*iterables):
    # chain('ABC', 'DEF') --> A B C D E F
    for it in iterables:
        for element in it:
            yield element
```

**itertools.chain.from_iterable**(*iterable*)

Alternate constructor for chain(). Gets chained inputs from a single iterable argument that is evaluated lazily. Equivalent to:

```python
@classmethod
def from_iterable(iterables):
    # chain.from_iterable(['ABC', 'DEF']) --> A B C D E F
    for it in iterables:
        for element in it:
            yield element
```

*New in version 2.6.*

**itertools.combinations**(iterable, r)**

Return r length subsequences of elements from the input iterable.**
Combinations are emitted in lexicographic sort order. So, if the input iterable is sorted, the combination tuples will be produced in sorted order.

Elements are treated as unique based on their position, not on their value. So if the input elements are unique, there will be no repeat values in each combination.

Equivalent to:

```python
def combinations(iterable, r):
    # combinations('ABCD', 2) --> AB AC AD BC BD CD
    # combinations(range(4), 3) --> 012 013 023 123
    pool = tuple(iterable)
    n = len(pool)
    indices = range(r)
    yield tuple(pool[i] for i in indices)
    while 1:
        for i in reversed(range(r)):
            if indices[i] != i + n - r:
                break
        else:
            return
        indices[i] += 1
        for j in range(i + 1, r):
            indices[j] = indices[j - 1] + 1
        yield tuple(pool[i] for i in indices)
```

The code for `combinations()` can be also expressed as a subsequence of `permutations()` after filtering entries where the elements are not in sorted order (according to their position in the input pool):

```python
def combinations(iterable, r):
    pool = tuple(iterable)
```
n = len(pool)
for indices in permutations(range(n), r):
    if sorted(indices) == list(indices):
        yield tuple(pool[i] for i in indices)

New in version 2.6.

`itertools.count([n])`
Make an iterator that returns consecutive integers starting with `n`. If not specified `n` defaults to zero. Often used as an argument to `imap()` to generate consecutive data points. Also, used with `izip()` to add sequence numbers. Equivalent to:

```python
def count(n=0):
    # count(10) --> 10 11 12 13 14 ...
    while True:
        yield n
    n += 1
```

`itertools.cycle(iterable)`
Make an iterator returning elements from the iterable and saving a copy of each. When the iterable is exhausted, return elements from the saved copy. Repeats indefinitely. Equivalent to:

```python
def cycle(iterable):
    # cycle('ABCD') --> A B C D A B C D A B C D ...
    saved = []
    for element in iterable:
        yield element
        saved.append(element)
    while saved:
        for element in saved:
            yield element
Note, this member of the toolkit may require significant auxiliary storage (depending on the length of the iterable).

**itertools.** **dropwhile**( ***predicate***, **iterable**)

Make an iterator that drops elements from the iterable as long as the predicate is true; afterwards, returns every element. Note, the iterator does not produce any output until the predicate first becomes false, so it may have a lengthy start-up time. Equivalent to:

```python
def dropwhile(predicate, iterable):
    # dropwhile(lambda x: x<5, [1,4,6,4,1]) --> 6 4 1
    iterable = iter(iterable)
    for x in iterable:
        if not predicate(x):
            yield x
            break
    for x in iterable:
        yield x
```

**itertools.** **groupby**( **iterable**, **[, key]**)

Make an iterator that returns consecutive keys and groups from the iterable. The key is a function computing a key value for each element. If not specified or is None, key defaults to an identity function and returns the element unchanged. Generally, the iterable needs to already be sorted on the same key function.

The operation of groupby() is similar to the uniq filter in Unix. It generates a break or new group every time the value of the key function changes (which is why it is usually necessary to have sorted the data using the same key function). That behavior differs from SQL's GROUP BY which aggregates common elements regardless of their input order.
The returned group is itself an iterator that shares the underlying iterable with `groupby()`. Because the source is shared, when the `groupby()` object is advanced, the previous group is no longer visible. So, if that data is needed later, it should be stored as a list:

```python
groups = []
uniquekeys = []
data = sorted(data, key=keyfunc)
for k, g in groupby(data, keyfunc):
    groups.append(list(g))  # Store group iterator as a list
    uniquekeys.append(k)
groupby() is equivalent to:

class groupby(object):
    # [k for k, g in groupby('AAAAABBBCCDAABBB')] --> A B C D
    # [(list(g)) for k, g in groupby('AAAABBBCCD')] --> AAAA
    def __init__(self, iterable, key=None):
        if key is None:
            key = lambda x: x
        self.keyfunc = key
        self.it = iter(iterable)
        self.tgtkey = self.currkey = self.currvalue = object
    def __iter__(self):
        return self
    def next(self):
        while self.currkey == self.tgtkey:
            self.currvalue = self.it.next()  # Exit on StopIteration
            self.currkey = self.keyfunc(self.currvalue)
        self.tgtkey = self.currkey
        return (self.currkey, self._grouper(self.tgtkey))
    def _grouper(self, tgtkey):
```

while self.currkey == tgtkey:
    yield self.currvalue
self.currvalue = self.it.next()  # Exit on StopIteration
self.currkey = self.keyfunc(self.currvalue)

New in version 2.4.

`itertools.ifilter(predicate, iterable)`
Make an iterator that filters elements from iterable returning only those for which the predicate is `True`. If `predicate` is `None`, return the items that are true. Equivalent to:

```python
def ifilter(predicate, iterable):
    # ifilter(lambda x: x%2, range(10)) --> 1 3 5 7 9
    if predicate is None:
        predicate = bool
    for x in iterable:
        if predicate(x):
            yield x
```

`itertools.ifilterfalse(predicate, iterable)`
Make an iterator that filters elements from iterable returning only those for which the predicate is `False`. If `predicate` is `None`, return the items that are false. Equivalent to:

```python
def ifilterfalse(predicate, iterable):
    # ifilterfalse(lambda x: x%2, range(10)) --> 0 2 4 6 8
    if predicate is None:
        predicate = bool
    for x in iterable:
        if not predicate(x):
            yield x
```
**itertools.** **imap**(function, *iterables)

Make an iterator that computes the function using arguments from each of the iterables. If function is set to None, then imap() returns the arguments as a tuple. Like map() but stops when the shortest iterable is exhausted instead of filling in None for shorter iterables. The reason for the difference is that infinite iterator arguments are typically an error for map() (because the output is fully evaluated) but represent a common and useful way of supplying arguments to imap(). Equivalent to:

```python
def imap(function, *iterables):
    # imap(pow, (2,3,10), (5,2,3)) --> 32 9 1000
    iterables = map(iter, iterables)
    while True:
        args = [it.next() for it in iterables]
        if function is None:
            yield tuple(args)
        else:
            yield function(*args)
```

**itertools.** **islice**(iterable[, start], stop[, step])

Make an iterator that returns selected elements from the iterable. If start is non-zero, then elements from the iterable are skipped until start is reached. Afterward, elements are returned consecutively unless step is set higher than one which results in items being skipped. If stop is None, then iteration continues until the iterator is exhausted, if at all; otherwise, it stops at the specified position. Unlike regular slicing, islice() does not support negative values for start, stop, or step. Can be used to extract related fields from data where the internal structure has been flattened (for example, a multi-line report may list a name field on every third line). Equivalent to:
def islice(iterable, *args):
    # islice('ABCDEFG', 2) --> A B
    # islice('ABCDEFG', 2, 4) --> C D
    # islice('ABCDEFG', 2, None) --> C D E F G
    # islice('ABCDEFG', 0, None, 2) --> A C E G
    s = slice(*args)
    it = iter(xrange(s.start or 0, s.stop or sys.maxint, s.step or 1))
    nexti = it.next()
    for i, element in enumerate(iterable):
        if i == nexti:
            yield element
        nexti = it.next()

If start is None, then iteration starts at zero. If step is None, then
the step defaults to one.

Changed in version 2.5: accept None values for default start and
step.

 itertools.izip(*iterables)
Make an iterator that aggregates elements from each of the
iterables. Like zip() except that it returns an iterator instead of a
list. Used for lock-step iteration over several iterables at a time.
Equivalent to:

def izip(*iterables):
    # izip('ABCD', 'xy') --> Ax By
    iterables = map(iter, iterables)
    while iterables:
        result = [it.next() for it in iterables]
        yield tuple(result)

Changed in version 2.4: When no iterables are specified, returns
a zero length iterator instead of raising a `TypeError` exception.

The left-to-right evaluation order of the iterables is guaranteed. This makes possible an idiom for clustering a data series into n-length groups using `izip(*[iter(s)]*n)`.

`izip()` should only be used with unequal length inputs when you don't care about trailing, unmatched values from the longer iterables. If those values are important, use `zip_longest()` instead.

`itertools.zip_longest(*iterables[, fillvalue])`

Make an iterator that aggregates elements from each of the iterables. If the iterables are of uneven length, missing values are filled-in with `fillvalue`. Iteration continues until the longest iterable is exhausted. Equivalent to:

```python
def zip_longest(*args, **kwds):
    fillvalue = kwds.get('fillvalue')
    def sentinel(counter = ([fillvalue]*(len(args)-1)).pop):
        yield counter()  # yields the fillvalue, or r
    fillers = repeat(fillvalue)
    iters = [chain(it, sentinel(), fillers) for it in args]
    try:
        for tup in izip(*iters):
            yield tup
    except IndexError:
        pass
```

If one of the iterables is potentially infinite, then the `zip_longest()` function should be wrapped with something that limits the number of calls (for example `islice()` or `takewhile()`).
If not specified, \textit{fillvalue} defaults to \texttt{None}.

\textit{New in version 2.6.}

\texttt{itertools.permutations(iterable[, r])}

Return successive $r$ length permutations of elements in the \texttt{iterable}.

If $r$ is not specified or is \texttt{None}, then $r$ defaults to the length of the \texttt{iterable} and all possible full-length permutations are generated.

Permutations are emitted in lexicographic sort order. So, if the input \texttt{iterable} is sorted, the permutation tuples will be produced in sorted order.

Elements are treated as unique based on their position, not on their value. So if the input elements are unique, there will be no repeat values in each permutation.

Equivalent to:

\begin{verbatim}
def permutations(iterable, r=None):
    # permutations('ABCD', 2) --> AB AC AD BA BC BD CA CB CD
    # permutations(range(3)) --> 012 021 102 120 201 210
    pool = tuple(iterable)
    n = len(pool)
    r = n if r is None else r
    indices = range(n)
    cycles = range(n, n-r, -1)
    yield tuple(pool[i] for i in indices[:r])
    while n:
        for i in reversed(range(r)):
            cycles[i] -= 1
            if cycles[i] == 0:
                indices[i:] = indices[i+1:] + indices[i:i+1]
        for i in range(r-1, -1, -1):
            cycles[i] += 1
            if cycles[i] == r:
                indices[i+1:] = indices[i+1:] + indices[i:i+1]
                break
        yield tuple(pool[i] for i in indices[:r])

def permutations2(iterable, r=None):
    pool = tuple(iterable)
    n = len(pool)
    r = n if r is None else r
    result = [[]]
    for i in range(n):
        newresult = []
        for sub in result:
            for j in range(r):
                if j < len(sub):
                    sub[j] = sub[j] + pool[i]
                else:
                    sub.append(pool[i])
                    j = 0
                newresult.append(sub[:j] + pool[i] + sub[j:])
        result = newresult
    return result
\end{verbatim}
cycles[i] = n - i

else:
    j = cycles[i]
    indices[i], indices[-j] = indices[-j], indic
    yield tuple(pool[i] for i in indices[:r])
    break
else:
    return

The code for permutations() can be also expressed as a subsequence of product(), filtered to exclude entries with repeated elements (those from the same position in the input pool):

```python
def permutations(iterable, r=None):
    pool = tuple(iterable)
    n = len(pool)
    r = n if r is None else r
    for indices in product(range(n), repeat=r):
        if len(set(indices)) == r:
            yield tuple(pool[i] for i in indices)
```

New in version 2.6.

```
from itertools import product
```

Cartesian product of input iterables.

Equivalent to nested for-loops in a generator expression. For example, product(A, B) returns the same as \([(x,y) \text{ for } x \text{ in } A \text{ for } y \text{ in } B]\).

The nested loops cycle like an odometer with the rightmost element advancing on every iteration. This pattern creates a lexicographic ordering so that if the input's iterables are sorted,
the product tuples are emitted in sorted order.

To compute the product of an iterable with itself, specify the number of repetitions with the optional repeat keyword argument. For example, \texttt{product(A, repeat=4)} means the same as \texttt{product(A, A, A, A)}.

This function is equivalent to the following code, except that the actual implementation does not build up intermediate results in memory:

```python
def product(*args, **kwds):
    # product('ABCD', 'xy') --> Ax Ay Bx By Cx Cy Dx Dy
    # product(range(2), repeat=3) --> 000 001 010 011 100 101 110 111
    pools = map(tuple, args) * kwds.get('repeat', 1)
    result = [[]]
    for pool in pools:
        result = [x+[y] for x in result for y in pool]
    for prod in result:
        yield tuple(prod)
```

\textit{New in version 2.6.}

\texttt{itertools.repeat(object[, times])}

Make an iterator that returns \texttt{object} over and over again. Runs indefinitely unless the \texttt{times} argument is specified. Used as argument to \texttt{imap()} for invariant function parameters. Also used with \texttt{izip()} to create constant fields in a tuple record. Equivalent to:

```python
def repeat(object, times=None):
    # repeat(10, 3) --> 10 10 10
    if times is None:
        while True:
```
```python
yield object
else:
    for i in xrange(times):
        yield object
```

**itertools.starmap(function, iterable)**

Make an iterator that computes the function using arguments obtained from the iterable. Used instead of `imap()` when argument parameters are already grouped in tuples from a single iterable (the data has been “pre-zipped”). The difference between `imap()` and `starmap()` parallels the distinction between `function(a,b)` and `function(*c)`. Equivalent to:

```python
def starmap(function, iterable):
    # starmap(pow, [(2,5), (3,2), (10,3)]) --> 32 9 1000
    for args in iterable:
        yield function(*args)
```

*Changed in version 2.6:* Previously, `starmap()` required the function arguments to be tuples. Now, any iterable is allowed.

**itertools.takewhile(predicate, iterable)**

Make an iterator that returns elements from the iterable as long as the predicate is true. Equivalent to:

```python
def takewhile(predicate, iterable):
    # takewhile(lambda x: x<5, [1,4,6,4,1]) --> 1 4
    for x in iterable:
        if predicate(x):
            yield x
        else:
            break
```
`itertools.tee(iterable[, n=2])`

Return \( n \) independent iterators from a single iterable. The case where \( n==2 \) is equivalent to:

```python
def tee(iterable):
    def gen(next, data={}):
        for i in count():
            if i in data:
                yield data.pop(i)
            else:
                data[i] = next()
            yield data[i]
    it = iter(iterable)
    return gen(it.next), gen(it.next)
```

Note, once `tee()` has made a split, the original `iterable` should not be used anywhere else; otherwise, the `iterable` could get advanced without the tee objects being informed.

Note, this member of the toolkit may require significant auxiliary storage (depending on how much temporary data needs to be stored). In general, if one iterator is going to use most or all of the data before the other iterator, it is faster to use `list()` instead of `tee()`.

*New in version 2.4.*
Examples

The following examples show common uses for each tool and demonstrate ways they can be combined.

```python
# Show a dictionary sorted and grouped by value
>>> from operator import itemgetter
>>> d = dict(a=1, b=2, c=1, d=2, e=1, f=2, g=3)
>>> di = sorted(d.iteritems(), key=itemgetter(1))
>>> for k, g in groupby(di, key=itemgetter(1)):
...    print k, map(itemgetter(0), g)
...
1 ['a', 'c', 'e']
2 ['b', 'd', 'f']
3 ['g']

# Find runs of consecutive numbers using groupby. The key to the solution is differencing with a range so that consecutive numbers all appear in the same group.
>>> data = [1, 4, 5, 6, 10, 15, 16, 17, 18, 22, 25, 26, 27, 28]
>>> for k, g in groupby(enumerate(data), lambda (i,x):i-x):
...    print map(itemgetter(1), g)
...
[1]
[4, 5, 6]
[10]
[15, 16, 17, 18]
[22]
[25, 26, 27, 28]
```
This section shows recipes for creating an extended toolset using the existing itertools as building blocks.

The extended tools offer the same high performance as the underlying toolset. The superior memory performance is kept by processing elements one at a time rather than bringing the whole iterable into memory all at once. Code volume is kept small by linking the tools together in a functional style which helps eliminate temporary variables. High speed is retained by preferring “vectorized” building blocks over the use of for-loops and generators which incur interpreter overhead.

```python
def take(n, iterable):
    "Return first n items of the iterable as a list"
    return list(islice(iterable, n))

def enumerate(iterable, start=0):
    return izip(count(start), iterable)

def tabulate(function, start=0):
    "Return function(0), function(1), ..."
    return imap(function, count(start))

def nth(iterable, n):
    "Returns the nth item or empty list"
    return list(islice(iterable, n, n+1))

def quantify(iterable, pred=bool):
    "Count how many times the predicate is true"
    return sum(imap(pred, iterable))

def padnone(iterable):
    """Returns the sequence elements and then returns None indefinitely. Useful for emulating the behavior of the built-in map() function.""
    return chain(iterable, repeat(None))

def ncycles(iterable, n):
    "Returns the sequence elements n times"
```
return chain.from_iterable(repeat(iterable, n))

def dotproduct(vec1, vec2):
    return sum(imap(operator.mul, vec1, vec2))

def flatten(listOfLists):
    return list(chain.from_iterable(listOfLists))

def repeatfunc(func, times=None, *args):
    """Repeat calls to func with specified arguments.
    Example: repeatfunc(random.random)
    """
    if times is None:
        return starmap(func, repeat(args))
    return starmap(func, repeat(args, times))

def pairwise(iterable):
    """s -> (s0,s1), (s1,s2), (s2, s3), ..."
    a, b = tee(iterable)
    for elem in b:
        break
    return izip(a, b)

def grouper(n, iterable, fillvalue=None):
    """grouper(3, 'ABCDEFG', 'x') --
    A B C
    D E F
    G xx"
    args = [iter(iterable)] * n
    return izip_longest(fillvalue=fillvalue, *args)

def roundrobin(*iterables):
    """roundrobin('ABC', 'D', 'EF') -- A D E B F C"
    # Recipe credited to George Sakkis
    pending = len(iterables)
    nexts = cycle(iter(it).next for it in iterables)
    while pending:
        try:
            for next in nexts:
                yield next()
        except StopIteration:
            pending -= 1
            nexts = cycle(islice(nexts, pending))

def powerset(iterable):
    """powerset('ab') --
    set([]), set(['a']), set(['b']), set(['a', 'b'])"
    # Recipe credited to Eric Raymond
    pairs = [(2**i, x) for i, x in enumerate(iterable)]
    for n in xrange(2**len(pairs)):
        yield set(x for m, x in pairs if m&n)

def compress(data, selectors):
    return
"compress('ABCDEF', [1,0,1,0,1,1]) --> A C E F"
return (d for d, s in izip(data, selectors) if s)
def combinations_with_replacement(iterable, r):
    "combinations_with_replacement('ABC', 3) --> AA AB AC BB BC"
    pool = tuple(iterable)
n = len(pool)
    indices = [0] * r
    yield tuple(pool[i] for i in indices)
while 1:
    for i in reversed(range(r)):
        if indices[i] != n - 1:
            break
    else:
        return
    indices[i:] = [indices[i] + 1] * (r - i)
    yield tuple(pool[i] for i in indices)
functools — Higher order functions and operations on callable objects

New in version 2.5.

The functools module is for higher-order functions: functions that act on or return other functions. In general, any callable object can be treated as a function for the purposes of this module.

The functools module defines the following functions:

functools.reduce(function, iterable[, initializer])

This is the same function as reduce(). It is made available in this module to allow writing code more forward-compatible with Python 3.

New in version 2.6.

functools.partial(func[, *args][, **keywords])

Return a new partial object which when called will behave like func called with the positional arguments args and keyword arguments keywords. If more arguments are supplied to the call, they are appended to args. If additional keyword arguments are supplied, they extend and override keywords. Roughly equivalent to:

```python
def partial(func, *args, **keywords):
    def newfunc(*fargs, **fkeywords):
        newkeywords = keywords.copy()
        newkeywords.update(fkeywords)
        return func(*(args + fargs), **newkeywords)
    newfunc.func = func
```
The `partial()` is used for partial function application which “freezes” some portion of a function’s arguments and/or keywords resulting in a new object with a simplified signature. For example, `partial()` can be used to create a callable that behaves like the `int()` function where the `base` argument defaults to two:

```python
>>> from functools import partial
>>> basetwo = partial(int, base=2)
>>> basetwo.__doc__ = 'Convert base 2 string to an int.'
>>> basetwo('10010')
18
```

`functools.update_wrapper(wrapper, wrapped[, assigned][, updated])`

Update a `wrapper` function to look like the `wrapped` function. The optional arguments are tuples to specify which attributes of the original function are assigned directly to the matching attributes on the wrapper function and which attributes of the wrapper function are updated with the corresponding attributes from the original function. The default values for these arguments are the module level constants `WRAPPER_ASSIGNMENTS` (which assigns to the wrapper function’s `__name__`, `__module__` and `__doc__`, the documentation string) and `WRAPPER_UPDATES` (which updates the wrapper function’s `__dict__`, i.e. the instance dictionary).

The main intended use for this function is in `decorator` functions which wrap the decorated function and return the wrapper. If the wrapper function is not updated, the metadata of the returned
function will reflect the wrapper definition rather than the original function definition, which is typically less than helpful.

functools.\texttt{wraps}([\texttt{wrapped}, \texttt{assigned}], \texttt{updated}])

This is a convenience function for invoking \texttt{partial(update_wrapper, wrapped=wrapped, assigned=assigned, updated=updated)} as a function decorator when defining a wrapper function. For example:

```python
>>> from functools import wraps
>>> def my_decorator(f):
...     @wraps(f)
...     def wrapper(*args, **kwds):
...         print 'Calling decorated function'
...         return f(*args, **kwds)
...     return wrapper
...

>>> @my_decorator
... def example():
...     """Docstring""
...     print 'Called example function'
...

>>> example()
Calling decorated function
Called example function

>>> example.__name__
'example'

>>> example.__doc__
'Docstring'
```

Without the use of this decorator factory, the name of the example function would have been 'wrapper', and the docstring of the original \texttt{example()} would have been lost.
**partial Objects**

`partial` objects are callable objects created by `partial()`. They have three read-only attributes:

- **`partial.func`**
  A callable object or function. Calls to the `partial` object will be forwarded to `func` with new arguments and keywords.

- **`partial.args`**
  The leftmost positional arguments that will be prepended to the positional arguments provided to a `partial` object call.

- **`partial.keywords`**
  The keyword arguments that will be supplied when the `partial` object is called.

`partial` objects are like `function` objects in that they are callable, weak referencable, and can have attributes. There are some important differences. For instance, the `__name__` and `__doc__` attributes are not created automatically. Also, `partial` objects defined in classes behave like static methods and do not transform into bound methods during instance attribute look-up.
The **operator** module exports a set of functions implemented in C corresponding to the intrinsic operators of Python. For example, `operator.add(x, y)` is equivalent to the expression `x+y`. The function names are those used for special class methods; variants without leading and trailing `__` are also provided for convenience.

The functions fall into categories that perform object comparisons, logical operations, mathematical operations, sequence operations, and abstract type tests.

The object comparison functions are useful for all objects, and are named after the rich comparison operators they support:

```python
operator.lt(a, b)
operator.le(a, b)
operator.eq(a, b)
operator.ne(a, b)
operator.ge(a, b)
operator.gt(a, b)
operator.__lt__(a, b)
operator.__le__(a, b)
operator.__eq__(a, b)
operator.__ne__(a, b)
operator.__ge__(a, b)
operator.__gt__(a, b)
```

Perform “rich comparisons” between `a` and `b`. Specifically, `lt(a, b)` is equivalent to `a < b`, `le(a, b)` is equivalent to `a <= b`, `eq(a, b)` is equivalent to `a == b`, `ne(a, b)` is equivalent to `a != b`, `gt(a, b)` is equivalent to `a > b` and `ge(a, b)` is equivalent to `a >= b`. 
Note that unlike the built-in `cmp()`, these functions can return any value, which may or may not be interpretable as a Boolean value. See *Comparisons* for more information about rich comparisons.

*New in version 2.2.*

The logical operations are also generally applicable to all objects, and support truth tests, identity tests, and boolean operations:

**operator**. `not_(obj)`
operator. `__not__(obj)`

Return the outcome of `not obj`. (Note that there is no `__not__()` method for object instances; only the interpreter core defines this operation. The result is affected by the `__nonzero__()` and `__len__()` methods.)

**operator**. `truth(obj)`

Return `True` if `obj` is true, and `False` otherwise. This is equivalent to using the `bool` constructor.

**operator**. `is_(a, b)`

Return `a is b`. Tests object identity.

*New in version 2.3.*

**operator**. `is_not(a, b)`

Return `a is not b`. Tests object identity.

*New in version 2.3.*

The mathematical and bitwise operations are the most numerous:

**operator**. `abs(obj)`
operator. `__abs__(obj)`

Return the absolute value of `obj`. 
operator. \texttt{add}(a, b) \\
operator. \texttt{__add__}(a, b) \\
    Return $a + b$, for $a$ and $b$ numbers.

operator. \texttt{and_}(a, b) \\
operator. \texttt{__and__}(a, b) \\
    Return the bitwise and of $a$ and $b$.

operator. \texttt{div}(a, b) \\
operator. \texttt{__div__}(a, b) \\
    Return $a / b$ when \_\_\_future\_.\_\_division is not in effect. This is also known as “classic” division.

operator. \texttt{floordiv}(a, b) \\
operator. \texttt{__floordiv__}(a, b) \\
    Return $a \mathbin{//} b$.

    \textit{New in version 2.2.}

operator. \texttt{inv}(obj) \\
operator. \texttt{invert}(obj) \\
operator. \texttt{__inv__}(obj) \\
operator. \texttt{__invert__}(obj) \\
    Return the bitwise inverse of the number \texttt{obj}. This is equivalent to $\overline{\texttt{obj}}$.

    \textit{New in version 2.0: The names \texttt{invert()} and \texttt{__invert__}.}

operator. \texttt{lshift}(a, b) \\
operator. \texttt{__lshift__}(a, b) \\
    Return $a$ shifted left by $b$.

operator. \texttt{mod}(a, b) \\
operator. \texttt{__mod__}(a, b)
Return \( a \ % \ b \).

```python
operator.mul(a, b)
operator.__mul__(a, b)
```

Return \( a \ * \ b \), for \( a \) and \( b \) numbers.

```python
operator.neg(obj)
operator.__neg__(obj)
```

Return \( obj \) negated.

```python
operator.or_(a, b)
operator.__or__(a, b)
```

Return the bitwise or of \( a \) and \( b \).

```python
operator.pos(obj)
operator.__pos__(obj)
```

Return \( obj \) positive.

```python
operator.pow(a, b)
operator.__pow__(a, b)
```

Return \( a \ ** \ b \), for \( a \) and \( b \) numbers.

*New in version 2.3.*

```python
operator.rshift(a, b)
operator.__rshift__(a, b)
```

Return \( a \) shifted right by \( b \).

```python
operator.sub(a, b)
operator.__sub__(a, b)
```

Return \( a \ - \ b \).

```python
operator.truediv(a, b)
operator.__truediv__(a, b)
```
Return \( a \div b \) when \_future\_.division is in effect. This is also known as “true” division.

*New in version 2.2.*

```python
operator.xor(a, b)
operator.__xor__(a, b)
```

Return the bitwise exclusive or of \( a \) and \( b \).

```python
operator.index(a)
operator.__index__(a)
```

Return \( a \) converted to an integer. Equivalent to \( a.__index__() \).

*New in version 2.5.*

Operations which work with sequences include:

```python
operator.concat(a, b)
operator.__concat__(a, b)
```

Return \( a + b \) for \( a \) and \( b \) sequences.

```python
operator.contains(a, b)
operator.__contains__(a, b)
```

Return the outcome of the test \( b \) in \( a \). Note the reversed operands.

*New in version 2.0: The name \_contains\_().*

```python
operator.countOf(a, b)
```

Return the number of occurrences of \( b \) in \( a \).

```python
operator.delitem(a, b)
operator.__delitem__(a, b)
```

Remove the value of \( a \) at index \( b \).
operator. **delslice***(a, b, c)*
operator. **_delslice_***(a, b, c)*

Delete the slice of *a* from index *b* to index *c-1*.

operator. **getitem**(a, b)
operator. **__getitem__**(a, b)

Return the value of *a* at index *b*.

operator. **getslice**(a, b, c)
operator. **__getslice__**(a, b, c)

Return the slice of *a* from index *b* to index *c-1*.

operator. **indexOf**(a, b)

Return the index of the first occurrence of *b* in *a*.

operator. **repeat**(a, b)
operator. **__repeat__**(a, b)

Return *a* * b where *a* is a sequence and *b* is an integer.

operator. **sequenceIncludes**(…)  

*Deprecated since version 2.0:* Use **contains()** instead.

Alias for **contains()**.

operator. **setitem**(a, b, c)
operator. **__setitem__**(a, b, c)

Set the value of *a* at index *b* to *c*.

operator. **setslice**(a, b, c, v)
operator. **__setslice__**(a, b, c, v)

Set the slice of *a* from index *b* to index *c-1* to the sequence *v*.

Many operations have an “in-place” version. The following functions provide a more primitive access to in-place operators than the usual
syntax does; for example, the statement \( x += y \) is equivalent to \( x = \) operator.iadd(x, y). Another way to put it is to say that \( z = \) operator.iadd(x, y) is equivalent to the compound statement \( z = x; z += y \).

```
operator.iadd(a, b)
```
```
operator.__iadd__(a, b)
a = iadd(a, b) is equivalent to a += b.
```

*New in version 2.5.*

```
operator.iand(a, b)
```
```
operator.__iand__(a, b)
a = iand(a, b) is equivalent to a &\= b.
```

*New in version 2.5.*

```
operator.iconcat(a, b)
```
```
operator.__iconcat__(a, b)
a = iconcat(a, b) is equivalent to a += b for a and b sequences.
```

*New in version 2.5.*

```
operator.idiv(a, b)
```
```
operator.__idiv__(a, b)
a = idiv(a, b) is equivalent to a /= b when __future__.division is not in effect.
```

*New in version 2.5.*

```
operator.ifloordiv(a, b)
```
```
operator.__ifloordiv__(a, b)
a = ifloordiv(a, b) is equivalent to a //= b.
```
New in version 2.5.

operator.ilshift(a, b)
operator.__ilshift__(a, b)
    a = ilshift(a, b) is equivalent to a <<= b.

New in version 2.5.

operator.imod(a, b)
operator.__imod__(a, b)
    a = imod(a, b) is equivalent to a %= b.

New in version 2.5.

operator.imul(a, b)
operator.__imul__(a, b)
    a = imul(a, b) is equivalent to a *= b.

New in version 2.5.

operator.ior(a, b)
operator.__ior__(a, b)
    a = ior(a, b) is equivalent to a |= b.

New in version 2.5.

operator.ipow(a, b)
operator.__ipow__(a, b)
    a = ipow(a, b) is equivalent to a **= b.

New in version 2.5.

operator.irepeat(a, b)
operator.__irepeat__(a, b)
    a = irepeat(a, b) is equivalent to a *= b where a is a sequence
and $b$ is an integer.

*New in version 2.5.*

```python
operator.irshift(a, b)
operator.__irshift__(a, b)
    a = irshift(a, b) is equivalent to $a >>= b$.
```

*New in version 2.5.*

```python
operator.isub(a, b)
operator.__isub__(a, b)
    a = isub(a, b) is equivalent to $a -= b$.
```

*New in version 2.5.*

```python
operator.itruediv(a, b)
operator.__itruediv__(a, b)
    a = itruediv(a, b) is equivalent to $a /= b$ when __future__.division is in effect.
```

*New in version 2.5.*

```python
operator.ixor(a, b)
operator.__ixor__(a, b)
    a = ixor(a, b) is equivalent to $a ^= b$.
```

*New in version 2.5.*

The `operator` module also defines a few predicates to test the type of objects.

**Note:** Be careful not to misinterpret the results of these functions; only `iscallable()` has any measure of reliability with instance objects. For example:
```python
>>> class C:
...     pass
...
>>> import operator
>>> obj = C()
>>> operator.isMappingType(obj)
True
```

**Note:** Python 3 is expected to introduce abstract base classes for collection types, so it should be possible to write, for example, `isinstance(obj, collections.Mapping) and isinstance(obj, collections.Sequence)`.

`operator.isCallable(obj)`

*Deprecated since version 2.0:* Use the `callable()` built-in function instead.

Returns true if the object `obj` can be called like a function, otherwise it returns false. True is returned for functions, bound and unbound methods, class objects, and instance objects which support the `__call__()` method.

`operator.isMappingType(obj)`

Returns true if the object `obj` supports the mapping interface. This is true for dictionaries `obj` and all instance objects defining `__getitem__()`.

**Warning:** There is no reliable way to test if an instance supports the complete mapping protocol since the interface itself is ill-defined. This makes this test less useful than it otherwise might be.

`operator.isNumberType(obj)`

Returns true if the object `obj` represents a number. This is true for
all numeric types implemented in C.

**Warning:** There is no reliable way to test if an instance supports the complete numeric interface since the interface itself is ill-defined. This makes this test less useful than it otherwise might be.

```
operator.isSequenceType(obj)
```

Returns true if the object `obj` supports the sequence protocol. This returns true for all objects which define sequence methods in C, and for all instance objects defining `__getitem__()`.

**Warning:** There is no reliable way to test if an instance supports the complete sequence interface since the interface itself is ill-defined. This makes this test less useful than it otherwise might be.

Example: Build a dictionary that maps the ordinals from 0 to 255 to their character equivalents.

```
>>> d = {}
>>> keys = range(256)
>>> vals = map(chr, keys)
>>> map(operator.setitem, [d]*len(keys), keys, vals)  # doctest
```

The `operator` module also defines tools for generalized attribute and item lookups. These are useful for making fast field extractors as arguments for `map()`, `sorted()`, `itertools.groupby()`, or other functions that expect a function argument.

```
operator.attrgetter(attr[, args...])
```

Return a callable object that fetches `attr` from its operand. If more than one attribute is requested, returns a tuple of attributes. After, 
```
f = attrgetter('name'), the call f(b) returns b.name. After, f =
```
attrgetter('name', 'date'), the call f(b) returns (b.name, b.date).

The attribute names can also contain dots; after f = attrgetter('date.month'), the call f(b) returns b.date.month.

New in version 2.4.

Changed in version 2.5: Added support for multiple attributes.

Changed in version 2.6: Added support for dotted attributes.

operator.itemgetter(item[, args...])
Return a callable object that fetches item from its operand using the operand's __getitem__() method. If multiple items are specified, returns a tuple of lookup values. Equivalent to:

```python
def itemgetter(*items):
    if len(items) == 1:
        item = items[0]
        def g(obj):
            return obj[item]
    else:
        def g(obj):
            return tuple(obj[item] for item in items)
    return g
```

The items can be any type accepted by the operand's __getitem__() method. Dictionaries accept any hashable value. Lists, tuples, and strings accept an index or a slice:

```python
>>> itemgetter(1)(['ABCDEFG'])
'B'
>>> itemgetter(1, 3, 5)(['ABCDEFG'])
```
New in version 2.4.

Changed in version 2.5: Added support for multiple item extraction.

Example of using `itemgetter()` to retrieve specific fields from a tuple record:

```python
>>> inventory = [('apple', 3), ('banana', 2), ('pear', 5), ('orange', 1)]
>>> getcount = itemgetter(1)
>>> map(getcount, inventory)
[3, 2, 5, 1]
>>> sorted(inventory, key=getcount)
[('orange', 1), ('banana', 2), ('apple', 3), ('pear', 5)]
```

`operator.methodcaller(name[, args...])`

Return a callable object that calls the method `name` on its operand. If additional arguments and/or keyword arguments are given, they will be given to the method as well. After `f = methodcaller('name')`, the call `f(b)` returns `b.name()`. After `f = methodcaller('name', 'foo', bar=1)`, the call `f(b)` returns `b.name('foo', bar=1).

New in version 2.6.
## Mapping Operators to Functions

This table shows how abstract operations correspond to operator symbols in the Python syntax and the functions in the `operator` module.

<table>

</table>
The modules described in this chapter deal with disk files and directories. For example, there are modules for reading the properties of files, manipulating paths in a portable way, and creating temporary files. The full list of modules in this chapter is:

- `os.path` — Common pathname manipulations
- `fileinput` — Iterate over lines from multiple input streams
- `stat` — Interpreting `stat` results
- `statvfs` — Constants used with `os.statvfs`
- `filecmp` — File and Directory Comparisons
  - The `dircmp` class
- `tempfile` — Generate temporary files and directories
- `glob` — Unix style pathname pattern expansion
- `fnmatch` — Unix filename pattern matching
- `linecache` — Random access to text lines
- `shutil` — High-level file operations
  - Example
- `dircache` — Cached directory listings
- `macpath` — Mac OS 9 path manipulation functions

See also:
Section **File Objects**

A description of Python’s built-in file objects.

**Module os**

Operating system interfaces, including functions to work with files at a lower level than the built-in file object.
This module implements some useful functions on pathnames. To read or write files see `open()`, and for accessing the filesystem see the `os` module.

**Warning:** On Windows, many of these functions do not properly support UNC pathnames. `splitunc()` and `ismount()` do handle them correctly.

- **os.path.abspath(path)**
  Return a normalized absolutized version of the pathname `path`. On most platforms, this is equivalent to `normpath(join(os.getcwd(), path))`. 
  
  *New in version 1.5.2.*

- **os.path.basename(path)**
  Return the base name of pathname `path`. This is the second half of the pair returned by `split(path)`. Note that the result of this function is different from the Unix `basename` program; where `basename` for `/foo/bar/` returns `bar`, the `basename()` function returns an empty string (`''`).

- **os.path.commonprefix(list)**
  Return the longest path prefix (taken character-by-character) that is a prefix of all paths in `list`. If `list` is empty, return the empty string (`''`). Note that this may return invalid paths because it works a character at a time.

- **os.path.dirname(path)**
Return the directory name of pathname `path`. This is the first half of the pair returned by `split(path)`.

`os.path.exists(path)`

Return `True` if `path` refers to an existing path. Returns `False` for broken symbolic links. On some platforms, this function may return `False` if permission is not granted to execute `os.stat()` on the requested file, even if the `path` physically exists.

`os.path.lexists(path)`

Return `True` if `path` refers to an existing path. Returns `True` for broken symbolic links. Equivalent to `exists()` on platforms lacking `os.lstat()`.

*New in version 2.4.*

`os.path.expanduser(path)`

On Unix and Windows, return the argument with an initial component of `~` or `~user` replaced by that user’s home directory.

On Unix, an initial `~` is replaced by the environment variable `HOME` if it is set; otherwise the current user’s home directory is looked up in the password directory through the built-in module `pwd`. An initial `~user` is looked up directly in the password directory.

On Windows, `HOME` and `USERPROFILE` will be used if set, otherwise a combination of `HOMEPATH` and `HOMEDRIVE` will be used. An initial `~user` is handled by stripping the last directory component from the created user path derived above.

If the expansion fails or if the path does not begin with a tilde, the path is returned unchanged.
os.path.expandvars(path)
Return the argument with environment variables expanded. Substrings of the form $name$ or ${name}$ are replaced by the value of environment variable name. Malformed variable names and references to non-existing variables are left unchanged.

On Windows, %name% expansions are supported in addition to $name$ and ${name}$.

os.path.getatime(path)
Return the time of last access of path. The return value is a number giving the number of seconds since the epoch (see the time module). Raise os.error if the file does not exist or is inaccessible.

New in version 1.5.2.

Changed in version 2.3: If os.stat_float_times() returns True, the result is a floating point number.

os.path.getmtime(path)
Return the time of last modification of path. The return value is a number giving the number of seconds since the epoch (see the time module). Raise os.error if the file does not exist or is inaccessible.

New in version 1.5.2.

Changed in version 2.3: If os.stat_float_times() returns True, the result is a floating point number.

os.path.getctime(path)
Return the system’s ctime which, on some systems (like Unix) is the time of the last change, and, on others (like Windows), is the creation time for path. The return value is a number giving the
number of seconds since the epoch (see the time module). Raise os.error if the file does not exist or is inaccessible.

New in version 2.3.

os.path.getsize(path)
Return the size, in bytes, of path. Raise os.error if the file does not exist or is inaccessible.

New in version 1.5.2.

os.path.isabs(path)
Return True if path is an absolute pathname. On Unix, that means it begins with a slash, on Windows that it begins with a (back)slash after chopping off a potential drive letter.

os.path.isfile(path)
Return True if path is an existing regular file. This follows symbolic links, so both islink() and.isfile() can be true for the same path.

os.path.isdir(path)
Return True if path is an existing directory. This follows symbolic links, so both islink() and isdir() can be true for the same path.

os.path.islink(path)
Return True if path refers to a directory entry that is a symbolic link. Always False if symbolic links are not supported.

os.path.ismount(path)
Return True if path is a mount point: a point in a file system where a different file system has been mounted. The function checks whether path's parent, path/.., is on a different
device than \textit{path}, or whether \texttt{path/../} and \textit{path} point to the same
i-node on the same device — this should detect mount points for
all Unix and POSIX variants.

\begin{verbatim}
\texttt{os.path.join(path1[, path2[, ...]])}
\end{verbatim}

Join one or more path components intelligently. If any component
is an absolute path, all previous components (on Windows,
including the previous drive letter, if there was one) are thrown
away, and joining continues. The return value is the
concatenation of \textit{path1}, and optionally \textit{path2}, etc., with exactly
one directory separator (\texttt{os.sep}) inserted between components,
unless \textit{path2} is empty. Note that on Windows, since there is a
current directory for each drive, \texttt{os.path.join("c:", "foo")}
represents a path relative to the current directory on drive c:
\texttt{(c:foo)}, not \texttt{c:\foo}.

\begin{verbatim}
\texttt{os.path.normcase(path)}
\end{verbatim}

Normalize the case of a pathname. On Unix, this returns the path
unchanged; on case-insensitive filesystems, it converts the path
to lowercase. On Windows, it also converts forward slashes to
backward slashes.

\begin{verbatim}
\texttt{os.path.normpath(path)}
\end{verbatim}

Normalize a pathname. This collapses redundant separators and
up-level references so that $A//B, A./B$ and $A/foo/../B$ all
become $A/B$. It does not normalize the case (use \texttt{normcase()} for
that). On Windows, it converts forward slashes to backward
slashes. It should be understood that this may change the
meaning of the path if it contains symbolic links!

\begin{verbatim}
\texttt{os.path.realpath(path)}
\end{verbatim}

Return the canonical path of the specified filename, eliminating
any symbolic links encountered in the path (if they are supported
by the operating system).

*New in version 2.2.*

**os.path.relpath(path[, start])**

Return a relative filepath to `path` either from the current directory or from an optional `start` point.

`start` defaults to `os.curdir`. Availability: Windows, Unix.

*New in version 2.6.*

**os.path.samefile(path1, path2)**

Return `True` if both pathname arguments refer to the same file or directory (as indicated by device number and i-node number). Raise an exception if a `os.stat()` call on either pathname fails. Availability: Unix.

**os.path.sameopenfile(fp1, fp2)**

Return `True` if the file descriptors `fp1` and `fp2` refer to the same file. Availability: Unix.

**os.path.samestat(stat1, stat2)**

Return `True` if the stat tuples `stat1` and `stat2` refer to the same file. These structures may have been returned by `fstat()`, `lstat()`, or `stat()`. This function implements the underlying comparison used by `samefile()` and `sameopenfile()`. Availability: Unix.

**os.path.split(path)**

Split the pathname `path` into a pair, `(head, tail)` where `tail` is the last pathname component and `head` is everything leading up to that. The `tail` part will never contain a slash; if `path` ends in a slash, `tail` will be empty. If there is no slash in `path`, `head` will be
empty. If path is empty, both head and tail are empty. Trailing slashes are stripped from head unless it is the root (one or more slashes only). In nearly all cases, join(head, tail) equals path (the only exception being when there were multiple slashes separating head from tail).

os.path.splitdrive(path)
Split the pathname path into a pair (drive, tail) where drive is either a drive specification or the empty string. On systems which do not use drive specifications, drive will always be the empty string. In all cases, drive + tail will be the same as path.

New in version 1.3.

os.path.splitext(path)
Split the pathname path into a pair (root, ext) such that root + ext == path, and ext is empty or begins with a period and contains at most one period. Leading periods on the basename are ignored; splitext('.cshrc') returns ('.cshrc', '').

Changed in version 2.6: Earlier versions could produce an empty root when the only period was the first character.

os.path.splitunc(path)
Split the pathname path into a pair (unc, rest) so that unc is the UNC mount point (such as r'\host\mount'), if present, and rest the rest of the path (such as r'\path\file.ext'). For paths containing drive letters, unc will always be the empty string. Availability: Windows.

os.path.walk(path, visit, arg)
Calls the function visit with arguments (arg, dirname, names) for each directory in the directory tree rooted at path (including path itself, if it is a directory). The argument dirname specifies the
visited directory, the argument *names* lists the files in the directory (gotten from `os.listdir(dirname)`). The *visit* function may modify *names* to influence the set of directories visited below *dirname*, e.g. to avoid visiting certain parts of the tree. (The object referred to by *names* must be modified in place, using `del` or slice assignment.)

**Note:** Symbolic links to directories are not treated as subdirectories, and that `walk()` therefore will not visit them. To visit linked directories you must identify them with `os.path.islink(file)` and `os.path.isdir(file)`, and invoke `walk()` as necessary.

**Warning:** This function is deprecated and has been removed in 3.0 in favor of `os.walk()`.

```
import os

os.path.supports_unicode_filenames
```

`os.path.supports_unicode_filenames`

True if arbitrary Unicode strings can be used as file names (within limitations imposed by the file system), and if `os.listdir()` returns Unicode strings for a Unicode argument.

*New in version 2.3.*
This module implements a helper class and functions to quickly write a loop over standard input or a list of files. If you just want to read or write one file see `open()`.

The typical use is:

```python
import fileinput
for line in fileinput.input():
    process(line)
```

This iterates over the lines of all files listed in `sys.argv[1:]`, defaulting to `sys.stdin` if the list is empty. If a filename is `-`, it is also replaced by `sys.stdin`. To specify an alternative list of filenames, pass it as the first argument to `input()`. A single file name is also allowed.

All files are opened in text mode by default, but you can override this by specifying the `mode` parameter in the call to `input()` or `FileInput()`. If an I/O error occurs during opening or reading a file, `IOError` is raised.

If `sys.stdin` is used more than once, the second and further use will return no lines, except perhaps for interactive use, or if it has been explicitly reset (e.g. using `sys.stdin.seek(0)`).

Empty files are opened and immediately closed; the only time their presence in the list of filenames is noticeable at all is when the last file opened is empty.

Lines are returned with any newlines intact, which means that the
last line in a file may not have one.

You can control how files are opened by providing an opening hook via the openhook parameter to `fileinput.input()` or `FileInput()`. The hook must be a function that takes two arguments, `filename` and `mode`, and returns an accordingly opened file-like object. Two useful hooks are already provided by this module.

The following function is the primary interface of this module:

```python
fileinput.input([files[, inplace[, backup[, mode[, openhook]]]]])
```

Create an instance of the `FileInput` class. The instance will be used as global state for the functions of this module, and is also returned to use during iteration. The parameters to this function will be passed along to the constructor of the `FileInput` class.

*Changed in version 2.5:* Added the `mode` and `openhook` parameters.

The following functions use the global state created by `fileinput.input()`; if there is no active state, `RuntimeError` is raised.

```python
fileinput.filename()
```

Return the name of the file currently being read. Before the first line has been read, returns `None`.

```python
fileinput.fileno()
```

Return the integer “file descriptor” for the current file. When no file is opened (before the first line and between files), returns `-1`.

*New in version 2.5.*

```python
fileinput.lineno()
```

Return the cumulative line number of the line that has just been read. Before the first line has been read, returns `0`. After the last
line of the last file has been read, returns the line number of that line.

fileinput. **filelineno()**
Return the line number in the current file. Before the first line has been read, returns 0. After the last line of the last file has been read, returns the line number of that line within the file.

fileinput. **isfirstline()**
Returns true if the line just read is the first line of its file, otherwise returns false.

fileinput. **isstdin()**
Returns true if the last line was read from **sys.stdin**, otherwise returns false.

fileinput. **nextfile()**
Close the current file so that the next iteration will read the first line from the next file (if any); lines not read from the file will not count towards the cumulative line count. The filename is not changed until after the first line of the next file has been read. Before the first line has been read, this function has no effect; it cannot be used to skip the first file. After the last line of the last file has been read, this function has no effect.

fileinput. **close()**
Close the sequence.

The class which implements the sequence behavior provided by the module is available for subclassing as well:

```python
class fileinput.FileInput([files[, inplace[, backup[, mode[, openhook]]]]])
```
Class **FileInput** is the implementation; its methods **filename()**, **filelineno()**, **isfirstline()**, **isstdin()**, **nextfile()**, and **close()** are provided.
fileno(), lineno(), filelineno(), isfirstline(), isstdin(), nextfile() and close() correspond to the functions of the same name in the module. In addition it has a readline() method which returns the next input line, and a __getitem__() method which implements the sequence behavior. The sequence must be accessed in strictly sequential order; random access and readline() cannot be mixed.

With mode you can specify which file mode will be passed to open(). It must be one of 'r', 'rU', 'U' and 'rb'.

The openhook, when given, must be a function that takes two arguments, filename and mode, and returns an accordingly opened file-like object. You cannot use inplace and openhook together.

*Changed in version 2.5:* Added the mode and openhook parameters.

**Optional in-place filtering:** if the keyword argument inplace=1 is passed to fileinput.input() or to the FileInput constructor, the file is moved to a backup file and standard output is directed to the input file (if a file of the same name as the backup file already exists, it will be replaced silently). This makes it possible to write a filter that rewrites its input file in place. If the backup parameter is given (typically as backup='.<some_extension>'), it specifies the extension for the backup file, and the backup file remains around; by default, the extension is '.bak' and it is deleted when the output file is closed. In-place filtering is disabled when standard input is read.

**Warning:** The current implementation does not work for MS-DOS 8+3 filesystems.

The two following opening hooks are provided by this module:
fileinput.\texttt{hook\_compressed}(\texttt{filename}, \texttt{mode})

  Transparently opens files compressed with gzip and bzip2 (recognized by the extensions '.gz' and '.bz2') using the \texttt{gzip} and \texttt{bzip2} modules. If the filename extension is not '.gz' or '.bz2', the file is opened normally (ie, using \texttt{open()} without any decompression).

  Usage example: \begin{verbatim}
  fi = fileinput.FileInput(openhook=fileinput.hook_compressed)
  \end{verbatim}

  \textit{New in version 2.5.}

fileinput.\texttt{hook\_encoded}(\texttt{encoding})

  Returns a hook which opens each file with \texttt{codecs.open()}, using the given \texttt{encoding} to read the file.

  Usage example: \begin{verbatim}
  fi = fileinput.FileInput(openhook=fileinput.hook_encoded("iso-8859-1"))
  \end{verbatim}

  \textbf{Note}: With this hook, \texttt{FileInput} might return Unicode strings depending on the specified \texttt{encoding}.

  \textit{New in version 2.5.}
The `stat` module defines constants and functions for interpreting the results of `os.stat()`, `os.fstat()` and `os.lstat()` (if they exist). For complete details about the `stat`, `fstat` and `lstat` calls, consult the documentation for your system.

The `stat` module defines the following functions to test for specific file types:

- **`S_ISDIR(mode)`**
  Return non-zero if the mode is from a directory.

- **`S_ISCHR(mode)`**
  Return non-zero if the mode is from a character special device file.

- **`S_ISBLK(mode)`**
  Return non-zero if the mode is from a block special device file.

- **`S_ISREG(mode)`**
  Return non-zero if the mode is from a regular file.

- **`S_ISFIFO(mode)`**
  Return non-zero if the mode is from a FIFO (named pipe).

- **`S_ISLNK(mode)`**
  Return non-zero if the mode is from a symbolic link.

- **`S_ISSOCK(mode)`**
  Return non-zero if the mode is from a socket.

Two additional functions are defined for more general manipulation of the file’s mode:
stat.S_MODE

Return the portion of the file’s mode that can be set by os.chmod()—that is, the file’s permission bits, plus the sticky bit, set-group-id, and set-user-id bits (on systems that support them).

stat.S_IFMT

Return the portion of the file’s mode that describes the file type (used by the s_is*() functions above).

Normally, you would use the os.path.is*() functions for testing the type of a file; the functions here are useful when you are doing multiple tests of the same file and wish to avoid the overhead of the stat system call for each test. These are also useful when checking for information about a file that isn’t handled by os.path, like the tests for block and character devices.

All the variables below are simply symbolic indexes into the 10-tuple returned by os.stat(), os.fstat() or os.lstat().

stat.ST_MODE

Inode protection mode.

stat.ST_INO

Inode number.

stat.ST_DEV

Device inode resides on.

stat.ST_NLINK

Number of links to the inode.

stat.ST_UID

User id of the owner.

stat.ST_GID

Group id of the owner.
**stat.ST_SIZE**
Size in bytes of a plain file; amount of data waiting on some special files.

**stat.ST_ATIME**
Time of last access.

**stat.ST_MTIME**
Time of last modification.

**stat.ST_CTIME**
The “ctime” as reported by the operating system. On some systems (like Unix) is the time of the last metadata change, and, on others (like Windows), is the creation time (see platform documentation for details).

The interpretation of “file size” changes according to the file type. For plain files this is the size of the file in bytes. For FIFOs and sockets under most flavors of Unix (including Linux in particular), the “size” is the number of bytes waiting to be read at the time of the call to `os.stat()`, `os.fstat()`, or `os.lstat()`; this can sometimes be useful, especially for polling one of these special files after a non-blocking open. The meaning of the size field for other character and block devices varies more, depending on the implementation of the underlying system call.

Example:

```python
import os, sys
from stat import *

def walktree(top, callback):
    '''recursively descend the directory tree rooted at top, calling the callback function for each regular file'''

    for f in os.listdir(top):
        pathname = os.path.join(top, f)
        mode = os.stat(pathname)[ST_MODE]
        if S_ISDIR(mode):
```
# It's a directory, recurse into it
walktree(pathname, callback)

elif S_ISREG(mode):
    # It's a file, call the callback function
    callback(pathname)

else:
    # Unknown file type, print a message
    print 'Skipping %s' % pathname

def visitfile(file):
    print 'visiting', file

if __name__ == '__main__':
    walktree(sys.argv[1], visitfile)
The `statvfs` module defines constants so interpreting the result if `os.statvfs()`, which returns a tuple, can be made without remembering “magic numbers.” Each of the constants defined in this module is the index of the entry in the tuple returned by `os.statvfs()` that contains the specified information.

- `statvfs.F_BSIZE`  
  Preferred file system block size.

- `statvfs.F_FRSIZE`  
  Fundamental file system block size.

- `statvfs.F_BLOCKS`  
  Total number of blocks in the filesystem.

- `statvfs.F_BFREE`  
  Total number of free blocks.

- `statvfs.F_BAVAIL`  
  Free blocks available to non-super user.

- `statvfs.F_FILES`  
  Total number of file nodes.

- `statvfs.F_FFREE`  
  Total number of free file nodes.

- `statvfs.F_FAVAIL`  
  Free nodes available to non-super user.
statvfs. **F_FLAG**

Flags. System dependent: see `statvfs` man page.

statvfs. **F_NAMEMAX**

Maximum file name length.
The filecmp module defines functions to compare files and directories, with various optional time/correctness trade-offs. For comparing files, see also the difflib module.

The filecmp module defines the following functions:

```python
filecmp.cmp(f1, f2[, shallow])

Compare the files named f1 and f2, returning True if they seem equal, False otherwise.

Unless shallow is given and is false, files with identical os.stat() signatures are taken to be equal.

Files that were compared using this function will not be compared again unless their os.stat() signature changes.

Note that no external programs are called from this function, giving it portability and efficiency.
```

```python
filecmp.cmpfiles(dir1, dir2, common[, shallow])

Returns three lists of file names: match, mismatch, errors. match contains the list of files match in both directories, mismatch includes the names of those that don't, and errors lists the names of files which could not be compared. Files may be listed in errors because the user may lack permission to read them or many other reasons, but always that the comparison could not be done for some reason.

The common parameter is a list of file names found in both
directories. The *shallow* parameter has the same meaning and
default value as for *filecmp.cmp()*.

Example:

```python
>>> import filecmp
>>> filecmp.cmp('undoc.rst', 'undoc.rst')
True
>>> filecmp.cmp('undoc.rst', 'index.rst')
False
```
The **dircmp** class

**dircmp** instances are built using this constructor:

```python
class filecmp. dircmp(a, b[, ignore[, hide]]
```

Construct a new directory comparison object, to compare the directories `a` and `b`. `ignore` is a list of names to ignore, and defaults to `['RCS', 'CVS', 'tags']`. `hide` is a list of names to hide, and defaults to `[os.curdir, os.pardir]`.

The **dircmp** class provides the following methods:

- **report()**
  - Print (to `sys.stdout`) a comparison between `a` and `b`.

- **report_partial_closure()**
  - Print a comparison between `a` and `b` and common immediate subdirectories.

- **report_full_closure()**
  - Print a comparison between `a` and `b` and common subdirectories (recursively).

The **dircmp** offers a number of interesting attributes that may be used to get various bits of information about the directory trees being compared.

Note that via `__getattr__()` hooks, all attributes are computed lazily, so there is no speed penalty if only those attributes which are lightweight to compute are used.

- **left_list**
  - Files and subdirectories in `a`, filtered by `hide` and `ignore`.
right_list
Files and subdirectories in $b$, filtered by $hide$ and $ignore$.

common
Files and subdirectories in both $a$ and $b$.

left_only
Files and subdirectories only in $a$.

right_only
Files and subdirectories only in $b$.

common_dirs
Subdirectories in both $a$ and $b$.

common_files
Files in both $a$ and $b$.

common_funny
Names in both $a$ and $b$, such that the type differs between the directories, or names for which $os.stat()$ reports an error.

same_files
Files which are identical in both $a$ and $b$.

diff_files
Files which are in both $a$ and $b$, whose contents differ.

funny_files
Files which are in both $a$ and $b$, but could not be compared.

subdirs
A dictionary mapping names in $common_dirs$ to $dircmp$ objects.
This module generates temporary files and directories. It works on all supported platforms.

In version 2.3 of Python, this module was overhauled for enhanced security. It now provides three new functions, `NamedTemporaryFile()`, `mkstemp()`, and `mkdtemp()`, which should eliminate all remaining need to use the insecure `mktemp()` function. Temporary file names created by this module no longer contain the process ID; instead a string of six random characters is used.

Also, all the user-callable functions now take additional arguments which allow direct control over the location and name of temporary files. It is no longer necessary to use the global `tempdir` and `template` variables. To maintain backward compatibility, the argument order is somewhat odd; it is recommended to use keyword arguments for clarity.

The module defines the following user-callable functions:

```python
tempfile.TemporaryFile([mode='w+b', bufsize=-1, suffix='', prefix='tmp', dir=None])
```

Return a file-like object that can be used as a temporary storage area. The file is created using `mkstemp()`. It will be destroyed as soon as it is closed (including an implicit close when the object is garbage collected). Under Unix, the directory entry for the file is removed immediately after the file is created. Other platforms do not support this; your code should not rely on a temporary file created using this function having or not having a visible name in the file system.
The `mode` parameter defaults to `'w+b'` so that the file created can be read and written without being closed. Binary mode is used so that it behaves consistently on all platforms without regard for the data that is stored. `bufsize` defaults to `-1`, meaning that the operating system default is used.

The `dir`, `prefix` and `suffix` parameters are passed to `mkstemp()`.

The returned object is a true file object on POSIX platforms. On other platforms, it is a file-like object whose `file` attribute is the underlying true file object. This file-like object can be used in a `with` statement, just like a normal file.

```python
tempfile.NamedTemporaryFile([mode='w+b', bufsize=-1, suffix='', prefix='tmp', dir=None, delete=True])
```

This function operates exactly as `TemporaryFile()` does, except that the file is guaranteed to have a visible name in the file system (on Unix, the directory entry is not unlinked). That name can be retrieved from the `name` member of the file object. Whether the name can be used to open the file a second time, while the named temporary file is still open, varies across platforms (it can be so used on Unix; it cannot on Windows NT or later). If `delete` is true (the default), the file is deleted as soon as it is closed.

The returned object is always a file-like object whose `file` attribute is the underlying true file object. This file-like object can be used in a `with` statement, just like a normal file.

_New in version 2.3._

_New in version 2.6:_ The `delete` parameter.

```python
tempfile.SpooledTemporaryFile([max_size=0, mode='w+b', bufsize=-1, suffix='', prefix='tmp', dir=None])
```
This function operates exactly as `TemporaryFile()` does, except that data is spooled in memory until the file size exceeds `max_size`, or until the file's `fileno()` method is called, at which point the contents are written to disk and operation proceeds as with `TemporaryFile()`.

The resulting file has one additional method, `rollover()`, which causes the file to roll over to an on-disk file regardless of its size.

The returned object is a file-like object whose `_file` attribute is either a `StringIO` object or a true file object, depending on whether `rollover()` has been called. This file-like object can be used in a `with` statement, just like a normal file.

*New in version 2.6.*

```
    tempfile.mkstemp([suffix='', prefix='tmp', dir=None, text=False])
```

Creates a temporary file in the most secure manner possible. There are no race conditions in the file's creation, assuming that the platform properly implements the `os.O_EXCL` flag for `os.open()`. The file is readable and writable only by the creating user ID. If the platform uses permission bits to indicate whether a file is executable, the file is executable by no one. The file descriptor is not inherited by child processes.

Unlike `TemporaryFile()`, the user of `mkstemp()` is responsible for deleting the temporary file when done with it.

If `suffix` is specified, the file name will end with that suffix, otherwise there will be no suffix. `mkstemp()` does not put a dot between the file name and the suffix; if you need one, put it at the beginning of `suffix`.  

If *prefix* is specified, the file name will begin with that prefix; otherwise, a default prefix is used.

If *dir* is specified, the file will be created in that directory; otherwise, a default directory is used. The default directory is chosen from a platform-dependent list, but the user of the application can control the directory location by setting the `TMPDIR`, `TEMP` or `TMP` environment variables. There is thus no guarantee that the generated filename will have any nice properties, such as not requiring quoting when passed to external commands via `os.popen()`.

If *text* is specified, it indicates whether to open the file in binary mode (the default) or text mode. On some platforms, this makes no difference.

`mkstemp()` returns a tuple containing an OS-level handle to an open file (as would be returned by `os.open()`) and the absolute pathname of that file, in that order.

*New in version 2.3.*

`tempfile.mkdtemp([suffix='", prefix='tmp", dir=None]])]
` Creates a temporary directory in the most secure manner possible. There are no race conditions in the directory’s creation. The directory is readable, writable, and searchable only by the creating user ID.

The user of `mkdtemp()` is responsible for deleting the temporary directory and its contents when done with it.

The *prefix*, *suffix*, and *dir* arguments are the same as for `mkstemp()`.

`mkdtemp()` returns the absolute pathname of the new directory.
New in version 2.3.

tempfile.mktemp([suffix='', prefix='tmp', dir=None])

Deprecated since version 2.3: Use mkstemp() instead.

Return an absolute pathname of a file that did not exist at the
time the call is made. The prefix, suffix, and dir arguments are the
same as for mkstemp().

Warning: Use of this function may introduce a security hole in
your program. By the time you get around to doing anything
with the file name it returns, someone else may have beaten
you to the punch. mktemp() usage can be replaced easily with
NamedTemporaryFile(), passing it the delete=False parameter:

```python
>>> f = NamedTemporaryFile(delete=False)
>>> f
<open file '<fdopen>', mode 'w+b' at 0x384698>
>>> f.name
'/var/folders/5q/5qTPn6xq2RaWqk+1Ytw3-U+++TI/-Tmp/-tmpG7V1'
>>> f.write("Hello World!\n")
>>> f.close()
>>> os.unlink(f.name)
>>> os.path.exists(f.name)
False
```

The module uses two global variables that tell it how to construct a
temporary name. They are initialized at the first call to any of the
functions above. The caller may change them, but this is
discouraged; use the appropriate function arguments, instead.

tempfile.tempdir
When set to a value other than None, this variable defines the default value for the dir argument to all the functions defined in this module.

If tempdir is unset or None at any call to any of the above functions, Python searches a standard list of directories and sets tempdir to the first one which the calling user can create files in. The list is:

1. The directory named by the TMPDIR environment variable.
2. The directory named by the TEMP environment variable.
3. The directory named by the TMP environment variable.
4. A platform-specific location:
   - On RiscOS, the directory named by the Wimp$ScrapDir environment variable.
   - On Windows, the directories C:\TEMP, C:\TMP, \TEMP, and \TMP, in that order.
   - On all other platforms, the directories /tmp, /var/tmp, and /usr/tmp, in that order.
5. As a last resort, the current working directory.

tempfile.gettempdir()
Return the directory currently selected to create temporary files in. If tempdir is not None, this simply returns its contents; otherwise, the search described above is performed, and the result returned.

tempfile.template

Deprecated since version 2.0: Use gettempprefix() instead.

When set to a value other than None, this variable defines the prefix of the final component of the filenames returned by mktemp(). A string of six random letters and digits is appended to the prefix to make the filename unique. The default prefix is tmp.
Older versions of this module used to require that `template` be set to `None` after a call to `os.fork()`; this has not been necessary since version 1.5.2.

`tempfile.gettempprefix()`

Return the filename prefix used to create temporary files. This does not contain the directory component. Using this function is preferred over reading the `template` variable directly.

*New in version 1.5.2.*
The `glob` module finds all the pathnames matching a specified pattern according to the rules used by the Unix shell. No tilde expansion is done, but `*`, `?`, and character ranges expressed with `[]` will be correctly matched. This is done by using the `os.listdir()` and `fnmatch.fnmatch()` functions in concert, and not by actually invoking a subshell. (For tilde and shell variable expansion, use `os.path.expanduser()` and `os.path.expandvars()`.)

### `glob.glob(pathname)`

Return a possibly-empty list of path names that match `pathname`, which must be a string containing a path specification. `pathname` can be either absolute (like `/usr/src/Python-1.5/Makefile`) or relative (like `../Tools/*//*.gif`), and can contain shell-style wildcards. Broken symlinks are included in the results (as in the shell).

### `glob.iglob(pathname)`

Return an iterator which yields the same values as `glob()` without actually storing them all simultaneously.

*New in version 2.5.*

For example, consider a directory containing only the following files: `1.gif`, `2.txt`, and `card.gif`. `glob()` will produce the following results. Notice how any leading components of the path are preserved.

```python
>>> import glob
>>> glob.glob('./[0-9].*')
['./1.gif', './2.txt']
>>> glob.glob('*.gif')
['1.gif', 'card.gif']
```
>>> glob.glob('?.gif')
['1.gif']

See also:

Module `fnmatch`

Shell-style filename (not path) expansion
This module provides support for Unix shell-style wildcards, which are not the same as regular expressions (which are documented in the re module). The special characters used in shell-style wildcards are:

<table>
<thead>
<tr>
<th>Pattern</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>*</td>
<td>matches everything</td>
</tr>
<tr>
<td>?</td>
<td>matches any single character</td>
</tr>
<tr>
<td>[seq]</td>
<td>matches any character in seq</td>
</tr>
<tr>
<td>[!seq]</td>
<td>matches any character not in seq</td>
</tr>
</tbody>
</table>

Note that the filename separator (’/’ on Unix) is not special to this module. See module glob for pathname expansion (glob uses fnmatch() to match pathname segments). Similarly, filenames starting with a period are not special for this module, and are matched by the * and ? patterns.

`fnmatch.fnmatch(filename, pattern)`

Test whether the filename string matches the pattern string, returning true or false. If the operating system is case-insensitive, then both parameters will be normalized to all lower- or upper-case before the comparison is performed. If you require a case-sensitive comparison regardless of whether that’s standard for your operating system, use fnmatchcase() instead.

This example will print all file names in the current directory with the extension .txt:
import os

for file in os.listdir('.
    if fnmatch.fnmatch(file, '*.txt'):
        print file

fnmatch.fnmatchcase(filename, pattern)
    Test whether filename matches pattern, returning true or false; the comparison is case-sensitive.

fnmatch.filter(names, pattern)
    Return the subset of the list of names that match pattern. It is the same as [n for n in names if fnmatch(n, pattern)], but implemented more efficiently.

    New in version 2.2.

fnmatch.translate(pattern)
    Return the shell-style pattern converted to a regular expression.

Example:

>>> import fnmatch, re
>>> regex = fnmatch.translate('*.txt')
>>> regex
'\.*\.txt$'
>>> reobj = re.compile(regex)
>>> print reobj.match('foobar.txt')
<_sre.SRE_Match object at 0x...>

See also:

Module glob
    Unix shell-style path expansion.
linecache — Random access to text lines

The linecache module allows one to get any line from any file, while attempting to optimize internally, using a cache, the common case where many lines are read from a single file. This is used by the traceback module to retrieve source lines for inclusion in the formatted traceback.

The linecache module defines the following functions:

linecache.getline(filename, lineno[, module_globals])
Get line lineno from file named filename. This function will never throw an exception — it will return '' on errors (the terminating newline character will be included for lines that are found).

If a file named filename is not found, the function will look for it in the module search path, sys.path, after first checking for a PEP 302 __loader__ in module_globals, in case the module was imported from a zipfile or other non-filesystem import source.

New in version 2.5: The module_globals parameter was added.

linecache.clearcache()
Clear the cache. Use this function if you no longer need lines from files previously read using getline().

linecache.checkcache([filename])
Check the cache for validity. Use this function if files in the cache may have changed on disk, and you require the updated version. If filename is omitted, it will check all the entries in the cache.
Example:

```python
>>> import linecache
>>> linecache.getline('/etc/passwd', 4)
'sys:x:3:3:sys:/dev:/bin/sh
'
The `shutil` module offers a number of high-level operations on files and collections of files. In particular, functions are provided which support file copying and removal. For operations on individual files, see also the `os` module.

**Warning:** Even the higher-level file copying functions (`copy()`, `copy2()`) can't copy all file metadata. On POSIX platforms, this means that file owner and group are lost as well as ACLs. On Mac OS, the resource fork and other metadata are not used. This means that resources will be lost and file type and creator codes will not be correct. On Windows, file owners, ACLs and alternate data streams are not copied.

`shutil.copyfileobj(fsrc, fdst[, length])`

Copy the contents of the file-like object `fsrc` to the file-like object `fdst`. The integer `length`, if given, is the buffer size. In particular, a negative `length` value means to copy the data without looping over the source data in chunks; by default the data is read in chunks to avoid uncontrolled memory consumption. Note that if the current file position of the `fsrc` object is not 0, only the contents from the current file position to the end of the file will be copied.

`shutil.copyfile(src, dst)`

Copy the contents (no metadata) of the file named `src` to a file named `dst`. `dst` must be the complete target file name; look at `copy()` for a copy that accepts a target directory path. The destination location must be writable; otherwise, an `IOError` exception will be raised. If `dst` already exists, it will be replaced. Special files such as character or block devices and pipes cannot
be copied with this function. \textit{src} and \textit{dst} are path names given as strings.

\texttt{shutil.copymode(src, dst)}

Copy the permission bits from \textit{src} to \textit{dst}. The file contents, owner, and group are unaffected. \textit{src} and \textit{dst} are path names given as strings.

\texttt{shutil.copystat(src, dst)}

Copy the permission bits, last access time, last modification time, and flags from \textit{src} to \textit{dst}. The file contents, owner, and group are unaffected. \textit{src} and \textit{dst} are path names given as strings.

\texttt{shutil.copy(src, dst)}

Copy the file \textit{src} to the file or directory \textit{dst}. If \textit{dst} is a directory, a file with the same basename as \textit{src} is created (or overwritten) in the directory specified. Permission bits are copied. \textit{src} and \textit{dst} are path names given as strings.

\texttt{shutil.copy2(src, dst)}

Similar to \texttt{copy()}, but metadata is copied as well – in fact, this is just \texttt{copy()} followed by \texttt{copystat()}. This is similar to the Unix command \texttt{cp -p}.

\texttt{shutil.ignore_patterns(*patterns)}

This factory function creates a function that can be used as a callable for \texttt{copytree()}'s \texttt{ignore} argument, ignoring files and directories that match one of the glob-style \texttt{patterns} provided. See the example below.

\textit{New in version 2.6.}

\texttt{shutil.copytree(src, dst[, symlinks=False[, ignore=None]])}

Recursively copy an entire directory tree rooted at \textit{src}. The
destination directory, named by *dst*, must not already exist; it will be created as well as missing parent directories. Permissions and times of directories are copied with `copystat()`, individual files are copied using `copy2()`.

If `symlinks` is true, symbolic links in the source tree are represented as symbolic links in the new tree; if false or omitted, the contents of the linked files are copied to the new tree.

If `ignore` is given, it must be a callable that will receive as its arguments the directory being visited by `copytree()`, and a list of its contents, as returned by `os.listdir()`. Since `copytree()` is called recursively, the `ignore` callable will be called once for each directory that is copied. The callable must return a sequence of directory and file names relative to the current directory (i.e. a subset of the items in its second argument); these names will then be ignored in the copy process. `ignore_patterns()` can be used to create such a callable that ignores names based on glob-style patterns.

If exception(s) occur, an `Error` is raised with a list of reasons.

The source code for this should be considered an example rather than the ultimate tool.

*Changed in version 2.3:* `Error` is raised if any exceptions occur during copying, rather than printing a message.

*Changed in version 2.5:* Create intermediate directories needed to create `dst`, rather than raising an error. Copy permissions and times of directories using `copystat()`.

*Changed in version 2.6:* Added the `ignore` argument to be able to influence what is being copied.
shutil.rmtree(path[, ignore_errors[, onerror]])
Delete an entire directory tree; path must point to a directory (but
not a symbolic link to a directory). If ignore_errors is true, errors
resulting from failed removals will be ignored; if false or omitted,
such errors are handled by calling a handler specified by onerror
or, if that is omitted, they raise an exception.

If onerror is provided, it must be a callable that accepts three
parameters: function, path, and excinfo. The first parameter,
function, is the function which raised the exception; it will be
os.path.islink(), os.listdir(), os.remove() or os.rmdir(). The
second parameter, path, will be the path name passed to
function. The third parameter, excinfo, will be the exception
information return by sys.exc_info(). Exceptions raised by
onerror will not be caught.

Changed in version 2.6: Explicitly check for path being a symbolic
link and raise OSError in that case.

shutil.move(src, dst)
Recursively move a file or directory to another location.

If the destination is on the current filesystem, then simply use
rename. Otherwise, copy src to the dst and then remove src.

New in version 2.3.

exception shutil.Error
This exception collects exceptions that raised during a multi-file
operation. For copytree(), the exception argument is a list of 3-
tuples (srcname, dstname, exception).

New in version 2.3.
Example

This example is the implementation of the `copytree()` function, described above, with the docstring omitted. It demonstrates many of the other functions provided by this module.

```python
def copytree(src, dst, symlinks=False, ignore=None):
    names = os.listdir(src)
    if ignore is not None:
        ignored_names = ignore(src, names)
    else:
        ignored_names = set()

    os.makedirs(dst)
    errors = []
    for name in names:
        if name in ignored_names:
            continue
        srcname = os.path.join(src, name)
        dstname = os.path.join(dst, name)
        try:
            if symlinks and os.path.islink(srcname):
                linkto = os.readlink(srcname)
                os.symlink(linkto, dstname)
            elif os.path.isdir(srcname):
                copytree(srcname, dstname, symlinks, ignore)
            else:
                copy2(srcname, dstname)
                # XXX What about devices, sockets etc.?
        except (IOError, os.error), why:
            errors.append((srcname, dstname, str(why)))
            # catch the Error from the recursive copytree so that we can
            # continue with other files
        except Error, err:
            errors.extend(err.args[0])
            try:
                copystat(src, dst)
                except WindowsError:
                    # can't copy file access times on Windows
                pass
        except OSError, why:
            errors.extend((src, dst, str(why)))
    if errors:
        raise Error, errors
```
Another example that uses the `ignore_patterns()` helper:

```python
from shutil import copytree, ignore_patterns

copytree(source, destination, ignore=ignore_patterns('*.pyc', 'tmp*'))
```

This will copy everything except `.pyc` files and files or directories whose name starts with `tmp`.

Another example that uses the `ignore` argument to add a logging call:

```python
from shutil import copytree
import logging

def _logpath(path, names):
    logging.info('Working in %s' % path)
    return []  # nothing will be ignored

copytree(source, destination, ignore=_logpath)
```
dircache — Cached directory listings

Deprecated since version 2.6: The dircache module has been removed in Python 3.0.

The dircache module defines a function for reading directory listing using a cache, and cache invalidation using the mtime of the directory. Additionally, it defines a function to annotate directories by appending a slash.

The dircache module defines the following functions:

dircache.reset()

Resets the directory cache.

dircache.listdir(path)

Return a directory listing of path, as gotten from os.listdir(). Note that unless path changes, further call to.listdir() will not re-read the directory structure.

Note that the list returned should be regarded as read-only. (Perhaps a future version should change it to return a tuple?)

dircache.opendir(path)

Same as.listdir(). Defined for backwards compatibility.

dircache.annotate(head, list)

Assume list is a list of paths relative to head, and append, in place, a '/ ' to each path which points to a directory.

```python
>>> import dircache
da = dircache.listdir('/')
a = a[:]  # Copy the return value so we can change 'a'
>>> a
['bin', 'boot', 'cdrom', 'dev', 'etc', 'floppy', 'home', 'initr
>>> dircache.annotate('/', a)
>>> a
['bin/', 'boot/', 'cdrom/', 'dev/', 'etc/', 'floppy/', 'home/', ', 'lost+found/', 'mnt/', 'proc/', 'root/', 'sbin/', 'tmp/', 'usr', 'var', 'vmlinuz']
This module is the Mac OS 9 (and earlier) implementation of the os.path module. It can be used to manipulate old-style Macintosh pathnames on Mac OS X (or any other platform).

The following functions are available in this module: normcase(), normpath(), isabs(), join(), split(), isdir(), isfile(), walk(), exists(). For other functions available in os.path dummy counterparts are available.
Data Persistence

The modules described in this chapter support storing Python data in a persistent form on disk. The pickle and marshal modules can turn many Python data types into a stream of bytes and then recreate the objects from the bytes. The various DBM-related modules support a family of hash-based file formats that store a mapping of strings to other strings. The bsddb module also provides such disk-based string-to-string mappings based on hashing, and also supports B-Tree and record-based formats.

The list of modules described in this chapter is:

- **pickle** — Python object serialization
  - Relationship to other Python modules
  - Data stream format
  - Usage
  - What can be pickled and unpickled?
  - The pickle protocol
    - Pickling and unpickling normal class instances
    - Pickling and unpickling extension types
    - Pickling and unpickling external objects
  - Subclassing Unpicklers
  - Example
- **cPickle** — A faster pickle
- **copy_reg** — Register pickle support functions
- **shelve** — Python object persistence
  - Restrictions
  - Example
- **marshal** — Internal Python object serialization
- anydbm — Generic access to DBM-style databases
- whichdb — Guess which DBM module created a database
- dbm — Simple “database” interface
- gdbm — GNU’s reinterpretation of dbm
- dbhash — DBM-style interface to the BSD database library
  - Database Objects
- bsddb — Interface to Berkeley DB library
  - Hash, BTree and Record Objects
- dumbdbm — Portable DBM implementation
  - Dumbdbm Objects
- sqlite3 — DB-API 2.0 interface for SQLite databases
  - Module functions and constants
  - Connection Objects
  - Cursor Objects
  - SQLite and Python types
    - Introduction
    - Using adapters to store additional Python types in SQLite databases
      - Letting your object adapt itself
      - Registering an adapter callable
    - Converting SQLite values to custom Python types
    - Default adapters and converters
  - Controlling Transactions
  - Using pysqlite efficiently
    - Using shortcut methods
    - Accessing columns by name instead of by index
    - Using the connection as a context manager
The **pickle** module implements a fundamental, but powerful algorithm for serializing and de-serializing a Python object structure. “Pickling” is the process whereby a Python object hierarchy is converted into a byte stream, and “unpickling” is the inverse operation, whereby a byte stream is converted back into an object hierarchy. Pickling (and unpickling) is alternatively known as “serialization”, “marshalling,” [1] or “flattening”, however, to avoid confusion, the terms used here are “pickling” and “unpickling”.

This documentation describes both the **pickle** module and the **cPickle** module.
Relationship to other Python modules

The pickle module has an optimized cousin called the cPickle module. As its name implies, cPickle is written in C, so it can be up to 1000 times faster than pickle. However it does not support subclassing of the Pickler() and Unpickler() classes, because in cPickle these are functions, not classes. Most applications have no need for this functionality, and can benefit from the improved performance of cPickle. Other than that, the interfaces of the two modules are nearly identical; the common interface is described in this manual and differences are pointed out where necessary. In the following discussions, we use the term “pickle” to collectively describe the pickle and cPickle modules.

The data streams the two modules produce are guaranteed to be interchangeable.

Python has a more primitive serialization module called marshal, but in general pickle should always be the preferred way to serialize Python objects. marshal exists primarily to support Python’s .pyc files.

The pickle module differs from marshal several significant ways:

- The pickle module keeps track of the objects it has already serialized, so that later references to the same object won’t be serialized again. marshal doesn’t do this.

This has implications both for recursive objects and object sharing. Recursive objects are objects that contain references to themselves. These are not handled by marshal, and in fact, attempting to marshal recursive objects will crash your Python
Object sharing happens when there are multiple references to the same object in different places in the object hierarchy being serialized. pickle stores such objects only once, and ensures that all other references point to the master copy. Shared objects remain shared, which can be very important for mutable objects.

- marshal cannot be used to serialize user-defined classes and their instances. pickle can save and restore class instances transparently, however the class definition must be importable and live in the same module as when the object was stored.

- The marshal serialization format is not guaranteed to be portable across Python versions. Because its primary job in life is to support .pyc files, the Python implementers reserve the right to change the serialization format in non-backwards compatible ways should the need arise. The pickle serialization format is guaranteed to be backwards compatible across Python releases.

**Warning:** The pickle module is not intended to be secure against erroneous or maliciously constructed data. Never unpickle data received from an untrusted or unauthenticated source.

Note that serialization is a more primitive notion than persistence; although pickle reads and writes file objects, it does not handle the issue of naming persistent objects, nor the (even more complicated) issue of concurrent access to persistent objects. The pickle module can transform a complex object into a byte stream and it can transform the byte stream into an object with the same internal structure. Perhaps the most obvious thing to do with these byte streams is to write them onto a file, but it is also conceivable to send them across a network or store them in a database. The module
shelve provides a simple interface to pickle and unpickle objects on DBM-style database files.
Data stream format

The data format used by `pickle` is Python-specific. This has the advantage that there are no restrictions imposed by external standards such as XDR (which can't represent pointer sharing); however it means that non-Python programs may not be able to reconstruct pickled Python objects.

By default, the `pickle` data format uses a printable ASCII representation. This is slightly more voluminous than a binary representation. The big advantage of using printable ASCII (and of some other characteristics of `pickle`'s representation) is that for debugging or recovery purposes it is possible for a human to read the pickled file with a standard text editor.

There are currently 3 different protocols which can be used for pickling.

- Protocol version 0 is the original ASCII protocol and is backwards compatible with earlier versions of Python.
- Protocol version 1 is the old binary format which is also compatible with earlier versions of Python.
- Protocol version 2 was introduced in Python 2.3. It provides much more efficient pickling of `new-style classes`.

Refer to PEP 307 for more information.

If a `protocol` is not specified, protocol 0 is used. If `protocol` is specified as a negative value or `HIGHEST_PROTOCOL`, the highest protocol version available will be used.

*Changed in version 2.3:* Introduced the `protocol` parameter.

A binary format, which is slightly more efficient, can be chosen by
specifying a *protocol* version $\geq 1$. 
Usage

To serialize an object hierarchy, you first create a pickler, then you call the pickler’s `dump()` method. To de-serialize a data stream, you first create an unpickler, then you call the unpickler’s `load()` method.

The `pickle` module provides the following constant:

`pickle.HIGHEST_PROTOCOL`

The highest protocol version available. This value can be passed as a `protocol` value.

*New in version 2.3.*

**Note:** Be sure to always open pickle files created with protocols `>= 1` in binary mode. For the old ASCII-based pickle protocol 0 you can use either text mode or binary mode as long as you stay consistent. A pickle file written with protocol 0 in binary mode will contain lone linefeeds as line terminators and therefore will look “funny” when viewed in Notepad or other editors which do not support this format.

The `pickle` module provides the following functions to make the pickling process more convenient:

`pickle.dump(obj, file[, protocol])`

Write a pickled representation of `obj` to the open file object `file`. This is equivalent to `Pickler(file, protocol).dump(obj)`.

If the `protocol` parameter is omitted, protocol 0 is used. If `protocol` is specified as a negative value or `HIGHEST_PROTOCOL`, the highest protocol version will be used.

*Changed in version 2.3:* Introduced the `protocol` parameter.
file must have a write() method that accepts a single string argument. It can thus be a file object opened for writing, a StringIO object, or any other custom object that meets this interface.

pickle.load(file)
Read a string from the open file object file and interpret it as a pickle data stream, reconstructing and returning the original object hierarchy. This is equivalent to Unpickler(file).load(). file must have two methods, a read() method that takes an integer argument, and a readline() method that requires no arguments. Both methods should return a string. Thus file can be a file object opened for reading, a StringIO object, or any other custom object that meets this interface.

This function automatically determines whether the data stream was written in binary mode or not.

pickle.dumps(obj[, protocol])
Return the pickled representation of the object as a string, instead of writing it to a file.

If the protocol parameter is omitted, protocol 0 is used. If protocol is specified as a negative value or HIGHEST_PROTOCOL, the highest protocol version will be used.

Changed in version 2.3: The protocol parameter was added.

pickle.loads(string)
Read a pickled object hierarchy from a string. Characters in the string past the pickled object’s representation are ignored.

The pickle module also defines three exceptions:
exception pickle.**PickleError**

A common base class for the other exceptions defined below. This inherits from *Exception*.

exception pickle.**PicklingError**

This exception is raised when an unpicklable object is passed to the `dump()` method.

exception pickle.**UnpicklingError**

This exception is raised when there is a problem unpickling an object. Note that other exceptions may also be raised during unpickling, including (but not necessarily limited to) *AttributeError*, *EOFError*, *ImportError*, and *IndexError*.

The pickle module also exports two callables [2], *Pickler* and *Unpickler*:

```python
class pickle.**Pickler**(file[, protocol])
    This takes a file-like object to which it will write a pickle data stream.

    If the *protocol* parameter is omitted, protocol 0 is used. If *protocol* is specified as a negative value or `HIGHEST_PROTOCOL`, the highest protocol version will be used.

    *Changed in version 2.3:* Introduced the *protocol* parameter.

    *file* must have a `write()` method that accepts a single string argument. It can thus be an open file object, a *StringIO* object, or any other custom object that meets this interface.

    *Pickler* objects define one (or two) public methods:

    `dump(obj)`
        Write a pickled representation of *obj* to the open file object
```
given in the constructor. Either the binary or ASCII format will be used, depending on the value of the protocol argument passed to the constructor.

**clear_memo()**

Clears the pickler’s “memo”. The memo is the data structure that remembers which objects the pickler has already seen, so that shared or recursive objects pickled by reference and not by value. This method is useful when re-using picklers.

**Note:** Prior to Python 2.3, `clear_memo()` was only available on the picklers created by `cPickle`. In the `pickle` module, picklers have an instance variable called `memo` which is a Python dictionary. So to clear the memo for a `pickle` module pickler, you could do the following:

```python
def clear_memo(self):
    self.memo.clear()
```

Code that does not need to support older versions of Python should simply use `clear_memo()`.

It is possible to make multiple calls to the `dump()` method of the same `Pickler` instance. These must then be matched to the same number of calls to the `load()` method of the corresponding `Unpickler` instance. If the same object is pickled by multiple `dump()` calls, the `load()` will all yield references to the same object. [3]

**Unpickler** objects are defined as:

```python
class pickle.Unpickler(file)
```

This takes a file-like object from which it will read a pickle data stream. This class automatically determines whether the data stream was written in binary mode or not, so it does not need a
flag as in the **Pickler** factory.

*file* must have two methods, a `read()` method that takes an integer argument, and a `readline()` method that requires no arguments. Both methods should return a string. Thus *file* can be a file object opened for reading, a `StringIO` object, or any other custom object that meets this interface.

**Unpickler** objects have one (or two) public methods:

- **load()**
  Read a pickled object representation from the open file object given in the constructor, and return the reconstituted object hierarchy specified therein.
  
  This method automatically determines whether the data stream was written in binary mode or not.

- **noload()**
  This is just like `load()` except that it doesn’t actually create any objects. This is useful primarily for finding what’s called “persistent ids” that may be referenced in a pickle data stream. See section *The pickle protocol* below for more details.

  **Note:** the `noload()` method is currently only available on **Unpickler** objects created with the `cPickle` module. **pickle** module **Unpicklers** do not have the `noload()` method.
What can be pickled and unpickled?

The following types can be pickled:

- None, True, and False
- integers, long integers, floating point numbers, complex numbers
- normal and Unicode strings
- tuples, lists, sets, and dictionaries containing only picklable objects
- functions defined at the top level of a module
- built-in functions defined at the top level of a module
- classes that are defined at the top level of a module
- instances of such classes whose \_dict\_ or \_setstate\_() is picklable (see section The pickle protocol for details)

Attempts to pickle unpicklable objects will raise the PicklingError exception; when this happens, an unspecified number of bytes may have already been written to the underlying file. Trying to pickle a highly recursive data structure may exceed the maximum recursion depth, a RuntimeError will be raised in this case. You can carefully raise this limit with sys.setrecursionlimit().

Note that functions (built-in and user-defined) are pickled by “fully qualified” name reference, not by value. This means that only the function name is pickled, along with the name of module the function is defined in. Neither the function’s code, nor any of its function attributes are pickled. Thus the defining module must be importable in the unpickling environment, and the module must contain the named object, otherwise an exception will be raised. [4]

Similarly, classes are pickled by named reference, so the same restrictions in the unpickling environment apply. Note that none of
the class's code or data is pickled, so in the following example the class attribute attr is not restored in the unpickling environment:

```python
class Foo:
    attr = 'a class attr'
picklestring = pickle.dumps(Foo)
```

These restrictions are why picklable functions and classes must be defined in the top level of a module.

Similarly, when class instances are pickled, their class's code and data are not pickled along with them. Only the instance data are pickled. This is done on purpose, so you can fix bugs in a class or add methods to the class and still load objects that were created with an earlier version of the class. If you plan to have long-lived objects that will see many versions of a class, it may be worthwhile to put a version number in the objects so that suitable conversions can be made by the class's `__setstate__()` method.
The pickle protocol

This section describes the “pickling protocol” that defines the interface between the pickler/unpickler and the objects that are being serialized. This protocol provides a standard way for you to define, customize, and control how your objects are serialized and deserialized. The description in this section doesn’t cover specific customizations that you can employ to make the unpickling environment slightly safer from untrusted pickle data streams; see section Subclassing Unpicklers for more details.

Pickling and unpickling normal class instances

object.__getinitargs__()  
When a pickled class instance is unpickled, its __init__() method is normally not invoked. If it is desirable that the __init__() method be called on unpickling, an old-style class can define a method __getinitargs__(), which should return a tuple containing the arguments to be passed to the class constructor (__init__() for example). The __getinitargs__() method is called at pickle time; the tuple it returns is incorporated in the pickle for the instance.

object.__getnewargs__()  
New-style types can provide a __getnewargs__() method that is used for protocol 2. Implementing this method is needed if the type establishes some internal invariants when the instance is created, or if the memory allocation is affected by the values passed to the __new__() method for the type (as it is for tuples and strings). Instances of a new-style class C are created using

    obj = C.__new__(C, *args)
where \textit{args} is the result of calling \texttt{__getnewargs__()} on the original object; if there is no \texttt{__getnewargs__()}, an empty tuple is assumed.

\textbf{Object. \texttt{__getstate__}()}  
Classes can further influence how their instances are pickled; if the class defines the method \texttt{__getstate__}(), it is called and the return state is pickled as the contents for the instance, instead of the contents of the instance's dictionary. If there is no \texttt{__getstate__}() method, the instance's \texttt{__dict__} is pickled.

\textbf{Object. \texttt{__setstate__}()}  
Upon unpickling, if the class also defines the method \texttt{__setstate__}(), it is called with the unpickled state. [5] If there is no \texttt{__setstate__}() method, the pickled state must be a dictionary and its items are assigned to the new instance's dictionary. If a class defines both \texttt{__getstate__}() and \texttt{__setstate__}(), the state object needn't be a dictionary and these methods can do what they want. [6]

\begin{shaded}
\textbf{Warning:} For \textit{new-style classes}, if \texttt{__getstate__}() returns a false value, the \texttt{__setstate__}() method will not be called.
\end{shaded}

\textbf{Pickling and unpickling extension types}

\textbf{Object. \texttt{__reduce__}()}  
When the \texttt{Pickler} encounters an object of a type it knows nothing about — such as an extension type — it looks in two places for a hint of how to pickle it. One alternative is for the object to implement a \texttt{__reduce__}() method. If provided, at pickling time \texttt{__reduce__}() will be called with no arguments, and it must return either a string or a tuple.
If a string is returned, it names a global variable whose contents are pickled as normal. The string returned by \texttt{\_\_reduce\_()} should be the object’s local name relative to its module; the pickle module searches the module namespace to determine the object’s module.

When a tuple is returned, it must be between two and five elements long. Optional elements can either be omitted, or \texttt{None} can be provided as their value. The contents of this tuple are pickled as normal and used to reconstruct the object at unpickling time. The semantics of each element are:

- A callable object that will be called to create the initial version of the object. The next element of the tuple will provide arguments for this callable, and later elements provide additional state information that will subsequently be used to fully reconstruct the pickled data.

  In the unpickling environment this object must be either a class, a callable registered as a “safe constructor” (see below), or it must have an attribute \texttt{\_\_safe\_for\_unpickling\_} with a true value. Otherwise, an \texttt{UnpicklingError} will be raised in the unpickling environment. Note that as usual, the callable itself is pickled by name.

- A tuple of arguments for the callable object.

  \textit{Changed in version 2.5:} Formerly, this argument could also be \texttt{None}.

- Optionally, the object’s state, which will be passed to the object’s \texttt{\_\_setstate\_()} method as described in section \textit{Pickling and unpickling normal class instances}. If the object has no \texttt{\_\_setstate\_()} method, then, as above, the value must be a dictionary and it will be added to the object’s
Optionally, an iterator (and not a sequence) yielding successive list items. These list items will be pickled, and appended to the object using either `obj.append(item)` or `obj.extend(list_of_items)`. This is primarily used for list subclasses, but may be used by other classes as long as they have `append()` and `extend()` methods with the appropriate signature. (Whether `append()` or `extend()` is used depends on which pickle protocol version is used as well as the number of items to append, so both must be supported.)

Optionally, an iterator (not a sequence) yielding successive dictionary items, which should be tuples of the form `(key, value)`. These items will be pickled and stored to the object using `obj[key] = value`. This is primarily used for dictionary subclasses, but may be used by other classes as long as they implement `__setitem__()`.  

```
object.__reduce_ex__(protocol)
```

It is sometimes useful to know the protocol version when implementing `__reduce__()`. This can be done by implementing a method named `__reduce_ex__(protocol)` instead of `__reduce__()`.  

`__reduce_ex__(protocol)`, when it exists, is called in preference over `__reduce__()` (you may still provide `__reduce__() for backwards compatibility). The `__reduce_ex__(protocol)` method will be called with a single integer argument, the protocol version.  

The `object` class implements both `__reduce__(protocol)` and `__reduce_ex__(protocol)`; however, if a subclass overrides `__reduce__(protocol)` but not `__reduce_ex__(protocol)`, the `__reduce_ex__(protocol)` implementation detects this and calls `__reduce__(protocol)`.  

```
object.__dict__.
```
An alternative to implementing a `__reduce__()` method on the object to be pickled, is to register the callable with the `copy_reg` module. This module provides a way for programs to register “reduction functions” and constructors for user-defined types. Reduction functions have the same semantics and interface as the `__reduce__()` method described above, except that they are called with a single argument, the object to be pickled.

The registered constructor is deemed a “safe constructor” for purposes of unpickling as described above.

Pickling and unpickling external objects

For the benefit of object persistence, the `pickle` module supports the notion of a reference to an object outside the pickled data stream. Such objects are referenced by a “persistent id”, which is just an arbitrary string of printable ASCII characters. The resolution of such names is not defined by the `pickle` module; it will delegate this resolution to user defined functions on the pickler and unpickler. [7]

To define external persistent id resolution, you need to set the `persistent_id` attribute of the pickler object and the `persistent_load` attribute of the unpickler object.

To pickle objects that have an external persistent id, the pickler must have a custom `persistent_id()` method that takes an object as an argument and returns either `None` or the persistent id for that object. When `None` is returned, the pickler simply pickles the object as normal. When a persistent id string is returned, the pickler will pickle that string, along with a marker so that the unpickler will recognize the string as a persistent id.

To unpickle external objects, the unpickler must have a custom `persistent_load()` function that takes a persistent id string and
returns the referenced object.

Here's a silly example that might shed more light:

```python
import pickle
from cStringIO import StringIO

src = StringIO()
p = pickle.Pickler(src)

def persistent_id(obj):
    if hasattr(obj, 'x'):
        return 'the value %d' % obj.x
    else:
        return None

p.persistent_id = persistent_id

class Integer:
    def __init__(self, x):
        self.x = x
    def __str__(self):
        return 'My name is integer %d' % self.x

i = Integer(7)
print i
p.dump(i)

datastream = src.getvalue()
print repr(datastream)
dst = StringIO(datastream)

up = pickle.Unpickler(dst)

class FancyInteger(Integer):
    def __str__(self):
        return 'I am the integer %d' % self.x

def persistent_load(persid):
    if persid.startswith('the value '):
        value = int(persid.split()[2])
        return FancyInteger(value)
    else:
        raise pickle.UnpicklingError, 'Invalid persistent id'

up.persistent_load = persistent_load

j = up.load()
```
In the cPickle module, the unpickler’s persistent_load attribute can also be set to a Python list, in which case, when the unpickler reaches a persistent id, the persistent id string will simply be appended to this list. This functionality exists so that a pickle data stream can be “sniffed” for object references without actually instantiating all the objects in a pickle. Setting persistent_load to a list is usually used in conjunction with the noLoad() method on the Unpickler.
Subclassing Unpicklers

By default, unpickling will import any class that it finds in the pickle data. You can control exactly what gets unpickled and what gets called by customizing your unpickler. Unfortunately, exactly how you do this is different depending on whether you’re using *pickle* or *cPickle*. [9]

In the *pickle* module, you need to derive a subclass from *Unpickler*, overriding the *load_global()* method. *load_global()* should read two lines from the pickle data stream where the first line will the name of the module containing the class and the second line will be the name of the instance’s class. It then looks up the class, possibly importing the module and digging out the attribute, then it appends what it finds to the unpickler’s stack. Later on, this class will be assigned to the **class** attribute of an empty class, as a way of magically creating an instance without calling its class’s **init**( ). Your job (should you choose to accept it), would be to have *load_global()* push onto the unpickler’s stack, a known safe version of any class you deem safe to unpickle. It is up to you to produce such a class. Or you could raise an error if you want to disallow all unpickling of instances. If this sounds like a hack, you’re right. Refer to the source code to make this work.

Things are a little cleaner with *cPickle*, but not by much. To control what gets unpickled, you can set the unpickler’s *find_global* attribute to a function or *None*. If it is *None* then any attempts to unpickle instances will raise an *UnpicklingError*. If it is a function, then it should accept a module name and a class name, and return the corresponding class object. It is responsible for looking up the class and performing any necessary imports, and it may raise an error to prevent instances of the class from being unpickled.
The moral of the story is that you should be really careful about the source of the strings your application unpickles.
Example

For the simplest code, use the `dump()` and `load()` functions. Note that a self-referencing list is pickled and restored correctly.

```python
import pickle

data1 = {'a': [1, 2.0, 3, 4+6j],
         'b': ('string', u'Unicode string'),
         'c': None}

selfref_list = [1, 2, 3]
selfref_list.append(selfref_list)

output = open('data.pkl', 'wb')

# Pickle dictionary using protocol 0.
pickle.dump(data1, output)

# Pickle the list using the highest protocol available.
pickle.dump(selfref_list, output, -1)

output.close()
```

The following example reads the resulting pickled data. When reading a pickle-containing file, you should open the file in binary mode because you can't be sure if the ASCII or binary format was used.

```python
import pprint, pickle

pkl_file = open('data.pkl', 'rb')

data1 = pickle.load(pkl_file)
pprint.pprint(data1)

data2 = pickle.load(pkl_file)
pprint.pprint(data2)

pkl_file.close()
```

Here's a larger example that shows how to modify pickling behavior
for a class. The `TextReader` class opens a text file, and returns the line number and line contents each time its `readline()` method is called. If a `TextReader` instance is pickled, all attributes except the file object member are saved. When the instance is unpickled, the file is reopened, and reading resumes from the last location. The `__setstate__()` and `__getstate__()` methods are used to implement this behavior.

```python
#!/usr/local/bin/python

class TextReader:
    """Print and number lines in a text file."""
    def __init__(self, file):
        self.file = file
        self.fh = open(file)
        self.lineno = 0

    def readline(self):
        self.lineno = self.lineno + 1
        line = self.fh.readline()
        if not line:
            return None
        if line.endswith("
        line = line[:-1]
        return "%d: %s" % (self.lineno, line)

    def __getstate__(self):
        odict = self.__dict__.copy()  # copy the dict since we c.
        del odict['fh']               # remove filehandle entry
        return odict

    def __setstate__(self, dict):
        fh = open(dict['file'])       # reopen file
        count = dict['lineno']        # read from file...
        while count:
            fh.readline()             # until line count is rest
            count = count - 1
        self.__dict__.update(dict)   # update attributes
        self.fh = fh                 # save the file object

A sample usage might be something like this:

```
>>> obj = TextReader.TextReader("TextReader.py")
>>> obj.readline()
'1: #!/usr/local/bin/python'
>>> obj.readline()
'2: '
>>> obj.readline()
'3: class TextReader:'
>>> import pickle
>>> pickle.dump(obj, open('save.p', 'wb'))

If you want to see that pickle works across Python processes, start another Python session, before continuing. What follows can happen from either the same process or a new process.

>>> import pickle
>>> reader = pickle.load(open('save.p', 'rb'))
>>> reader.readline()
'4: """Print and number lines in a text file."""'

Module copy_reg
   Pickle interface constructor registration for extension types.

Module shelve
   Indexed databases of objects; uses pickle.

Module copy
   Shallow and deep object copying.

Module marshal
   High-performance serialization of built-in types.
The `cPickle` module supports serialization and de-serialization of Python objects, providing an interface and functionality nearly identical to the `pickle` module. There are several differences, the most important being performance and subclassability.

First, `cPickle` can be up to 1000 times faster than `pickle` because the former is implemented in C. Second, in the `cPickle` module the callables `Pickler()` and `Unpickler()` are functions, not classes. This means that you cannot use them to derive custom pickling and unpickling subclasses. Most applications have no need for this functionality and should benefit from the greatly improved performance of the `cPickle` module.

The pickle data stream produced by `pickle` and `cPickle` are identical, so it is possible to use `pickle` and `cPickle` interchangeably with existing pickles. [10]

There are additional minor differences in API between `cPickle` and `pickle`, however for most applications, they are interchangeable. More documentation is provided in the `pickle` module documentation, which includes a list of the documented differences.

**Footnotes**

[1] Don’t confuse this with the `marshal` module

   In the `pickle` module these callables are classes, which you could subclass to customize the behavior. However, in the `cPickle` module these callables are factory functions and so cannot be subclassed. One common reason to subclass is to control what objects can actually be unpickled. See section `Subclassing Unpicklers` for more details.
Warning: this is intended for pickling multiple objects without intervening modifications to the objects or their parts. If you modify an object and then pickle it again using the same

Pickler instance, the object is not pickled again — a reference to it is pickled and the Unpickler will return the old value, not the modified one. There are two problems here: (1) detecting changes, and (2) marshalling a minimal set of changes. Garbage Collection may also become a problem here.

The exception raised will likely be an ImportError or an AttributeError but it could be something else.

These methods can also be used to implement copying class instances.

This protocol is also used by the shallow and deep copying operations defined in the copy module.

The actual mechanism for associating these user defined functions is slightly different for pickle and cPickle. The description given here works the same for both implementations. Users of the pickle module could also use subclassing to effect the same results, overriding the persistent_id() and persistent_load() methods in the derived classes.

We'll leave you with the image of Guido and Jim sitting around sniffing pickles in their living rooms.

A word of caution: the mechanisms described here use internal attributes and methods, which are subject to change in future versions of Python. We intend to someday provide a common interface for controlling this behavior, which will work in either pickle or cPickle.

Since the pickle data format is actually a tiny stack-oriented programming language, and some freedom is taken in the encodings of certain objects, it is possible that the two modules produce different data streams for the same input objects. However it is guaranteed that they will always be able to read each other's data streams.
The copy_reg module has been renamed to copyreg in Python 3.0. The 2to3 tool will automatically adapt imports when converting your sources to 3.0.

The copy_reg module provides support for the pickle and cPickle modules. The copy module is likely to use this in the future as well. It provides configuration information about object constructors which are not classes. Such constructors may be factory functions or class instances.

**copy_reg.constructor(object)**

Declares *object* to be a valid constructor. If *object* is not callable (and hence not valid as a constructor), raises TypeError.

**copy_reg.pickle(type, function[, constructor])**

Declares that *function* should be used as a “reduction” function for objects of type *type*; *type* must not be a “classic” class object. (Classic classes are handled differently; see the documentation for the pickle module for details.) *function* should return either a string or a tuple containing two or three elements.

The optional *constructor* parameter, if provided, is a callable object which can be used to reconstruct the object when called with the tuple of arguments returned by *function* at pickling time. TypeError will be raised if *object* is a class or *constructor* is not callable.

See the pickle module for more details on the interface expected of *function* and *constructor*. 
A “shelf” is a persistent, dictionary-like object. The difference with “dbm” databases is that the values (not the keys!) in a shelf can be essentially arbitrary Python objects — anything that the pickle module can handle. This includes most class instances, recursive data types, and objects containing lots of shared sub-objects. The keys are ordinary strings.

```python
shelve.open(filename[, flag='c', protocol=None[, writeback=False]])
```

Open a persistent dictionary. The filename specified is the base filename for the underlying database. As a side-effect, an extension may be added to the filename and more than one file may be created. By default, the underlying database file is opened for reading and writing. The optional flag parameter has the same interpretation as the flag parameter of anydbm.open().

By default, version 0 pickles are used to serialize values. The version of the pickle protocol can be specified with the protocol parameter.

*Changed in version 2.3:* The protocol parameter was added.

By default, mutations to persistent-dictionary mutable entries are not automatically written back. If the optional writeback parameter is set to True, all entries accessed are cached in memory, and written back at close time; this can make it handier to mutate mutable entries in the persistent dictionary, but, if many entries are accessed, it can consume vast amounts of memory for the cache, and it can make the close operation very slow since all accessed entries are written back (there is no way to determine which accessed entries are mutable, nor which ones were
actually mutated).

Shelve objects support all methods supported by dictionaries. This eases the transition from dictionary based scripts to those requiring persistent storage.

One additional method is supported:

```
Shelf.sync()
```

Write back all entries in the cache if the shelf was opened with `writeback` set to `True`. Also empty the cache and synchronize the persistent dictionary on disk, if feasible. This is called automatically when the shelf is closed with `close()`.
Restrictions

- The choice of which database package will be used (such as `dbm`, `gdbm` or `bsddb`) depends on which interface is available. Therefore it is not safe to open the database directly using `dbm`. The database is also (unfortunately) subject to the limitations of `dbm`, if it is used — this means that (the pickled representation of) the objects stored in the database should be fairly small, and in rare cases key collisions may cause the database to refuse updates.
- Depending on the implementation, closing a persistent dictionary may or may not be necessary to flush changes to disk. The `__del__()` method of the `Shelf` class calls the `close()` method, so the programmer generally need not do this explicitly.
- The `shelve` module does not support concurrent read/write access to shelved objects. (Multiple simultaneous read accesses are safe.) When a program has a shelf open for writing, no other program should have it open for reading or writing. Unix file locking can be used to solve this, but this differs across Unix versions and requires knowledge about the database implementation used.

```python
class shelf.Shelf(dict[, protocol=None[, writeback=False]])
A subclass of UserDict.DictMixin which stores pickled values in the dict object.

By default, version 0 pickles are used to serialize values. The version of the pickle protocol can be specified with the protocol parameter. See the pickle documentation for a discussion of the pickle protocols.

Changed in version 2.3: The protocol parameter was added.
```
If the `writeback` parameter is `True`, the object will hold a cache of all entries accessed and write them back to the `dict` at sync and close times. This allows natural operations on mutable entries, but can consume much more memory and make sync and close take a long time.

```python
class shelve.BsddbShelf(dict[, protocol=None[, writeback=False]])
```
A subclass of `Shelf` which exposes `first()`, `next()`, `previous()`, `last()` and `set_location()` which are available in the `bsddb` module but not in other database modules. The `dict` object passed to the constructor must support those methods. This is generally accomplished by calling one of `bsddb.hashopen()`, `bsddb.btopen()` or `bsddb.rnopen()`. The optional `protocol` and `writeback` parameters have the same interpretation as for the `Shelf` class.

```python
class shelve.DbfilenameShelf(filename[, flag='c'[, protocol=None[, writeback=False]])
```
A subclass of `Shelf` which accepts a `filename` instead of a dict-like object. The underlying file will be opened using `anydbm.open()`. By default, the file will be created and opened for both read and write. The optional `flag` parameter has the same interpretation as for the `open()` function. The optional `protocol` and `writeback` parameters have the same interpretation as for the `Shelf` class.
Example

To summarize the interface (key is a string, data is an arbitrary object):

```
import shelve

d = shelve.open(filename)  # open -- file may get suffix added by library

# store data at key (overwrites old data if using an existing key)
d[key] = data

# retrieve a COPY of data at key (raise KeyError if such key)
data = d[key]

# delete data stored at key (raises KeyError if no such key)
del d[key]

# true if the key exists
flag = d.has_key(key)

# a list of all existing keys (slow!)
klist = d.keys()

# as d was opened WITHOUT writeback=True, beware:
d['xx'] = range(4)  # this works as expected, but...
d['xx'].append(5)  # *this doesn't!* -- d['xx'] is STILL range

# having opened d without writeback=True, you need to code carefully:
temp = d['xx']  # extracts the copy
temp.append(5)  # mutates the copy
d['xx'] = temp  # stores the copy right back, to persist it

# or, d=shelve.open(filename,writeback=True) would let you just
# d['xx'].append(5) and have it work as expected, BUT it would:
# consume more memory and make the d.close() operation slower.

d.close()  # close it
```

**Module** anydbm

Generic interface to dbm-style databases.

**Module** bsddb

BSD db database interface.
**Module dbhash**
Thin layer around the *bsddb* which provides an `open()` function like the other database modules.

**Module dbm**
Standard Unix database interface.

**Module dumbdbm**
Portable implementation of the `dbm` interface.

**Module gdbm**
GNU database interface, based on the `dbm` interface.

**Module pickle**
Object serialization used by `shelve`.

**Module cPickle**
High-performance version of `pickle`. 
marshal — Internal Python object serialization

This module contains functions that can read and write Python values in a binary format. The format is specific to Python, but independent of machine architecture issues (e.g., you can write a Python value to a file on a PC, transport the file to a Sun, and read it back there). Details of the format are undocumented on purpose; it may change between Python versions (although it rarely does). [1]

This is not a general “persistence” module. For general persistence and transfer of Python objects through RPC calls, see the modules pickle and shelve. The marshal module exists mainly to support reading and writing the “pseudo-compiled” code for Python modules of .pyc files. Therefore, the Python maintainers reserve the right to modify the marshal format in backward incompatible ways should the need arise. If you’re serializing and de-serializing Python objects, use the pickle module instead – the performance is comparable, version independence is guaranteed, and pickle supports a substantially wider range of objects than marshal.

**Warning:** The marshal module is not intended to be secure against erroneous or maliciously constructed data. Never unmarshal data received from an untrusted or unauthenticated source.

Not all Python object types are supported; in general, only objects whose value is independent from a particular invocation of Python can be written and read by this module. The following types are supported: None, integers, long integers, floating point numbers, strings, Unicode objects, tuples, lists, sets, dictionaries, and code objects, where it should be understood that tuples, lists and
dictionaries are only supported as long as the values contained therein are themselves supported; and recursive lists and dictionaries should not be written (they will cause infinite loops).

**Warning:** On machines where C's `long int` type has more than 32 bits (such as the DEC Alpha), it is possible to create plain Python integers that are longer than 32 bits. If such an integer is marshaled and read back in on a machine where C's `long int` type has only 32 bits, a Python long integer object is returned instead.

While of a different type, the numeric value is the same. (This behavior is new in Python 2.2. In earlier versions, all but the least-significant 32 bits of the value were lost, and a warning message was printed.)

There are functions that read/write files as well as functions operating on strings.

The module defines these functions:

```python
marshal.dump(value, file[, version])
```

Write the value on the open file. The value must be a supported type. The file must be an open file object such as `sys.stdout` or returned by `open()` or `os.popen()`. It must be opened in binary mode (`'wb'` or `'w+b'`).

If the value has (or contains an object that has) an unsupported type, a `ValueError` exception is raised — but garbage data will also be written to the file. The object will not be properly read back by `load()`.

*New in version 2.4:* The `version` argument indicates the data format that `dump` should use (see below).

```python
marshal.load(file)
```
Read one value from the open file and return it. If no valid value is read (e.g. because the data has a different Python version's incompatible marshal format), raise **EOFError**, **ValueError** or **TypeError**. The file must be an open file object opened in binary mode ('rb' or 'r+b').

**Warning:** If an object containing an unsupported type was marshalled with `dump()`, `load()` will substitute `None` for the unmarshallable type.

**marshal.dumps(value[, version])**

Return the string that would be written to a file by `dump(value, file)`. The value must be a supported type. Raise a **ValueError** exception if value has (or contains an object that has) an unsupported type.

*New in version 2.4:* The `version` argument indicates the data format that `dumps` should use (see below).

**marshal.loads(string)**

Convert the string to a value. If no valid value is found, raise **EOFError**, **ValueError** or **TypeError**. Extra characters in the string are ignored.

In addition, the following constants are defined:

**marshal.version**

Indicates the format that the module uses. Version 0 is the historical format, version 1 (added in Python 2.4) shares interned strings and version 2 (added in Python 2.5) uses a binary format for floating point numbers. The current version is 2.

*New in version 2.4.*
The name of this module stems from a bit of terminology used by the designers of Modula-3 (amongst others), who use the term “marshalling” for shipping of data around in a self-contained form. Strictly speaking, “to marshal” means to convert some data from internal to external form (in an RPC buffer for instance) and “unmarshalling” for the reverse process.

[1]
anydbm — Generic access to DBM-style databases

**Note:** The *anydbm* module has been renamed to *dbm* in Python 3.0. The 2to3 tool will automatically adapt imports when converting your sources to 3.0.

*anydbm* is a generic interface to variants of the DBM database — *dbhash* (requires *bsd*), *gdbm*, or *dbm*. If none of these modules is installed, the slow-but-simple implementation in module *dumbdbm* will be used.

```python
anydbm.open(filename[, flag[, mode]])
```

Open the database file *filename* and return a corresponding object.

If the database file already exists, the *whichdb* module is used to determine its type and the appropriate module is used; if it does not exist, the first module listed above that can be imported is used.

The optional *flag* argument can be 'r' to open an existing database for reading only, 'w' to open an existing database for reading and writing, 'c' to create the database if it doesn't exist, or 'n', which will always create a new empty database. If not specified, the default value is 'r'.

The optional *mode* argument is the Unix mode of the file, used only when the database has to be created. It defaults to octal 0666 (and will be modified by the prevailing umask).

```
except anydbm.error
```
A tuple containing the exceptions that can be raised by each of the supported modules, with a unique exception also named \texttt{anydbm.error} as the first item — the latter is used when \texttt{anydbm.error} is raised.

The object returned by \texttt{open()} supports most of the same functionality as dictionaries; keys and their corresponding values can be stored, retrieved, and deleted, and the \texttt{has_key()} and \texttt{keys()} methods are available. Keys and values must always be strings.

The following example records some hostnames and a corresponding title, and then prints out the contents of the database:

```python
import anydbm

# Open database, creating it if necessary.
db = anydbm.open('cache', 'c')

# Record some values
db['www.python.org'] = 'Python Website'
db['www.cnn.com'] = 'Cable News Network'

# Loop through contents. Other dictionary methods
# such as .keys(), .values() also work.
for k, v in db.iteritems():
    print k, '\t', v

# Storing a non-string key or value will raise an exception (most
# likely a TypeError).
db['www.yahoo.com'] = 4

# Close when done.
db.close()
```

**Module whichdb**
UTILITY MODULE USED TO DETERMINE THE TYPE OF AN EXISTING DATABASE.
whichdb — Guess which DBM module created a database

Note: The whichdb module’s only function has been put into the dbm module in Python 3.0. The 2to3 tool will automatically adapt imports when converting your sources to 3.0.

The single function in this module attempts to guess which of the several simple database modules available—dbm, gdbm, or dbhash—should be used to open a given file.

whichdb.whichdb(filename)

Returns one of the following values: None if the file can’t be opened because it’s unreadable or doesn’t exist; the empty string ("") if the file’s format can’t be guessed; or a string containing the required module name, such as 'dbm' or 'gdbm'.
The dbm module provides an interface to the Unix "(n)dbm" library. Dbm objects behave like mappings (dictionaries), except that keys and values are always strings. Printing a dbm object doesn't print the keys and values, and the `items()` and `values()` methods are not supported.

This module can be used with the "classic" ndbm interface, the BSD DB compatibility interface, or the GNU GDBM compatibility interface. On Unix, the `configure` script will attempt to locate the appropriate header file to simplify building this module.

The module defines the following:

```python
exception dbm.error
    Raised on dbm-specific errors, such as I/O errors. KeyError is raised for general mapping errors like specifying an incorrect key.

dbm.library
    Name of the ndbm implementation library used.

dbm.open(filename[, flag[, mode]])
    Open a dbm database and return a dbm object. The `filename` argument is the name of the database file (without the `.dir` or `.pag` extensions; note that the BSD DB implementation of the interface will append the extension `.db` and only create one file).
```
The optional *flag* argument must be one of these values:

<table>
<thead>
<tr>
<th>Value</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>'r'</td>
<td>Open existing database for reading only (default)</td>
</tr>
<tr>
<td>'w'</td>
<td>Open existing database for reading and writing</td>
</tr>
<tr>
<td>'c'</td>
<td>Open database for reading and writing, creating it if it doesn’t exist</td>
</tr>
<tr>
<td>'n'</td>
<td>Always create a new, empty database, open for reading and writing</td>
</tr>
</tbody>
</table>

The optional *mode* argument is the Unix mode of the file, used only when the database has to be created. It defaults to octal 0666 (and will be modified by the prevailing umask).

See also:

**Module** *anydbm*

Generic interface to *dbm*-style databases.

**Module** *gdbm*

Similar interface to the GNU GDBM library.

**Module** *whichdb*

Utility module used to determine the type of an existing database.
The `gdbm` module has been renamed to `dbm.gnu` in Python 3.0. The `2to3` tool will automatically adapt imports when converting your sources to 3.0.

This module is quite similar to the `dbm` module, but uses `gdbm` instead to provide some additional functionality. Please note that the file formats created by `gdbm` and `dbm` are incompatible.

The `gdbm` module provides an interface to the GNU DBM library. `gdbm` objects behave like mappings (dictionaries), except that keys and values are always strings. Printing a `gdbm` object doesn't print the keys and values, and the `items()` and `values()` methods are not supported.

The module defines the following constant and functions:

- `exception gdbm.error`
  
  Raised on `gdbm`-specific errors, such as I/O errors. `KeyError` is raised for general mapping errors like specifying an incorrect key.

- `gdbm.open(filename[, flag[, mode]])`
  
  Open a `gdbm` database and return a `gdbm` object. The `filename` argument is the name of the database file.

  The optional `flag` argument can be:

<table>
<thead>
<tr>
<th>Value</th>
<th>Meaning</th>
</tr>
</thead>
</table>
The following additional characters may be appended to the flag to control how the database is opened:

<table>
<thead>
<tr>
<th>Value</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>'f'</td>
<td>Open the database in fast mode. Writes to the database will not be synchronized.</td>
</tr>
<tr>
<td>'s'</td>
<td>Synchronized mode. This will cause changes to the database to be immediately written to the file.</td>
</tr>
<tr>
<td>'u'</td>
<td>Do not lock database.</td>
</tr>
</tbody>
</table>

Not all flags are valid for all versions of `gdbm`. The module constant `open_flags` is a string of supported flag characters. The exception `error` is raised if an invalid flag is specified.

The optional `mode` argument is the Unix mode of the file, used only when the database has to be created. It defaults to octal 0666.

In addition to the dictionary-like methods, `gdbm` objects have the following methods:

```python
gdbm.firstkey()
```

It's possible to loop over every key in the database using this method and the `nextkey()` method. The traversal is ordered by `gdbm`'s internal hash values, and won't be sorted by the key values. This method returns the starting key.

```python
gdbm.nextkey(key)
```
Returns the key that follows `key` in the traversal. The following code prints every key in the database `db`, without having to create a list in memory that contains them all:

```python
k = db.firstkey()
while k != None:
    print k
    k = db.nextkey(k)
```

`gdbm.reorganize()`

If you have carried out a lot of deletions and would like to shrink the space used by the `gdbm` file, this routine will reorganize the database. `gdbm` will not shorten the length of a database file except by using this reorganization; otherwise, deleted file space will be kept and reused as new (key, value) pairs are added.

`gdbm.sync()`

When the database has been opened in fast mode, this method forces any unwritten data to be written to the disk.

**See also:**

**Module** `anydbm`

Generic interface to `dbm`-style databases.

**Module** `whichdb`

Utility module used to determine the type of an existing database.
dbhash — DBM-style interface to the BSD database library

Deprecated since version 2.6: The dbhash module has been deprecated for removal in Python 3.0.

The dbhash module provides a function to open databases using the BSD db library. This module mirrors the interface of the other Python database modules that provide access to DBM-style databases. The bsddb module is required to use dbhash.

This module provides an exception and a function:

exception dbhash.error

  Exception raised on database errors other than KeyError. It is a synonym for bsddb.error.

dbhash.open(path[, flag[, mode]])

  Open a db database and return the database object. The path argument is the name of the database file.

  The flag argument can be:

<table>
<thead>
<tr>
<th>Value</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>'r'</td>
<td>Open existing database for reading only (default)</td>
</tr>
<tr>
<td>'w'</td>
<td>Open existing database for reading and writing</td>
</tr>
<tr>
<td>'c'</td>
<td>Open database for reading and writing, creating it if it doesn't exist</td>
</tr>
<tr>
<td>'n'</td>
<td>Always create a new, empty database, open for reading and writing</td>
</tr>
</tbody>
</table>

  For platforms on which the BSD db library supports locking, an 'l' can be appended to indicate that locking should be used.
The optional *mode* parameter is used to indicate the Unix permission bits that should be set if a new database must be created; this will be masked by the current umask value for the process.

**See also:**

**Module anydbm**
Generic interface to *dbm*-style databases.

**Module bsddb**
Lower-level interface to the BSD *db* library.

**Module whichdb**
Utility module used to determine the type of an existing database.
Database Objects

The database objects returned by `open()` provide the methods common to all the DBM-style databases and mapping objects. The following methods are available in addition to the standard methods.

**dbhash.** *first()*

It's possible to loop over every key/value pair in the database using this method and the `next()` method. The traversal is ordered by the databases internal hash values, and won't be sorted by the key values. This method returns the starting key.

**dbhash.** *last()*

Return the last key/value pair in a database traversal. This may be used to begin a reverse-order traversal; see `previous()`.

**dbhash.** *next()*

Returns the key next key/value pair in a database traversal. The following code prints every key in the database `db`, without having to create a list in memory that contains them all:

```python
print db.first()
for i in xrange(1, len(db)):
    print db.next()
```

**dbhash.** *previous()*

Returns the previous key/value pair in a forward-traversal of the database. In conjunction with `last()`, this may be used to implement a reverse-order traversal.

**dbhash.** *sync()*

This method forces any unwritten data to be written to the disk.
bsddb — Interface to Berkeley DB library

 Deprecated since version 2.6: The `bsddb` module has been deprecated for removal in Python 3.0.

 The `bsddb` module provides an interface to the Berkeley DB library. Users can create hash, btree or record based library files using the appropriate open call. Bsddb objects behave generally like dictionaries. Keys and values must be strings, however, so to use other objects as keys or to store other kinds of objects the user must serialize them somehow, typically using `marshal.dumps()` or `pickle.dumps()`.

 The `bsddb` module requires a Berkeley DB library version from 3.3 thru 4.7.

 See also:

 http://www.jcea.es/programacion/pybsddb.htm
 The website with documentation for the `bsddb.db` Python Berkeley DB interface that closely mirrors the object oriented interface provided in Berkeley DB 4.x itself.

 http://www.oracle.com/database/berkeley-db/
The Berkeley DB library.

 A more modern DB, DBEnv and DBSequence object interface is available in the `bsddb.db` module which closely matches the Berkeley DB C API documented at the above URLs. Additional features provided by the `bsddb.db` API include fine tuning, transactions, logging, and multiprocess concurrent database access.
The following is a description of the legacy `bsddb` interface compatible with the old Python `bsddb` module. Starting in Python 2.5 this interface should be safe for multithreaded access. The `bsddb.db` API is recommended for threading users as it provides better control.

The `bsddb` module defines the following functions that create objects that access the appropriate type of Berkeley DB file. The first two arguments of each function are the same. For ease of portability, only the first two arguments should be used in most instances.

```python
bsddb.hashopen(filename[, flag[, mode[, pgsizer[, ffactor[, nelem[, cachesize[, lorder[, hflags]]]]]]]])
```

Open the hash format file named `filename`. Files never intended to be preserved on disk may be created by passing `None` as the `filename`. The optional `flag` identifies the mode used to open the file. It may be `'r'` (read only), `'w'` (read-write), `'c'` (read-write - create if necessary; the default) or `'n'` (read-write - truncate to zero length). The other arguments are rarely used and are just passed to the low-level `dbopen` function. Consult the Berkeley DB documentation for their use and interpretation.

```python
bsddb.btopen(filename[, flag[, mode[, btflags[, cachesize[, maxkeypage[, minkeypage[, pgsizer[, lorder]]]]]]]])
```

Open the btree format file named `filename`. Files never intended to be preserved on disk may be created by passing `None` as the `filename`. The optional `flag` identifies the mode used to open the file. It may be `'r'` (read only), `'w'` (read-write), `'c'` (read-write - create if necessary; the default) or `'n'` (read-write - truncate to zero length). The other arguments are rarely used and are just passed to the low-level `dbopen` function. Consult the Berkeley DB documentation for their use and interpretation.
bsddb. **rnonopen**(*filename*, *flag*, *mode*, *rnflags*, *cachesize*, *pgsize*, *lorder*, *rlen*, *delim*, *source*, *pad))

Open a DB record format file named *filename*. Files never intended to be preserved on disk may be created by passing **None** as the *filename*. The optional *flag* identifies the mode used to open the file. It may be `r` (read only), `w` (read-write), `c` (read-write - create if necessary; the default) or `n` (read-write - truncate to zero length). The other arguments are rarely used and are just passed to the low-level dbopen function. Consult the Berkeley DB documentation for their use and interpretation.

**Note:** Beginning in 2.3 some Unix versions of Python may have a bsddb185 module. This is present only to allow backwards compatibility with systems which ship with the old Berkeley DB 1.85 database library. The bsddb185 module should never be used directly in new code. The module has been removed in Python 3.0. If you find you still need it look in PyPI.

### See also:

**Module** dbhash

DBM-style interface to the bsddb
Once instantiated, hash, btree and record objects support the same methods as dictionaries. In addition, they support the methods listed below.

*Changed in version 2.3.1: Added dictionary methods.*

**bsddbobject.close()**

Close the underlying file. The object can no longer be accessed. Since there is no open `open()` method for these objects, to open the file again a new `bsddb` module open function must be called.

**bsddbobject.keys()**

Return the list of keys contained in the DB file. The order of the list is unspecified and should not be relied on. In particular, the order of the list returned is different for different file formats.

**bsddbobject.has_key(key)**

Return 1 if the DB file contains the argument as a key.

**bsddbobject.set_location(key)**

Set the cursor to the item indicated by `key` and return a tuple containing the key and its value. For binary tree databases (opened using `btopen()`), if `key` does not actually exist in the database, the cursor will point to the next item in sorted order and return that key and value. For other databases, `KeyError` will be raised if `key` is not found in the database.

**bsddbobject.first()**

Set the cursor to the first item in the DB file and return it. The order of keys in the file is unspecified, except in the case of B-Tree databases. This method raises `bsddb.error` if the database
is empty.

bsddbobject.next()

Set the cursor to the next item in the DB file and return it. The order of keys in the file is unspecified, except in the case of B-Tree databases.

bsddbobject.previous()

Set the cursor to the previous item in the DB file and return it. The order of keys in the file is unspecified, except in the case of B-Tree databases. This is not supported on hashtable databases (those opened with hashopen()).

bsddbobject.last()

Set the cursor to the last item in the DB file and return it. The order of keys in the file is unspecified. This is not supported on hashtable databases (those opened with hashopen()). This method raises bsddb.error if the database is empty.

bsddbobject.sync()

Synchronize the database on disk.

Example:

```python
>>> import bsddb
>>> db = bsddb.btopen('/tmp/spam.db', 'c')
>>> for i in range(10): db['%d' %i] = '%d' % (i*i)
... >>> db['3']
'9'
>>> db.keys()
['0', '1', '2', '3', '4', '5', '6', '7', '8', '9']
>>> db.first()
('0', '0')
>>> db.next()
('1', '1')
>>> db.last()
('9', '81')
>>> db.set_location('2')
```
(('2', '4')
>>> db.previous()
('1', '1')
>>> for k, v in db.iteritems():
    ...     print k, v
 0 0
 1 1
 2 4
 3 9
 4 16
 5 25
 6 36
 7 49
 8 64
 9 81
>>> '8' in db
True
>>> db.sync()
0

Python v2.6 documentation » The Python Standard Library previous | next | modules | index
**dumbdbm — Portable DBM implementation**

**Note:** The `dumbdbm` module has been renamed to `dbm.dumb` in Python 3.0. The `2to3` tool will automatically adapt imports when converting your sources to 3.0.

**Note:** The `dumbdbm` module is intended as a last resort fallback for the `anydbm` module when no more robust module is available. The `dumbdbm` module is not written for speed and is not nearly as heavily used as the other database modules.

The `dumbdbm` module provides a persistent dictionary-like interface which is written entirely in Python. Unlike other modules such as `gdbm` and `bsddb`, no external library is required. As with other persistent mappings, the keys and values must always be strings.

The module defines the following:

```python
exception dumbdbm.error

Raised on dumbdbm-specific errors, such as I/O errors. `KeyError` is raised for general mapping errors like specifying an incorrect key.
```

```python
dumbdbm.open(filename[, flag[, mode]])

Open a dumbdbm database and return a dumbdbm object. The `filename` argument is the basename of the database file (without any specific extensions). When a dumbdbm database is created, files with `.dat` and `.dir` extensions are created.

The optional `flag` argument is currently ignored; the database is always opened for update, and will be created if it does not exist.
```
The optional *mode* argument is the Unix mode of the file, used only when the database has to be created. It defaults to octal \texttt{0666} (and will be modified by the prevailing umask).

*Changed in version 2.2:* The *mode* argument was ignored in earlier versions.

**See also:**

**Module** \texttt{anydbm}
- Generic interface to \texttt{dbm}-style databases.

**Module** \texttt{dbm}
- Similar interface to the DBM/NDBM library.

**Module** \texttt{gdbm}
- Similar interface to the GNU GDBM library.

**Module** \texttt{shelve}
- Persistence module which stores non-string data.

**Module** \texttt{whichdb}
- Utility module used to determine the type of an existing database.
Dumbdbm Objects

In addition to the methods provided by the `UserDict.DictMixin` class, `dumbdbm` objects provide the following methods.

```python
dumbdbm.sync()
```

Synchronize the on-disk directory and data files. This method is called by the `sync()` method of `shelve` objects.
**sqlite3 — DB-API 2.0 interface for SQLite databases**

*New in version 2.5.*

SQLite is a C library that provides a lightweight disk-based database that doesn’t require a separate server process and allows accessing the database using a nonstandard variant of the SQL query language. Some applications can use SQLite for internal data storage. It’s also possible to prototype an application using SQLite and then port the code to a larger database such as PostgreSQL or Oracle.

pysqlite was written by Gerhard Häring and provides a SQL interface compliant with the DB-API 2.0 specification described by [PEP 249](https://www.python.org/dev/peps/pep-0249/).

To use the module, you must first create a `Connection` object that represents the database. Here the data will be stored in the `/tmp/example` file:

```python
conn = sqlite3.connect('/tmp/example')
```

You can also supply the special name `:memory:` to create a database in RAM.

Once you have a `Connection`, you can create a `Cursor` object and call its `execute()` method to perform SQL commands:

```python
c = conn.cursor()

# Create table
c.execute('''create table stocks
(date text, trans text, symbol text,
 qty real, price real)''')

# Insert a row of data
c.execute("'insert into stocks
values ('2006-01-05','BUY','RHAT',100,35.14)"'")

# Save (commit) the changes
c.conn.commit()

# We can also close the cursor if we are done with it
c.close()

Usually your SQL operations will need to use values from Python variables. You shouldn't assemble your query using Python's string operations because doing so is insecure; it makes your program vulnerable to an SQL injection attack.

Instead, use the DB-API's parameter substitution. Put ? as a placeholder wherever you want to use a value, and then provide a tuple of values as the second argument to the cursor's `execute()` method. (Other database modules may use a different placeholder, such as %s or :1.) For example:

```python
# Never do this -- insecure!
symbol = 'IBM'
c.execute("select *
from stocks
where symbol = ?", (symbol,))

# Do this instead
t = (symbol,)
c.execute('select *
from stocks
where symbol=?', t)
```

```python
# Larger example
for t in (('2006-03-28', 'BUY', 'IBM', 1000, 45.00),
 ('2006-04-05', 'BUY', 'MSOFT', 1000, 72.00),
 ('2006-04-06', 'SELL', 'IBM', 500, 53.00),
):
    c.execute('insert into stocks values (?,?,?,?,?)', t)
```

To retrieve data after executing a SELECT statement, you can either treat the cursor as an *iterator*, call the cursor's `fetchone()` method to retrieve a single matching row, or call `fetchall()` to get a list of the matching rows.

This example uses the iterator form:
```python
>>> c = conn.cursor()
>>> c.execute('select * from stocks order by price')
...    for row in c:
...        print row
...
(u'2006-01-05', u'BUY', u'RHAT', 100, 35.140000000000001)
(u'2006-03-28', u'BUY', u'IBM', 1000, 45.0)
(u'2006-04-06', u'SELL', u'IBM', 500, 53.0)
(u'2006-04-05', u'BUY', u'MSOFT', 1000, 72.0)

```
Module functions and constants

sqlite3.PARSE_DECLTYPES
This constant is meant to be used with the detect_types parameter of the connect() function.

Setting it makes the sqlite3 module parse the declared type for each column it returns. It will parse out the first word of the declared type, i.e. for “integer primary key”, it will parse out “integer”, or for “number(10)” it will parse out “number”. Then for that column, it will look into the converters dictionary and use the converter function registered for that type there.

sqlite3.PARSE_COLNAMES
This constant is meant to be used with the detect_types parameter of the connect() function.

Setting this makes the SQLite interface parse the column name for each column it returns. It will look for a string formed [mytype] in there, and then decide that ‘mytype’ is the type of the column. It will try to find an entry of ‘mytype’ in the converters dictionary and then use the converter function found there to return the value. The column name found in cursor.description is only the first word of the column name, i.e. if you use something like "as "x [datetime]" in your SQL, then we will parse out everything until the first blank for the column name: the column name would simply be “x”.

sqlite3.connect(database[, timeout, isolation_level, detect_types, factory])
Opens a connection to the SQLite database file database. You can use ":memory:" to open a database connection to a database
that resides in RAM instead of on disk.

When a database is accessed by multiple connections, and one of the processes modifies the database, the SQLite database is locked until that transaction is committed. The `timeout` parameter specifies how long the connection should wait for the lock to go away until raising an exception. The default for the timeout parameter is 5.0 (five seconds).

For the `isolation_level` parameter, please see the `Connection.isolation_level` property of `Connection` objects.

SQLite natively supports only the types TEXT, INTEGER, FLOAT, BLOB and NULL. If you want to use other types you must add support for them yourself. The `detect_types` parameter and the using custom converters registered with the module-level `register_converter()` function allow you to easily do that.

`detect_types` defaults to 0 (i.e. off, no type detection), you can set it to any combination of `PARSE_DECLTYPES` and `PARSE_COLNAMES` to turn type detection on.

By default, the `sqlite3` module uses its `Connection` class for the `connect` call. You can, however, subclass the `Connection` class and make `connect()` use your class instead by providing your class for the `factory` parameter.

Consult the section `SQLite and Python types` of this manual for details.

The `sqlite3` module internally uses a statement cache to avoid SQL parsing overhead. If you want to explicitly set the number of statements that are cached for the connection, you can set the `cached_statements` parameter. The currently implemented default is to cache 100 statements.
sqlite3. `register_converter` *(typename, callable)*

Registers a callable to convert a bytestring from the database into a custom Python type. The callable will be invoked for all database values that are of the type `typename`. Confer the parameter `detect_types` of the `connect()` function for how the type detection works. Note that the case of `typename` and the name of the type in your query must match!

sqlite3. `register_adapter` *(type, callable)*

Registers a callable to convert the custom Python type `type` into one of SQLite's supported types. The callable `callable` accepts as single parameter the Python value, and must return a value of the following types: int, long, float, str (UTF-8 encoded), unicode or buffer.

sqlite3. `complete_statement` *(sql)*

Returns `True` if the string `sql` contains one or more complete SQL statements terminated by semicolons. It does not verify that the SQL is syntactically correct, only that there are no unclosed string literals and the statement is terminated by a semicolon.

This can be used to build a shell for SQLite, as in the following example:

```
# A minimal SQLite shell for experiments

import sqlite3

con = sqlite3.connect(":memory:")
con.isolation_level = None
cur = con.cursor()
buffer = ""
```
print "Enter your SQL commands to execute in sqlite3."
print "Enter a blank line to exit."

while True:
    line = raw_input()
    if line == "":
        break
    buffer += line
    if sqlite3.complete_statement(buffer):
        try:
            buffer = buffer.strip()
            cur.execute(buffer)

            if buffer.lstrip().upper().startswith("SELECT"):
                print cur.fetchall()
        except sqlite3.Error, e:
            print "An error occurred:", e.args[0]
            buffer = ""

con.close()

sqlite3.enable_callback_tracebacks(flag)

By default you will not get any tracebacks in user-defined functions, aggregates, converters, authorizer callbacks etc. If you want to debug them, you can call this function with flag as True. Afterwards, you will get tracebacks from callbacks on sys.stderr. Use False to disable the feature again.
Connection Objects

A Connection instance has the following attributes and methods:

Connection.**isolation_level**
Get or set the current isolation level. None for autocommit mode or one of “DEFERRED”, “IMMEDIATE” or “EXCLUSIVE”. See section *Controlling Transactions* for a more detailed explanation.

Connection.**cursor([cursorClass])**
The cursor method accepts a single optional parameter *cursorClass*. If supplied, this must be a custom cursor class that extends sqlite3.Cursor.

Connection.**commit()**
This method commits the current transaction. If you don’t call this method, anything you did since the last call to commit() is not visible from from other database connections. If you wonder why you don’t see the data you’ve written to the database, please check you didn’t forget to call this method.

Connection.**rollback()**
This method rolls back any changes to the database since the last call to commit().

Connection.**close()**
This closes the database connection. Note that this does not automatically call commit(). If you just close your database connection without calling commit() first, your changes will be lost!

Connection.**execute(sql[, parameters])**
This is a nonstandard shortcut that creates an intermediate
cursor object by calling the cursor method, then calls the cursor’s
`execute()` method with the parameters given.

Connection. **`executemany(sql[, parameters])`**
This is a nonstandard shortcut that creates an intermediate
cursor object by calling the cursor method, then calls the cursor’s
`executemany()` method with the parameters given.

Connection. **`executescript(sql_script)`**
This is a nonstandard shortcut that creates an intermediate
cursor object by calling the cursor method, then calls the cursor’s
`executescript()` method with the parameters given.

Connection. **`create_function(name, num_params, func)`**
Creates a user-defined function that you can later use from within
SQL statements under the function name `name`. `num_params` is
the number of parameters the function accepts, and `func` is a
Python callable that is called as the SQL function.

The function can return any of the types supported by SQLite:
unicode, str, int, long, float, buffer and None.

Example:

```python
import sqlite3
import md5

def md5sum(t):
    return md5.md5(t).hexdigest()

con = sqlite3.connect(":memory:")
con.create_function("md5", 1, md5sum)
cur = con.cursor()
```
Connection.create_aggregate(name, num_params, aggregate_class)

Creates a user-defined aggregate function.

The aggregate class must implement a step method, which accepts the number of parameters num_params, and a finalize method which will return the final result of the aggregate.

The finalize method can return any of the types supported by SQLite: unicode, str, int, long, float, buffer and None.

Example:

```python
import sqlite3

class MySum:
    def __init__(self):
        self.count = 0

    def step(self, value):
        self.count += value

    def finalize(self):
        return self.count

con = sqlite3.connect(":memory:")
con.create_aggregate("mysum", 1, MySum)
cur = con.cursor()
cur.execute("create table test(i)")
cur.execute("insert into test(i) values (1)")
cur.execute("insert into test(i) values (2)")
```
cur.execute("select mysum(i) from test")
print cur.fetchone()[0]

Connection.**create_collation**(name, callable)

Creates a collation with the specified name and callable. The callable will be passed two string arguments. It should return -1 if the first is ordered lower than the second, 0 if they are ordered equal and 1 if the first is ordered higher than the second. Note that this controls sorting (ORDER BY in SQL) so your comparisons don’t affect other SQL operations.

Note that the callable will get its parameters as Python bytestrings, which will normally be encoded in UTF-8.

The following example shows a custom collation that sorts “the wrong way”:

```python
import sqlite3
def collate_reverse(string1, string2):
    return -cmp(string1, string2)

con = sqlite3.connect(":memory:")
con.create_collation("reverse", collate_reverse)

cur = con.cursor()
cur.execute("create table test(x)")
cur.executemany("insert into test(x) values (?)", ["a",],)
cur.execute("select x from test order by x collate reverse")
for row in cur:
    print row
con.close()
```

To remove a collation, call **create_collation** with None as
callable:

```python
con.create_collation("reverse", None)
```

**Connection.interrupt()**

You can call this method from a different thread to abort any queries that might be executing on the connection. The query will then abort and the caller will get an exception.

**Connection.set_authorizer(authorizer_callback)**

This routine registers a callback. The callback is invoked for each attempt to access a column of a table in the database. The callback should return `SQLITE_OK` if access is allowed, `SQLITE_DENY` if the entire SQL statement should be aborted with an error and `SQLITE_IGNORE` if the column should be treated as a NULL value. These constants are available in the `sqlite3` module.

The first argument to the callback signifies what kind of operation is to be authorized. The second and third argument will be arguments or `None` depending on the first argument. The 4th argument is the name of the database ("main", "temp", etc.) if applicable. The 5th argument is the name of the inner-most trigger or view that is responsible for the access attempt or `None` if this access attempt is directly from input SQL code.

Please consult the SQLite documentation about the possible values for the first argument and the meaning of the second and third argument depending on the first one. All necessary constants are available in the `sqlite3` module.

**Connection.set_progress_handler(handler, n)**

*New in version 2.6.*
This routine registers a callback. The callback is invoked for every $n$ instructions of the SQLite virtual machine. This is useful if you want to get called from SQLite during long-running operations, for example to update a GUI.

If you want to clear any previously installed progress handler, call the method with `None` for `handler`.

**Connection. row_factory**

You can change this attribute to a callable that accepts the cursor and the original row as a tuple and will return the real result row. This way, you can implement more advanced ways of returning results, such as returning an object that can also access columns by name.

Example:

```python
import sqlite3

def dict_factory(cursor, row):
    d = {}
    for idx, col in enumerate(cursor.description):
        d[col[0]] = row[idx]
    return d

con = sqlite3.connect(':memory:)
con.row_factory = dict_factory
cur = con.cursor()
cur.execute("select 1 as a")
print cur.fetchone()['a']
```

If returning a tuple doesn’t suffice and you want name-based access to columns, you should consider setting `row_factory` to the highly-optimized `sqlite3.Row` type. `Row` provides both index-based and case-insensitive name-based access to columns with
almost no memory overhead. It will probably be better than your own custom dictionary-based approach or even a db_row based solution.

Connection. `text_factory`
Using this attribute you can control what objects are returned for the TEXT data type. By default, this attribute is set to `unicode` and the `sqlite3` module will return Unicode objects for TEXT. If you want to return bytestrings instead, you can set it to `str`.

For efficiency reasons, there’s also a way to return Unicode objects only for non-ASCII data, and bytestrings otherwise. To activate it, set this attribute to `sqlite3.OptimizedUnicode`.

You can also set it to any other callable that accepts a single bytestring parameter and returns the resulting object.

See the following example code for illustration:

```python
import sqlite3

con = sqlite3.connect(':memory:)
cur = con.cursor()

# Create the table
c.on.execute("create table person(lastname, firstname)"

AUSTRIA = u"\xd6sterreich"

# by default, rows are returned as Unicode
cur.execute("select ?", (AUSTRIA,))
row = cur.fetchone()
assert row[0] == AUSTRIA

# but we can make pysqlite always return bytestrings ...
```
con.text_factory = str
cur.execute("select ?", (AUSTRIA,))
row = cur.fetchone()
assert type(row[0]) == str
# the bytestrings will be encoded in UTF-8, unless you store
# database ...
assert row[0] == AUSTRIA.encode("utf-8")

# we can also implement a custom text_factory ...
# here we implement one that will ignore Unicode characters
# decoded from UTF-8
con.text_factory = lambda x: unicode(x, "utf-8", "ignore")
cur.execute("select ?", ("this is latin1 and would normally create errors" + u"\xe4\xf6\xfc".encode("latin1"),))
row = cur.fetchone()
assert type(row[0]) == unicode

# pysqlite offers a built-in optimized text_factory that will
# objects, if the data is in ASCII only, and otherwise return
con.text_factory = sqlite3.OptimizedUnicode
cur.execute("select ?", (AUSTRIA,))
row = cur.fetchone()
assert type(row[0]) == unicode

cur.execute("select ?", ("Germany",))
row = cur.fetchone()
assert type(row[0]) == str

Connection.total_changes

Returns the total number of database rows that have been
modified, inserted, or deleted since the database connection was
opened.

Connection.iterdump

Returns an iterator to dump the database in an SQL text format.
Useful when saving an in-memory database for later restoration. This function provides the same capabilities as the \texttt{.dump} command in the \texttt{sqlite3} shell.

\textit{New in version 2.6.}

Example:

```python
# Convert file existing_db.db to SQL dump file dump.sql
import sqlite3, os

con = sqlite3.connect('existing_db.db')
full_dump = os.linesep.join(con.iterdump())
f = open('dump.sql', 'w')
f.writelines(full_dump)
f.close()
```
Cursor Objects

A **Cursor** instance has the following attributes and methods:

```python
Cursor.execute(sql[, parameters])
```

Executes an SQL statement. The SQL statement may be parametrized (i.e., placeholders instead of SQL literals). The `sqlite3` module supports two kinds of placeholders: question marks (qmark style) and named placeholders (named style).

This example shows how to use parameters with qmark style:

```python
import sqlite3

con = sqlite3.connect("mydb")

cur = con.cursor()

who = "Yeltsin"
age = 72

cur.execute("select name_last, age from people where name_last=? and age=?", (who, age))
print cur.fetchone()
```

This example shows how to use the named style:

```python
import sqlite3

con = sqlite3.connect("mydb")

cur = con.cursor()
```
who = "Yeltsin"
age = 72

cur.execute("select name_last, age from people where name_last=:who
               and age=:age",
               {"who": who, "age": age})
print cur.fetchone()

execute() will only execute a single SQL statement. If you try to execute more than one statement with it, it will raise a Warning. Use executescript() if you want to execute multiple SQL statements with one call.

Cursor.executemany(sql, seq_of_parameters)
Executes an SQL command against all parameter sequences or mappings found in the sequence sql. The sqlite3 module also allows using an iterator yielding parameters instead of a sequence.

import sqlite3

class IterChars:
    def __init__(self):
        self.count = ord('a')

    def __iter__(self):
        return self

    def next(self):
        if self.count > ord('z'):
            raise StopIteration
        self.count += 1
        return (chr(self.count - 1),) # this is a 1-tuple
con = sqlite3.connect(":memory:")
cur = con.cursor()
cur.execute("create table characters(c)")

theIter = IterChars()
cur.executemany("insert into characters(c) values (?)", theIter)

cur.execute("select c from characters")
print cur.fetchall()
*sql_script* can be a bytestring or a Unicode string.

Example:

```python
import sqlite3

con = sqlite3.connect(':memory:)
cur = con.cursor()
cur.executescript('"
    create table person(
        firstname,
        lastname,
        age
    );

    create table book(
        title,
        author,
        published
    );

    insert into book(title, author, published)
    values (                      
        'Dirk Gently''s Holistic Detective Agency',
        'Douglas Adams',
        1987
    );

)"
```

**Cursor.*fetchone()*  
Fetches the next row of a query result set, returning a single sequence, or *None* when no more data is available.

**Cursor.*fetchmany()*  
Slices of *size* rows, or the entire remaining result set when *size* is not set, or *None* when no more data is available.
Fetches the next set of rows of a query result, returning a list. An empty list is returned when no more rows are available.

The number of rows to fetch per call is specified by the `size` parameter. If it is not given, the cursor’s arraysize determines the number of rows to be fetched. The method should try to fetch as many rows as indicated by the size parameter. If this is not possible due to the specified number of rows not being available, fewer rows may be returned.

Note there are performance considerations involved with the `size` parameter. For optimal performance, it is usually best to use the arraysize attribute. If the `size` parameter is used, then it is best for it to retain the same value from one `fetchmany()` call to the next.

**Cursor. `fetchall()`**

Fetches all (remaining) rows of a query result, returning a list. Note that the cursor’s arraysize attribute can affect the performance of this operation. An empty list is returned when no rows are available.

**Cursor. `rowcount`**

Although the `Cursor` class of the `sqlite3` module implements this attribute, the database engine’s own support for the determination of “rows affected”/”rows selected” is quirky.

For `DELETE` statements, SQLite reports `rowcount` as 0 if you make a `DELETE FROM table` without any condition.

For `executemany()` statements, the number of modifications are summed up into `rowcount`.

As required by the Python DB API Spec, the `rowcount` attribute “is -1 in case no executeXX() has been performed on the cursor or the rowcount of the last operation is not determinable by the
This includes `SELECT` statements because we cannot determine the number of rows a query produced until all rows were fetched.

**Cursor. `lastrowid`**

This read-only attribute provides the rowid of the last modified row. It is only set if you issued a `INSERT` statement using the `execute()` method. For operations other than `INSERT` or when `executemany()` is called, `lastrowid` is set to `None`. 
SQLite and Python types

Introduction

SQLite natively supports the following types: NULL, INTEGER, REAL, TEXT, BLOB.

The following Python types can thus be sent to SQLite without any problem:

<table>
<thead>
<tr>
<th>Python type</th>
<th>SQLite type</th>
</tr>
</thead>
<tbody>
<tr>
<td>None</td>
<td>NULL</td>
</tr>
<tr>
<td>int</td>
<td>INTEGER</td>
</tr>
<tr>
<td>long</td>
<td>INTEGER</td>
</tr>
<tr>
<td>float</td>
<td>REAL</td>
</tr>
<tr>
<td>str (UTF8-encoded)</td>
<td>TEXT</td>
</tr>
<tr>
<td>unicode</td>
<td>TEXT</td>
</tr>
<tr>
<td>buffer</td>
<td>BLOB</td>
</tr>
</tbody>
</table>

This is how SQLite types are converted to Python types by default:

<table>
<thead>
<tr>
<th>SQLite type</th>
<th>Python type</th>
</tr>
</thead>
<tbody>
<tr>
<td>NULL</td>
<td>None</td>
</tr>
<tr>
<td>INTEGER</td>
<td>int or long, depending on size</td>
</tr>
<tr>
<td>REAL</td>
<td>float</td>
</tr>
<tr>
<td>TEXT</td>
<td>depends on text_factory, unicode by default</td>
</tr>
<tr>
<td>BLOB</td>
<td>buffer</td>
</tr>
</tbody>
</table>

The type system of the sqlite3 module is extensible in two ways: you can store additional Python types in a SQLite database via object adaptation, and you can let the sqlite3 module convert
Using adapters to store additional Python types in SQLite databases

As described before, SQLite supports only a limited set of types natively. To use other Python types with SQLite, you must adapt them to one of the sqlite3 module’s supported types for SQLite: one of NoneType, int, long, float, str, unicode, buffer.

The sqlite3 module uses Python object adaptation, as described in PEP 246 for this. The protocol to use is PrepareProtocol.

There are two ways to enable the sqlite3 module to adapt a custom Python type to one of the supported ones.

Letting your object adapt itself

This is a good approach if you write the class yourself. Let’s suppose you have a class like this:

```python
class Point(object):
    def __init__(self, x, y):
        self.x, self.y = x, y
```

Now you want to store the point in a single SQLite column. First you'll have to choose one of the supported types first to be used for representing the point. Let's just use str and separate the coordinates using a semicolon. Then you need to give your class a method `__conform__(self, protocol)` which must return the converted value. The parameter `protocol` will be PrepareProtocol.

```python
import sqlite3
class Point(object):
    def __init__(self, x, y):
```

def __conform__(self, protocol):
    if protocol is sqlite3.PrepareProtocol:
        return "%f;%f" % (self.x, self.y)

con = sqlite3.connect(":memory:"
cur = con.cursor()

p = Point(4.0, -3.2)
cur.execute("select ?", (p,))
print cur.fetchone()[0]

The other possibility is to create a function that converts the type to
the string representation and register the function with
register_adapter().

Note: The type/class to adapt must be a new-style class, i.e. it
must have object as one of its bases.

import sqlite3

class Point(object):
    def __init__(self, x, y):
        self.x, self.y = x, y

def adapt_point(point):
    return "%f;%f" % (point.x, point.y)

sqlite3.register_adapter(Point, adapt_point)

con = sqlite3.connect(":memory:"
cur = con.cursor()

p = Point(4.0, -3.2)
cur.execute("select ?", (p,))
print cur.fetchone()[0]

The sqlite3 module has two default adapters for Python's built-in
datetime.date and datetime.datetime types. Now let's suppose we
want to store `datetime.datetime` objects not in ISO representation, but as a Unix timestamp.

```python
import sqlite3
import datetime, time

def adapt_datetime(ts):
    return time.mktime(ts.timetuple())

sqlite3.register_adapter(datetime.datetime, adapt_datetime)

con = sqlite3.connect(':memory:)
cur = con.cursor()

now = datetime.datetime.now()
cur.execute("select ?", (now,))
print cur.fetchone()[0]
```

## Converting SQLite values to custom Python types

Writing an adapter lets you send custom Python types to SQLite. But to make it really useful we need to make the Python to SQLite to Python roundtrip work.

Enter converters.

Let's go back to the `Point` class. We stored the x and y coordinates separated via semicolons as strings in SQLite.

First, we'll define a converter function that accepts the string as a parameter and constructs a `Point` object from it.

**Note:** Converter functions **always** get called with a string, no matter under which data type you sent the value to SQLite.

```python
def convert_point(s):
    x, y = map(float, s.split(";"))
    return Point(x, y)
```
Now you need to make the `sqlite3` module know that what you select from the database is actually a point. There are two ways of doing this:

- Implicitly via the declared type
- Explicitly via the column name

Both ways are described in section *Module functions and constants*, in the entries for the constants `PARSE_DECLTYPES` and `PARSE_COLNAMES`.

The following example illustrates both approaches.

```python
import sqlite3

class Point(object):
    def __init__(self, x, y):
        self.x, self.y = x, y

    def __repr__(self):
        return "(%f;%f)" % (self.x, self.y)

def adapt_point(point):
    return "%f;%f" % (point.x, point.y)

def convert_point(s):
    x, y = map(float, s.split(";"))
    return Point(x, y)

# Register the adapter
sqlite3.register_adapter(Point, adapt_point)

# Register the converter
sqlite3.register_converter("point", convert_point)

p = Point(4.0, -3.2)

# 1) Using declared types
con = sqlite3.connect(":memory:", detect_types=sqlite3.PARSE_DECLTYPES)
cur = con.cursor()
cur.execute("create table test(p point)")
cur.execute("insert into test(p) values (?)", (p,))
cur.execute("select p from test")
print "with declared types:", cur.fetchone()[0]
```
cur.close()
con.close()

# 1) Using column names
con = sqlite3.connect(':memory:', detect_types=sqlite3.PARSE_COLNAMES)
cur = con.cursor()
cur.execute("create table test(p)"

cur.execute("insert into test(p) values (?)", (p,))
cur.execute('select p as "p [point]" from test')
print "with column names ", cur.fetchone()[0]
cur.close()
con.close()

Default adapters and converters

There are default adapters for the date and datetime types in the datetime module. They will be sent as ISO dates/ISO timestamps to SQLite.

The default converters are registered under the name “date” for \texttt{datetime.date} and under the name “timestamp” for \texttt{datetime.datetime}.

This way, you can use date/timestamps from Python without any additional fiddling in most cases. The format of the adapters is also compatible with the experimental SQLite date/time functions.

The following example demonstrates this.

```
import sqlite3
import datetime

con = sqlite3.connect(':memory:', detect_types=sqlite3.PARSE_DECLTYPES|sqlite3.PARSE_COLNAMES)
cur = con.cursor()
cur.execute("create table test(d date, ts timestamp)"

today = datetime.date.today()
now = datetime.datetime.now()
```
cur.execute("insert into test(d, ts) values (?, ?)", (today, now))
row = cur.fetchone()
print today, "=>", row[0], type(row[0])
print now, "=>", row[1], type(row[1])

cur.execute('select current_date as "d [date]", current_timestamp as "ts [timestamp]"')
row = cur.fetchone()
print "current_date", row[0], type(row[0])
print "current_timestamp", row[1], type(row[1])
Controlling Transactions

By default, the sqlite3 module opens transactions implicitly before a Data Modification Language (DML) statement (i.e. INSERT/UPDATE/DELETE/REPLACE), and commits transactions implicitly before a non-DML, non-query statement (i.e. anything other than SELECT/INSERT/UPDATE/DELETE/REPLACE).

So if you are within a transaction and issue a command like CREATE TABLE ..., VACUUM, PRAGMA, the sqlite3 module will commit implicitly before executing that command. There are two reasons for doing that. The first is that some of these commands don’t work within transactions. The other reason is that pysqlite needs to keep track of the transaction state (if a transaction is active or not).

You can control which kind of “BEGIN” statements pysqlite implicitly executes (or none at all) via the isolation_level parameter to the connect() call, or via the isolation_level property of connections.

If you want autocommit mode, then set isolation_level to None.

Otherwise leave it at its default, which will result in a plain “BEGIN” statement, or set it to one of SQLite’s supported isolation levels: DEFERRED, IMMEDIATE or EXCLUSIVE.
Using 

pysqlite 
efficiently

Using shortcut methods

Using the nonstandard `execute()`, `executemany()` and `executescript()` methods of the `Connection` object, your code can be written more concisely because you don’t have to create the (often superfluous) `Cursor` objects explicitly. Instead, the `Cursor` objects are created implicitly and these shortcut methods return the cursor objects. This way, you can execute a SELECT statement and iterate over it directly using only a single call on the `Connection` object.

```python
import sqlite3

persons = [
    ("Hugo", "Boss"),
    ("Calvin", "Klein")
]

con = sqlite3.connect(":memory:")
# Create the table
con.execute("create table person(firstname, lastname)"")
# Fill the table
con.executemany("insert into person(firstname, lastname) values (?, ?)", persons)
# Print the table contents
for row in con.execute("select firstname, lastname from person"):
    print row
# Using a dummy WHERE clause to not let SQLite take the shortcut
print "I just deleted", con.execute("delete from person where 1"")
```

Accessing columns by name instead of by index
One useful feature of the sqlite3 module is the builtin sqlite3.Row class designed to be used as a row factory.

Rows wrapped with this class can be accessed both by index (like tuples) and case-insensitively by name:

```python
import sqlite3
con = sqlite3.connect("mydb")
con.row_factory = sqlite3.Row

cur = con.cursor()
cur.execute("select name_last, age from people")
for row in cur:
    assert row[0] == row["name_last"]
    assert row["name_last"] == row["nAmE_lAsT"]
    assert row[1] == row["age"]
    assert row[1] == row["AgE"]
```

Using the connection as a context manager

New in version 2.6.

Connection objects can be used as context managers that automatically commit or rollback transactions. In the event of an exception, the transaction is rolled back; otherwise, the transaction is committed:

```python
import sqlite3
con = sqlite3.connect(":memory:"
con.execute("create table person (id integer primary key, first

# Successful, con.commit() is called automatically afterwards
with con:
    con.execute("insert into person(firstname) values (?)", ("J

# con.rollback() is called after the with block finishes with a
# exception is still raised and must be catched
try:
    with con:
        con.execute("insert into person(firstname) values (?)",
```
except sqlite3.IntegrityError:
    print "couldn't add Joe twice"
Data Compression and Archiving

The modules described in this chapter support data compression with the zlib, gzip, and bzip2 algorithms, and the creation of ZIP- and tar-format archives.

- **zlib** — Compression compatible with **gzip**

- **gzip** — Support for **gzip** files
  - Examples of usage

- **bz2** — Compression compatible with **bzip2**
  - (De)compression of files
  - Sequential (de)compression
  - One-shot (de)compression

- **zipfile** — Work with ZIP archives
  - ZipFile Objects

For applications that require data compression, the functions in this module allow compression and decompression, using the zlib library. The zlib library has its own home page at http://www.zlib.net. There are known incompatibilities between the Python module and versions of the zlib library earlier than 1.1.3; 1.1.3 has a security vulnerability, so we recommend using 1.1.4 or later.

zlib’s functions have many options and often need to be used in a particular order. This documentation doesn’t attempt to cover all of the permutations; consult the zlib manual at http://www.zlib.net/manual.html for authoritative information.

For reading and writing .gz files see the gzip module. For other archive formats, see the bz2, zipfile, and tarfile modules.

The available exception and functions in this module are:

**exception zlib.error**

Exception raised on compression and decompression errors.

**zlib.adler32(string[, value])**

Computes a Adler-32 checksum of string. (An Adler-32 checksum is almost as reliable as a CRC32 but can be computed much more quickly.) If value is present, it is used as the starting value of the checksum; otherwise, a fixed default value is used. This allows computing a running checksum over the concatenation of several input strings. The algorithm is not cryptographically strong, and should not be used for authentication or digital signatures. Since the algorithm is designed for use as a checksum algorithm, it is not suitable for use as a general hash
This function always returns an integer object.

*Changed in version 2.6:* For consistent cross-platform behavior we always return a signed integer. i.e: Results in the \((2^{31})\ldots(2^{32}-1)\) range will be negative.

```python
zlib.compress(string[, level])
```
Compresses the data in `string`, returning a string contained compressed data. `level` is an integer from 1 to 9 controlling the level of compression; 1 is fastest and produces the least compression, 9 is slowest and produces the most. The default value is 6. Raises the `error` exception if any error occurs.

```python
zlib.crc32(string[, value])
```
Computes a CRC (Cyclic Redundancy Check) checksum of `string`. If `value` is present, it is used as the starting value of the checksum; otherwise, a fixed default value is used. This allows computing a running checksum over the concatenation of several input strings. The algorithm is not cryptographically strong, and should not be used for authentication or digital signatures. Since the algorithm is designed for use as a checksum algorithm, it is not suitable for use as a general hash algorithm.

This function always returns an integer object.
Changed in version 2.6: For consistent cross-platform behavior we always return a signed integer. ie: Results in the (2**31)...(2**32-1) range will be negative.

zlib.decompress(string[, wbits[, bufsize]])

Decompresses the data in string, returning a string containing the uncompressed data. The wbits parameter controls the size of the window buffer. If bufsize is given, it is used as the initial size of the output buffer. Raises the error exception if any error occurs.

The absolute value of wbits is the base two logarithm of the size of the history buffer (the “window size”) used when compressing data. Its absolute value should be between 8 and 15 for the most recent versions of the zlib library, larger values resulting in better compression at the expense of greater memory usage. The default value is 15. When wbits is negative, the standard gzip header is suppressed; this is an undocumented feature of the zlib library, used for compatibility with unzip’s compression file format.

bufsize is the initial size of the buffer used to hold decompressed data. If more space is required, the buffer size will be increased as needed, so you don’t have to get this value exactly right; tuning it will only save a few calls to malloc. The default size is 16384.

zlib.decompressobj([wbits])

Returns a decompression object, to be used for decompressing data streams that won’t fit into memory at once. The wbits parameter controls the size of the window buffer.

Compression objects support the following methods:

Compress.compress(string)
Compress *string*, returning a string containing compressed data for at least part of the data in *string*. This data should be concatenated to the output produced by any preceding calls to the `compress()` method. Some input may be kept in internal buffers for later processing.

**Compress.`flush([mode])`**
All pending input is processed, and a string containing the remaining compressed output is returned. *mode* can be selected from the constants `Z_SYNC_FLUSH`, `Z_FULL_FLUSH`, or `Z_FINISH`, defaulting to `Z_FINISH`. `Z_SYNC_FLUSH` and `Z_FULL_FLUSH` allow compressing further strings of data, while `Z_FINISH` finishes the compressed stream and prevents compressing any more data. After calling `flush()` with *mode* set to `Z_FINISH`, the `compress()` method cannot be called again; the only realistic action is to delete the object.

**Compress.`copy()`**
Returns a copy of the compression object. This can be used to efficiently compress a set of data that share a common initial prefix.

*New in version 2.5.*

Decompression objects support the following methods, and two attributes:

**Decompress.`unused_data`**
A string which contains any bytes past the end of the compressed data. That is, this remains `""` until the last byte that contains compression data is available. If the whole string turned out to contain compressed data, this is `""`, the empty string.

The only way to determine where a string of compressed data
ends is by actually decompressing it. This means that when compressed data is contained part of a larger file, you can only find the end of it by reading data and feeding it followed by some non-empty string into a decompression object's `decompress()` method until the `unused_data` attribute is no longer the empty string.

**Decompress. `unconsumed_tail`**
A string that contains any data that was not consumed by the last `decompress()` call because it exceeded the limit for the uncompressed data buffer. This data has not yet been seen by the zlib machinery, so you must feed it (possibly with further data concatenated to it) back to a subsequent `decompress()` method call in order to get correct output.

**Decompress. `decompress`(`string`, `max_length`)**
Decompress `string`, returning a string containing the uncompressed data corresponding to at least part of the data in `string`. This data should be concatenated to the output produced by any preceding calls to the `decompress()` method. Some of the input data may be preserved in internal buffers for later processing.

If the optional parameter `max_length` is supplied then the return value will be no longer than `max_length`. This may mean that not all of the compressed input can be processed; and uncompressed data will be stored in the attribute `unconsumed_tail`. This string must be passed to a subsequent call to `decompress()` if decompression is to continue. If `max_length` is not supplied then the whole input is decompressed, and `unconsumed_tail` is an empty string.

**Decompress. `flush`([`length`])**
All pending input is processed, and a string containing the remaining uncompressed output is returned. After calling `flush()`, the `decompress()` method cannot be called again; the only realistic action is to delete the object.

The optional parameter `length` sets the initial size of the output buffer.

Decompress. `copy()`
Returns a copy of the decompression object. This can be used to save the state of the decompressor midway through the data stream in order to speed up random seeks into the stream at a future point.

*New in version 2.5.*

**Module gzip**
Reading and writing `gzip`-format files.

**http://www.zlib.net**
The zlib library home page.

**http://www.zlib.net/manual.html**
The zlib manual explains the semantics and usage of the library’s many functions.
This module provides a simple interface to compress and decompress files just like the GNU programs `gzip` and `gunzip` would.

The data compression is provided by the `:mod:`zlib module.

The `gzip` module provides the `GzipFile` class which is modeled after Python’s File Object. The `GzipFile` class reads and writes `gzip`-format files, automatically compressing or decompressing the data so that it looks like an ordinary file object.

Note that additional file formats which can be decompressed by the `gzip` and `gunzip` programs, such as those produced by `compress` and `pack`, are not supported by this module.

For other archive formats, see the `bz2`, `zipfile`, and `tarfile` modules.

The module defines the following items:

```python
class gzip.GzipFile([filename[, mode[, compresslevel[, fileobj]]]])
```

Constructor for the `GzipFile` class, which simulates most of the methods of a file object, with the exception of the `readinto()` and `truncate()` methods. At least one of `fileobj` and `filename` must be given a non-trivial value.

The new class instance is based on `fileobj`, which can be a regular file, a `StringIO` object, or any other object which simulates a file. It defaults to `None`, in which case `filename` is opened to provide a file object.

When `fileobj` is not `None`, the `filename` argument is only used to
be included in the `gzip` file header, which may includes the original filename of the uncompressed file. It defaults to the filename of `fileobj`, if discernible; otherwise, it defaults to the empty string, and in this case the original filename is not included in the header.

The mode argument can be any of `'r'`, `'rb'`, `'a'`, `'ab'`, `'w'`, or `'wb'`, depending on whether the file will be read or written. The default is the mode of `fileobj` if discernible; otherwise, the default is `'rb'`. If not given, the ‘b’ flag will be added to the mode to ensure the file is opened in binary mode for cross-platform portability.

The compresslevel argument is an integer from 1 to 9 controlling the level of compression; 1 is fastest and produces the least compression, and 9 is slowest and produces the most compression. The default is 9.

Calling a `GzipFile` object’s `close()` method does not close `fileobj`, since you might wish to append more material after the compressed data. This also allows you to pass a `StringIO` object opened for writing as `fileobj`, and retrieve the resulting memory buffer using the `StringIO` object’s `getvalue()` method.

gzip.open(`filename[, mode[, compresslevel]]`) This is a shorthand for `GzipFile(filename, mode, compresslevel)`. The `filename` argument is required; `mode` defaults to `'rb'` and `compresslevel` defaults to 9.
Examples of usage

Example of how to read a compressed file:

```python
import gzip
f = gzip.open('/home/joe/file.txt.gz', 'rb')
file_content = f.read()
f.close()
```

Example of how to create a compressed GZIP file:

```python
import gzip
content = "Lots of content here"
f = gzip.open('/home/joe/file.txt.gz', 'wb')
f.write(content)
f.close()
```

Example of how to GZIP compress an existing file:

```python
import gzip
f_in = open('/home/joe/file.txt', 'rb')
f_out = gzip.open('/home/joe/file.txt.gz', 'wb')
f_out.writelines(f_in)
f_out.close()
f_in.close()
```

Module `zlib`  

The basic data compression module needed to support the `gzip` file format.
bz2 — Compression compatible with bzip2

New in version 2.3.

This module provides a comprehensive interface for the bz2 compression library. It implements a complete file interface, one-shot (de)compression functions, and types for sequential (de)compression.

For other archive formats, see the gzip, zipfile, and tarfile modules.

Here is a summary of the features offered by the bz2 module:

- **BZ2File** class implements a complete file interface, including `readline()`, `readlines()`, `writelines()`, `seek()`, etc;
- **BZ2File** class implements emulated `seek()` support;
- **BZ2File** class implements universal newline support;
- **BZ2File** class offers an optimized line iteration using the readahead algorithm borrowed from file objects;
- Sequential (de)compression supported by **BZ2Compressor** and **BZ2Decompressor** classes;
- One-shot (de)compression supported by `compress()` and `decompress()` functions;
- Thread safety uses individual locking mechanism.
(De)compression of files

Handling of compressed files is offered by the BZ2File class.

```python
class bz2.BZ2File(filename[, mode[, buffering[, compresslevel]]])
```

Open a bz2 file. Mode can be either `'r'` or `'w'`, for reading (default) or writing. When opened for writing, the file will be created if it doesn’t exist, and truncated otherwise. If `buffering` is given, 0 means unbuffered, and larger numbers specify the buffer size; the default is 0. If `compresslevel` is given, it must be a number between 1 and 9; the default is 9. Add a `'u'` to mode to open the file for input with universal newline support. Any line ending in the input file will be seen as a `\n` in Python. Also, a file so opened gains the attribute `newlines`; the value for this attribute is one of `None` (no newline read yet), `\r`, `\n`, `\r\n` or a tuple containing all the newline types seen. Universal newlines are available only when reading. Instances support iteration in the same way as normal file instances.

```python
    close()
```

Close the file. Sets data attribute `closed` to true. A closed file cannot be used for further I/O operations. `close()` may be called more than once without error.

```python
    read([size])
```

Read at most size uncompressed bytes, returned as a string. If the size argument is negative or omitted, read until EOF is reached.

```python
    readline([size])
```

Return the next line from the file, as a string, retaining newline. A non-negative size argument limits the maximum
number of bytes to return (an incomplete line may be returned then). Return an empty string at EOF.

`readlines([size])`
Return a list of lines read. The optional `size` argument, if given, is an approximate bound on the total number of bytes in the lines returned.

`xreadlines()`
For backward compatibility. `BZ2File` objects now include the performance optimizations previously implemented in the `xreadlines` module.

*Deprecated since version 2.3:* This exists only for compatibility with the method by this name on `file` objects, which is deprecated. Use `for line in file` instead.

`seek(offset[, whence])`
Move to new file position. Argument `offset` is a byte count. Optional argument `whence` defaults to `os.SEEK_SET` or 0 (offset from start of file; offset should be >= 0); other values are `os.SEEK_CUR` or 1 (move relative to current position; offset can be positive or negative), and `os.SEEK_END` or 2 (move relative to end of file; offset is usually negative, although many platforms allow seeking beyond the end of a file).

Note that seeking of bz2 files is emulated, and depending on the parameters the operation may be extremely slow.

`tell()`
Return the current file position, an integer (may be a long integer).

`write(data)`
Write string data to file. Note that due to buffering, close() may be needed before the file on disk reflects the data written.

writelines(sequence_of_strings)
Write the sequence of strings to the file. Note that newlines are not added. The sequence can be any iterable object producing strings. This is equivalent to calling write() for each string.
Sequential (de)compression

Sequential compression and decompression is done using the classes `BZ2Compressor` and `BZ2Decompressor`.

```python
class bz2.BZ2Compressor([compresslevel])
    Create a new compressor object. This object may be used to compress data sequentially. If you want to compress data in one shot, use the `compress()` function instead. The `compresslevel` parameter, if given, must be a number between 1 and 9; the default is 9.

    compress(data)
        Provide more data to the compressor object. It will return chunks of compressed data whenever possible. When you've finished providing data to compress, call the `flush()` method to finish the compression process, and return what is left in internal buffers.

    flush()
        Finish the compression process and return what is left in internal buffers. You must not use the compressor object after calling this method.

class bz2.BZ2Decompressor
    Create a new decompressor object. This object may be used to decompress data sequentially. If you want to decompress data in one shot, use the `decompress()` function instead.

    decompress(data)
        Provide more data to the decompressor object. It will return chunks of decompressed data whenever possible. If you try to
decompress data after the end of stream is found, `EOFError` will be raised. If any data was found after the end of stream, it'll be ignored and saved in `unused_data` attribute.
One-shot (de)compression

One-shot compression and decompression is provided through the `compress()` and `decompress()` functions.

```python
bz2.compress(data[, compresslevel])
```

Compress `data` in one shot. If you want to compress data sequentially, use an instance of `BZ2Compressor` instead. The `compresslevel` parameter, if given, must be a number between 1 and 9; the default is 9.

```python
bz2.decompress(data)
```

Decompress `data` in one shot. If you want to decompress data sequentially, use an instance of `BZ2Decompressor` instead.
The ZIP file format is a common archive and compression standard. This module provides tools to create, read, write, append, and list a ZIP file. Any advanced use of this module will require an understanding of the format, as defined in PKZIP Application Note.

This module does not currently handle multi-disk ZIP files, or ZIP files which have appended comments (although it correctly handles comments added to individual archive members—for which see the ZipInfo Objects documentation). It can handle ZIP files that use the ZIP64 extensions (that is ZIP files that are more than 4 GByte in size). It supports decryption of encrypted files in ZIP archives, but it currently cannot create an encrypted file. Decryption is extremely slow as it is implemented in native python rather than C.

For other archive formats, see the bz2, gzip, and tarfile modules.

The module defines the following items:

exception zipfile.BadZipfile
    The error raised for bad ZIP files (old name: zipfile.error).

exception zipfile.LargeZipFile
    The error raised when a ZIP file would require ZIP64 functionality but that has not been enabled.

class zipfile.ZipFile
    The class for reading and writing ZIP files. See section ZipFile Objects for constructor details.

class zipfile.PyZipFile
    Class for creating ZIP archives containing Python libraries.
class zipfile.ZipInfo([filename, date_time])

Class used to represent information about a member of an archive. Instances of this class are returned by the getinfo() and infolist() methods of ZipFile objects. Most users of the zipfile module will not need to create these, but only use those created by this module. filename should be the full name of the archive member, and date_time should be a tuple containing six fields which describe the time of the last modification to the file; the fields are described in section ZipInfo Objects.

zipfile.is_zipfile(filename)

Returns True if filename is a valid ZIP file based on its magic number, otherwise returns False. This module does not currently handle ZIP files which have appended comments.

zipfile.ZIP_STORED

The numeric constant for an uncompressed archive member.

zipfile.ZIP_DEFLATED

The numeric constant for the usual ZIP compression method. This requires the zlib module. No other compression methods are currently supported.

See also:

PKZIP Application Note

Documentation on the ZIP file format by Phil Katz, the creator of the format and algorithms used.

Info-ZIP Home Page

Information about the Info-ZIP project's ZIP archive programs and development libraries.
class zipfile.ZipFile(file[, mode[, compression[, allowZip64]]])

Open a ZIP file, where file can be either a path to a file (a string) or a file-like object. The mode parameter should be 'r' to read an existing file, 'w' to truncate and write a new file, or 'a' to append to an existing file. If mode is 'a' and file refers to an existing ZIP file, then additional files are added to it. If file does not refer to a ZIP file, then a new ZIP archive is appended to the file. This is meant for adding a ZIP archive to another file, such as python.exe. Using

```
cat myzip.zip >> python.exe
```

also works, and at least WinZip can read such files. If mode is 'a' and the file does not exist at all, it is created. compression is the ZIP compression method to use when writing the archive, and should be ZIP_STORED or ZIP_DEFLATED; unrecognized values will cause RuntimeError to be raised. If ZIP_DEFLATED is specified but the zlib module is not available, RuntimeError is also raised. The default is ZIP_STORED. If allowZip64 is True zipfile will create ZIP files that use the ZIP64 extensions when the zipfile is larger than 2 GB. If it is false (the default) zipfile will raise an exception when the ZIP file would require ZIP64 extensions. ZIP64 extensions are disabled by default because the default zip and unzip commands on Unix (the InfoZIP utilities) don’t support these extensions.

*Changed in version 2.6:* If the file does not exist, it is created if the mode is ‘a’.

ZipFile.close()
Close the archive file. You must call `close()` before exiting your program or essential records will not be written.

**ZipFile.getinfo(name)**

Return a `ZipInfo` object with information about the archive member `name`. Calling `getinfo()` for a name not currently contained in the archive will raise a `KeyError`.

**ZipFile.infolist()**

Return a list containing a `ZipInfo` object for each member of the archive. The objects are in the same order as their entries in the actual ZIP file on disk if an existing archive was opened.

**ZipFile.namelist()**

Return a list of archive members by name.

**ZipFile.open(name[, mode[, pwd]])**

Extract a member from the archive as a file-like object (ZipExtFile). `name` is the name of the file in the archive, or a `ZipInfo` object. The `mode` parameter, if included, must be one of the following: 'r' (the default), 'u', or 'ru'. Choosing 'u' or 'ru' will enable universal newline support in the read-only object. `pwd` is the password used for encrypted files. Calling `open()` on a closed ZipFile will raise a `RuntimeError`.

**Note:** The file-like object is read-only and provides the following methods: `read()`, `readline()`, `readlines()`, `__iter__()`, `next()`.

**Note:** If the ZipFile was created by passing in a file-like object as the first argument to the constructor, then the object returned by `open()` shares the ZipFile's file pointer. Under these circumstances, the object returned by `open()` should not be
used after any additional operations are performed on the ZipFile object. If the ZipFile was created by passing in a string (the filename) as the first argument to the constructor, then open() will create a new file object that will be held by the ZipExtFile, allowing it to operate independently of the ZipFile.

**Note:** The open(), read() and extract() methods can take a filename or a `ZipInfo` object. You will appreciate this when trying to read a ZIP file that contains members with duplicate names.

*New in version 2.6.*

`ZipFile.extract(member[, path[, pwd]])`

Extract a member from the archive to the current working directory; member must be its full name or a `ZipInfo` object. Its file information is extracted as accurately as possible. path specifies a different directory to extract to. member can be a filename or a `ZipInfo` object. pwd is the password used for encrypted files.

*New in version 2.6.*

`ZipFile.extractall([path[, members[, pwd]]])`

Extract all members from the archive to the current working directory. path specifies a different directory to extract to. members is optional and must be a subset of the list returned by namelist(). pwd is the password used for encrypted files.

*New in version 2.6.*

`ZipFile.printdir()`

Print a table of contents for the archive to `sys.stdout`. 
ZipFile. **setpassword**(*pwd*)

Set *pwd* as default password to extract encrypted files.

*New in version 2.6.*

ZipFile. **read**(*name*, *pwd*)

Return the bytes of the file *name* in the archive. *name* is the name of the file in the archive, or a *ZipInfo* object. The archive must be open for read or append. *pwd* is the password used for encrypted files and, if specified, it will override the default password set with **setpassword()**. Calling **read()** on a closed ZipFile will raise a **RuntimeError**.

*Changed in version 2.6:* *pwd* was added, and *name* can now be a *ZipInfo* object.

ZipFile. **testzip**()

Read all the files in the archive and check their CRC’s and file headers. Return the name of the first bad file, or else return *None*. Calling **testzip()** on a closed ZipFile will raise a **RuntimeError**.

ZipFile. **write**(*filename*, *arcname*, *compress_type*)

Write the file named *filename* to the archive, giving it the archive name *arcname* (by default, this will be the same as *filename*, but without a drive letter and with leading path separators removed). If given, *compress_type* overrides the value given for the *compression* parameter to the constructor for the new entry. The archive must be open with mode `'w'` or `'a'` — calling **write()** on a ZipFile created with mode `'r'` will raise a **RuntimeError**. Calling **write()** on a closed ZipFile will raise a **RuntimeError**.

**Note:** There is no official file name encoding for ZIP files. If you have unicode file names, you must convert them to byte
strings in your desired encoding before passing them to `write()`. WinZip interprets all file names as encoded in CP437, also known as DOS Latin.

**Note:** Archive names should be relative to the archive root, that is, they should not start with a path separator.

**Note:** If `arcname` (or `filename`, if `arcname` is not given) contains a null byte, the name of the file in the archive will be truncated at the null byte.

`ZipFile.writestr(zinfo_or_arcname, bytes)`

Write the string `bytes` to the archive; `zinfo_or_arcname` is either the file name it will be given in the archive, or a `ZipInfo` instance. If it’s an instance, at least the filename, date, and time must be given. If it’s a name, the date and time is set to the current date and time. The archive must be opened with mode `'w'` or `'a'` – calling `writestr()` on a ZipFile created with mode `'r'` will raise a `RuntimeError`. Calling `writestr()` on a closed ZipFile will raise a `RuntimeError`.

**Note:** When passing a `ZipInfo` instance as the `zinfo_or_arcname` parameter, the compression method used will be that specified in the `compress_type` member of the given `ZipInfo` instance. By default, the `ZipInfo` constructor sets this member to `ZIP_STORED`.

The following data attributes are also available:

`ZipFile.debug`

The level of debug output to use. This may be set from `0` (the default, no output) to `3` (the most output). Debugging information is written to `sys.stdout`. 
ZipFile. **comment**

The comment text associated with the ZIP file. If assigning a comment to a `ZipFile` instance created with mode ‘a’ or ‘w’, this should be a string no longer than 65535 bytes. Comments longer than this will be truncated in the written archive when `ZipFile.close()` is called.
PyZipFile Objects

The `PyZipFile` constructor takes the same parameters as the `ZipFile` constructor. Instances have one method in addition to those of `ZipFile` objects.

`PyZipFile.writepy(pathname[, basename])`

Search for files `*.py` and add the corresponding file to the archive. The corresponding file is a `*.pyo` file if available, else a `*.pyc` file, compiling if necessary. If the pathname is a file, the filename must end with `.py`, and just the (corresponding `*.py[co]`) file is added at the top level (no path information). If the pathname is a file that does not end with `.py`, a `RuntimeError` will be raised. If it is a directory, and the directory is not a package directory, then all the files `*.py[co]` are added at the top level. If the directory is a package directory, then all `*.py[co]` are added under the package name as a file path, and if any subdirectories are package directories, all of these are added recursively. `basename` is intended for internal use only. The `writepy()` method makes archives with file names like this:

```
string.pyc # Top level name
test/__init__.pyc # Package directory
test/test_support.pyc # Module test
test/bogus/__init__.pyc # Subpackage directory
test/bogus/myfile.pyc # Submodule test.b
```
ZipInfo Objects

Instances of the `ZipInfo` class are returned by the `getinfo()` and `infolist()` methods of `ZipFile` objects. Each object stores information about a single member of the ZIP archive.

Instances have the following attributes:

`ZipInfo.filename`
Name of the file in the archive.

`ZipInfo.date_time`
The time and date of the last modification to the archive member. This is a tuple of six values:

<table>
<thead>
<tr>
<th>Index</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>Year</td>
</tr>
<tr>
<td>1</td>
<td>Month (one-based)</td>
</tr>
<tr>
<td>2</td>
<td>Day of month (one-based)</td>
</tr>
<tr>
<td>3</td>
<td>Hours (zero-based)</td>
</tr>
<tr>
<td>4</td>
<td>Minutes (zero-based)</td>
</tr>
<tr>
<td>5</td>
<td>Seconds (zero-based)</td>
</tr>
</tbody>
</table>

`ZipInfo.compress_type`
Type of compression for the archive member.

`ZipInfo.comment`
Comment for the individual archive member.

`ZipInfo.extra`
Expansion field data. The PKZIP Application Note contains some comments on the internal structure of the data contained in this string.
`ZipInfo.create_system`
System which created ZIP archive.

`ZipInfo.create_version`
PKZIP version which created ZIP archive.

`ZipInfo.extract_version`
PKZIP version needed to extract archive.

`ZipInfo.reserved`
Must be zero.

`ZipInfo.flag_bits`
ZIP flag bits.

`ZipInfo.volume`
Volume number of file header.

`ZipInfo.internal_attr`
Internal attributes.

`ZipInfo.external_attr`
External file attributes.

`ZipInfo.header_offset`
Byte offset to the file header.

`ZipInfo.CRC`
CRC-32 of the uncompressed file.

`ZipInfo.compress_size`
Size of the compressed data.

`ZipInfo.file_size`
Size of the uncompressed file.
Tarfile — Read and write tar archive files

New in version 2.3.

The tarfile module makes it possible to read and write tar archives, including those using gzip or bz2 compression. (.zip files can be read and written using the zipfile module.)

Some facts and figures:

- reads and writes gzip and bz2 compressed archives.
- read/write support for the POSIX.1-1988 (ustar) format.
- read/write support for the GNU tar format including longname and longlink extensions, read-only support for the sparse extension.
- read/write support for the POSIX.1-2001 (pax) format.

  New in version 2.6.

- handles directories, regular files, hardlinks, symbolic links, fifos, character devices and block devices and is able to acquire and restore file information like timestamp, access permissions and owner.

tarfile.open(name=None, mode='r', fileobj=None, bufsize=10240, **kwargs)

Return a TarFile object for the pathname name. For detailed information on TarFile objects and the keyword arguments that are allowed, see TarFile Objects.
*mode* has to be a string of the form `'filemode[:compression]'`, it defaults to `'r'`. Here is a full list of mode combinations:

<table>
<thead>
<tr>
<th>mode</th>
<th>action</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>'r'</code> or <code>'r:*'</code></td>
<td>Open for reading with transparent compression (recommended).</td>
</tr>
<tr>
<td><code>'r:'</code></td>
<td>Open for reading exclusively without compression.</td>
</tr>
<tr>
<td><code>'r:gz'</code></td>
<td>Open for reading with gzip compression.</td>
</tr>
<tr>
<td><code>'r:bz2'</code></td>
<td>Open for reading with bzip2 compression.</td>
</tr>
<tr>
<td><code>'a'</code> or <code>'a:'</code></td>
<td>Open for appending with no compression. The file is created if it does not exist.</td>
</tr>
<tr>
<td><code>'w'</code> or <code>'w:'</code></td>
<td>Open for uncompressed writing.</td>
</tr>
<tr>
<td><code>'w:gz'</code></td>
<td>Open for gzip compressed writing.</td>
</tr>
<tr>
<td><code>'w:bz2'</code></td>
<td>Open for bzip2 compressed writing.</td>
</tr>
</tbody>
</table>

Note that `'a:gz'` or `'a:bz2'` is not possible. If *mode* is not suitable to open a certain (compressed) file for reading, `ReadError` is raised. Use *mode* `'r'` to avoid this. If a compression method is not supported, `CompressionError` is raised.

If *fileobj* is specified, it is used as an alternative to a file object opened for *name*. It is supposed to be at position 0.

For special purposes, there is a second format for *mode*: `'filemode[:compression]'`. `tarfile.open()` will return a `TarFile` object that processes its data as a stream of blocks. No random seeking will be done on the file. If given, *fileobj* may be any object that has a `read()` or `write()` method (depending on the *mode*). `bufsize` specifies the blocksize and defaults to `20 * 512` bytes. Use this variant in combination with e.g. `sys.stdin`, a socket file object or a tape device. However, such a `TarFile` object is limited in that it does not allow to be accessed randomly, see `Examples`. The currently possible modes:
<table>
<thead>
<tr>
<th>Mode</th>
<th>Action</th>
</tr>
</thead>
<tbody>
<tr>
<td>'r*'</td>
<td>Open a stream of tar blocks for reading with transparent compression.</td>
</tr>
<tr>
<td>'r'</td>
<td>Open a stream of uncompressed tar blocks for reading.</td>
</tr>
<tr>
<td>'r</td>
<td>gz'</td>
</tr>
<tr>
<td>'r</td>
<td>bz2'</td>
</tr>
<tr>
<td>'w'</td>
<td>Open an uncompressed stream for writing.</td>
</tr>
<tr>
<td>'w</td>
<td>gz'</td>
</tr>
<tr>
<td>'w</td>
<td>bz2'</td>
</tr>
</tbody>
</table>

class tarfile.TarFile

Class for reading and writing tar archives. Do not use this class directly, better use `tarfile.open()` instead. See TarFile Objects.

tarfile.is_tarfile(name)

Return True if name is a tar archive file, that the tarfile module can read.

class tarfile.TarFileCompat(filename, mode='r', compression=TARPlain)

Class for limited access to tar archives with a zipfile-like interface. Please consult the documentation of the zipfile module for more details. compression must be one of the following constants:

TARPlain

Constant for an uncompressed tar archive.

TARGZipped

Constant for a gzip compressed tar archive.

Deprecated since version 2.6: The TarFileCompat class has been deprecated for removal in Python 3.0.
exception tarfile.TarError
    Base class for all tarfile exceptions.

exception tarfile.ReadError
    Is raised when a tar archive is opened, that either cannot be handled by the tarfile module or is somehow invalid.

exception tarfile.CompressionError
    Is raised when a compression method is not supported or when the data cannot be decoded properly.

exception tarfile.StreamError
    Is raised for the limitations that are typical for stream-like TarFile objects.

exception tarfile.ExtractError
    Is raised for non-fatal errors when using TarFile.extract(), but only if TarFile.errorlevel==2.

exception tarfile.HeaderError
    Is raised by TarInfo.frombuf() if the buffer it gets is invalid.

    New in version 2.6.

Each of the following constants defines a tar archive format that the tarfile module is able to create. See section Supported tar formats for details.

tarfile.USTAR_FORMAT
    POSIX.1-1988 (ustar) format.

tarfile.GNU_FORMAT
    GNU tar format.

tarfile.PAX_FORMAT
    POSIX.1-2001 (pax) format.
**tarfile.** `DEFAULT_FORMAT`

The default format for creating archives. This is currently `GNU_FORMAT`.

The following variables are available on module level:

**tarfile.** `ENCODING`

The default character encoding i.e. the value from either `sys.getfilesystemencoding()` or `sys.getdefaultencoding()`.

---

**See also:**

**Module zipfile**

Documentation of the `zipfile` standard module.

**GNU tar manual, Basic Tar Format**

Documentation for tar archive files, including GNU tar extensions.
TarFile Objects

The `TarFile` object provides an interface to a tar archive. A tar archive is a sequence of blocks. An archive member (a stored file) is made up of a header block followed by data blocks. It is possible to store a file in a tar archive several times. Each archive member is represented by a `TarInfo` object, see `TarInfo Objects` for details.

```python
class tarfile.TarFile(name=None, mode='r', fileobj=None, format=DEFAULT_FORMAT, tarinfo=TarInfo, dereference=False, ignore_zeros=False, encoding=ENCODING, errors=None, pax_headers=None, debug=0, errorlevel=0)
```

All following arguments are optional and can be accessed as instance attributes as well.

- `name` is the pathname of the archive. It can be omitted if `fileobj` is given. In this case, the file object’s `name` attribute is used if it exists.

- `mode` is either `'r'` to read from an existing archive, `'a'` to append data to an existing file or `'w'` to create a new file overwriting an existing one.

If `fileobj` is given, it is used for reading or writing data. If it can be determined, `mode` is overridden by `fileobj`'s mode. `fileobj` will be used from position 0.

**Note:** `fileobj` is not closed, when `TarFile` is closed.

- `format` controls the archive format. It must be one of the constants `USTAR_FORMAT`, `GNU_FORMAT` or `PAX_FORMAT` that are defined at module level.
New in version 2.6.

The tarinfo argument can be used to replace the default TarInfo class with a different one.

New in version 2.6.

If dereference is False, add symbolic and hard links to the archive. If it is True, add the content of the target files to the archive. This has no effect on systems that do not support symbolic links.

If ignore_zeros is False, treat an empty block as the end of the archive. If it is True, skip empty (and invalid) blocks and try to get as many members as possible. This is only useful for reading concatenated or damaged archives.

debug can be set from 0 (no debug messages) up to 3 (all debug messages). The messages are written to sys.stderr.

If errorlevel is 0, all errors are ignored when using TarFile.extract(). Nevertheless, they appear as error messages in the debug output, when debugging is enabled. If 1, all fatal errors are raised as OSError or IOError exceptions. If 2, all non-fatal errors are raised as TarError exceptions as well.

The encoding and errors arguments control the way strings are converted to unicode objects and vice versa. The default settings will work for most users. See section Unicode issues for in-depth information.

New in version 2.6.

The pax_headers argument is an optional dictionary of unicode strings which will be added as a pax global header if format is
New in version 2.6.

**TarFile**. `open(...)`

Alternative constructor. The `tarfile.open()` function is actually a shortcut to this classmethod.

**TarFile**. `getmember(name)`

Return a `TarInfo` object for member `name`. If `name` can not be found in the archive, `KeyError` is raised.

**Note:** If a member occurs more than once in the archive, its last occurrence is assumed to be the most up-to-date version.

**TarFile**. `getmembers()`

Return the members of the archive as a list of `TarInfo` objects. The list has the same order as the members in the archive.

**TarFile**. `getnames()`

Return the members as a list of their names. It has the same order as the list returned by `getmembers()`.

**TarFile**. `list(verbosetCode: `True`)`

Print a table of contents to `sys.stdout`. If `verbose` is `False`, only the names of the members are printed. If it is `True`, output similar to that of `ls -l` is produced.

**TarFile**. `next()`

Return the next member of the archive as a `TarInfo` object, when `TarFile` is opened for reading. Return `None` if there is no more available.
**TarFile**. **extractall**(path=".", members=None)

Extract all members from the archive to the current working directory or directory path. If optional members is given, it must be a subset of the list returned by getmembers(). Directory information like owner, modification time and permissions are set after all members have been extracted. This is done to work around two problems: A directory’s modification time is reset each time a file is created in it. And, if a directory’s permissions do not allow writing, extracting files to it will fail.

**Warning:** Never extract archives from untrusted sources without prior inspection. It is possible that files are created outside of path, e.g. members that have absolute filenames starting with "/" or filenames with two dots "..".

*New in version 2.5.*

**TarFile**. **extract**(member, path="")

Extract a member from the archive to the current working directory, using its full name. Its file information is extracted as accurately as possible. member may be a filename or a **TarInfo** object. You can specify a different directory using path.

**Note:** The extract() method does not take care of several extraction issues. In most cases you should consider using the extractall() method.

**Warning:** See the warning for extractall().

**TarFile**. **extractfile**(member)

Extract a member from the archive as a file object. member may be a filename or a **TarInfo** object. If member is a regular file, a file-like object is returned. If member is a link, a file-like object is
constructed from the link’s target. If *member* is none of the above, **None** is returned.

**Note:** The file-like object is read-only and provides the following methods: `read()`, `readline()`, `readlines()`, `seek()`, `tell()`.

**TarFile.** `add(name, arcname=None, recursive=True, exclude=None)`  
Add the file *name* to the archive. *name* may be any type of file (directory, fifo, symbolic link, etc.). If given, *arcname* specifies an alternative name for the file in the archive. Directories are added recursively by default. This can be avoided by setting `recursive` to **False**. If `exclude` is given it must be a function that takes one filename argument and returns a boolean value. Depending on this value the respective file is either excluded (**True**) or added (**False**).

*Changed in version 2.6:* Added the `exclude` parameter.

**TarFile.** `addfile(tarinfo, fileobj=None)`  
Add the **TarInfo** object *tarinfo* to the archive. If *fileobj* is given, *tarinfo.size* bytes are read from it and added to the archive. You can create **TarInfo** objects using `gettarinfo()`.

**Note:** On Windows platforms, *fileobj* should always be opened with mode 'rb' to avoid irritation about the file size.

**TarFile.** `gettarinfo(name=None, arcname=None, fileobj=None)`  
Create a **TarInfo** object for either the file *name* or the file object *fileobj* (using `os.fstat()` on its file descriptor). You can modify some of the **TarInfo**'s attributes before you add it using `addfile()`. If given, *arcname* specifies an alternative name for the
file in the archive.

`TarFile.close()`

Close the `TarFile`. In write mode, two finishing zero blocks are appended to the archive.

`TarFile.posix`

Setting this to `True` is equivalent to setting the `format` attribute to `USTAR_FORMAT`, `False` is equivalent to `GNU_FORMAT`.

*Changed in version 2.4: posix defaults to `False`.*

*Deprecated since version 2.6: Use the `format` attribute instead.*

`TarFile.pax_headers`

A dictionary containing key-value pairs of pax global headers.

*New in version 2.6.*
A **TarInfo** object represents one member in a **TarFile**. Aside from storing all required attributes of a file (like file type, size, time, permissions, owner etc.), it provides some useful methods to determine its type. It does *not* contain the file’s data itself.

**TarInfo** objects are returned by **TarFile**'s methods `getmember()`, `getmembers()` and `gettarinfo()`.

```python
class tarfile.TarInfo(name="")
    Create a **TarInfo** object.

TarInfo.frombuf(buf)
    Create and return a **TarInfo** object from string buffer `buf`.

    *New in version 2.6:* Raises **HeaderError** if the buffer is invalid.

TarInfo.fromtarfile(tarfile)
    Read the next member from the **TarFile** object `tarfile` and return it as a **TarInfo** object.

    *New in version 2.6.*

TarInfo.tobuf(format=DEFAULT_FORMAT, encoding=ENCODING, errors='strict')
    Create a string buffer from a **TarInfo** object. For information on the arguments see the constructor of the **TarFile** class.

    *Changed in version 2.6:* The arguments were added.
```

A **TarInfo** object has the following public data attributes:
TarInfo.name
Name of the archive member.

TarInfo.size
Size in bytes.

TarInfo.mtime
Time of last modification.

TarInfo.mode
Permission bits.

TarInfo.type
File type. *type* is usually one of these constants: REGTYPE, AREGTYPE, LNKTYPE, SYMTYPE, DIRTYPE, FIFOTYPE, CONTTYPE, CHRTYPE, BLKTYPE, GNUTYPE_SPARSE. To determine the type of a TarInfo object more conveniently, use the is_*( ) methods below.

TarInfo.linkname
Name of the target file name, which is only present in TarInfo objects of type LNKTYPE and SYMTYPE.

TarInfo.uid
User ID of the user who originally stored this member.

TarInfo.gid
Group ID of the user who originally stored this member.

TarInfo.uname
User name.

TarInfo.gname
Group name.

TarInfo.pax_headers
A dictionary containing key-value pairs of an associated pax
extended header.

_New in version 2.6._

A `TarInfo` object also provides some convenient query methods:

`TarInfo.isfile()`  
Return _True_ if the `TarInfo` object is a regular file.

`TarInfo.isreg()`  
Same as `isfile()`.

`TarInfo.isdir()`  
Return _True_ if it is a directory.

`TarInfo.issym()`  
Return _True_ if it is a symbolic link.

`TarInfo.islnk()`  
Return _True_ if it is a hard link.

`TarInfo.ischr()`  
Return _True_ if it is a character device.

`TarInfo.isblk()`  
Return _True_ if it is a block device.

`TarInfo.isfifo()`  
Return _True_ if it is a FIFO.

`TarInfo.isdev()`  
Return _True_ if it is one of character device, block device or FIFO.
Examples

How to extract an entire tar archive to the current working directory:

```python
import tarfile
tar = tarfile.open("sample.tar.gz")
tar.extractall()
tar.close()
```

How to extract a subset of a tar archive with `TarFile.extractall()` using a generator function instead of a list:

```python
import os
import tarfile
def py_files(members):
    for tarinfo in members:
        if os.path.splitext(tarinfo.name)[1] == ".py":
            yield tarinfo

tar = tarfile.open("sample.tar.gz")
tar.extractall(members=py_files(tar))
tar.close()
```

How to create an uncompressed tar archive from a list of filenames:

```python
import tarfile
tar = tarfile.open("sample.tar", "w")
for name in ["foo", "bar", "quux"]:
    tar.add(name)
tar.close()
```

How to read a gzip compressed tar archive and display some member information:

```python
import tarfile
tar = tarfile.open("sample.tar.gz", "r:gz")
for tarinfo in tar:
    print tarinfo.name, "is", tarinfo.size, "bytes in size and"
    if tarinfo.isreg():
        print "a regular file."
```
elif tarinfo.isdir():
    print "a directory."
else:
    print "something else."
tar.close()
Supported tar formats

There are three tar formats that can be created with the `tarfile` module:

- The POSIX.1-1988 ustar format (`USTAR_FORMAT`). It supports filenames up to a length of at best 256 characters and linknames up to 100 characters. The maximum file size is 8 gigabytes. This is an old and limited but widely supported format.

- The GNU tar format (`GNU_FORMAT`). It supports long filenames and linknames, files bigger than 8 gigabytes and sparse files. It is the de facto standard on GNU/Linux systems. `tarfile` fully supports the GNU tar extensions for long names, sparse file support is read-only.

- The POSIX.1-2001 pax format (`PAX_FORMAT`). It is the most flexible format with virtually no limits. It supports long filenames and linknames, large files and stores pathnames in a portable way. However, not all tar implementations today are able to handle pax archives properly.

The `pax` format is an extension to the existing `ustar` format. It uses extra headers for information that cannot be stored otherwise. There are two flavours of pax headers: Extended headers only affect the subsequent file header, global headers are valid for the complete archive and affect all following files. All the data in a pax header is encoded in `UTF-8` for portability reasons.

There are some more variants of the tar format which can be read, but not created:
• The ancient V7 format. This is the first tar format from Unix Seventh Edition, storing only regular files and directories. Names must not be longer than 100 characters, there is no user/group name information. Some archives have miscalculated header checksums in case of fields with non-ASCII characters.

• The SunOS tar extended format. This format is a variant of the POSIX.1-2001 pax format, but is not compatible.
Unicode issues

The tar format was originally conceived to make backups on tape drives with the main focus on preserving file system information. Nowadays tar archives are commonly used for file distribution and exchanging archives over networks. One problem of the original format (that all other formats are merely variants of) is that there is no concept of supporting different character encodings. For example, an ordinary tar archive created on a UTF-8 system cannot be read correctly on a Latin-1 system if it contains non-ASCII characters. Names (i.e. filenames, linknames, user/group names) containing these characters will appear damaged. Unfortunately, there is no way to autodetect the encoding of an archive.

The pax format was designed to solve this problem. It stores non-ASCII names using the universal character encoding UTF-8. When a pax archive is read, these UTF-8 names are converted to the encoding of the local file system.

The details of unicode conversion are controlled by the `encoding` and `errors` keyword arguments of the `TarFile` class.

The default value for `encoding` is the local character encoding. It is deduced from `sys.getfilesystemencoding()` and `sys.getdefaultencoding()`. In read mode, `encoding` is used exclusively to convert unicode names from a pax archive to strings in the local character encoding. In write mode, the use of `encoding` depends on the chosen archive format. In case of `PAX_FORMAT`, input names that contain non-ASCII characters need to be decoded before being stored as UTF-8 strings. The other formats do not make use of `encoding` unless unicode objects are used as input names. These are converted to 8-bit character strings before they are added to the archive.
The `errors` argument defines how characters are treated that cannot be converted to or from `encoding`. Possible values are listed in section *Codec Base Classes*. In read mode, there is an additional scheme `utf-8` which means that bad characters are replaced by their UTF-8 representation. This is the default scheme. In write mode the default value for `errors` is `'strict'` to ensure that name information is not altered unnoticed.
File Formats

The modules described in this chapter parse various miscellaneous file formats that aren’t markup languages or are related to e-mail.

- **csv** — CSV File Reading and Writing
  - Module Contents
  - Dialects and Formatting Parameters
  - Reader Objects
  - Writer Objects
  - Examples

- **ConfigParser** — Configuration file parser
  - RawConfigParser Objects
  - ConfigParser Objects
  - SafeConfigParser Objects
  - Examples

- **robotparser** — Parser for robots.txt

- **netrc** — netrc file processing
  - netrc Objects

- **xdrlib** — Encode and decode XDR data
  - Packer Objects
  - Unpacker Objects
  - Exceptions

- **plistlib** — Generate and parse Mac OS X .plist files
  - Examples
using Sphinx 0.5.
The so-called CSV (Comma Separated Values) format is the most common import and export format for spreadsheets and databases. There is no “CSV standard”, so the format is operationally defined by the many applications which read and write it. The lack of a standard means that subtle differences often exist in the data produced and consumed by different applications. These differences can make it annoying to process CSV files from multiple sources. Still, while the delimiters and quoting characters vary, the overall format is similar enough that it is possible to write a single module which can efficiently manipulate such data, hiding the details of reading and writing the data from the programmer.

The csv module implements classes to read and write tabular data in CSV format. It allows programmers to say, “write this data in the format preferred by Excel,” or “read data from this file which was generated by Excel,” without knowing the precise details of the CSV format used by Excel. Programmers can also describe the CSV formats understood by other applications or define their own special-purpose CSV formats.

The csv module's reader and writer objects read and write sequences. Programmers can also read and write data in dictionary form using the DictReader and DictWriter classes.

Note: This version of the csv module doesn’t support Unicode input. Also, there are currently some issues regarding ASCII NUL characters. Accordingly, all input should be UTF-8 or printable ASCII to be safe; see the examples in section Examples. These
restrictions will be removed in the future.

See also:

**PEP 305 - CSV File API**

The Python Enhancement Proposal which proposed this addition to Python.
The `csv` module defines the following functions:

```python
csv.reader(csvfile[, dialect='excel'][, fmtparam])
```

Return a reader object which will iterate over lines in the given `csvfile`. `csvfile` can be any object which supports the `iterator` protocol and returns a string each time its `next()` method is called — file objects and list objects are both suitable. If `csvfile` is a file object, it must be opened with the ‘b’ flag on platforms where that makes a difference. An optional `dialect` parameter can be given which is used to define a set of parameters specific to a particular CSV dialect. It may be an instance of a subclass of the `Dialect` class or one of the strings returned by the `list_dialects()` function. The other optional `fmtparam` keyword arguments can be given to override individual formatting parameters in the current dialect. For full details about the dialect and formatting parameters, see section `Dialects and Formatting Parameters`.

All data read are returned as strings. No automatic data type conversion is performed.

A short usage example:

```python
>>> import csv
>>> spamReader = csv.reader(open('eggs.csv'), delimiter=' ',
>>> for row in spamReader:
...     print ', '.join(row)
Spam, Spam, Spam, Spam, Spam, Baked Beans
Spam, Lovely Spam, Wonderful Spam
```
Changed in version 2.5: The parser is now stricter with respect to multi-line quoted fields. Previously, if a line ended within a quoted field without a terminating newline character, a newline would be inserted into the returned field. This behavior caused problems when reading files which contained carriage return characters within fields. The behavior was changed to return the field without inserting newlines. As a consequence, if newlines embedded within fields are important, the input should be split into lines in a manner which preserves the newline characters.

```python
csv.writer(csvfile[, dialect='excel'][, fmtparam])
```

Return a writer object responsible for converting the user’s data into delimited strings on the given file-like object. `csvfile` can be any object with a `write()` method. If `csvfile` is a file object, it must be opened with the ‘b’ flag on platforms where that makes a difference. An optional `dialect` parameter can be given which is used to define a set of parameters specific to a particular CSV dialect. It may be an instance of a subclass of the `Dialect` class or one of the strings returned by the `list_dialects()` function. The other optional `fmtparam` keyword arguments can be given to override individual formatting parameters in the current dialect. For full details about the dialect and formatting parameters, see section `Dialects and Formatting Parameters`. To make it as easy as possible to interface with modules which implement the DB API, the value `None` is written as the empty string. While this isn’t a reversible transformation, it makes it easier to dump SQL NULL data values to CSV files without preprocessing the data returned from a `cursor.fetchall()` call. All other non-string data are stringified with `str()` before being written.

A short usage example:

```python
>>> import csv
>>> spamWriter = csv.writer(open('eggs.csv', 'w'), delimiter
```
csv.register_dialect(name[, dialect][, fmtparam])

Associate dialect with name. name must be a string or Unicode object. The dialect can be specified either by passing a sub-class of Dialect, or by fmtparam keyword arguments, or both, with keyword arguments overriding parameters of the dialect. For full details about the dialect and formatting parameters, see section Dialects and Formatting Parameters.

csv.unregister_dialect(name)

Delete the dialect associated with name from the dialect registry. An Error is raised if name is not a registered dialect name.

csv.get_dialect(name)

Return the dialect associated with name. An Error is raised if name is not a registered dialect name.

Changed in version 2.5: This function now returns an immutable Dialect. Previously an instance of the requested dialect was returned. Users could modify the underlying class, changing the behavior of active readers and writers.

csv.list_dialects()

Return the names of all registered dialects.

csv.field_size_limit([new_limit])

Returns the current maximum field size allowed by the parser. If new_limit is given, this becomes the new limit.

New in version 2.5.
The `csv` module defines the following classes:

```python
class csv.DictReader(csvfile[, fieldnames=None[, restkey=None[, restval=None[, dialect='excel'[,...]]]]])
```

Create an object which operates like a regular reader but maps the information read into a dict whose keys are given by the optional `fieldnames` parameter. If the `fieldnames` parameter is omitted, the values in the first row of the `csvfile` will be used as the fieldnames. If the row read has fewer fields than the fieldnames sequence, the value of `restval` will be used as the default value. If the row read has more fields than the fieldnames sequence, the remaining data is added as a sequence keyed by the value of `restkey`. If the row read has fewer fields than the fieldnames sequence, the remaining keys take the value of the optional `restval` parameter. Any other optional or keyword arguments are passed to the underlying `reader` instance.

```python
class csv.DictWriter(csvfile, fieldnames[, restval='', extrasaction='raise', dialect='excel'[,...]])
```

Create an object which operates like a regular writer but maps dictionaries onto output rows. The `fieldnames` parameter identifies the order in which values in the dictionary passed to the `writerow()` method are written to the `csvfile`. The optional `restval` parameter specifies the value to be written if the dictionary is missing a key in `fieldnames`. If the dictionary passed to the `writerow()` method contains a key not found in `fieldnames`, the optional `extrasaction` parameter indicates what action to take. If it is set to `'raise'` a `ValueError` is raised. If it is set to `'ignore'`, extra values in the dictionary are ignored. Any other optional or keyword arguments are passed to the underlying `writer` instance.

Note that unlike the `DictReader` class, the `fieldnames` parameter
of the *DictWriter* is not optional. Since Python’s *dict* objects are not ordered, there is not enough information available to deduce the order in which the row should be written to the *csvfile*.

**class csv.Dialect**

The *Dialect* class is a container class relied on primarily for its attributes, which are used to define the parameters for a specific *reader* or *writer* instance.

**class csv.excel**

The *excel* class defines the usual properties of an Excel-generated CSV file. It is registered with the dialect name *'excel'*.

**class csv.excel_tab**

The *excel_tab* class defines the usual properties of an Excel-generated TAB-delimited file. It is registered with the dialect name *'excel-tab'*

**class csv.Sniffer**

The *Sniffer* class is used to deduce the format of a CSV file.

The *Sniffer* class provides two methods:

**sniff(sample[, delimiters=None])**

Analyze the given *sample* and return a *Dialect* subclass reflecting the parameters found. If the optional *delimiters* parameter is given, it is interpreted as a string containing possible valid delimiter characters.

**has_header(sample)**

Analyze the sample text (presumed to be in CSV format) and return *True* if the first row appears to be a series of column headers.
An example for **Sniffer** use:

```python
csvfile = open("example.csv")
dialect = csv.Sniffer().sniff(csvfile.read(1024))
csvfile.seek(0)
reader = csv.reader(csvfile, dialect)
# ... process CSV file contents here ...
```

The **csv** module defines the following constants:

**csv.QUOTE_ALL**
Instructs **writer** objects to quote all fields.

**csv.QUOTE_MINIMAL**
Instructs **writer** objects to only quote those fields which contain special characters such as *delimiter*, *quotechar* or any of the characters in *lineterminator*.

**csv.QUOTE_NONNUMERIC**
Instructs **writer** objects to quote all non-numeric fields.

  Instructs the reader to convert all non-quoted fields to type *float*.

**csv.QUOTE_NONE**
Instructs **writer** objects to never quote fields. When the current *delimiter* occurs in output data it is preceded by the current *escapechar* character. If *escapechar* is not set, the writer will raise **Error** if any characters that require escaping are encountered.

  Instructs **reader** to perform no special processing of quote characters.

The **csv** module defines the following exception:

**exception csv.Error**
Raised by any of the functions when an error is detected.
Dialects and Formatting Parameters

To make it easier to specify the format of input and output records, specific formatting parameters are grouped together into dialects. A dialect is a subclass of the `Dialect` class having a set of specific methods and a single `validate()` method. When creating `reader` or `writer` objects, the programmer can specify a string or a subclass of the `Dialect` class as the dialect parameter. In addition to, or instead of, the `dialect` parameter, the programmer can also specify individual formatting parameters, which have the same names as the attributes defined below for the `Dialect` class.

Dialects support the following attributes:

**Dialect.delimiter**
A one-character string used to separate fields. It defaults to `','`.

**Dialect.doublequote**
Controls how instances of `quotechar` appearing inside a field should be themselves be quoted. When `True`, the character is doubled. When `False`, the `escapechar` is used as a prefix to the `quotechar`. It defaults to `True`.

On output, if `doublequote` is `False` and no `escapechar` is set, `Error` is raised if a `quotechar` is found in a field.

**Dialect.escapechar**
A one-character string used by the writer to escape the `delimiter` if `quoting` is set to `QUOTE_NONE` and the `quotechar` if `doublequote` is `False`. On reading, the `escapechar` removes any special meaning from the following character. It defaults to `None`, which disables escaping.
Dialect. **lineterminator**

The string used to terminate lines produced by the writer. It defaults to '\r\n'.

**Note:** The reader is hard-coded to recognise either '\r' or '\n' as end-of-line, and ignores *lineterminator*. This behavior may change in the future.

Dialect. **quotechar**

A one-character string used to quote fields containing special characters, such as the *delimiter* or *quotechar*, or which contain new-line characters. It defaults to '"'.

Dialect. **quoting**

Controls when quotes should be generated by the writer and recognised by the reader. It can take on any of the *QUOTE_* constants (see section *Module Contents*) and defaults to *QUOTE_MINIMAL*.

Dialect. **skipinitialspace**

When True, whitespace immediately following the *delimiter* is ignored. The default is False.
Reader Objects

Reader objects (DictReader instances and objects returned by the reader() function) have the following public methods:

\texttt{csvreader.next()}
- Return the next row of the reader’s iterable object as a list, parsed according to the current dialect.

Reader objects have the following public attributes:

\texttt{csvreader.dialect}
- A read-only description of the dialect in use by the parser.

\texttt{csvreader.line_num}
- The number of lines read from the source iterator. This is not the same as the number of records returned, as records can span multiple lines.

\textit{New in version 2.5.}

DictReader objects have the following public attribute:

\texttt{csvreader.fieldnames}
- If not passed as a parameter when creating the object, this attribute is initialized upon first access or when the first record is read from the file.

\textit{Changed in version 2.6.}
**Writer Objects**

Writer objects (DictWriter instances and objects returned by the writer() function) have the following public methods. A row must be a sequence of strings or numbers for Writer objects and a dictionary mapping fieldnames to strings or numbers (by passing them through str() first) for DictWriter objects. Note that complex numbers are written out surrounded by parens. This may cause some problems for other programs which read CSV files (assuming they support complex numbers at all).

```python
csvwriter.writerow(row)
```
Write the row parameter to the writer's file object, formatted according to the current dialect.

```python
csvwriter.writerows(rows)
```
Write all the rows parameters (a list of row objects as described above) to the writer's file object, formatted according to the current dialect.

Writer objects have the following public attribute:

```python
csvwriter.dialect
```
A read-only description of the dialect in use by the writer.
Examples

The simplest example of reading a CSV file:

```python
import csv
reader = csv.reader(open("some.csv", "rb"))
for row in reader:
    print row
```

Reading a file with an alternate format:

```python
import csv
reader = csv.reader(open("passwd", "rb"), delimiter=':', quoting=csv.QUOTE_MINIMAL)
for row in reader:
    print row
```

The corresponding simplest possible writing example is:

```python
import csv
writer = csv.writer(open("some.csv", "wb"))
writer.writerows(some iterable)
```

Registering a new dialect:

```python
import csv
csv.register_dialect('unixpwd', delimiter=':', quoting=csv.QUOTE_NONE)
reader = csv.reader(open("passwd", "rb"), 'unixpwd')
```

A slightly more advanced use of the reader — catching and reporting errors:

```python
import csv, sys
filename = "some.csv"
reader = csv.reader(open(filename, "rb"))
try:
    for row in reader:
```
And while the module doesn’t directly support parsing strings, it can easily be done:

```python
import csv
for row in csv.reader(['one,two,three']):
    print row
```

The `csv` module doesn’t directly support reading and writing Unicode, but it is 8-bit-clean save for some problems with ASCII NUL characters. So you can write functions or classes that handle the encoding and decoding for you as long as you avoid encodings like UTF-16 that use NULs. UTF-8 is recommended.

`unicode_csv_reader()` below is a `generator` that wraps `csv.reader` to handle Unicode CSV data (a list of Unicode strings). `utf_8_encoder()` is a `generator` that encodes the Unicode strings as UTF-8, one string (or row) at a time. The encoded strings are parsed by the CSV reader, and `unicode_csv_reader()` decodes the UTF-8-encoded cells back into Unicode:

```python
import csv

def unicode_csv_reader(unicode_csv_data, dialect=csv.excel, **kwargs):
    # csv.py doesn't do Unicode; encode temporarily as UTF-8:
    csv_reader = csv.reader(utf_8_encoder(unicode_csv_data),
                            dialect=dialect, **kwargs)
    for row in csv_reader:
        # decode UTF-8 back to Unicode, cell by cell:
        yield [unicode(cell, 'utf-8') for cell in row]

def utf_8_encoder(unicode_csv_data):
    for line in unicode_csv_data:
        yield line.encode('utf-8')
```
For all other encodings the following `UnicodeReader` and `UnicodeWriter` classes can be used. They take an additional `encoding` parameter in their constructor and make sure that the data passes the real reader or writer encoded as UTF-8:

```python
import csv, codecs, cStringIO

class UTF8Recoder:
    """Iterator that reads an encoded stream and reencodes the input to UTF-8""
    def __init__(self, f, encoding):
        self.reader = codecs.getreader(encoding)(f)

    def __iter__(self):
        return self

    def next(self):
        return self.reader.next().encode("utf-8")

class UnicodeReader:
    """A CSV reader which will iterate over lines in the CSV file which is encoded in the given encoding.""
    def __init__(self, f, dialect=csv.excel, encoding="utf-8", **kwds):
        f = UTF8Recoder(f, encoding)
        self.reader = csv.reader(f, dialect=dialect, **kwds)

    def next(self):
        row = self.reader.next()
        return [unicode(s, "utf-8") for s in row]

    def __iter__(self):
        return self

class UnicodeWriter:
    """A CSV writer which will write rows to CSV file "f", which is encoded in the given encoding.""
    def __init__(self, f, dialect=csv.excel, encoding="utf-8",
                 # Redirect output to a queue
                 queue = cStringIO.StringIO()
                 self.writer = csv.writer(self.queue, dialect=dialect, **kwds)
                 self.stream = cStringIO.StringIO()
                 self.writer = csv.writer(self.stream, dialect=dialect, **kwds)
                 self.queue = self.stream
                 return self
```
```python
self.stream = f
self.encoder = codecs.getincrementalencoder(encoding)()

def writerow(self, row):
    self.writer.writerow([s.encode("utf-8") for s in row])
    # Fetch UTF-8 output from the queue ...
    data = self.queue.getvalue()
    data = data.decode("utf-8")
    # ... and reencode it into the target encoding
    data = self.encoder.encode(data)
    # write to the target stream
    self.stream.write(data)
    # empty queue
    self.queue.truncate(0)

def writerows(self, rows):
    for row in rows:
        self.writerow(row)
```

Python v2.6 documentation » The Python Standard Library previous | next | modules | index
ConfigParser — Configuration file parser

Note: The ConfigParser module has been renamed to configparser in Python 3.0. The 2to3 tool will automatically adapt imports when converting your sources to 3.0.

This module defines the class ConfigParser. The ConfigParser class implements a basic configuration file parser language which provides a structure similar to what you would find on Microsoft Windows INI files. You can use this to write Python programs which can be customized by end users easily.

Warning: This library does not interpret or write the value-type prefixes used in the Windows Registry extended version of INI syntax.

The configuration file consists of sections, led by a [section] header and followed by name: value entries, with continuations in the style of RFC 822 (see section 3.1.1, “LONG HEADER FIELDS”); name=value is also accepted. Note that leading whitespace is removed from values. The optional values can contain format strings which refer to other values in the same section, or values in a special DEFAULT section. Additional defaults can be provided on initialization and retrieval. Lines beginning with '#' or ';' are ignored and may be used to provide comments.

For example:

[My Section]
foodir: %(%(dir)s/whatever
dir=frob
long: this value continues
would resolve the %\(\text{dir}\)s to the value of \texttt{dir} \texttt{(frob in this case). All reference expansions are done on demand.}

Default values can be specified by passing them into the \texttt{ConfigParser} constructor as a dictionary. Additional defaults may be passed into the \texttt{get()} method which will override all others.

Sections are normally stored in a builtin dictionary. An alternative dictionary type can be passed to the \texttt{ConfigParser} constructor. For example, if a dictionary type is passed that sorts its keys, the sections will be sorted on write-back, as will be the keys within each section.

\begin{verbatim}
class ConfigParser.RawConfigParser([defaults[, dict_type]])
    The basic configuration object. When \texttt{defaults} is given, it is initialized into the dictionary of intrinsic defaults. When \texttt{dict_type} is given, it will be used to create the dictionary objects for the list of sections, for the options within a section, and for the default values. This class does not support the magical interpolation behavior.

    \textit{New in version 2.3.}

    \textit{Changed in version 2.6: dict_type was added.}
\end{verbatim}

\begin{verbatim}
class ConfigParser.ConfigParser([defaults])
    Derived class of \texttt{RawConfigParser} that implements the magical interpolation feature and adds optional arguments to the \texttt{get()} and \texttt{items()} methods. The values in \texttt{defaults} must be appropriate for the %\(\text{s string interpolation. Note that __name__ is an intrinsic default; its value is the section name, and will override any value provided in defaults.}

\end{verbatim}
All option names used in interpolation will be passed through the `optionxform()` method just like any other option name reference. For example, using the default implementation of `optionxform()` (which converts option names to lower case), the values `foo %(bar)s` and `foo %(BAR)s` are equivalent.

```
class ConfigParser.SafeConfigParser([defaults])
```

Derived class of `ConfigParser` that implements a more-sane variant of the magical interpolation feature. This implementation is more predictable as well. New applications should prefer this version if they don’t need to be compatible with older versions of Python.

*New in version 2.3.*

```
expection ConfigParser.NoSectionError
```

Exception raised when a specified section is not found.

```
expection ConfigParser.DuplicateSectionError
```

Exception raised if `add_section()` is called with the name of a section that is already present.

```
expection ConfigParser.NoOptionError
```

Exception raised when a specified option is not found in the specified section.

```
expection ConfigParser.InterpolationError
```

Base class for exceptions raised when problems occur performing string interpolation.

```
expection ConfigParser.InterpolationDepthError
```

Exception raised when string interpolation cannot be completed because the number of iterations exceeds `MAX_INTERPOLATION_DEPTH`. Subclass of `InterpolationError`. 
exception ConfigParser.InterpolationMissingOptionError

Exception raised when an option referenced from a value does not exist. Subclass of InterpolationError.

New in version 2.3.

exception ConfigParser.InterpolationSyntaxError

Exception raised when the source text into which substitutions are made does not conform to the required syntax. Subclass of InterpolationError.

New in version 2.3.

exception ConfigParser.MissingSectionHeaderError

Exception raised when attempting to parse a file which has no section headers.

exception ConfigParser.ParsingError

Exception raised when errors occur attempting to parse a file.

ConfigParser.MAX_INTERPOLATION_DEPTH

The maximum depth for recursive interpolation for get() when the raw parameter is false. This is relevant only for the ConfigParser class.

See also:

Module shlex

Support for a creating Unix shell-like mini-languages which can be used as an alternate format for application configuration files.
RawConfigParser instances have the following methods:

RawConfigParser. `defaults()`
Return a dictionary containing the instance-wide defaults.

RawConfigParser. `sections()`
Return a list of the sections available; `DEFAULT` is not included in the list.

RawConfigParser. `add_section(section)`
Add a section named `section` to the instance. If a section by the given name already exists, `DuplicateSectionError` is raised. If the name `DEFAULT` (or any of its case-insensitive variants) is passed, `ValueError` is raised.

RawConfigParser. `has_section(section)`
Indicates whether the named section is present in the configuration. The `DEFAULT` section is not acknowledged.

RawConfigParser. `options(section)`
Returns a list of options available in the specified `section`.

RawConfigParser. `has_option(section, option)`
If the given section exists, and contains the given option, return `True`; otherwise return `False`.

*New in version 1.6.*

RawConfigParser. `read(filenames)`
Attempt to read and parse a list of filenames, returning a list of filenames which were successfully parsed. If `filenames` is a string
or Unicode string, it is treated as a single filename. If a file named in filenames cannot be opened, that file will be ignored. This is designed so that you can specify a list of potential configuration file locations (for example, the current directory, the user’s home directory, and some system-wide directory), and all existing configuration files in the list will be read. If none of the named files exist, the ConfigParser instance will contain an empty dataset. An application which requires initial values to be loaded from a file should load the required file or files using readfp() before calling read() for any optional files:

```python
import ConfigParser, os

config = ConfigParser.ConfigParser()
config.readfp(open('defaults.cfg'))
config.read(["site.cfg", os.path.expanduser('~/myapp.cfg')])
```

*Changed in version 2.4:* Returns list of successfully parsed filenames.

RawConfigParser.**readfp**(fp[, filename])

Read and parse configuration data from the file or file-like object in fp (only the readline() method is used). If filename is omitted and fp has a name attribute, that is used for filename; the default is <???>.

RawConfigParser.**get**(section, option)

Get an option value for the named section.

RawConfigParser.**getint**(section, option)

A convenience method which coerces the option in the specified section to an integer.
RawConfigParser.getfloat(section, option)

A convenience method which coerces the option in the specified section to a floating point number.

RawConfigParser.getboolean(section, option)

A convenience method which coerces the option in the specified section to a Boolean value. Note that the accepted values for the option are "1", "yes", "true", and "on", which cause this method to return True, and "0", "no", "false", and "off", which cause it to return False. These string values are checked in a case-insensitive manner. Any other value will cause it to raise ValueError.

RawConfigParser.items(section)

Return a list of (name, value) pairs for each option in the given section.

RawConfigParser.set(section, option, value)

If the given section exists, set the given option to the specified value; otherwise raise NoSectionError. While it is possible to use RawConfigParser (or ConfigParser with raw parameters set to true) for internal storage of non-string values, full functionality (including interpolation and output to files) can only be achieved using string values.

New in version 1.6.

RawConfigParser.write(fileobject)

Write a representation of the configuration to the specified file object. This representation can be parsed by a future read() call.

New in version 1.6.

RawConfigParser.remove_option(section, option)
Remove the specified `option` from the specified `section`. If the section does not exist, raise `NoSectionError`. If the option existed to be removed, return `True`; otherwise return `False`.

*New in version 1.6.*

`RawConfigParser.remove_section(section)`

Remove the specified `section` from the configuration. If the section in fact existed, return `True`. Otherwise return `False`.

`RawConfigParser.optionxform(option)`

Transforms the option name `option` as found in an input file or as passed in by client code to the form that should be used in the internal structures. The default implementation returns a lower-case version of `option`; subclasses may override this or client code can set an attribute of this name on instances to affect this behavior. Setting this to `str()`, for example, would make option names case sensitive.
ConfigParser Objects

The ConfigParser class extends some methods of the RawConfigParser interface, adding some optional arguments.

ConfigParser.get(section, option[, raw[, vars]])

Get an option value for the named section. All the '%' interpolations are expanded in the return values, based on the defaults passed into the constructor, as well as the options vars provided, unless the raw argument is true.

ConfigParser.items(section[, raw[, vars]])

Return a list of (name, value) pairs for each option in the given section. Optional arguments have the same meaning as for the get() method.

New in version 2.3.
The `SafeConfigParser` class implements the same extended interface as `ConfigParser`, with the following addition:

`SafeConfigParser.set(section, option, value)`

If the given section exists, set the given option to the specified value; otherwise raise `NoSectionError`. `value` must be a string (`str` or `unicode`); if not, `TypeError` is raised.

*New in version 2.4.*
Examples

An example of writing to a configuration file:

```python
import ConfigParser

config = ConfigParser.RawConfigParser()

# When adding sections or items, add them in the reverse order
# how you want them to be displayed in the actual file.
# In addition, please note that using RawConfigParser's and the
# mode of ConfigParser's respective set functions, you can assign
# non-string values to keys internally, but will receive an error
# when attempting to write to a file or when you get it in non-
# SafeConfigParser does not allow such assignments to take place.
config.add_section('Section1')
config.set('Section1', 'int', '15')
config.set('Section1', 'bool', 'true')
config.set('Section1', 'float', '3.1415')
config.set('Section1', 'baz', 'fun')
config.set('Section1', 'bar', 'Python')
config.set('Section1', 'foo', '\%(bar)s is \%(baz)s!')

# Writing our configuration file to 'example.cfg'
with open('example.cfg', 'wb') as configfile:
    config.write(configfile)
```

An example of reading the configuration file again:

```python
import ConfigParser

config = ConfigParser.RawConfigParser()
config.read('example.cfg')

# getfloat() raises an exception if the value is not a float
# getint() and getboolean() also do this for their respective types.
float = config.getfloat('Section1', 'float')
int = config.getint('Section1', 'int')
print float + int

# Notice that the next output does not interpolate '\%(bar)s' or
# This is because we are using a RawConfigParser().
if config.getboolean('Section1', 'bool'):
    print config.get('Section1', 'foo')
```
To get interpolation, you will need to use a `ConfigParser` or `SafeConfigParser`:

```python
import ConfigParser
config = ConfigParser.ConfigParser()
config.read('example.cfg')

# Set the third, optional argument of get to 1 if you wish to use raw mode.
print config.get('Section1', 'foo', 0) # -> "Python is fun!"
print config.get('Section1', 'foo', 1) # -> "%(bar)s is %(baz)s"

# The optional fourth argument is a dict with members that will take precedence in interpolation.
print config.get('Section1', 'foo', 0, {'bar': 'Documentation', 'baz': 'evil'})
```

Defaults are available in all three types of ConfigParsers. They are used in interpolation if an option used is not defined elsewhere.

```python
import ConfigParser

# New instance with 'bar' and 'baz' defaulting to 'Life' and 'hard'
config = ConfigParser.SafeConfigParser({'bar': 'Life', 'baz': 'hard'})
config.read('example.cfg')

print config.get('Section1', 'foo') # -> "Python is fun!"
config.remove_option('Section1', 'bar')
config.remove_option('Section1', 'baz')
print config.get('Section1', 'foo') # -> "Life is hard!"
```

The function `opt_move` below can be used to move options between sections:

```python
def opt_move(config, section1, section2, option):
    try:
        config.set(section2, option, config.get(section1, option))
    except ConfigParser.NoSectionError:
        # Create non-existent section
        config.add_section(section2)
```
```python
opt_move(config, section1, section2, option)
else:
    config.remove_option(section1, option)
```
**Note:** The `robotparser` module has been renamed `urllib.robotparser` in Python 3.0. The `2to3` tool will automatically adapt imports when converting your sources to 3.0.

This module provides a single class, `RobotFileParser`, which answers questions about whether or not a particular user agent can fetch a URL on the Web site that published the `robots.txt` file. For more details on the structure of `robots.txt` files, see http://www.robotstxt.org/orig.html.

```python
class robotparser.RobotFileParser
    This class provides a set of methods to read, parse and answer questions about a single `robots.txt` file.

    set_url(url)
        Sets the URL referring to a `robots.txt` file.

    read()
        Reads the `robots.txt` URL and feeds it to the parser.

    parse(lines)
        Parses the lines argument.

    can_fetch(useragent, url)
        Returns True if the `useragent` is allowed to fetch the `url` according to the rules contained in the parsed `robots.txt` file.

    mtime()
        Returns the time the `robots.txt` file was last fetched. This is useful for long-running web spiders that need to check for new `robots.txt` files periodically.
```
modified()

Sets the time the robots.txt file was last fetched to the current time.

The following example demonstrates basic use of the RobotFileParser class.

```python
>>> import robotparser
>>> rp = robotparser.RobotFileParser()
>>> rp.set_url("http://www.musi-cal.com/robots.txt")
>>> rp.read()
>>> rp.can_fetch("*", "http://www.musi-cal.com/cgi-bin/search?city=San+Francisco")
False
>>> rp.can_fetch("*", "http://www.musi-cal.com/")
True
```
The **netrc** class parses and encapsulates the netrc file format used by the Unix **ftp** program and other FTP clients.

```python
class netrc
```

A netrc instance or subclass instance encapsulates data from a netrc file. The initialization argument, if present, specifies the file to parse. If no argument is given, the file `~/.netrc` in the user’s home directory will be read. Parse errors will raise `NetrcParseError` with diagnostic information including the file name, line number, and terminating token.

```python
exception NetrcParseError
```

Exception raised by the netrc class when syntactical errors are encountered in source text. Instances of this exception provide three interesting attributes: `msg` is a textual explanation of the error, `filename` is the name of the source file, and `lineno` gives the line number on which the error was found.
A **netrc** instance has the following methods:

**netrc.authenticators** *(host)*

Return a 3-tuple \((login, account, password)\) of authenticators for *host*. If the netrc file did not contain an entry for the given host, return the tuple associated with the ‘default’ entry. If neither matching host nor default entry is available, return **None**.

**netrc.__repr__()**

Dump the class data as a string in the format of a netrc file. (This discards comments and may reorder the entries.)

Instances of **netrc** have public instance variables:

**netrc.hosts**

Dictionary mapping host names to \((login, account, password)\) tuples. The ‘default’ entry, if any, is represented as a pseudo-host by that name.

**netrc.macros**

Dictionary mapping macro names to string lists.

**Note:** Passwords are limited to a subset of the ASCII character set. Versions of this module prior to 2.3 were extremely limited. Starting with 2.3, all ASCII punctuation is allowed in passwords. However, note that whitespace and non-printable characters are not allowed in passwords. This is a limitation of the way the .netrc file is parsed and may be removed in the future.
The *xdrlib* module supports the External Data Representation Standard as described in RFC 1014, written by Sun Microsystems, Inc. June 1987. It supports most of the data types described in the RFC.

The *xdrlib* module defines two classes, one for packing variables into XDR representation, and another for unpacking from XDR representation. There are also two exception classes.

```python
class xdrlib.Packer

    Packer is the class for packing data into XDR representation. The Packer class is instantiated with no arguments.
```

```python
class xdrlib.Unpacker(data)

    Unpacker is the complementary class which unpacks XDR data values from a string buffer. The input buffer is given as *data*.
```

**See also:**

**RFC 1014 - XDR: External Data Representation Standard**

This RFC defined the encoding of data which was XDR at the time this module was originally written. It has apparently been obsoleted by RFC 1832.

**RFC 1832 - XDR: External Data Representation Standard**

Newer RFC that provides a revised definition of XDR.
Packer instances have the following methods:

**Packer.get_buffer()**
Returns the current pack buffer as a string.

**Packer.reset()**
Resets the pack buffer to the empty string.

In general, you can pack any of the most common XDR data types by calling the appropriate `pack_type()` method. Each method takes a single argument, the value to pack. The following simple data type packing methods are supported: `pack_uint()`, `pack_int()`, `pack_enum()`, `pack_bool()`, `pack_uhyper()`, and `pack_hyper()`.

**Packer.pack_float(value)**
Packs the single-precision floating point number `value`.

**Packer.pack_double(value)**
Packs the double-precision floating point number `value`.

The following methods support packing strings, bytes, and opaque data:

**Packer.pack_fstring(n, s)**
Packs a fixed length string, s. n is the length of the string but it is *not* packed into the data buffer. The string is padded with null bytes if necessary to guaranteed 4 byte alignment.

**Packer.pack_fopaque(n, data)**
Packs a fixed length opaque data stream, similarly to `pack_fstring()`.
Packer. **pack_string**

Packs a variable length string, s. The length of the string is first packed as an unsigned integer, then the string data is packed with **pack_fstring()**.

Packer. **pack_opaque**

Packs a variable length opaque data string, similarly to **pack_string()**.

Packer. **pack_bytes**

Packs a variable length byte stream, similarly to **pack_string()**.

The following methods support packing arrays and lists:

Packer. **pack_list**

Packs a list of homogeneous items. This method is useful for lists with an indeterminate size; i.e. the size is not available until the entire list has been walked. For each item in the list, an unsigned integer 1 is packed first, followed by the data value from the list. **pack_item** is the function that is called to pack the individual item. At the end of the list, an unsigned integer 0 is packed.

For example, to pack a list of integers, the code might appear like this:

```python
import xdrlib
p = xdrlib.Packer()
p.pack_list([1, 2, 3], p.pack_int)
```

Packer. **pack_farray**

Packs a fixed length list (array) of homogeneous items. n is the length of the list; it is not packed into the buffer, but a **ValueError** exception is raised if len(array) is not equal to n. As above, **pack_item** is the function used to pack each element.
Packer. **pack_array**(list, pack_item)

Packs a variable length *list* of homogeneous items. First, the length of the list is packed as an unsigned integer, then each element is packed as in **pack_farray()** above.
Unpacker Objects

The **Unpacker** class offers the following methods:

Unpacker. **reset**(data)
   Resets the string buffer with the given *data*.

Unpacker. **get_position**()
   Returns the current unpack position in the data buffer.

Unpacker. **set_position**(position)
   Sets the data buffer unpack position to *position*. You should be careful about using **get_position**() and **set_position**().

Unpacker. **get_buffer**()
   Returns the current unpack data buffer as a string.

Unpacker. **done**()
   Indicates unpack completion. Raises an **Error** exception if all of the data has not been unpacked.

In addition, every data type that can be packed with a **Packer**, can be unpacked with an **Unpacker**. Unpacking methods are of the form **unpack_type**(), and take no arguments. They return the unpacked object.

Unpacker. **unpack_float**()
   Unpacks a single-precision floating point number.

Unpacker. **unpack_double**()
   Unpacks a double-precision floating point number, similarly to **unpack_float**().
In addition, the following methods unpack strings, bytes, and opaque data:

**Unpacker**. `unpack_fstring(n)`

Unpacks and returns a fixed length string. *n* is the number of characters expected. Padding with null bytes to guaranteed 4 byte alignment is assumed.

**Unpacker**. `unpack_fopaque(n)`

Unpacks and returns a fixed length opaque data stream, similarly to `unpack_fstring()`.

**Unpacker**. `unpack_string()`

Unpacks and returns a variable length string. The length of the string is first unpacked as an unsigned integer, then the string data is unpacked with `unpack_fstring()`.

**Unpacker**. `unpack_opaque()`

Unpacks and returns a variable length opaque data string, similarly to `unpack_string()`.

**Unpacker**. `unpack_bytes()`

Unpacks and returns a variable length byte stream, similarly to `unpack_string()`.

The following methods support unpacking arrays and lists:

**Unpacker**. `unpack_list(unpack_item)`

Unpacks and returns a list of homogeneous items. The list is unpacked one element at a time by first unpacking an unsigned integer flag. If the flag is 1, then the item is unpacked and appended to the list. A flag of 0 indicates the end of the list. `unpack_item` is the function that is called to unpack the items.
Unpacker. **unpack_farray**(\(n, \text{unpack\_item}\))

Unpacks and returns (as a list) a fixed length array of homogeneous items. \(n\) is number of list elements to expect in the buffer. As above, \text{unpack\_item} is the function used to unpack each element.

Unpacker. **unpack_array**(\text{unpack\_item})

Unpacks and returns a variable length list of homogeneous items. First, the length of the list is unpacked as an unsigned integer, then each element is unpacked as in \text{unpack\_farray()} above.
Exceptions

Exceptions in this module are coded as class instances:

exception xdrlib.\texttt{Error}

The base exception class. \texttt{Error} has a single public data member \texttt{msg} containing the description of the error.

exception xdrlib.\texttt{ConversionError}

Class derived from \texttt{Error}. Contains no additional instance variables.

Here is an example of how you would catch one of these exceptions:

```python
import xdrlib
p = xdrlib.Packer()
try:
    p.pack_double(8.01)
except xdrlib.ConversionError, instance:
    print 'packing the double failed:', instance.msg
```
Changed in version 2.6: This module was previously only available in the Mac-specific library, it is now available for all platforms.

This module provides an interface for reading and writing the “property list” XML files used mainly by Mac OS X.

The property list (.plist) file format is a simple XML pickle supporting basic object types, like dictionaries, lists, numbers and strings. Usually the top level object is a dictionary.

Values can be strings, integers, floats, booleans, tuples, lists, dictionaries (but only with string keys), Data or datetime.datetime objects. String values (including dictionary keys) may be unicode strings – they will be written out as UTF-8.

The <data> plist type is supported through the Data class. This is a thin wrapper around a Python string. Use Data if your strings contain control characters.

See also:

PList manual page
<http://developer.apple.com/documentation/Darwin/Reference/Ma>

Apple’s documentation of the file format.

This module defines the following functions:

plistlib.readPlist(pathOrFile)
Read a plist file. pathOrFile may either be a file name or a (readable) file object. Return the unpacked root object (which
usually is a dictionary).

The XML data is parsed using the Expat parser from `xml.parsers.expat` — see its documentation for possible exceptions on ill-formed XML. Unknown elements will simply be ignored by the plist parser.

```python
plistlib.writePlist(rootObject, pathOrFile)
```

Write `rootObject` to a plist file. `pathOrFile` may either be a file name or a (writable) file object.

A `TypeError` will be raised if the object is of an unsupported type or a container that contains objects of unsupported types.

```python
plistlib.readPlistFromString(data)
```

Read a plist from a string. Return the root object.

```python
plistlib.writePlistToString(rootObject)
```

Return `rootObject` as a plist-formatted string.

```python
plistlib.readPlistFromResource(path[, restype='plst'[, resid=0]])
```

Read a plist from the resource with type `restype` from the resource fork of `path`. Availability: Mac OS X.

**Warning:** In 3.0, this function is removed.

```python
plistlib.writePlistToResource(rootObject, path[, restype='plst'[, resid=0]])
```

Write `rootObject` as a resource with type `restype` to the resource fork of `path`. Availability: Mac OS X.

**Warning:** In 3.0, this function is removed.
The following class is available:

class plistlib.Data(data)

Return a “data” wrapper object around the string data. This is used in functions converting from/to plists to represent the <data> type available in plists.

It has one attribute, data, that can be used to retrieve the Python string stored in it.
Examples

Generating a plist:

```python
def dict(aString="Doodah",
aList=["A", "B", 12, 32.1, [1, 2, 3]],
aFloat = 0.1,
anInt = 728,
aDict=dict(
    anotherString="<hello & hi there!>",
aUnicodeValue=u'M\xe4ssig, Ma\xdf',
aTrueValue=True,
aFalseValue=False,
),
someData = Data("<binary gunk>"),
someMoreData = Data("<lots of binary gunk>" * 10),
aDate = datetime.datetime.fromtimestamp(time.mktime(time.gmtime(0)))

# unicode keys are possible, but a little awkward to use:
pl[u'\xc5benraa'] = "That was a unicode key."
writePlist(pl, fileName)
```

Parsing a plist:

```python
pl = readPlist(pathOrFile)
print pl["aKey"]
```
Cryptographic Services

The modules described in this chapter implement various algorithms of a cryptographic nature. They are available at the discretion of the installation. Here’s an overview:

- **hashlib** — Secure hashes and message digests
- **hmac** — Keyed-Hashing for Message Authentication
- **md5** — MD5 message digest algorithm
- **sha** — SHA-1 message digest algorithm

Hardcore cypherpunks will probably find the cryptographic modules written by A.M. Kuchling of further interest; the package contains modules for various encryption algorithms, most notably AES. These modules are not distributed with Python but available separately. See the URL [http://www.amk.ca/python/code/crypto.html](http://www.amk.ca/python/code/crypto.html) for more information.
**hashlib — Secure hashes and message digests**

*New in version 2.5.*

This module implements a common interface to many different secure hash and message digest algorithms. Included are the FIPS secure hash algorithms SHA1, SHA224, SHA256, SHA384, and SHA512 (defined in FIPS 180-2) as well as RSA's MD5 algorithm (defined in Internet RFC 1321). The terms secure hash and message digest are interchangeable. Older algorithms were called message digests. The modern term is secure hash.

**Note:** If you want the adler32 or crc32 hash functions they are available in the *zlib* module.

**Warning:** Some algorithms have known hash collision weaknesses, see the FAQ at the end.

There is one constructor method named for each type of hash. All return a hash object with the same simple interface. For example: use `sha1()` to create a SHA1 hash object. You can now feed this object with arbitrary strings using the `update()` method. At any point you can ask it for the *digest* of the concatenation of the strings fed to it so far using the `digest()` or `hexdigest()` methods.

Constructors for hash algorithms that are always present in this module are `md5()`, `sha1()`, `sha224()`, `sha256()`, `sha384()`, and `sha512()`. Additional algorithms may also be available depending upon the OpenSSL library that Python uses on your platform.

For example, to obtain the digest of the string 'Nobody inspects the
spammish repetition':

```
>>> import hashlib
>>> m = hashlib.md5()
>>> m.update("Nobody inspects")
>>> m.update(" the spammish repetition")
>>> m.digest()
'\xbbd\x9c\x83\xdd\xe1\xe5\xc9\xd9\xde\xc9\xa1\x8d\xf0\xff\xe9'
>>> m.digest_size
16
>>> m.block_size
64
```

More condensed:

```
>>> hashlib.sha224("Nobody inspects the spammish repetition").hexdigest()
'a4337bc45a8fc544c03f52dc550cd6e1e87021bc896588bd79e901e2'
```

A generic `new()` constructor that takes the string name of the desired algorithm as its first parameter also exists to allow access to the above listed hashes as well as any other algorithms that your OpenSSL library may offer. The named constructors are much faster than `new()` and should be preferred.

Using `new()` with an algorithm provided by OpenSSL:

```
>>> h = hashlib.new('ripemd160')
>>> h.update("Nobody inspects the spammish repetition")
>>> h.hexdigest()
'cc4a5ce1b3df48aec5d22d1f16b894a0b894ecc'
```

The following values are provided as constant attributes of the hash objects returned by the constructors:

```
hashlib.digest_size
   The size of the resulting hash in bytes.
hashlib.block_size
```
The internal block size of the hash algorithm in bytes.

A hash object has the following methods:

hash. **update**(arg)

Update the hash object with the string arg. Repeated calls are equivalent to a single call with the concatenation of all the arguments: `m.update(a); m.update(b)` is equivalent to `m.update(a+b)`.

hash. **digest**()

Return the digest of the strings passed to the `update()` method so far. This is a string of `digest_size` bytes which may contain non-ASCII characters, including null bytes.

hash. **hexdigest**()

Like `digest()` except the digest is returned as a string of double length, containing only hexadecimal digits. This may be used to exchange the value safely in email or other non-binary environments.

hash. **copy**()

Return a copy (“clone”) of the hash object. This can be used to efficiently compute the digests of strings that share a common initial substring.

**Module hmac**

A module to generate message authentication codes using hashes.

**Module base64**

Another way to encode binary hashes for non-binary environments.
   The FIPS 180-2 publication on Secure Hash Algorithms.

http://www.cryptography.com/cnews/hash.html
   Hash Collision FAQ with information on which algorithms have
   known issues and what that means regarding their use.
**hmac — Keyed-Hashing for Message Authentication**

*New in version 2.2.*

This module implements the HMAC algorithm as described by [RFC 2104](https://tools.ietf.org/html/rfc2104).

```python
hmac.new(key[, msg[, digestmod]])
```

Return a new `hmac` object. If `msg` is present, the method call `update(msg)` is made. `digestmod` is the digest constructor or module for the HMAC object to use. It defaults to the `hashlib.md5()` constructor.

**Note:** The md5 hash has known weaknesses but remains the default for backwards compatibility. Choose a better one for your application.

An HMAC object has the following methods:

```python
hmac.update(msg)
```

Update the hmac object with the string `msg`. Repeated calls are equivalent to a single call with the concatenation of all the arguments: `m.update(a); m.update(b)` is equivalent to `m.update(a + b)`.

```python
hmac.digest()
```

Return the digest of the strings passed to the `update()` method so far. This string will be the same length as the `digest_size` of the digest given to the constructor. It may contain non-ASCII characters, including NUL bytes.
**hmac.hexdigest()**

Like `digest()` except the digest is returned as a string twice the length containing only hexadecimal digits. This may be used to exchange the value safely in email or other non-binary environments.

**hmac.copy()**

Return a copy (“clone”) of the hmac object. This can be used to efficiently compute the digests of strings that share a common initial substring.

---

**See also:**

**Module hashlib**

The python module providing secure hash functions.
**md5 — MD5 message digest algorithm**

*Deprecated since version 2.5:* Use the `hashlib` module instead.

This module implements the interface to RSA’s MD5 message digest algorithm (see also Internet RFC 1321). Its use is quite straightforward: use `new()` to create an md5 object. You can now feed this object with arbitrary strings using the `update()` method, and at any point you can ask it for the `digest` (a strong kind of 128-bit checksum, a.k.a. “fingerprint”) of the concatenation of the strings fed to it so far using the `digest()` method.

For example, to obtain the digest of the string `'Nobody inspects the spammish repetition'`:

```python
>>> import md5
>>> m = md5.new()
>>> m.update("Nobody inspects")
>>> m.update(" the spammish repetition")
>>> m.digest()
'\xbbd\x9c\x83\xdd\x1e\xa5\xc9\xd9\xde\xc9\xa1\x8d\xf0\xff\xe9'
```

More condensed:

```python
>>> md5.new("Nobody inspects the spammish repetition").digest()
'\xbbd\x9c\x83\xdd\x1e\xa5\xc9\xd9\xde\xc9\xa1\x8d\xf0\xff\xe9'
```

The following values are provided as constants in the module and as attributes of the md5 objects returned by `new()`:

`md5.digest_size`

The size of the resulting digest in bytes. This is always 16.
The md5 module provides the following functions:

**md5.** `new([arg])`

Return a new md5 object. If `arg` is present, the method call `update(arg)` is made.

**md5.** `md5([arg])`

For backward compatibility reasons, this is an alternative name for the `new()` function.

An md5 object has the following methods:

**md5.** `update(arg)`

Update the md5 object with the string `arg`. Repeated calls are equivalent to a single call with the concatenation of all the arguments: `m.update(a); m.update(b)` is equivalent to `m.update(a+b)`.

**md5.** `digest()`

Return the digest of the strings passed to the `update()` method so far. This is a 16-byte string which may contain non-ASCII characters, including null bytes.

**md5.** `hexdigest()`

Like `digest()` except the digest is returned as a string of length 32, containing only hexadecimal digits. This may be used to exchange the value safely in email or other non-binary environments.

**md5.** `copy()`

Return a copy (“clone”) of the md5 object. This can be used to efficiently compute the digests of strings that share a common initial substring.
See also:

**Module sha**

Similar module implementing the Secure Hash Algorithm (SHA). The SHA algorithm is considered a more secure hash.
SHA — SHA-1 message digest algorithm

*Deprecated since version 2.5:* Use the `hashlib` module instead.

This module implements the interface to NIST’s secure hash algorithm, known as SHA-1. SHA-1 is an improved version of the original SHA hash algorithm. It is used in the same way as the `md5` module: use `new()` to create a sha object, then feed this object with arbitrary strings using the `update()` method, and at any point you can ask it for the `digest` of the concatenation of the strings fed to it so far. SHA-1 digests are 160 bits instead of MD5’s 128 bits.

```python
sha.new([string])
```

Return a new sha object. If `string` is present, the method call `update(string)` is made.

The following values are provided as constants in the module and as attributes of the sha objects returned by `new()`:

```python
sha.blocksize
```

Size of the blocks fed into the hash function; this is always 1. This size is used to allow an arbitrary string to be hashed.

```python
sha.digest_size
```

The size of the resulting digest in bytes. This is always 20.

An sha object has the same methods as md5 objects:

```python
sha.update(arg)
```

Update the sha object with the string `arg`. Repeated calls are equivalent to a single call with the concatenation of all the arguments: `m.update(a); m.update(b)` is equivalent to...
m.update(a+b).

sha.digest()
Return the digest of the strings passed to the update() method so far. This is a 20-byte string which may contain non-ASCII characters, including null bytes.

sha.hexdigest()
Like digest() except the digest is returned as a string of length 40, containing only hexadecimal digits. This may be used to exchange the value safely in email or other non-binary environments.

sha.copy()
Return a copy ("clone") of the sha object. This can be used to efficiently compute the digests of strings that share a common initial substring.

Generic Operating System Services

The modules described in this chapter provide interfaces to operating system features that are available on (almost) all operating systems, such as files and a clock. The interfaces are generally modeled after the Unix or C interfaces, but they are available on most other systems as well. Here’s an overview:

- **os** — Miscellaneous operating system interfaces
  - Process Parameters
  - File Object Creation
  - File Descriptor Operations
  - Files and Directories
  - Process Management
  - Miscellaneous System Information
  - Miscellaneous Functions

- **io** — Core tools for working with streams
  - Module Interface
  - I/O Base Classes
  - Raw File I/O
  - Buffered Streams
  - Text I/O

- **time** — Time access and conversions

- **optparse** — More powerful command line option parser
  - Background
    - Terminology
    - What are options for?
    - What are positional arguments for?
  - Tutorial
    - Understanding option actions
    - The store action
• Handling boolean (flag) options
• Other actions
• Default values
• Generating help
• Printing a version string
• How **optparse** handles errors
• Putting it all together

○ Reference Guide
  • Creating the parser
  • Populating the parser
  • Defining options
  • Standard option actions
  • Option attributes
  • Standard option types
  • Parsing arguments
  • Querying and manipulating your option parser
  • Conflicts between options
  • Cleanup
  • Other methods

○ Option Callbacks
  • Defining a callback option
  • How callbacks are called
  • Raising errors in a callback
  • Callback example 1: trivial callback
  • Callback example 2: check option order
  • Callback example 3: check option order (generalized)
  • Callback example 4: check arbitrary condition
  • Callback example 5: fixed arguments
  • Callback example 6: variable arguments

○ Extending **optparse**
  • Adding new types
  • Adding new actions

• **getopt** — Parser for command line options
• **logging** — Logging facility for Python

using Sphinx 0.5.
This module provides a portable way of using operating system dependent functionality. If you just want to read or write a file see `open()`, if you want to manipulate paths, see the `os.path` module, and if you want to read all the lines in all the files on the command line see the `fileinput` module. For creating temporary files and directories see the `tempfile` module, and for high-level file and directory handling see the `shutil` module.

The design of all built-in operating system dependent modules of Python is such that as long as the same functionality is available, it uses the same interface; for example, the function `os.stat(path)` returns stat information about `path` in the same format (which happens to have originated with the POSIX interface).

Extensions peculiar to a particular operating system are also available through the `os` module, but using them is of course a threat to portability!

**Note:** If not separately noted, all functions that claim “Availability: Unix” are supported on Mac OS X, which builds on a Unix core.

**Note:** All functions in this module raise `OSError` in the case of invalid or inaccessible file names and paths, or other arguments that have the correct type, but are not accepted by the operating system.

```
exception os.error

An alias for the built-in OSError exception.
```
os.name
The name of the operating system dependent module imported. The following names have currently been registered: 'posix', 'nt', 'mac', 'os2', 'ce', 'java', 'riscos'.

os.path
The corresponding operating system dependent standard module for pathname operations, such as posixpath or ntpath. Thus, given the proper imports, os.path.split(file) is equivalent to but more portable than posixpath.split(file). Note that this is also an importable module: it may be imported directly as os.path.
These functions and data items provide information and operate on the current process and user.

**os.environ**
A mapping object representing the string environment. For example, `environ['HOME']` is the pathname of your home directory (on some platforms), and is equivalent to `getenv("HOME")` in C.

This mapping is captured the first time the os module is imported, typically during Python startup as part of processing `site.py`. Changes to the environment made after this time are not reflected in `os.environ`, except for changes made by modifying `os.environ` directly.

If the platform supports the `putenv()` function, this mapping may be used to modify the environment as well as query the environment. `putenv()` will be called automatically when the mapping is modified.

**Note:** Calling `putenv()` directly does not change `os.environ`, so it's better to modify `os.environ`.

**Note:** On some platforms, including FreeBSD and Mac OS X, setting `environ` may cause memory leaks. Refer to the system documentation for `putenv`.

If `putenv()` is not provided, a modified copy of this mapping may be passed to the appropriate process-creation functions to cause child processes to use a modified environment.
If the platform supports the `unsetenv()` function, you can delete items in this mapping to unset environment variables. `unsetenv()` will be called automatically when an item is deleted from `os.environ`, and when one of the `pop()` or `clear()` methods is called.

*Changed in version 2.6:* Also unset environment variables when calling `os.environ.clear()` and `os.environ.pop()`.

```python
os.chdir(path)
```

```python
os.fchdir(fd)
```

```python
os.getcwd()
```

These functions are described in *Files and Directories*.

```python
os.ctermid()
```

Return the filename corresponding to the controlling terminal of the process. Availability: Unix.

```python
os.getegid()
```

Return the effective group id of the current process. This corresponds to the “set id” bit on the file being executed in the current process. Availability: Unix.

```python
os.geteuid()
```

Return the current process’s effective user id. Availability: Unix.

```python
os.getgid()
```

Return the real group id of the current process. Availability: Unix.

```python
os.getgroups()
```

Return list of supplemental group ids associated with the current process. Availability: Unix.

```python
os.getlogin()
```
Return the name of the user logged in on the controlling terminal of the process. For most purposes, it is more useful to use the environment variable `LOGNAME` to find out who the user is, or `pwd.getpwuid(os.getuid())[0]` to get the login name of the currently effective user id. Availability: Unix.

```python
os.getpgid(pid)
```
Return the process group id of the process with process id `pid`. If `pid` is 0, the process group id of the current process is returned. Availability: Unix.

*New in version 2.3.*

```python
os.getpgrp()
```
Return the id of the current process group. Availability: Unix.

```python
os.getpid()
```
Return the current process id. Availability: Unix, Windows.

```python
os.getppid()
```
Return the parent’s process id. Availability: Unix.

```python
os.getuid()
```
Return the current process’s user id. Availability: Unix.

```python
os.getenv(varname[, value])
```
Return the value of the environment variable `varname` if it exists, or `value` if it doesn’t. `value` defaults to `None`. Availability: most flavors of Unix, Windows.

```python
os.putenv(varname, value)
```
Set the environment variable named `varname` to the string `value`. Such changes to the environment affect subprocesses started with `os.system()`, `popen()` or `fork()` and `execv()`. Availability:
most flavors of Unix, Windows.

**Note:** On some platforms, including FreeBSD and Mac OS X, setting `environ` may cause memory leaks. Refer to the system documentation for `putenv`.

When `putenv()` is supported, assignments to items in `os.environ` are automatically translated into corresponding calls to `putenv()`; however, calls to `putenv()` don’t update `os.environ`, so it is actually preferable to assign to items of `os.environ`.

`os.setegid(egid)`
Set the current process’s effective group id. Availability: Unix.

`os.seteuid(euid)`
Set the current process’s effective user id. Availability: Unix.

`os.setgid(gid)`
Set the current process’ group id. Availability: Unix.

`os.setgroups(groups)`
Set the list of supplemental group ids associated with the current process to `groups`. `groups` must be a sequence, and each element must be an integer identifying a group. This operation is typically available only to the superuser. Availability: Unix.

*New in version 2.2.*

`os.setpgrp()`
Call the system call `setpgrp` or `setpgrp(0, 0)` depending on which version is implemented (if any). See the Unix manual for the semantics. Availability: Unix.

`os.setpgid(pid, pgrp)}`
Call the system call `setpgid` to set the process group id of the process with id `pid` to the process group with id `pgrp`. See the Unix manual for the semantics. Availability: Unix.

`os.setreuid(ruid, euid)`  
Set the current process’s real and effective user ids. Availability: Unix.

`os.setregid(rgid, egid)`  
Set the current process’s real and effective group ids. Availability: Unix.

`os.getsid(pid)`  
Call the system call `getsid`. See the Unix manual for the semantics. Availability: Unix.

    New in version 2.4.

`os.setsid()`  
Call the system call `setsid`. See the Unix manual for the semantics. Availability: Unix.

`os.setuid(uid)`  
Set the current process’s user id. Availability: Unix.

`os.strerror(code)`  
Return the error message corresponding to the error code in `code`. On platforms where `strerror` returns `NULL` when given an unknown error number, `ValueError` is raised. Availability: Unix, Windows.

`os.umask(mask)`  
Set the current numeric umask and return the previous umask. Availability: Unix, Windows.
os.\texttt{uname}()

Return a 5-tuple containing information identifying the current operating system. The tuple contains 5 strings: \texttt{(sysname, nodename, release, version, machine)}. Some systems truncate the nodename to 8 characters or to the leading component; a better way to get the hostname is \texttt{socket.gethostname()} or even \texttt{socket.gethostbyaddr(socket.gethostname())}. Availability: recent flavors of Unix.

\textbf{os.\texttt{unsetenv}(\textit{varname})}

Unset (delete) the environment variable named \textit{varname}. Such changes to the environment affect subprocesses started with \texttt{os.system()}, \texttt{popen()} or \texttt{fork()} and \texttt{execv()}. Availability: most flavors of Unix, Windows.

When \texttt{unsetenv()} is supported, deletion of items in \texttt{os.environ} is automatically translated into a corresponding call to \texttt{unsetenv()}; however, calls to \texttt{unsetenv()} don't update \texttt{os.environ}, so it is actually preferable to delete items of \texttt{os.environ}. 
File Object Creation

These functions create new file objects. (See also open().)

```python
os.fdopen(fd[, mode[, bufsize]])
```

Return an open file object connected to the file descriptor `fd`. The `mode` and `bufsize` arguments have the same meaning as the corresponding arguments to the built-in open() function. Availability: Unix, Windows.

*Changed in version 2.3:* When specified, the `mode` argument must now start with one of the letters `'r'`, `'w'`, or `'a'`, otherwise a `ValueError` is raised.

*Changed in version 2.5:* On Unix, when the `mode` argument starts with `'a'`, the `O_APPEND` flag is set on the file descriptor (which the `fdopen` implementation already does on most platforms).

```python
os.popen(command[, mode[, bufsize]])
```

Open a pipe to or from `command`. The return value is an open file object connected to the pipe, which can be read or written depending on whether `mode` is `'r'` (default) or `'w'`. The `bufsize` argument has the same meaning as the corresponding argument to the built-in open() function. The exit status of the command (encoded in the format specified for wait()) is available as the return value of the close() method of the file object, except that when the exit status is zero (termination without errors), `None` is returned. Availability: Unix, Windows.

*Deprecated since version 2.6:* This function is obsolete. Use the subprocess module. Check especially the `Replacing Older`
Functions with the subprocess Module section.

Changed in version 2.0: This function worked unreliably under Windows in earlier versions of Python. This was due to the use of the _popen function from the libraries provided with Windows. Newer versions of Python do not use the broken implementation from the Windows libraries.

**os.tmpfile()**

Return a new file object opened in update mode (w+b). The file has no directory entries associated with it and will be automatically deleted once there are no file descriptors for the file. Availability: Unix, Windows.

There are a number of different popen*() functions that provide slightly different ways to create subprocesses.

Deprecated since version 2.6: All of the popen*() functions are obsolete. Use the subprocess module.

For each of the popen*() variants, if bufsize is specified, it specifies the buffer size for the I/O pipes. mode, if provided, should be the string 'b' or 't'; on Windows this is needed to determine whether the file objects should be opened in binary or text mode. The default value for mode is 't'.

Also, for each of these variants, on Unix, cmd may be a sequence, in which case arguments will be passed directly to the program without shell intervention (as with os.spawnv()). If cmd is a string it will be passed to the shell (as with os.system()).

These methods do not make it possible to retrieve the exit status from the child processes. The only way to control the input and output streams and also retrieve the return codes is to use the
subprocess module; these are only available on Unix.

For a discussion of possible deadlock conditions related to the use of these functions, see *Flow Control Issues*.

**os.popen2(cmd[, mode[, bufsize]])**
Execute *cmd* as a sub-process and return the file objects *(child_stdin, child_stdout)*.

*Deprecated since version 2.6:* This function is obsolete. Use the subprocess module. Check especially the *Replacing Older Functions with the subprocess Module* section.

Availability: Unix, Windows.

*New in version 2.0.*

**os.popen3(cmd[, mode[, bufsize]])**
Execute *cmd* as a sub-process and return the file objects *(child_stdin, child.stdout, child.stderr)*.

*Deprecated since version 2.6:* This function is obsolete. Use the subprocess module. Check especially the *Replacing Older Functions with the subprocess Module* section.

Availability: Unix, Windows.

*New in version 2.0.*

**os.popen4(cmd[, mode[, bufsize]])**
Execute *cmd* as a sub-process and return the file objects *(child_stdin, child.stdout_and_stderr)*.

*Deprecated since version 2.6:* This function is obsolete. Use the subprocess module. Check especially the *Replacing Older Functions with the subprocess Module* section.
Functions with the subprocess Module section.

Availability: Unix, Windows.

New in version 2.0.

(Note that child_stdin, child_stdout, and child_stderr are named from the point of view of the child process, so child_stdin is the child's standard input.)

This functionality is also available in the popen2 module using functions of the same names, but the return values of those functions have a different order.
File Descriptor Operations

These functions operate on I/O streams referenced using file descriptors.

File descriptors are small integers corresponding to a file that has been opened by the current process. For example, standard input is usually file descriptor 0, standard output is 1, and standard error is 2. Further files opened by a process will then be assigned 3, 4, 5, and so forth. The name “file descriptor” is slightly deceptive; on Unix platforms, sockets and pipes are also referenced by file descriptors.

```python
os.close(fd)
```

**Note:** This function is intended for low-level I/O and must be applied to a file descriptor as returned by `open()` or `pipe()`. To close a “file object” returned by the built-in function `open()` or by `popen()` or `fdopen()`, use its `close()` method.

```python
os.closerange(fd_low, fd_high)
```

Close all file descriptors from `fd_low` (inclusive) to `fd_high` (exclusive), ignoring errors. Availability: Unix, Windows. Equivalent to:

```python
for fd in xrange(fd_low, fd_high):
    try:
        os.close(fd)
    except OSError:
        pass
```

`New in version 2.6.`
**os. `dup(fd)`**

**os. `dup2(fd, fd2)`**
Duplicate file descriptor `fd` to `fd2`, closing the latter first if necessary. Availability: Unix, Windows.

**os. `fchmod(fd, mode)`**
Change the mode of the file given by `fd` to the numeric `mode`. See the docs for `chmod()` for possible values of `mode`. Availability: Unix.

*New in version 2.6.*

**os. `fchown(fd, uid, gid)`**
Change the owner and group id of the file given by `fd` to the numeric `uid` and `gid`. To leave one of the ids unchanged, set it to -1. Availability: Unix.

*New in version 2.6.*

**os. `fdatasync(fd)`**

**os. `fpathconf(fd, name)`**
Return system configuration information relevant to an open file. `name` specifies the configuration value to retrieve; it may be a string which is the name of a defined system value; these names are specified in a number of standards (POSIX.1, Unix 95, Unix 98, and others). Some platforms define additional names as well. The names known to the host operating system are given in the `pathconf_names` dictionary. For configuration variables not included in that mapping, passing an integer for `name` is also
accepted. Availability: Unix.

If `name` is a string and is not known, `ValueError` is raised. If a specific value for `name` is not supported by the host system, even if it is included in `pathconf_names`, an `OSError` is raised with `errno.EINVAL` for the error number.

`os.fstat(fd)`

`os.fstatvfs(fd)`
Return information about the filesystem containing the file associated with file descriptor `fd`, like `statvfs()`. Availability: Unix.

`os.fsync(fd)`
Force write of file with file descriptor `fd` to disk. On Unix, this calls the native `fsync` function; on Windows, the MS `commit` function.

If you’re starting with a Python file object `f`, first do `f.flush()`, and then do `os.fsync(f.fileno())`, to ensure that all internal buffers associated with `f` are written to disk. Availability: Unix, and Windows starting in 2.2.3.

`os.ftruncate(fd, length)`
Truncate the file corresponding to file descriptor `fd`, so that it is at most `length` bytes in size. Availability: Unix.

`os.isatty(fd)`
Return `True` if the file descriptor `fd` is open and connected to a `tty`(-like) device, else `False`. Availability: Unix.

`os.lseek(fd, pos, how)`
Set the current position of file descriptor `fd` to position `pos`,
modified by how: SEEK_SET or 0 to set the position relative to the beginning of the file; SEEK_CUR or 1 to set it relative to the current position; os.SEEK_END or 2 to set it relative to the end of the file. Availability: Unix, Windows.

os.open(file, flags[, mode])
Open the file file and set various flags according to flags and possibly its mode according to mode. The default mode is 0777 (octal), and the current umask value is first masked out. Return the file descriptor for the newly opened file. Availability: Unix, Windows.

For a description of the flag and mode values, see the C run-time documentation; flag constants (like O_RDONLY and O_WRONLY) are defined in this module too (see below).

**Note:** This function is intended for low-level I/O. For normal usage, use the built-in function open(), which returns a “file object” with read() and write() methods (and many more). To wrap a file descriptor in a “file object”, use fdopen().

os.openpty()
Open a new pseudo-terminal pair. Return a pair of file descriptors (master, slave) for the pty and the tty, respectively. For a (slightly) more portable approach, use the pty module. Availability: some flavors of Unix.

os.pipe()
Create a pipe. Return a pair of file descriptors (r, w) usable for reading and writing, respectively. Availability: Unix, Windows.

os.read(fd, n)
Read at most n bytes from file descriptor fd. Return a string
containing the bytes read. If the end of the file referred to by \textit{fd} has been reached, an empty string is returned. Availability: Unix, Windows.

\textbf{Note:} This function is intended for low-level I/O and must be applied to a file descriptor as returned by \texttt{open()} or \texttt{pipe()}. To read a “file object” returned by the built-in function \texttt{open()} or by \texttt{popen()} or \texttt{fdopen()}, or \texttt{sys.stdin}, use its \texttt{read()} or \texttt{readline()} methods.

\begin{verbatim}
\texttt{os.tcgetpgrp}(fd)
Return the process group associated with the terminal given by \textit{fd} (an open file descriptor as returned by \texttt{open()}). Availability: Unix.

\texttt{os.tcsetpgrp}(fd, pg)
Set the process group associated with the terminal given by \textit{fd} (an open file descriptor as returned by \texttt{open()}) to \textit{pg}. Availability: Unix.

\texttt{os.ttyname}(fd)
Return a string which specifies the terminal device associated with file descriptor \textit{fd}. If \textit{fd} is not associated with a terminal device, an exception is raised. Availability: Unix.

\texttt{os.write}(fd, str)
Write the string \textit{str} to file descriptor \textit{fd}. Return the number of bytes actually written. Availability: Unix, Windows.
\end{verbatim}

\textbf{Note:} This function is intended for low-level I/O and must be applied to a file descriptor as returned by \texttt{open()} or \texttt{pipe()}. To write a “file object” returned by the built-in function \texttt{open()} or by \texttt{popen()} or \texttt{fdopen()}, or \texttt{sys.stdout} or \texttt{sys.stderr}, use its \texttt{write()} method.
The following data items are available for use in constructing the *flags* parameter to the `open()` function. Some items will not be available on all platforms. For descriptions of their availability and use, consult `open(2)`.

```c
os._RDONLY
os._WONLY
os._RDWR
os._APPEND
os._CREAT
os._EXCL
os._TRUNC
```
Options for the *flag* argument to the `open()` function. These can be combined using the bitwise OR operator `|`. Availability: Unix, Windows.

```c
os._DSYNC
os._RSYNC
os._SYNC
os._NDELAY
os._NONBLOCK
os._NOCTTY
os._SHLOCK
os._EXLOCK
```
More options for the *flag* argument to the `open()` function. Availability: Unix.

```c
os._BINARY
os._NOINHERIT
os._SHORT_LIVED
os._TEMPORARY
os._RANDOM
os._SEQUENTIAL
os._TEXT
```
Options for the *flag* argument to the `open()` function. These can be combined using the bitwise OR operator `|`. Availability: Windows.
os.O_ASYNC
os.O_DIRECT
os.O_DIRECTORY
os.O_NOFOLLOW
os.O_NOATIME
Options for the flag argument to the open() function. These are GNU extensions and not present if they are not defined by the C library.

os.SEEK_SET
os.SEEK_CUR
os.SEEK_END
Parameters to the lseek() function. Their values are 0, 1, and 2, respectively. Availability: Windows, Unix.

New in version 2.5.
Files and Directories

`os.access(path, mode)`

Use the real uid/gid to test for access to `path`. Note that most operations will use the effective uid/gid, therefore this routine can be used in a suid/sgid environment to test if the invoking user has the specified access to `path`. `mode` should be `F_OK` to test the existence of `path`, or it can be the inclusive OR of one or more of `R_OK`, `W_OK`, and `X_OK` to test permissions. Return `True` if access is allowed, `False` if not. See the Unix man page `access(2)` for more information. Availability: Unix, Windows.

**Note:** Using `access()` to check if a user is authorized to e.g. open a file before actually doing so using `open()` creates a security hole, because the user might exploit the short time interval between checking and opening the file to manipulate it.

**Note:** I/O operations may fail even when `access()` indicates that they would succeed, particularly for operations on network filesystems which may have permissions semantics beyond the usual POSIX permission-bit model.

`os.F_OK`

Value to pass as the `mode` parameter of `access()` to test the existence of `path`.

`os.R_OK`

Value to include in the `mode` parameter of `access()` to test the readability of `path`.

`os.W_OK`

Value to include in the `mode` parameter of `access()` to test the
writability of path.

**os. X_OK**
Value to include in the mode parameter of access() to determine if path can be executed.

**os. chdir(path)**
Change the current working directory to path. Availability: Unix, Windows.

**os. fchdir(fd)**
Change the current working directory to the directory represented by the file descriptor fd. The descriptor must refer to an opened directory, not an open file. Availability: Unix.

*New in version 2.3.*

**os. getcwd()**
Return a string representing the current working directory. Availability: Unix, Windows.

**os. getcwd()**
Return a Unicode object representing the current working directory. Availability: Unix, Windows.

*New in version 2.3.*

**os. chflags(path, flags)**
Set the flags of path to the numeric flags. flags may take a combination (bitwise OR) of the following values (as defined in the stat module):

- **UF_NODUMP**
- **UF_IMMUTABLE**
- **UF_APPEND**
Availability: Unix.

New in version 2.6.

```python
os.chroot(path)
```
Change the root directory of the current process to `path`. Availability: Unix.

New in version 2.2.

```python
os.chmod(path, mode)
```
Change the mode of `path` to the numeric `mode`. `mode` may take one of the following values (as defined in the `stat` module) or bitwise ORed combinations of them:

- `stat.S_ISUID`
- `stat.S_ISGID`
- `stat.S_ENFMT`
- `stat.S_ISVTX`
- `stat.S_IREAD`
- `stat.S_IWRITE`
- `stat.S_IEXEC`
- `stat.S_IRWXU`
- `stat.S_IRUSR`
- `stat.S_IWUSR`
Availability: Unix, Windows.

**Note:** Although Windows supports `chmod()`, you can only set the file's read-only flag with it (via the `stat.S_IWRITE` and `stat.S_IREAD` constants or a corresponding integer value). All other bits are ignored.

```python
os.chown(path, uid, gid)
```
Change the owner and group id of `path` to the numeric `uid` and `gid`. To leave one of the ids unchanged, set it to -1. Availability: Unix.

```python
os.lchflags(path, flags)
```
Set the flags of `path` to the numeric `flags`, like `chflags()`, but do not follow symbolic links. Availability: Unix.

*New in version 2.6.*

```python
os.lchmod(path, mode)
```
Change the mode of `path` to the numeric `mode`. If path is a symlink, this affects the symlink rather than the target. See the docs for `chmod()` for possible values of `mode`. Availability: Unix.
New in version 2.6.

```python
os.lchown(path, uid, gid)
```
Change the owner and group id of `path` to the numeric `uid` and `gid`. This function will not follow symbolic links. Availability: Unix.

New in version 2.3.

```python
os.link(src, dst)
```
Create a hard link pointing to `src` named `dst`. Availability: Unix.

```python
os.listdir(path)
```
Return a list containing the names of the entries in the directory. The list is in arbitrary order. It does not include the special entries `.' and `..' even if they are present in the directory. Availability: Unix, Windows.

*Changed in version 2.3:* On Windows NT/2k/XP and Unix, if `path` is a Unicode object, the result will be a list of Unicode objects.

```python
os.lstat(path)
```
Like `stat()`, but do not follow symbolic links. This is an alias for `stat()` on platforms that do not support symbolic links, such as Windows.

```python
os.mkfifo(path[, mode])
```
Create a FIFO (a named pipe) named `path` with numeric mode `mode`. The default `mode` is 0666 (octal). The current umask value is first masked out from the mode. Availability: Unix.

FIFOs are pipes that can be accessed like regular files. FIFOs exist until they are deleted (for example with `os.unlink()`). Generally, FIFOs are used as rendezvous between “client” and “server” type processes: the server opens the FIFO for reading,
and the client opens it for writing. Note that \texttt{mkfifo()} doesn't open the FIFO — it just creates the rendezvous point.

\texttt{os.mknod(filename[, mode=0600, device])}

Create a filesystem node (file, device special file or named pipe) named \texttt{filename}. \texttt{mode} specifies both the permissions to use and the type of node to be created, being combined (bitwise OR) with one of \texttt{stat.S_IFREG}, \texttt{stat.S_IFCHR}, \texttt{stat.S_IFBLK}, and \texttt{stat.S_IFIFO} (those constants are available in \texttt{stat}). For \texttt{stat.S_IFCHR} and \texttt{stat.S_IFBLK}, \texttt{device} defines the newly created device special file (probably using \texttt{os.makedev()}), otherwise it is ignored.

\textit{New in version 2.3.}

\texttt{os.major(device)}

Extract the device major number from a raw device number (usually the \texttt{st_dev} or \texttt{st_rdev} field from \texttt{stat}).

\textit{New in version 2.3.}

\texttt{os.minor(device)}

Extract the device minor number from a raw device number (usually the \texttt{st_dev} or \texttt{st_rdev} field from \texttt{stat}).

\textit{New in version 2.3.}

\texttt{os.makedev(major, minor)}

Compose a raw device number from the major and minor device numbers.

\textit{New in version 2.3.}

\texttt{os.mkdir(path[, mode])}
Create a directory named `path` with numeric mode `mode`. The default `mode` is `0777` (octal). On some systems, `mode` is ignored. Where it is used, the current umask value is first masked out. Availability: Unix, Windows.

It is also possible to create temporary directories; see the `tempfile` module's `tempfile.mkdtemp()` function.

```python
os.makedirs(path[, mode])
```

Recursive directory creation function. Like `mkdir()`, but makes all intermediate-level directories needed to contain the leaf directory. Throws an error exception if the leaf directory already exists or cannot be created. The default `mode` is `0777` (octal). On some systems, `mode` is ignored. Where it is used, the current umask value is first masked out.

**Note:** `makedirs()` will become confused if the path elements to create include `os.pardir`.

*New in version 1.5.2.*

*Changed in version 2.3:* This function now handles UNC paths correctly.

```python
os.pathconf(path, name)
```

Return system configuration information relevant to a named file. `name` specifies the configuration value to retrieve; it may be a string which is the name of a defined system value; these names are specified in a number of standards (POSIX.1, Unix 95, Unix 98, and others). Some platforms define additional names as well. The names known to the host operating system are given in the `pathconf_names` dictionary. For configuration variables not included in that mapping, passing an integer for `name` is also accepted. Availability: Unix.
If `name` is a string and is not known, `ValueError` is raised. If a specific value for `name` is not supported by the host system, even if it is included in `pathconf_names`, an `OSError` is raised with `errno.EINVAL` for the error number.

**os.pathconf_names**

Dictionary mapping names accepted by `pathconf()` and `fpathconf()` to the integer values defined for those names by the host operating system. This can be used to determine the set of names known to the system. Availability: Unix.

**os.readlink(path)**

Return a string representing the path to which the symbolic link points. The result may be either an absolute or relative pathname; if it is relative, it may be converted to an absolute pathname using `os.path.join(os.path.dirname(path), result)`.

*Changed in version 2.6:* If the `path` is a Unicode object the result will also be a Unicode object.

Availability: Unix.

**os.remove(path)**

Remove the file `path`. If `path` is a directory, `OSError` is raised; see `rmdir()` below to remove a directory. This is identical to the `unlink()` function documented below. On Windows, attempting to remove a file that is in use causes an exception to be raised; on Unix, the directory entry is removed but the storage allocated to the file is not made available until the original file is no longer in use. Availability: Unix, Windows.

**os.removedirs(path)**

Remove directories recursively. Works like `rmdir()` except that, if the leaf directory is successfully removed, `removedirs()` tries to
successively remove every parent directory mentioned in *path* until an error is raised (which is ignored, because it generally means that a parent directory is not empty). For example, `os.removedirs('foo/bar/baz')` will first remove the directory 'foo/bar/baz', and then remove 'foo/bar' and 'foo' if they are empty. Raises OSError if the leaf directory could not be successfully removed.

*New in version 1.5.2.*

**os.rename(src, dst)**

Rename the file or directory *src* to *dst*. If *dst* is a directory, OSError will be raised. On Unix, if *dst* exists and is a file, it will be replaced silently if the user has permission. The operation may fail on some Unix flavors if *src* and *dst* are on different filesystems. If successful, the renaming will be an atomic operation (this is a POSIX requirement). On Windows, if *dst* already exists, OSError will be raised even if it is a file; there may be no way to implement an atomic rename when *dst* names an existing file. Availability: Unix, Windows.

**os.renames(old, new)**

Recursive directory or file renaming function. Works like rename(), except creation of any intermediate directories needed to make the new pathname good is attempted first. After the rename, directories corresponding to rightmost path segments of the old name will be pruned away using `removedirs()`.

*New in version 1.5.2.*

**Note:** This function can fail with the new directory structure made if you lack permissions needed to remove the leaf directory or file.
**os. rmdir**(*path*)

Remove the directory *path*. Availability: Unix, Windows.

**os. stat**(*path*)

Perform a `stat` system call on the given path. The return value is an object whose attributes correspond to the members of the `stat` structure, namely: `st_mode` (protection bits), `st_ino` (inode number), `st_dev` (device), `st_nlink` (number of hard links), `st_uid` (user id of owner), `st_gid` (group id of owner), `st_size` (size of file, in bytes), `st_atime` (time of most recent access), `st_mtime` (time of most recent content modification), `st_ctime` (platform dependent; time of most recent metadata change on Unix, or the time of creation on Windows):

```python
>>> import os
>>> statinfo = os.stat('somefile.txt')
>>> statinfo
(33188, 422511L, 769L, 1, 1032, 100, 926L, 1105022698, 1105022732, 1105022732)
>>> statinfo.st_size
926L
```

*Changed in version 2.3:* If `stat_float_times()` returns `True`, the time values are floats, measuring seconds. Fractions of a second may be reported if the system supports that. On Mac OS, the times are always floats. See `stat_float_times()` for further discussion.

On some Unix systems (such as Linux), the following attributes may also be available: `st_blocks` (number of blocks allocated for file), `st_blksize` (filesystem blocksize), `st_rdev` (type of device if an inode device). `st_flags` (user defined flags for file).
On other Unix systems (such as FreeBSD), the following attributes may be available (but may be only filled out if root tries to use them): \texttt{st\_gen} (file generation number), \texttt{st\_birthtime} (time of file creation).

On Mac OS systems, the following attributes may also be available: \texttt{st\_rs}ize, \texttt{st\_creator}, \texttt{st\_type}.

On RISCOS systems, the following attributes are also available: \texttt{st\_ftime} (file type), \texttt{st\_attrs} (attributes), \texttt{st\_obtype} (object type).

For backward compatibility, the return value of \texttt{stat()} is also accessible as a tuple of at least 10 integers giving the most important (and portable) members of the \texttt{stat} structure, in the order \texttt{st\_mode}, \texttt{st\_ino}, \texttt{st\_dev}, \texttt{st\_nlink}, \texttt{st\_uid}, \texttt{st\_gid}, \texttt{st\_size}, \texttt{st\_atime}, \texttt{st\_mtime}, \texttt{st\_ctime}. More items may be added at the end by some implementations. The standard module \texttt{stat} defines functions and constants that are useful for extracting information from a \texttt{stat} structure. (On Windows, some items are filled with dummy values.)

\begin{quote}
\textbf{Note:} The exact meaning and resolution of the \texttt{st\_atime}, \texttt{st\_mtime}, and \texttt{st\_ctime} members depends on the operating system and the file system. For example, on Windows systems using the FAT or FAT32 file systems, \texttt{st\_mtime} has 2-second resolution, and \texttt{st\_atime} has only 1-day resolution. See your operating system documentation for details.
\end{quote}

Availability: Unix, Windows.

\textit{Changed in version 2.2}: Added access to values as attributes of the returned object.

\textit{Changed in version 2.5}: Added \texttt{st\_gen} and \texttt{st\_birthtime}.
os.stat_float_times([newvalue])

Determine whether stat_result represents time stamps as float objects. If newvalue is True, future calls to stat() return floats, if it is False, future calls return ints. If newvalue is omitted, return the current setting.

For compatibility with older Python versions, accessing stat_result as a tuple always returns integers.

Changed in version 2.5: Python now returns float values by default. Applications which do not work correctly with floating point time stamps can use this function to restore the old behaviour.

The resolution of the timestamps (that is the smallest possible fraction) depends on the system. Some systems only support second resolution; on these systems, the fraction will always be zero.

It is recommended that this setting is only changed at program startup time in the __main__ module; libraries should never change this setting. If an application uses a library that works incorrectly if floating point time stamps are processed, this application should turn the feature off until the library has been corrected.

os.statvfs(path)

Perform a statvfs system call on the given path. The return value is an object whose attributes describe the filesystem on the given path, and correspond to the members of the statvfs structure, namely: f_bsize, f_frsize, f_blocks, f_bfree, f_bavail, f_files, f_ffree, f_favail, f_flag, f_namemax. Availability: Unix.
For backward compatibility, the return value is also accessible as a tuple whose values correspond to the attributes, in the order given above. The standard module `statvfs` defines constants that are useful for extracting information from a `statvfs` structure when accessing it as a sequence; this remains useful when writing code that needs to work with versions of Python that don’t support accessing the fields as attributes.

*Changed in version 2.2:* Added access to values as attributes of the returned object.

```python
os.symlink(src, dst)
```

Create a symbolic link pointing to `src` named `dst`. Availability: Unix.

```python
os.tempnam([dir[, prefix]])
```

Return a unique path name that is reasonable for creating a temporary file. This will be an absolute path that names a potential directory entry in the directory `dir` or a common location for temporary files if `dir` is omitted or `None`. If given and not `None`, `prefix` is used to provide a short prefix to the filename. Applications are responsible for properly creating and managing files created using paths returned by `tempnam()`; no automatic cleanup is provided. On Unix, the environment variable `TMPDIR` overrides `dir`, while on Windows `TMP` is used. The specific behavior of this function depends on the C library implementation; some aspects are underspecified in system documentation.

**Warning:** Use of `tempnam()` is vulnerable to symlink attacks; consider using `tmpfile()` (section *File Object Creation*) instead.

Availability: Unix, Windows.
**os.tmpnam()**

Return a unique path name that is reasonable for creating a temporary file. This will be an absolute path that names a potential directory entry in a common location for temporary files. Applications are responsible for properly creating and managing files created using paths returned by `tmpnam()`; no automatic cleanup is provided.

*Warning:* Use of `tmpnam()` is vulnerable to symlink attacks; consider using `tmpfile()` (section *File Object Creation*) instead.

Availability: Unix, Windows. This function probably shouldn’t be used on Windows, though: Microsoft’s implementation of `tmpnam()` always creates a name in the root directory of the current drive, and that’s generally a poor location for a temp file (depending on privileges, you may not even be able to open a file using this name).

**os.TMP_MAX**

The maximum number of unique names that `tmpnam()` will generate before reusing names.

**os.unlink(path)**

Remove the file `path`. This is the same function as `remove()`; the `unlink()` name is its traditional Unix name. Availability: Unix, Windows.

**os.utime(path, times)**

Set the access and modified times of the file specified by `path`. If `times` is `None`, then the file’s access and modified times are set to the current time. (The effect is similar to running the Unix program `touch` on the path.) Otherwise, `times` must be a 2-tuple of numbers, of the form `(atime, mtime)` which is used to set the access and modified times, respectively. Whether a directory can
be given for path depends on whether the operating system implements directories as files (for example, Windows does not). Note that the exact times you set here may not be returned by a subsequent stat() call, depending on the resolution with which your operating system records access and modification times; see stat().

*Changed in version 2.0:* Added support for None for times.

**Availability:** Unix, Windows.

```python
os.walk(top[, topdown=True[, onerror=None[, followlinks=False]]]])
```

Generate the file names in a directory tree by walking the tree either top-down or bottom-up. For each directory in the tree rooted at directory top (including top itself), it yields a 3-tuple (dirpath, dirnames, filenames).

dirpath is a string, the path to the directory. dirnames is a list of the names of the subdirectories in dirpath (excluding '.' and '..'). filenames is a list of the names of the non-directory files in dirpath. Note that the names in the lists contain no path components. To get a full path (which begins with top) to a file or directory in dirpath, do os.path.join(dirpath, name).

If optional argument topdown is True or not specified, the triple for a directory is generated before the triples for any of its subdirectories (directories are generated top-down). If topdown is False, the triple for a directory is generated after the triples for all of its subdirectories (directories are generated bottom-up).

When topdown is True, the caller can modify the dirnames list in-place (perhaps using del or slice assignment), and walk() will only recurse into the subdirectories whose names remain in dirnames; this can be used to prune the search, impose a
specific order of visiting, or even to inform \texttt{walk()} about directories the caller creates or renames before it resumes \texttt{walk()} again. Modifying \texttt{dirnames} when \texttt{topdown} is \texttt{False} is ineffective, because in bottom-up mode the directories in \texttt{dirnames} are generated before \texttt{dirpath} itself is generated.

By default errors from the \texttt{listdir()} call are ignored. If optional argument \texttt{onerror} is specified, it should be a function; it will be called with one argument, an \texttt{OSError} instance. It can report the error to continue with the walk, or raise the exception to abort the walk. Note that the filename is available as the \texttt{filename} attribute of the exception object.

By default, \texttt{walk()} will not walk down into symbolic links that resolve to directories. Set \texttt{followlinks} to \texttt{True} to visit directories pointed to by symlinks, on systems that support them.

\textit{New in version 2.6: The followlinks parameter.}

\textbf{Note:} Be aware that setting \texttt{followlinks} to \texttt{True} can lead to infinite recursion if a link points to a parent directory of itself. \texttt{walk()} does not keep track of the directories it visited already.

\textbf{Note:} If you pass a relative pathname, don’t change the current working directory between resumptions of \texttt{walk()}. \texttt{walk()} never changes the current directory, and assumes that its caller doesn’t either.

This example displays the number of bytes taken by non-directory files in each directory under the starting directory, except that it doesn’t look under any CVS subdirectory:

```python
import os
from os.path import join, getsize
```
for root, dirs, files in os.walk('python/Lib/email'):
    print root, "consumes",
    print sum(getsize(join(root, name)) for name in files),
    print "bytes in", len(files), "non-directory files"
if 'CVS' in dirs:
    dirs.remove('CVS')  # don't visit CVS directories

In the next example, walking the tree bottom-up is essential: `rmdir()` doesn't allow deleting a directory before the directory is empty:

    # Delete everything reachable from the directory named in "top",
    # assuming there are no symbolic links.
    # CAUTION: This is dangerous! For example, if top == '/',
    # could delete all your disk files.
import os
for root, dirs, files in os.walk(top, topdown=False):
    for name in files:
        os.remove(os.path.join(root, name))
    for name in dirs:
        os.rmdir(os.path.join(root, name))

New in version 2.3.
Process Management

These functions may be used to create and manage processes.

The various `exec*()` functions take a list of arguments for the new program loaded into the process. In each case, the first of these arguments is passed to the new program as its own name rather than as an argument a user may have typed on a command line. For the C programmer, this is the `argv[0]` passed to a program's `main`. For example, `os.execv('/bin/echo', ['foo', 'bar'])` will only print `bar` on standard output; `foo` will seem to be ignored.

`os.abort()`  
Generate a SIGABRT signal to the current process. On Unix, the default behavior is to produce a core dump; on Windows, the process immediately returns an exit code of 3. Be aware that programs which use `signal.signal()` to register a handler for SIGABRT will behave differently. Availability: Unix, Windows.

`os.exec1(path, arg0, arg1, ...)`
`os.execle(path, arg0, arg1, ..., env)`  
`os.execlp(file, arg0, arg1, ...)`  
`os.exec1pe(file, arg0, arg1, ..., env)`  
`os.execv(path, args)`  
`os.execve(path, args, env)`  
`os.execvp(file, args)`  
`os.execvpe(file, args, env)`  
These functions all execute a new program, replacing the current process; they do not return. On Unix, the new executable is loaded into the current process, and will have the same process id as the caller. Errors will be reported as OSError exceptions.
The current process is replaced immediately. Open file objects and descriptors are not flushed, so if there may be data buffered on these open files, you should flush them using `sys.stdout.flush()` or `os.fsync()` before calling an `exec*()` function.

The “I” and “v” variants of the `exec*()` functions differ in how command-line arguments are passed. The “I” variants are perhaps the easiest to work with if the number of parameters is fixed when the code is written; the individual parameters simply become additional parameters to the `execI*()` functions. The “v” variants are good when the number of parameters is variable, with the arguments being passed in a list or tuple as the `args` parameter. In either case, the arguments to the child process should start with the name of the command being run, but this is not enforced.

The variants which include a “p” near the end (`execlp()`, `execle()`, `execvp()`, and `execve()`) will use the `PATH` environment variable to locate the program file. When the environment is being replaced (using one of the `exec*e()` variants, discussed in the next paragraph), the new environment is used as the source of the `PATH` variable. The other variants, `execI()`, `exectle()`, `execv()`, and `execve()`, will not use the `PATH` variable to locate the executable; `path` must contain an appropriate absolute or relative path.

For `execle()`, `execle()`, `execve()`, and `execvp()` (note that these all end in “e”), the `env` parameter must be a mapping which is used to define the environment variables for the new process (these are used instead of the current process’ environment); the functions `execI()`, `execlp()`, `execv()`, and `execvp()` all cause the new process to inherit the environment of the current process.
Availability: Unix, Windows.

`os._exit(n)`
Exit to the system with status `n`, without calling cleanup handlers, flushing stdio buffers, etc. Availability: Unix, Windows.

**Note:** The standard way to exit is `sys.exit(n)`. `_exit()` should normally only be used in the child process after a `fork()`.

The following exit codes are defined and can be used with `_exit()`, although they are not required. These are typically used for system programs written in Python, such as a mail server’s external command delivery program.

**Note:** Some of these may not be available on all Unix platforms, since there is some variation. These constants are defined where they are defined by the underlying platform.

- `os.EX_OK`
  Exit code that means no error occurred. Availability: Unix.

  *New in version 2.3.*

- `os.EX_USAGE`
  Exit code that means the command was used incorrectly, such as when the wrong number of arguments are given. Availability: Unix.

  *New in version 2.3.*

- `os.EX_DATAERR`
  Exit code that means the input data was incorrect. Availability: Unix.

  *New in version 2.3.*
os. **EX_NOINPUT**

Exit code that means an input file did not exist or was not readable. Availability: Unix.

*New in version 2.3.*

os. **EX_NOUSER**

Exit code that means a specified user did not exist. Availability: Unix.

*New in version 2.3.*

os. **EX_NOHOST**

Exit code that means a specified host did not exist. Availability: Unix.

*New in version 2.3.*

os. **EX_UNAVAILABLE**

Exit code that means that a required service is unavailable. Availability: Unix.

*New in version 2.3.*

os. **EX_SOFTWARE**

Exit code that means an internal software error was detected. Availability: Unix.

*New in version 2.3.*

os. **EX_OSERR**

Exit code that means an operating system error was detected, such as the inability to fork or create a pipe. Availability: Unix.

*New in version 2.3.*

os. **EX_OSFIL**

Exit code that means some system file did not exist, could not be opened, or had some other kind of error. Availability: Unix.

*New in version 2.3.*

**os. EX_CANTCREAT**
Exit code that means a user specified output file could not be created. Availability: Unix.

*New in version 2.3.*

**os. EX_IOERR**
Exit code that means that an error occurred while doing I/O on some file. Availability: Unix.

*New in version 2.3.*

**os. EX_TEMPFAIL**
Exit code that means a temporary failure occurred. This indicates something that may not really be an error, such as a network connection that couldn’t be made during a retryable operation. Availability: Unix.

*New in version 2.3.*

**os. EX_PROTOCOL**
Exit code that means that a protocol exchange was illegal, invalid, or not understood. Availability: Unix.

*New in version 2.3.*

**os. EX_NOPERM**
Exit code that means that there were insufficient permissions to perform the operation (but not intended for file system problems). Availability: Unix.

*New in version 2.3.*
os. **EX_CONFIG**
Exit code that means that some kind of configuration error occurred. Availability: Unix.

*New in version 2.3.*

os. **EX_NOTFOUND**
Exit code that means something like “an entry was not found”. Availability: Unix.

*New in version 2.3.*

os. **fork()**
Fork a child process. Return 0 in the child and the child's process id in the parent. If an error occurs **OSError** is raised.

Note that some platforms including FreeBSD <= 6.3, Cygwin and OS/2 EMX have known issues when using fork() from a thread.

Availability: Unix.

os. **forkpty()**
Fork a child process, using a new pseudo-terminal as the child's controlling terminal. Return a pair of (pid, fd), where pid is 0 in the child, the new child's process id in the parent, and fd is the file descriptor of the master end of the pseudo-terminal. For a more portable approach, use the **pty** module. If an error occurs **OSError** is raised. Availability: some flavors of Unix.

os. **kill(pid, sig)**
Send signal sig to the process pid. Constants for the specific signals available on the host platform are defined in the **signal** module. Availability: Unix.

os. **killpg(pgid, sig)**
Send the signal sig to the process group pgid. Availability: Unix.

New in version 2.3.

os.\texttt{nice}(increment)
Add increment to the process's "niceness". Return the new niceness. Availability: Unix.

os.\texttt{plock}(op)
Lock program segments into memory. The value of op (defined in <sys/lock.h>) determines which segments are locked. Availability: Unix.

os.\texttt{popen}(...)
  os.\texttt{popen2}(...)
  os.\texttt{popen3}(...)
  os.\texttt{popen4}(...)
Run child processes, returning opened pipes for communications. These functions are described in section \textit{File Object Creation}.

os.\texttt{spawnl}(mode, path, ...)
  os.\texttt{spawnle}(mode, path, ..., env)
  os.\texttt{spawnlp}(mode, file, ...)
  os.\texttt{spawnlpe}(mode, file, ..., env)
  os.\texttt{spawnv}(mode, path, args)
  os.\texttt{spawnve}(mode, path, args, env)
  os.\texttt{spawnvp}(mode, file, args)
  os.\texttt{spawnvpe}(mode, file, args, env)
Execute the program path in a new process.

(Note that the \texttt{subprocess} module provides more powerful facilities for spawning new processes and retrieving their results; using that module is preferable to using these functions. Check specially the \textit{Replacing Older Functions with the subprocess}}
Module section in that documentation page.)

If mode is `P_NOWAIT`, this function returns the process id of the new process; if mode is `P_WAIT`, returns the process’s exit code if it exits normally, or `-signal`, where signal is the signal that killed the process. On Windows, the process id will actually be the process handle, so can be used with the `waitpid()` function.

The “l” and “v” variants of the `spawn*()` functions differ in how command-line arguments are passed. The “l” variants are perhaps the easiest to work with if the number of parameters is fixed when the code is written; the individual parameters simply become additional parameters to the `spawnl*()` functions. The “v” variants are good when the number of parameters is variable, with the arguments being passed in a list or tuple as the `args` parameter. In either case, the arguments to the child process must start with the name of the command being run.

The variants which include a second “p” near the end (`spawnlp()`, `spawnlpe()`, `spawnvp()`, and `spawnvpe()`) will use the `PATH` environment variable to locate the program file. When the environment is being replaced (using one of the `spawn*e()` variants, discussed in the next paragraph), the new environment is used as the source of the `PATH` variable. The other variants, `spawnl()`, `spawnle()`, `spawnv()`, and `spawnve()`, will not use the `PATH` variable to locate the executable; `path` must contain an appropriate absolute or relative path.

For `spawnle()`, `spawnlpe()`, `spawnve()`, and `spawnvpe()` (note that these all end in “e”), the `env` parameter must be a mapping which is used to define the environment variables for the new process (they are used instead of the current process’ environment); the functions `spawnl()`, `spawnlp()`, `spawnv()`, and `spawnvp()` all cause the new process to inherit the environment of the current
process.

As an example, the following calls to `spawnlp()` and `spawnvpe()` are equivalent:

```python
import os
os.spawnlp(os.P_WAIT, 'cp', 'cp', 'index.html', '/dev/null')

L = ['cp', 'index.html', '/dev/null']
os.spawnvpe(os.P_WAIT, 'cp', L, os.environ)
```

Availability: Unix, Windows. `spawnlp()`, `spawnlpe()`, `spawnvp()` and `spawnvpe()` are not available on Windows.

*New in version 1.6.*

`os.P_NOWAIT`

`os.P_NOWAITO`

Possible values for the `mode` parameter to the `spawn*()` family of functions. If either of these values is given, the `spawn*()` functions will return as soon as the new process has been created, with the process id as the return value. Availability: Unix, Windows.

*New in version 1.6.*

`os.P_WAIT`

Possible value for the `mode` parameter to the `spawn*()` family of functions. If this is given as `mode`, the `spawn*()` functions will not return until the new process has run to completion and will return the exit code of the process the run is successful, or `-signal` if a signal kills the process. Availability: Unix, Windows.

*New in version 1.6.*

`os.P_DETACH`
os. **P_OVERLAY**

Possible values for the *mode* parameter to the spawn*() family of functions. These are less portable than those listed above. **P_DETACH** is similar to **P_NOWAIT**, but the new process is detached from the console of the calling process. If **P_OVERLAY** is used, the current process will be replaced; the spawn*() function will not return. Availability: Windows.

*New in version 1.6.*

os. **startfile(path[, operation])**

Start a file with its associated application.

When *operation* is not specified or 'open', this acts like double-clicking the file in Windows Explorer, or giving the file name as an argument to the **start** command from the interactive command shell: the file is opened with whatever application (if any) its extension is associated.

When another *operation* is given, it must be a “command verb” that specifies what should be done with the file. Common verbs documented by Microsoft are 'print' and 'edit' (to be used on files) as well as 'explore' and 'find' (to be used on directories).

**startfile()** returns as soon as the associated application is launched. There is no option to wait for the application to close, and no way to retrieve the application's exit status. The *path* parameter is relative to the current directory. If you want to use an absolute path, make sure the first character is not a slash ('/'); the underlying Win32 **ShellExecute** function doesn't work if it is. Use the **os.path.normpath()** function to ensure that the path is properly encoded for Win32. Availability: Windows.

*New in version 2.0.*
New in version 2.5: The operation parameter.

```python
os.system(command)
```
Execute the command (a string) in a subshell. This is implemented by calling the Standard C function `system`, and has the same limitations. Changes to `os.environ`, `sys.stdin`, etc. are not reflected in the environment of the executed command.

On Unix, the return value is the exit status of the process encoded in the format specified for `wait()`. Note that POSIX does not specify the meaning of the return value of the C `system` function, so the return value of the Python function is system-dependent.

On Windows, the return value is that returned by the system shell after running `command`, given by the Windows environment variable `COMSPEC`: on `command.com` systems (Windows 95, 98 and ME) this is always 0; on `cmd.exe` systems (Windows NT, 2000 and XP) this is the exit status of the command run; on systems using a non-native shell, consult your shell documentation.

Availability: Unix, Windows.

The `subprocess` module provides more powerful facilities for spawning new processes and retrieving their results; using that module is preferable to using this function. Use the `subprocess` module. Check especially the Replacing Older Functions with the `subprocess Module` section.

```python
os.times()
```
Return a 5-tuple of floating point numbers indicating accumulated (processor or other) times, in seconds. The items are: user time, system time, children's user time, children's system time, and
elapsed real time since a fixed point in the past, in that order. See the Unix manual page

`times(2)` or the corresponding Windows Platform API documentation. Availability: Unix, Windows. On Windows, only the first two items are filled, the others are zero.

```python
os.wait()
```
Wait for completion of a child process, and return a tuple containing its pid and exit status indication: a 16-bit number, whose low byte is the signal number that killed the process, and whose high byte is the exit status (if the signal number is zero); the high bit of the low byte is set if a core file was produced. Availability: Unix.

```python
os.waitpid(pid, options)
```
The details of this function differ on Unix and Windows.

On Unix: Wait for completion of a child process given by process id `pid`, and return a tuple containing its process id and exit status indication (encoded as for `wait()`). The semantics of the call are affected by the value of the integer `options`, which should be 0 for normal operation.

If `pid` is greater than 0, `waitpid()` requests status information for that specific process. If `pid` is 0, the request is for the status of any child in the process group of the current process. If `pid` is -1, the request pertains to any child of the current process. If `pid` is less than -1, status is requested for any process in the process group `-pid` (the absolute value of `pid`).

An OSError is raised with the value of errno when the syscall returns -1.

On Windows: Wait for completion of a process given by process handle `pid`, and return a tuple containing `pid`, and its exit status
shifted left by 8 bits (shifting makes cross-platform use of the function easier). A pid less than or equal to 0 has no special meaning on Windows, and raises an exception. The value of integer options has no effect. pid can refer to any process whose id is known, not necessarily a child process. The spawn() functions called with P_NOWAIT return suitable process handles.

**os.wait3([options])**

Similar to waitpid(), except no process id argument is given and a 3-element tuple containing the child’s process id, exit status indication, and resource usage information is returned. Refer to resource.getrusage() for details on resource usage information. The option argument is the same as that provided to waitpid() and wait4(). Availability: Unix.

*New in version 2.5.*

**os.wait4(pid, options)**

Similar to waitpid(), except a 3-element tuple, containing the child’s process id, exit status indication, and resource usage information is returned. Refer to resource.getrusage() for details on resource usage information. The arguments to wait4() are the same as those provided to waitpid(). Availability: Unix.

*New in version 2.5.*

**os.WNOHANG**

The option for waitpid() to return immediately if no child process status is available immediately. The function returns (0, 0) in this case. Availability: Unix.

**os.WCONTINUED**

This option causes child processes to be reported if they have been continued from a job control stop since their status was last
reported. Availability: Some Unix systems.

*New in version 2.3.*

**os. WUNTRACED**

This option causes child processes to be reported if they have been stopped but their current state has not been reported since they were stopped. Availability: Unix.

*New in version 2.3.*

The following functions take a process status code as returned by `system()`, `wait()`, or `waitpid()` as a parameter. They may be used to determine the disposition of a process.

**os. WCOREDUMP**(status)  
Return `True` if a core dump was generated for the process, otherwise return `False`. Availability: Unix.

*New in version 2.3.*

**os. WIFCONTINUED**(status)  
Return `True` if the process has been continued from a job control stop, otherwise return `False`. Availability: Unix.

*New in version 2.3.*

**os. WIFSTOPPED**(status)  
Return `True` if the process has been stopped, otherwise return `False`. Availability: Unix.

**os. WIFSIGNALED**(status)  
Return `True` if the process exited due to a signal, otherwise return `False`. Availability: Unix.
os. **WIFEXITED**(status)
Return **True** if the process exited using the *exit(2)* system call, otherwise return **False**. Availability: Unix.

os. **WEXITSTATUS**(status)
If **WIFEXITED**(status) is true, return the integer parameter to the *exit(2)* system call. Otherwise, the return value is meaningless. Availability: Unix.

os. **WSTOPSIG**(status)
Return the signal which caused the process to stop. Availability: Unix.

os. **WTERMSIG**(status)
Return the signal which caused the process to exit. Availability: Unix.
os.confstr(name)

Return string-valued system configuration values. *name* specifies the configuration value to retrieve; it may be a string which is the name of a defined system value; these names are specified in a number of standards (POSIX, Unix 95, Unix 98, and others). Some platforms define additional names as well. The names known to the host operating system are given as the keys of the `confstr_names` dictionary. For configuration variables not included in that mapping, passing an integer for *name* is also accepted. Availability: Unix.

If the configuration value specified by *name* isn’t defined, `None` is returned.

If *name* is a string and is not known, `ValueError` is raised. If a specific value for *name* is not supported by the host system, even if it is included in `confstr_names`, an `OSError` is raised with `errno.EINVAL` for the error number.

os.confstr_names

Dictionary mapping names accepted by `confstr()` to the integer values defined for those names by the host operating system. This can be used to determine the set of names known to the system. Availability: Unix.

os.getloadavg()

Return the number of processes in the system run queue averaged over the last 1, 5, and 15 minutes or raises `OSError` if the load average was unobtainable. Availability: Unix.

*New in version 2.3.*
os.\texttt{sysconf}(name)
Return integer-valued system configuration values. If the configuration value specified by \texttt{name} isn't defined, \texttt{-1} is returned. The comments regarding the \texttt{name} parameter for \texttt{confstr()} apply here as well; the dictionary that provides information on the known names is given by \texttt{sysconf_names}. Availability: Unix.

os.\texttt{sysconf\_names}
Dictionary mapping names accepted by \texttt{sysconf()} to the integer values defined for those names by the host operating system. This can be used to determine the set of names known to the system. Availability: Unix.

The following data values are used to support path manipulation operations. These are defined for all platforms.

Higher-level operations on pathnames are defined in the \texttt{os.path} module.

os.\texttt{curdir}
The constant string used by the operating system to refer to the current directory. This is '.\' for Windows and POSIX. Also available via \texttt{os.path}.

os.\texttt{pardir}
The constant string used by the operating system to refer to the parent directory. This is '..' for Windows and POSIX. Also available via \texttt{os.path}.

os.\texttt{sep}
The character used by the operating system to separate pathname components. This is '/' for POSIX and '\\' for Windows. Note that knowing this is not sufficient to be able to
parse or concatenate pathnames — use `os.path.split()` and `os.path.join()` — but it is occasionally useful. Also available via `os.path`.

**os.** **altsep**
An alternative character used by the operating system to separate pathname components, or `None` if only one separator character exists. This is set to `'/'` on Windows systems where `sep` is a backslash. Also available via `os.path`.

**os.** **extsep**
The character which separates the base filename from the extension; for example, the `'.` in `os.py`. Also available via `os.path`.

*New in version 2.2.*

**os.** **pathsep**
The character conventionally used by the operating system to separate search path components (as in `PATH`), such as `': '` for POSIX or `'; '` for Windows. Also available via `os.path`.

**os.** **defpath**
The default search path used by `exec*p*()` and `spawn*p*()` if the environment doesn’t have a `'PATH'` key. Also available via `os.path`.

**os.** **linesep**
The string used to separate (or, rather, terminate) lines on the current platform. This may be a single character, such as `'
'` for POSIX, or multiple characters, for example, `'
'` for Windows. Do not use `os.linesep` as a line terminator when writing files opened in text mode (the default); use a single `'
'` instead, on all platforms.
**os.devnull**

The file path of the null device. For example: `'/dev/null'` for POSIX. Also available via `os.path`.  

*New in version 2.4.*
os.urandom(n)

Return a string of n random bytes suitable for cryptographic use.

This function returns random bytes from an OS-specific randomness source. The returned data should be unpredictable enough for cryptographic applications, though its exact quality depends on the OS implementation. On a UNIX-like system this will query /dev/urandom, and on Windows it will use CryptGenRandom. If a randomness source is not found, `NotImplementedError` will be raised.

*New in version 2.4.*
io — Core tools for working with streams

New in version 2.6.

The io module provides the Python interfaces to stream handling. The builtin open() function is defined in this module.

At the top of the I/O hierarchy is the abstract base class IOBase. It defines the basic interface to a stream. Note, however, that there is no separation between reading and writing to streams; implementations are allowed to throw an IOError if they do not support a given operation.

Extending IOBase is RawIOBase which deals simply with the reading and writing of raw bytes to a stream. FileIO subclasses RawIOBase to provide an interface to files in the machine's file system.

BufferedIOBase deals with buffering on a raw byte stream (RawIOBase). Its subclasses, BufferedWriter, BufferedReader, and BufferedRWPair buffer streams that are readable, writable, and both readable and writable. BufferedRandom provides a buffered interface to random access streams. BytesIO is a simple stream of in-memory bytes.

Another IOBase subclass, TextIOBase, deals with streams whose bytes represent text, and handles encoding and decoding from and to strings. TextIOWrapper, which extends it, is a buffered text interface to a buffered raw stream (BufferedIOBase). Finally, StringIO is an in-memory stream for text.

Argument names are not part of the specification, and only the
arguments of `open()` are intended to be used as keyword arguments.
Module Interface

io. **DEFAULT_BUFFER_SIZE**

An int containing the default buffer size used by the module's buffered I/O classes. `open()` uses the file's blksize (as obtained by `os.stat()`) if possible.

```python
io.open(file[, mode[, buffering[, encoding[, errors[, newline[, closefd=1]]]]]]))
```

Open *file* and return a stream. If the file cannot be opened, an *IOError* is raised.

*file* is either a string giving the name (and the path if the file isn’t in the current working directory) of the file to be opened or a file descriptor of the file to be opened. (If a file descriptor is given, for example, from `os.fdopen()`, it is closed when the returned I/O object is closed, unless *closefd* is set to *False*.)

*mode* is an optional string that specifies the mode in which the file is opened. It defaults to `'r'` which means open for reading in text mode. Other common values are `'w'` for writing (truncating the file if it already exists), and `'a'` for appending (which on some Unix systems, means that all writes append to the end of the file regardless of the current seek position). In text mode, if *encoding* is not specified the encoding used is platform dependent. (For reading and writing raw bytes use binary mode and leave *encoding* unspecified.) The available modes are:

<table>
<thead>
<tr>
<th>Character</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>'r'</code></td>
<td>open for reading (default)</td>
</tr>
<tr>
<td><code>'w'</code></td>
<td>open for writing, truncating the file first</td>
</tr>
<tr>
<td></td>
<td>open for writing, appending to the end of the file if it</td>
</tr>
</tbody>
</table>
The default mode is 'rt' (open for reading text). For binary random access, the mode 'w+b' opens and truncates the file to 0 bytes, while 'r+b' opens the file without truncation.

Python distinguishes between files opened in binary and text modes, even when the underlying operating system doesn’t. Files opened in binary mode (including 'b' in the mode argument) return contents as bytes objects without any decoding. In text mode (the default, or when 't' is included in the mode argument), the contents of the file are returned as strings, the bytes having been first decoded using a platform-dependent encoding or using the specified encoding if given.

buffering is an optional integer used to set the buffering policy. By default full buffering is on. Pass 0 to switch buffering off (only allowed in binary mode), 1 to set line buffering, and an integer > 1 for full buffering.

encoding is the name of the encoding used to decode or encode the file. This should only be used in text mode. The default encoding is platform dependent, but any encoding supported by Python can be used. See the codecs module for the list of supported encodings.

errors is an optional string that specifies how encoding and decoding errors are to be handled. Pass 'strict' to raise a ValueError exception if there is an encoding error (the default of
None has the same effect), or pass 'ignore' to ignore errors. (Note that ignoring encoding errors can lead to data loss.) 'replace' causes a replacement marker (such as '?') to be inserted where there is malformed data. When writing, 'xmlcharrefreplace' (replace with the appropriate XML character reference) or 'backslashreplace' (replace with backslashed escape sequences) can be used. Any other error handling name that has been registered with codecs.register_error() is also valid.

newline controls how universal newlines works (it only applies to text mode). It can be None, '', '\n', '\r', and '\r\n'. It works as follows:

- On input, if newline is None, universal newlines mode is enabled. Lines in the input can end in '\n', '\r', or '\r\n', and these are translated into '\n' before being returned to the caller. If it is '', universal newline mode is enabled, but line endings are returned to the caller untranslated. If it has any of the other legal values, input lines are only terminated by the given string, and the line ending is returned to the caller untranslated.
- On output, if newline is None, any '\n' characters written are translated to the system default line separator, os.linesep. If newline is '', no translation takes place. If newline is any of the other legal values, any '\n' characters written are translated to the given string.

If closefd is False and a file descriptor rather than a filename was given, the underlying file descriptor will be kept open when the file is closed. If a filename is given closefd has no effect but must be True (the default).
The type of file object returned by the `open()` function depends on the mode. When `open()` is used to open a file in a text mode ('w', 'r', 'wt', 'rt', etc.), it returns a `TextIOWrapper`. When used to open a file in a binary mode, the returned class varies: in read binary mode, it returns a `BufferedReader`; in write binary and append binary modes, it returns a `BufferedWriter`, and in read/write mode, it returns a `BufferedRandom`.

It is also possible to use a string or bytearray as a file for both reading and writing. For strings `StringIO` can be used like a file opened in a text mode, and for bytearrays a `BytesIO` can be used like a file opened in a binary mode.

exception `io.BlockingIOError`
Error raised when blocking would occur on a non-blocking stream. It inherits `IOError`.

In addition to those of `IOError`, `BlockingIOError` has one attribute:

characters_written
An integer containing the number of characters written to the stream before it blocked.

exception `io.UnsupportedOperation`
An exception inheriting `IOError` and `ValueError` that is raised when an unsupported operation is called on a stream.
**I/O Base Classes**

```python
class io.IOBase

The abstract base class for all I/O classes, acting on streams of bytes. There is no public constructor.

This class provides empty abstract implementations for many methods that derived classes can override selectively; the default implementations represent a file that cannot be read, written or seeked.

Even though IOBase does not declare `read()`, `readinto()`, or `write()` because their signatures will vary, implementations and clients should consider those methods part of the interface. Also, implementations may raise a IOError when operations they do not support are called.

The basic type used for binary data read from or written to a file is bytes. bytearrays are accepted too, and in some cases (such as `readinto`) required. Text I/O classes work with str data.

Note that calling any method (even inquiries) on a closed stream is undefined. Implementations may raise IOError in this case.

IOBase (and its subclasses) support the iterator protocol, meaning that an IOBase object can be iterated over yielding the lines in a stream.

IOBase is also a context manager and therefore supports the with statement. In this example, file is closed after the with statement’s suite is finished—even if an exception occurs:

```
file.write('Spam and eggs!')

**IOBase** provides these data attributes and methods:

**close()**
Flush and close this stream. This method has no effect if the file is already closed.

**closed**
True if the stream is closed.

**fileno()**
Return the underlying file descriptor (an integer) of the stream if it exists. An **IOError** is raised if the IO object does not use a file descriptor.

**flush()**
Flush the write buffers of the stream if applicable. This does nothing for read-only and non-blocking streams.

**isatty()**
Return **True** if the stream is interactive (i.e., connected to a terminal/tty device).

**readable()**
Return **True** if the stream can be read from. If False, **read()** will raise **IOError**.

**readline([limit])**
Read and return one line from the stream. If **limit** is specified, at most **limit** bytes will be read.

The line terminator is always b'\n' for binary files; for text files, the **newlines** argument to **open()** can be used to select the line terminator(s) recognized.
readlines([hint])
Read and return a list of lines from the stream. hint can be specified to control the number of lines read: no more lines will be read if the total size (in bytes/characters) of all lines so far exceeds hint.

seek(offset[, whence])
Change the stream position to the given byte offset. offset is interpreted relative to the position indicated by whence. Values for whence are:

- 0 – start of the stream (the default); offset should be zero or positive
- 1 – current stream position; offset may be negative
- 2 – end of the stream; offset is usually negative

Return the new absolute position.

seekable()
Return True if the stream supports random access. If False, seek(), tell() and truncate() will raise IOError.

tell()
Return the current stream position.

truncate([size])
Truncate the file to at most size bytes. size defaults to the current file position, as returned by tell().

writable()
Return True if the stream supports writing. If False, write() and truncate() will raise IOError.

writelines(lines)
Write a list of lines to the stream. Line separators are not
added, so it is usual for each of the lines provided to have a line separator at the end.

**class io.RawIOBase**

Base class for raw binary I/O. It inherits `IOBase`. There is no public constructor.

In addition to the attributes and methods from `IOBase`, `RawIOBase` provides the following methods:

**read([n])**

Read and return all the bytes from the stream until EOF, or if `n` is specified, up to `n` bytes. Only one system call is ever made. An empty bytes object is returned on EOF; `None` is returned if the object is set not to block and has no data to read.

**readall()**

Read and return all the bytes from the stream until EOF, using multiple calls to the stream if necessary.

**readinto(b)**

Read up to `len(b)` bytes into bytearray `b` and return the number of bytes read.

**write(b)**

Write the given bytes or bytearray object, `b`, to the underlying raw stream and return the number of bytes written (This is never less than `len(b)`, since if the write fails, an `IOError` will be raised).
class io.FileIO(name[, mode])

FileIO represents a file containing bytes data. It implements the RawIOBase interface (and therefore the IOBase interface, too).

The mode can be 'r', 'w' or 'a' for reading (default), writing, or appending. The file will be created if it doesn’t exist when opened for writing or appending; it will be truncated when opened for writing. Add a '+' to the mode to allow simultaneous reading and writing.

In addition to the attributes and methods from IOBase and RawIOBase, FileIO provides the following data attributes and methods:

mode
The mode as given in the constructor.

name
The file name. This is the file descriptor of the file when no name is given in the constructor.

read([n])
Read and return at most n bytes. Only one system call is made, so it is possible that less data than was requested is returned. Use len() on the returned bytes object to see how many bytes were actually returned. (In non-blocking mode, None is returned when no data is available.)

readall()
Read and return the entire file's contents in a single bytes object. As much as immediately available is returned in non-
blocking mode. If the EOF has been reached, `b''` is returned.

**write**(\(b\))

Write the bytes or bytestring object, \(b\), to the file, and return the number actually written. Only one system call is made, so it is possible that only some of the data is written.

Note that the inherited `readinto()` method should not be used on `FileIO` objects.
Buffered Streams

class io.BufferedIOBase

Base class for streams that support buffering. It inherits IOBase. There is no public constructor.

The main difference with RawIOBase is that the read() method supports omitting the size argument, and does not have a default implementation that defers to readinto().

In addition, read(), readinto(), and write() may raise BlockingIOError if the underlying raw stream is in non-blocking mode and not ready; unlike their raw counterparts, they will never return None.

A typical implementation should not inherit from a RawIOBase implementation, but wrap one like BufferedWriter and BufferedReader.

BufferedIOBase provides or overrides these methods in addition to those from IOBase:

read([n])

Read and return up to n bytes. If the argument is omitted, None, or negative, data is read and returned until EOF is reached. An empty bytes object is returned if the stream is already at EOF.

If the argument is positive, and the underlying raw stream is not interactive, multiple raw reads may be issued to satisfy the byte count (unless EOF is reached first). But for interactive raw streams, at most one raw read will be issued, and a short
result does not imply that EOF is imminent.

A **BlockingIOError** is raised if the underlying raw stream has no data at the moment.

### `readinto(b)`
Read up to `len(b)` bytes into bytearray `b` and return the number of bytes read.

Like `read()`, multiple reads may be issued to the underlying raw stream, unless the latter is ‘interactive.’

A **BlockingIOError** is raised if the underlying raw stream has no data at the moment.

### `write(b)`
Write the given bytes or bytearray object, `b`, to the underlying raw stream and return the number of bytes written (never less than `len(b)`, since if the write fails an **IOError** will be raised).

A **BlockingIOError** is raised if the buffer is full, and the underlying raw stream cannot accept more data at the moment.

### `class io.BytesIO([initial_bytes])`
A stream implementation using an in-memory bytes buffer. It inherits **BufferedIOBase**.

The argument `initial_bytes` is an optional initial bytearray.

**BytesIO** provides or overrides these methods in addition to those from **BufferedIOBase** and **IOBase**:

### `getvalue()`
Return *bytes* containing the entire contents of the buffer.
**read1()**

In **BytesIO**, this is the same as **read()**.

**truncate([size])**

Truncate the buffer to at most **size** bytes. **size** defaults to the current stream position, as returned by **tell()**.

**class io.BufferedReader([raw[, buffer_size]])**

A buffer for a readable, sequential **RawIOBase** object. It inherits **BufferedIOBase**.

The constructor creates a **BufferedReader** for the given readable **raw** stream and **buffer_size**. If **buffer_size** is omitted, **DEFAULT_BUFFER_SIZE** is used.

**BufferedReader** provides or overrides these methods in addition to those from **BufferedIOBase** and **IOBase**:

**peek([n])**

Return 1 (or **n** if specified) bytes from a buffer without advancing the position. Only a single read on the raw stream is done to satisfy the call. The number of bytes returned may be less than requested since at most all the buffer’s bytes from the current position to the end are returned.

**read([n])**

Read and return **n** bytes, or if **n** is not given or negative, until EOF or if the read call would block in non-blocking mode.

**read1(n)**

Read and return up to **n** bytes with only one call on the raw stream. If at least one byte is buffered, only buffered bytes are returned. Otherwise, one raw stream read call is made.
class `io.BufferedWriter`(raw[, buffer_size[, max_buffer_size]])

A buffer for a writeable sequential RawIO object. It inherits `BufferedIOBase`.

The constructor creates a `BufferedWriter` for the given writeable raw stream. If the `buffer_size` is not given, it defaults to `DEFAULT_BUFFER_SIZE`. If `max_buffer_size` is omitted, it defaults to twice the buffer size.

`BufferedWriter` provides or overrides these methods in addition to those from `BufferedIOBase` and `IOBase`:

- **flush()**
  Force bytes held in the buffer into the raw stream. A `BlockingIOError` should be raised if the raw stream blocks.

- **write(b)**
  Write the bytes or bytearray object, `b`, onto the raw stream and return the number of bytes written. A `BlockingIOError` is raised when the raw stream blocks.

class `io.BufferedRWPair`(reader, writer[, buffer_size[, max_buffer_size]])

A combined buffered writer and reader object for a raw stream that can be written to and read from. It has and supports both `read()`, `write()`, and their variants. This is useful for sockets and two-way pipes. It inherits `BufferedIOBase`.

`reader` and `writer` are `RawIOBase` objects that are readable and writeable respectively. If the `buffer_size` is omitted it defaults to `DEFAULT_BUFFER_SIZE`. The `max_buffer_size` (for the buffered writer) defaults to twice the buffer size.
BufferedReader implements all of BufferedReader's methods.

class io.BufferedRandom(raw[, buffer_size[, max_buffer_size]])
A buffered interface to random access streams. It inherits
BufferedReader and BufferedWriter.

The constructor creates a reader and writer for a seekable raw
stream, given in the first argument. If the buffer_size is omitted it
defaults to DEFAULT_BUFFER_SIZE. The max_buffer_size (for the
buffered writer) defaults to twice the buffer size.

BufferedReader is capable of anything BufferedReader or
BufferedWriter can do.
Text I/O

class io.TextIOWrapper:
    Base class for text streams. This class provides a character and line based interface to stream I/O. There is no readinto() method because Python’s character strings are immutable. It inherits IOBase. There is no public constructor.

    TextIOWrapper provides or overrides these data attributes and methods in addition to those from I0Base:

    encoding
        The name of the encoding used to decode the stream’s bytes into strings, and to encode strings into bytes.

    newlines
        A string, a tuple of strings, or None, indicating the newlines translated so far.

    read(n)
        Read and return at most n characters from the stream as a single str. If n is negative or None, reads to EOF.

    readline()
        Read until newline or EOF and return a single str. If the stream is already at EOF, an empty string is returned.

    write(s)
        Write the string s to the stream and return the number of characters written.

class io.TextIOBase
    Base class for text streams. This class provides a character and line based interface to stream I/O. There is no readinto() method because Python’s character strings are immutable. It inherits IOBase. There is no public constructor.

    TextIOBase provides or overrides these data attributes and methods in addition to those from IOBase:

    encoding
        The name of the encoding used to decode the stream’s bytes into strings, and to encode strings into bytes.

    newlines
        A string, a tuple of strings, or None, indicating the newlines translated so far.

    read(n)
        Read and return at most n characters from the stream as a single str. If n is negative or None, reads to EOF.

    readline()
        Read until newline or EOF and return a single str. If the stream is already at EOF, an empty string is returned.

    write(s)
        Write the string s to the stream and return the number of characters written.
A buffered text stream over a BufferedIOBase raw stream, buffer. It inherits TextIOBase.

encoding gives the name of the encoding that the stream will be decoded or encoded with. It defaults to locale.getpreferredencoding().

events is an optional string that specifies how encoding and decoding errors are to be handled. Pass 'strict' to raise a ValueError exception if there is an encoding error (the default of None has the same effect), or pass 'ignore' to ignore errors. (Note that ignoring encoding errors can lead to data loss.) 'replace' causes a replacement marker (such as '?' ) to be inserted where there is malformed data. When writing, 'xmlcharrefreplace' (replace with the appropriate XML character reference) or 'backslashreplace' (replace with backslashed escape sequences) can be used. Any other error handling name that has been registered with codecs.register_error() is also valid.

newline can be None, '', '\n', '\r', or '\r\n'. It controls the handling of line endings. If it is None, universal newlines is enabled. With this enabled, on input, the lines endings '\n', '\r', or '\r\n' are translated to '\n' before being returned to the caller. Conversely, on output, '\n' is translated to the system default line separator, os.linesep. If newline is any other of its legal values, that newline becomes the newline when the file is read and it is returned untranslated. On output, '\n' is converted to the newline.

If line_buffering is True, flush() is implied when a call to write contains a newline character.
TextIOWrapper provides these data attributes in addition to those of TextIOBase and its parents:

errors
The encoding and decoding error setting.

line_buffering
Whether line buffering is enabled.

class io.StringIO([initial_value[, encoding[, errors[, newline]]]])
An in-memory stream for text. It inherits TextIOWrapper.

Create a new StringIO stream with an initial value, encoding, error handling, and newline setting. See TextIOWrapper's constructor for more information.

StringIO provides this method in addition to those from TextIOWrapper and its parents:

getvalue()
Return a str containing the entire contents of the buffer.

class io.IncrementalNewlineDecoder
A helper codec that decodes newlines for universal newlines mode. It inherits codecs.IncrementalDecoder.

This module provides various time-related functions. For related functionality, see also the `datetime` and `calendar` modules.

Although this module is always available, not all functions are available on all platforms. Most of the functions defined in this module call platform C library functions with the same name. It may sometimes be helpful to consult the platform documentation, because the semantics of these functions varies among platforms.

An explanation of some terminology and conventions is in order.

- **The epoch** is the point where the time starts. On January 1st of that year, at 0 hours, the “time since the epoch” is zero. For Unix, the epoch is 1970. To find out what the epoch is, look at `gmtime(0)`.

- The functions in this module do not handle dates and times before the epoch or far in the future. The cut-off point in the future is determined by the C library; for Unix, it is typically in 2038.

- **Year 2000 (Y2K) issues**: Python depends on the platform’s C library, which generally doesn’t have year 2000 issues, since all dates and times are represented internally as seconds since the epoch. Functions accepting a `struct_time` (see below) generally require a 4-digit year. For backward compatibility, 2-digit years are supported if the module variable `accept2dyear` is a non-zero integer; this variable is initialized to 1 unless the environment variable `PYTHONY2K` is set to a non-empty string, in which case it is initialized to 0. Thus, you can set `PYTHONY2K` to a
non-empty string in the environment to require 4-digit years for all year input. When 2-digit years are accepted, they are converted according to the POSIX or X/Open standard: values 69-99 are mapped to 1969-1999, and values 0–68 are mapped to 2000–2068. Values 100–1899 are always illegal. Note that this is new as of Python 1.5.2(a2); earlier versions, up to Python 1.5.1 and 1.5.2a1, would add 1900 to year values below 1900.

- UTC is Coordinated Universal Time (formerly known as Greenwich Mean Time, or GMT). The acronym UTC is not a mistake but a compromise between English and French.

- DST is Daylight Saving Time, an adjustment of the timezone by (usually) one hour during part of the year. DST rules are magic (determined by local law) and can change from year to year. The C library has a table containing the local rules (often it is read from a system file for flexibility) and is the only source of True Wisdom in this respect.

- The precision of the various real-time functions may be less than suggested by the units in which their value or argument is expressed. E.g. on most Unix systems, the clock “ticks” only 50 or 100 times a second.

- On the other hand, the precision of \texttt{time()} and \texttt{sleep()} is better than their Unix equivalents: times are expressed as floating point numbers, \texttt{time()} returns the most accurate time available (using Unix \texttt{gettimeofday} where available), and \texttt{sleep()} will accept a time with a nonzero fraction (Unix \texttt{select} is used to implement this, where available).

- The time value as returned by \texttt{gmtime()}, \texttt{localtime()}, and \texttt{strptime()}, and accepted by \texttt{asctime()}, \texttt{mktime()} and \texttt{strftime()}, may be considered as a sequence of 9 integers.
The return values of `gmtime()`, `localtime()`, and `strptime()` also offer attribute names for individual fields.

<td>tm_isdst</td>
<td>0, 1 or -1; see below</td>
</tr>
</tbody>
</table>

Note that unlike the C structure, the month value is a range of 1-12, not 0-11. A year value will be handled as described under “Year 2000 (Y2K) issues” above. A -1 argument as the daylight savings flag, passed to `mktime()` will usually result in the correct daylight savings state to be filled in.

When a tuple with an incorrect length is passed to a function expecting a `struct_time`, or having elements of the wrong type, a `TypeError` is raised.
Changed in version 2.2: The time value sequence was changed from a tuple to a `struct_time`, with the addition of attribute names for the fields.

The module defines the following functions and data items:

**time.** **accept2dyear**
Booleans value indicating whether two-digit year values will be accepted. This is true by default, but will be set to false if the environment variable PYTHONY2K has been set to a non-empty string. It may also be modified at run time.

**time.** **altzone**
The offset of the local DST timezone, in seconds west of UTC, if one is defined. This is negative if the local DST timezone is east of UTC (as in Western Europe, including the UK). Only use this if daylight is nonzero.

**time.** **asctime([t])**
Convert a tuple or `struct_time` representing a time as returned by `gmtime()` or `localtime()` to a 24-character string of the following form: 'Sun Jun 20 23:21:05 1993'. If t is not provided, the current time as returned by `localtime()` is used. Locale information is not used by `asctime()`.

**Note:** Unlike the C function of the same name, there is no trailing newline.

Changed in version 2.1: Allowed t to be omitted.

**time.** **clock()**
On Unix, return the current processor time as a floating point number expressed in seconds. The precision, and in fact the very definition of the meaning of “processor time”, depends on that of
the C function of the same name, but in any case, this is the function to use for benchmarking Python or timing algorithms.

On Windows, this function returns wall-clock seconds elapsed since the first call to this function, as a floating point number, based on the Win32 function `QueryPerformanceCounter`. The resolution is typically better than one microsecond.

```
time.ctime([secs])
```

Convert a time expressed in seconds since the epoch to a string representing local time. If `secs` is not provided or `None`, the current time as returned by `time()` is used. `ctime(secs)` is equivalent to `asctime(localtime(secs))`. Locale information is not used by `ctime()`.

*Changed in version 2.1:* Allowed `secs` to be omitted.

*Changed in version 2.4:* If `secs` is `None`, the current time is used.

```
time.daylight
```

Nonzero if a DST timezone is defined.

```
time.gmtime([secs])
```

Convert a time expressed in seconds since the epoch to a `struct_time` in UTC in which the dst flag is always zero. If `secs` is not provided or `None`, the current time as returned by `time()` is used. Fractions of a second are ignored. See above for a description of the `struct_time` object. See `calendar.timegm()` for the inverse of this function.

*Changed in version 2.1:* Allowed `secs` to be omitted.

*Changed in version 2.4:* If `secs` is `None`, the current time is used.
time.localtime([secs])

Like gmtime() but converts to local time. If secs is not provided or None, the current time as returned by time() is used. The dst flag is set to 1 when DST applies to the given time.

*Changed in version 2.1:* Allowed secs to be omitted.

*Changed in version 2.4:* If secs is None, the current time is used.

time.mktime(t)

This is the inverse function of localtime(). Its argument is the struct_time or full 9-tuple (since the dst flag is needed; use -1 as the dst flag if it is unknown) which expresses the time in local time, not UTC. It returns a floating point number, for compatibility with time(). If the input value cannot be represented as a valid time, either OverflowError or ValueError will be raised (which depends on whether the invalid value is caught by Python or the underlying C libraries). The earliest date for which it can generate a time is platform-dependent.

time.sleep(secs)

Suspend execution for the given number of seconds. The argument may be a floating point number to indicate a more precise sleep time. The actual suspension time may be less than that requested because any caught signal will terminate the sleep() following execution of that signal's catching routine. Also, the suspension time may be longer than requested by an arbitrary amount because of the scheduling of other activity in the system.

time.strftime(format[, t])

Convert a tuple or struct_time representing a time as returned by gmtime() or localtime() to a string as specified by the format
argument. If \( t \) is not provided, the current time as returned by `localtime()` is used. `format` must be a string. `ValueError` is raised if any field in \( t \) is outside of the allowed range.

*Changed in version 2.1:* Allowed \( t \) to be omitted.

*Changed in version 2.4:* `ValueError` raised if a field in \( t \) is out of range.

*Changed in version 2.5:* 0 is now a legal argument for any position in the time tuple; if it is normally illegal the value is forced to a correct one..

The following directives can be embedded in the `format` string. They are shown without the optional field width and precision specification, and are replaced by the indicated characters in the `strftime()` result:

<table>
<thead>
<tr>
<th>Directive</th>
<th>Meaning</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>%a</td>
<td>Locale's abbreviated weekday name.</td>
<td></td>
</tr>
<tr>
<td>%A</td>
<td>Locale's full weekday name.</td>
<td></td>
</tr>
<tr>
<td>%b</td>
<td>Locale's abbreviated month name.</td>
<td></td>
</tr>
<tr>
<td>%B</td>
<td>Locale's full month name.</td>
<td></td>
</tr>
<tr>
<td>%c</td>
<td>Locale's appropriate date and time representation.</td>
<td></td>
</tr>
<tr>
<td>%d</td>
<td>Day of the month as a decimal number [01,31].</td>
<td></td>
</tr>
<tr>
<td>%H</td>
<td>Hour (24-hour clock) as a decimal number [00,23].</td>
<td></td>
</tr>
<tr>
<td>%I</td>
<td>Hour (12-hour clock) as a decimal number [01,12].</td>
<td></td>
</tr>
<tr>
<td>%j</td>
<td>Day of the year as a decimal number [001,366].</td>
<td></td>
</tr>
<tr>
<td>%m</td>
<td>Month as a decimal number [01,12].</td>
<td></td>
</tr>
<tr>
<td>%M</td>
<td>Minute as a decimal number [00,59].</td>
<td></td>
</tr>
<tr>
<td><code>%p</code></td>
<td>Locale's equivalent of either AM or PM. (1)</td>
<td></td>
</tr>
<tr>
<td>------------</td>
<td>---------------------------------------------</td>
<td></td>
</tr>
<tr>
<td><code>%S</code></td>
<td>Second as a decimal number [00,61]. (2)</td>
<td></td>
</tr>
<tr>
<td><code>%U</code></td>
<td>Week number of the year (Sunday as the first day of the week) as a decimal number [00,53]. All days in a new year preceding the first Sunday are considered to be in week 0. (3)</td>
<td></td>
</tr>
<tr>
<td><code>%W</code></td>
<td>Week number of the year (Monday as the first day of the week) as a decimal number [00,53]. All days in a new year preceding the first Monday are considered to be in week 0. (3)</td>
<td></td>
</tr>
<tr>
<td><code>%W</code></td>
<td>Weekday as a decimal number [0(Sunday),6].</td>
<td></td>
</tr>
<tr>
<td><code>%x</code></td>
<td>Locale’s appropriate date representation.</td>
<td></td>
</tr>
<tr>
<td><code>%X</code></td>
<td>Locale’s appropriate time representation.</td>
<td></td>
</tr>
<tr>
<td><code>%y</code></td>
<td>Year without century as a decimal number [00,99].</td>
<td></td>
</tr>
<tr>
<td><code>%Y</code></td>
<td>Year with century as a decimal number.</td>
<td></td>
</tr>
<tr>
<td><code>%Z</code></td>
<td>Time zone name (no characters if no time zone exists).</td>
<td></td>
</tr>
<tr>
<td><code>%</code></td>
<td>A literal '%' character.</td>
<td></td>
</tr>
</tbody>
</table>

Notes:

1. When used with the `strptime()` function, the `%p` directive only affects the output hour field if the `%I` directive is used to parse the hour.
2. The range really is 0 to 61; this accounts for leap seconds and the (very rare) double leap seconds.
3. When used with the `strptime()` function, `%U` and `%W` are only used in calculations when the day of the week and the year are specified.
Here is an example, a format for dates compatible with that specified in the RFC 2822 Internet email standard. [1]

```python
>>> from time import gmtime, strftime
>>> strftime("%a, %d %b %Y %H:%M:%S +0000", gmtime())
'Thu, 28 Jun 2001 14:17:15 +0000'
```

Additional directives may be supported on certain platforms, but only the ones listed here have a meaning standardized by ANSI C.

On some platforms, an optional field width and precision specification can immediately follow the initial '%%' of a directive in the following order; this is also not portable. The field width is normally 2 except for %j where it is 3.

```
time.strptime(string[, format])
```

Parse a string representing a time according to a format. The return value is a `struct_time` as returned by `gmtime()` or `localtime()`.

The `format` parameter uses the same directives as those used by `strftime()`; it defaults to "%a %b %d %H:%M:%S %Y" which matches the formatting returned by `ctime()`. If `string` cannot be parsed according to `format`, or if it has excess data after parsing, `ValueError` is raised. The default values used to fill in any missing data when more accurate values cannot be inferred are (1900, 1, 1, 0, 0, 0, 0, 1, -1).

For example:

```python
>>> import time
>>> time.strptime("30 Nov 00", "%d %b %y")  # doctest: +NORMALIZE_WHITESPACE
time.struct_time(tm_year=2000, tm_mon=11, tm_mday=30, tm_hour=0, tm_min=0, tm_sec=0, tm_wday=1, tm_yday=330, tm_isdst=-1)
```
Support for the %Z directive is based on the values contained in `tzname` and whether `daylight` is true. Because of this, it is platform-specific except for recognizing UTC and GMT which are always known (and are considered to be non-daylight savings timezones).

Only the directives specified in the documentation are supported. Because `strftime()` is implemented per platform it can sometimes offer more directives than those listed. But `strptime()` is independent of any platform and thus does not necessarily support all directives available that are not documented as supported.

**time. struct_time**

The type of the time value sequence returned by `gmtime()`, `localtime()`, and `strptime()`.

*New in version 2.2.*

**time. time()**

Return the time as a floating point number expressed in seconds since the epoch, in UTC. Note that even though the time is always returned as a floating point number, not all systems provide time with a better precision than 1 second. While this function normally returns non-decreasing values, it can return a lower value than a previous call if the system clock has been set back between the two calls.

**time. timezone**

The offset of the local (non-DST) timezone, in seconds west of UTC (negative in most of Western Europe, positive in the US, zero in the UK).
time.tzname
A tuple of two strings: the first is the name of the local non-DST timezone, the second is the name of the local DST timezone. If no DST timezone is defined, the second string should not be used.

time.tzset()
Resets the time conversion rules used by the library routines. The environment variable TZ specifies how this is done.

New in version 2.3.

Availability: Unix.

Note: Although in many cases, changing the TZ environment variable may affect the output of functions like localtime() without calling tzset(), this behavior should not be relied on. The TZ environment variable should contain no whitespace.

The standard format of the TZ environment variable is (whitespace added for clarity):

```
std offset [dst [offset [,start[/time], end[/time]]]]
```

Where the components are:

std and dst
Three or more alphanumerics giving the timezone abbreviations. These will be propagated into time.tzname

offset
The offset has the form: ± hh[:mm[:ss]]. This indicates the value added the local time to arrive at UTC. If preceded by a ‘-‘, the timezone is east of the Prime Meridian; otherwise, it is west. If no offset follows dst, summer time is assumed to be
one hour ahead of standard time.

`start[/time], end[/time]`

Indicates when to change to and back from DST. The format of the start and end dates are one of the following:

\[Jn\]

The Julian day \( n \) (1 <= \( n \) <= 365). Leap days are not counted, so in all years February 28 is day 59 and March 1 is day 60.

\[n\]

The zero-based Julian day (0 <= \( n \) <= 365). Leap days are counted, and it is possible to refer to February 29.

\[Mm.n.d\]

The \( d \)th day (0 <= \( d \) <= 6) or week \( n \) of month \( m \) of the year (1 <= \( n \) <= 5, 1 <= \( m \) <= 12, where week 5 means “the last \( d \) day in month \( m \)” which may occur in either the fourth or the fifth week). Week 1 is the first week in which the \( d \)th day occurs. Day zero is Sunday.

`time` has the same format as `offset` except that no leading sign (‘-‘ or ‘+’) is allowed. The default, if `time` is not given, is 02:00:00.

```python
>>> os.environ['TZ'] = 'EST+05EDT,M4.1.0,M10.5.0'
>>> time.tzset()
>>> time.strftime('%X %x %Z')
'02:07:36 05/08/03 EDT'
>>> os.environ['TZ'] = 'AEST-10AEDT-11,M10.5.0,M3.5.0'
>>> time.tzset()
>>> time.strftime('%X %x %Z')
'16:08:12 05/08/03 AEST'
```

On many Unix systems (including *BSD, Linux, Solaris, and
Darwin), it is more convenient to use the system’s zoneinfo (tzfile(5)) database to specify the timezone rules. To do this, set the TZ environment variable to the path of the required timezone datafile, relative to the root of the systems ‘zoneinfo’ timezone database, usually located at /usr/share/zoneinfo. For example, 'US/Eastern', 'Australia/Melbourne', 'Egypt' or 'Europe/Amsterdam'.

>>> os.environ['TZ'] = 'US/Eastern'
>>> time.tzset()
>>> time.tzname
('EST', 'EDT')
>>> os.environ['TZ'] = 'Egypt'
>>> time.tzset()
>>> time.tzname
('EET', 'EEST')

See also:

**Module datetime**

More object-oriented interface to dates and times.

**Module locale**

Internationalization services. The locale settings can affect the return values for some of the functions in the time module.

**Module calendar**

General calendar-related functions. timegm() is the inverse of gmtime() from this module.

Footnotes

The use of %Z is now deprecated, but the %z escape that expands to the preferred hour/minute offset is not supported by
all ANSI C libraries. Also, a strict reading of the original 1982
RFC 822 standard calls for a two-digit year (%y rather than
%Y), but practice moved to 4-digit years long before the year
2000. The 4-digit year has been mandated by RFC 2822, which
obsoletes RFC 822.

[1]
optparse — More powerful command line option parser

New in version 2.3.

optparse is a more convenient, flexible, and powerful library for parsing command-line options than the old getopt module. optparse uses a more declarative style of command-line parsing: you create an instance of OptionParser, populate it with options, and parse the command line. optparse allows users to specify options in the conventional GNU/POSIX syntax, and additionally generates usage and help messages for you.

Here's an example of using optparse in a simple script:

```python
from optparse import OptionParser

from optparse import OptionParser

parser = OptionParser()

parser.add_option("-f", "--file", dest="filename",
                  help="write report to FILE", metavar="FILE")

parser.add_option("-q", "--quiet",
                  action="store_false",
                  dest="verbose",
                  default=True,
                  help="don't print status messages to stdout")

(options, args) = parser.parse_args()
```

With these few lines of code, users of your script can now do the “usual thing” on the command-line, for example:

```
<yourscript> --file=outfile -q
```

As it parses the command line, optparse sets attributes of the options object returned by parse_args() based on user-supplied command-line values. When parse_args() returns from parsing this command line, options.filename will be "outfile" and
options.verbose will be False. optparse supports both long and short options, allows short options to be merged together, and allows options to be associated with their arguments in a variety of ways. Thus, the following command lines are all equivalent to the above example:

```
<yourscript> -f outfile --quiet
<yourscript> --quiet --file outfile
<yourscript> -q -f outfile
<yourscript> -qf outfile
```

Additionally, users can run one of

```
<yourscript> -h
<yourscript> --help
```

and optparse will print out a brief summary of your script's options:

```
usage: <yourscript> [options]

options:
  -h, --help             show this help message and exit
  -f FILE, --file=FILE   write report to FILE
  -q, --quiet           don't print status messages to stdout
```

where the value of yoursproc is determined at runtime (normally from sys.argv[0]).
Background

`optparse` was explicitly designed to encourage the creation of programs with straightforward, conventional command-line interfaces. To that end, it supports only the most common command-line syntax and semantics conventionally used under Unix. If you are unfamiliar with these conventions, read this section to acquaint yourself with them.

Terminology

**argument**

A string entered on the command-line, and passed by the shell to `exec1()` or `execv()`. In Python, arguments are elements of `sys.argv[1:]` (`sys.argv[0]` is the name of the program being executed). Unix shells also use the term “word”.

It is occasionally desirable to substitute an argument list other than `sys.argv[1:]`, so you should read “argument” as “an element of `sys.argv[1:]`, or of some other list provided as a substitute for `sys.argv[1:]`“.

**option**

An argument used to supply extra information to guide or customize the execution of a program. There are many different syntaxes for options; the traditional Unix syntax is a hyphen (“-“) followed by a single letter, e.g. "-x" or "-F". Also, traditional Unix syntax allows multiple options to be merged into a single argument, e.g. "-x  -F" is equivalent to "-xF". The GNU project introduced "--" followed by a series of hyphen-separated words, e.g. "--file" or "--dry-run". These are the only two option syntaxes provided by `optparse`. 
Some other option syntaxes that the world has seen include:

- a hyphen followed by a few letters, e.g. ":pf:“ (this is not the same as multiple options merged into a single argument)
- a hyphen followed by a whole word, e.g. ":file:“ (this is technically equivalent to the previous syntax, but they aren’t usually seen in the same program)
- a plus sign followed by a single letter, or a few letters, or a word, e.g. ":f:“, ":rgb:"
- a slash followed by a letter, or a few letters, or a word, e.g. ":/f:“, ":/file:"

These option syntaxes are not supported by optparse, and they never will be. This is deliberate: the first three are non-standard on any environment, and the last only makes sense if you’re exclusively targeting VMS, MS-DOS, and/or Windows.

option argument

an argument that follows an option, is closely associated with that option, and is consumed from the argument list when that option is. With optparse, option arguments may either be in a separate argument from their option:

\[-f \text{foo}\]
\[--\text{file} \text{foo}\]

or included in the same argument:

\[-f\text{foo}\]
\[--\text{file}=\text{foo}\]

Typically, a given option either takes an argument or it doesn’t. Lots of people want an “optional option arguments” feature, meaning that some options will take an argument if they see it, and won’t if they don’t. This is somewhat controversial, because it
makes parsing ambiguous: if "-a" takes an optional argument and "-b" is another option entirely, how do we interpret "-ab"? Because of this ambiguity, optparse does not support this feature.

positional argument

something leftover in the argument list after options have been parsed, i.e. after options and their arguments have been parsed and removed from the argument list.

required option

an option that must be supplied on the command-line; note that the phrase “required option” is self-contradictory in English. optparse doesn’t prevent you from implementing required options, but doesn’t give you much help at it either. See examples/required_1.py and examples/required_2.py in the optparse source distribution for two ways to implement required options with optparse.

For example, consider this hypothetical command-line:

```
prog -v --report /tmp/report.txt foo bar
```

"-v" and "--report" are both options. Assuming that --report takes one argument, "/tmp/report.txt" is an option argument. "foo" and "bar" are positional arguments.

What are options for?

Options are used to provide extra information to tune or customize the execution of a program. In case it wasn't clear, options are usually optional. A program should be able to run just fine with no options whatsoever. (Pick a random program from the Unix or GNU toolsets. Can it run without any options at all and still make sense?)
The main exceptions are `find`, `tar`, and `dd`—all of which are mutant oddballs that have been rightly criticized for their non-standard syntax and confusing interfaces.)

Lots of people want their programs to have “required options”. Think about it. If it’s required, then it’s *not optional!* If there is a piece of information that your program absolutely requires in order to run successfully, that’s what positional arguments are for.

As an example of good command-line interface design, consider the humble `cp` utility, for copying files. It doesn’t make much sense to try to copy files without supplying a destination and at least one source. Hence, `cp` fails if you run it with no arguments. However, it has a flexible, useful syntax that does not require any options at all:

```
cp SOURCE DEST
cp SOURCE ... DEST-DIR
```

You can get pretty far with just that. Most `cp` implementations provide a bunch of options to tweak exactly how the files are copied: you can preserve mode and modification time, avoid following symlinks, ask before clobbering existing files, etc. But none of this distracts from the core mission of `cp`, which is to copy either one file to another, or several files to another directory.

**What are positional arguments for?**

Positional arguments are for those pieces of information that your program absolutely, positively requires to run.

A good user interface should have as few absolute requirements as possible. If your program requires 17 distinct pieces of information in order to run successfully, it doesn’t much matter *how* you get that information from the user—most people will give up and walk away before they successfully run the program. This applies whether the
user interface is a command-line, a configuration file, or a GUI: if you make that many demands on your users, most of them will simply give up.

In short, try to minimize the amount of information that users are absolutely required to supply—use sensible defaults whenever possible. Of course, you also want to make your programs reasonably flexible. That’s what options are for. Again, it doesn’t matter if they are entries in a config file, widgets in the “Preferences” dialog of a GUI, or command-line options—the more options you implement, the more flexible your program is, and the more complicated its implementation becomes. Too much flexibility has drawbacks as well, of course; too many options can overwhelm users and make your code much harder to maintain.
While `optparse` is quite flexible and powerful, it's also straightforward to use in most cases. This section covers the code patterns that are common to any `optparse`-based program.

First, you need to import the OptionParser class; then, early in the main program, create an OptionParser instance:

```python
from optparse import OptionParser

parser = OptionParser()
```

Then you can start defining options. The basic syntax is:

```python
parser.add_option(opt_str, ..., attr=value, ...)
```

Each option has one or more option strings, such as `-f` or `--file`, and several option attributes that tell `optparse` what to expect and what to do when it encounters that option on the command line.

Typically, each option will have one short option string and one long option string, e.g.:

```python
parser.add_option("-f", "--file", ...)
```

You're free to define as many short option strings and as many long option strings as you like (including zero), as long as there is at least one option string overall.

The option strings passed to `add_option()` are effectively labels for the option defined by that call. For brevity, we will frequently refer to `encountering an option` on the command line; in reality, `optparse` encounters `option strings` and looks up options from them.
Once all of your options are defined, instruct `optparse` to parse your program’s command line:

```
(options, args) = parser.parse_args()
```

(If you like, you can pass a custom argument list to `parse_args()`, but that’s rarely necessary: by default it uses `sys.argv[1:]`.)

`parse_args()` returns two values:

- **options**, an object containing values for all of your options—e.g. if `--file` takes a single string argument, then `options.file` will be the filename supplied by the user, or `None` if the user did not supply that option
- **args**, the list of positional arguments leftover after parsing options

This tutorial section only covers the four most important option attributes: `action`, `type`, `dest` (destination), and `help`. Of these, `action` is the most fundamental.

**Understanding option actions**

Actions tell `optparse` what to do when it encounters an option on the command line. There is a fixed set of actions hard-coded into `optparse`; adding new actions is an advanced topic covered in section *Extending optparse*. Most actions tell `optparse` to store a value in some variable—for example, take a string from the command line and store it in an attribute of `options`.

If you don’t specify an option action, `optparse` defaults to `store`.

**The store action**
The most common option action is `store`, which tells optparse to take the next argument (or the remainder of the current argument), ensure that it is of the correct type, and store it to your chosen destination.

For example:

```python
parser.add_option("-f", "--file",
                   action="store", type="string", dest="filename"
                   )
```

Now let's make up a fake command line and ask optparse to parse it:

```python
args = ["-f", "foo.txt"]
(options, args) = parser.parse_args(args)
```

When optparse sees the option string "-f", it consumes the next argument, "foo.txt", and stores it in options.filename. So, after this call to parse_args(), options.filename is "foo.txt".

Some other option types supported by optparse are `int` and `float`. Here's an option that expects an integer argument:

```python
parser.add_option("-n", type="int", dest="num")
```

Note that this option has no long option string, which is perfectly acceptable. Also, there's no explicit action, since the default is `store`.

Let's parse another fake command-line. This time, we'll jam the option argument right up against the option: since "-n42" (one argument) is equivalent to "-n 42" (two arguments), the code

```python
(options, args) = parser.parse_args(["-n42")
print options.num
```
will print "42".

If you don't specify a type, `optparse` assumes `string`. Combined with the fact that the default action is `store`, that means our first example can be a lot shorter:

```python
parser.add_option("-f", "--file", dest="filename")
```

If you don't supply a destination, `optparse` figures out a sensible default from the option strings: if the first long option string is "--foo-bar", then the default destination is `foo_bar`. If there are no long option strings, `optparse` looks at the first short option string: the default destination for "-f" is `f`.

`optparse` also includes built-in `long` and `complex` types. Adding types is covered in section `Extending optparse`.

### Handling boolean (flag) options

Flag options—set a variable to true or false when a particular option is seen—are quite common. `optparse` supports them with two separate actions, `store_true` and `store_false`. For example, you might have a `verbose` flag that is turned on with "-v" and off with "-q":

```python
parser.add_option("-v", action="store_true", dest="verbose")
parser.add_option("-q", action="store_false", dest="verbose")
```

Here we have two different options with the same destination, which is perfectly OK. (It just means you have to be a bit careful when setting default values—see below.)

When `optparse` encounters "-v" on the command line, it sets `options.verbose` to `True`; when it encounters "-q", `options.verbose`
is set to False.

Other actions

Some other actions supported by **optparse** are:

- **store_const**
  - store a constant value
- **append**
  - append this option’s argument to a list
- **count**
  - increment a counter by one
- **callback**
  - call a specified function

These are covered in section *Reference Guide*, Reference Guide and section *Option Callbacks*.

Default values

All of the above examples involve setting some variable (the “destination”) when certain command-line options are seen. What happens if those options are never seen? Since we didn’t supply any defaults, they are all set to **None**. This is usually fine, but sometimes you want more control. **optparse** lets you supply a default value for each destination, which is assigned before the command line is parsed.

First, consider the verbose/quiet example. If we want **optparse** to set **verbose** to **True** unless "-q" is seen, then we can do this:

```
parser.add_option("-v", action="store_true", dest="verbose", default=True)
parser.add_option("-q", action="store_false", dest="verbose")
```
Since default values apply to the destination rather than to any particular option, and these two options happen to have the same destination, this is exactly equivalent:

```python
parser.add_option("-v", action="store_true", dest="verbose")
parser.add_option("-q", action="store_false", dest="verbose")
```

Consider this:

```python
parser.add_option("-v", action="store_true", dest="verbose")
parser.add_option("-q", action="store_false", dest="verbose")
```

Again, the default value for `verbose` will be `True`: the last default value supplied for any particular destination is the one that counts.

A clearer way to specify default values is the `set_defaults()` method of OptionParser, which you can call at any time before calling `parse_args()`:

```python
parser.set_defaults(verbose=True)
parser.add_option("")
(options, args) = parser.parse_args()
```

As before, the last value specified for a given option destination is the one that counts. For clarity, try to use one method or the other of setting default values, not both.

---

**Generating help**

`optparse`'s ability to generate help and usage text automatically is useful for creating user-friendly command-line interfaces. All you have to do is supply a `help` value for each option, and optionally a short usage message for your whole program. Here's an OptionParser populated with user-friendly (documented) options:
usage = "usage: %prog [options] arg1 arg2"
parser = OptionParser(usage=usage)
parser.add_option("-v", "--verbose",
    action="store_true", dest="verbose", default="make lots of noise [default]"
)
parser.add_option("-q", "--quiet",
    action="store_false", dest="verbose",
    help="be vewwy quiet (I'm hunting wabbits)"
)
parser.add_option("-f", "--filename",
    metavar="FILE", help="write output to FILE"
)
parser.add_option("-m", "--mode",
    default="intermediate",
    help="interaction mode: novice, intermediate, or expert [default: intermediate"
)

If `optparse` encounters either `-h` or `--help` on the command-line, or if you just call `parser.print_help()`, it prints the following to standard output:

```
usage: <yourscript> [options] arg1 arg2

options:
    -h, --help                show this help message and exit
    -v, --verbose             make lots of noise [default]
    -q, --quiet               be vewwy quiet (I'm hunting wabbits)
    -f FILE, --filename=FILE  write output to FILE
    -m MODE, --mode=MODE      interaction mode: novice, intermediate, or expert [default: intermediate]
```

(If the help output is triggered by a help option, `optparse` exits after printing the help text.)

There's a lot going on here to help `optparse` generate the best possible help message:

- the script defines its own usage message:

  ```
  usage = "usage: %prog [options] arg1 arg2"
  ```
optparse expands "%prog" in the usage string to the name of the current program, i.e. `os.path.basename(sys.argv[0])`. The expanded string is then printed before the detailed option help.

If you don’t supply a usage string, optparse uses a bland but sensible default: "usage: %prog [options]", which is fine if your script doesn’t take any positional arguments.

- every option defines a help string, and doesn’t worry about line-wrapping—optparse takes care of wrapping lines and making the help output look good.

- options that take a value indicate this fact in their automatically-generated help message, e.g. for the “mode” option:

```
-m MODE, --mode=MODE
```

Here, “MODE” is called the meta-variable: it stands for the argument that the user is expected to supply to `-m/--mode`. By default, optparse converts the destination variable name to uppercase and uses that for the meta-variable. Sometimes, that’s not what you want—for example, the `--filename` option explicitly sets `metavar="FILE"`, resulting in this automatically-generated option description:

```
-f FILE, --filename=FILE
```

This is important for more than just saving space, though: the manually written help text uses the meta-variable “FILE” to clue the user in that there’s a connection between the semi-formal syntax “-f FILE” and the informal semantic description “write output to FILE”. This is a simple but effective way to make your help text a lot clearer and more useful for end users.
New in version 2.4: Options that have a default value can include %default in the help string—optparse will replace it with str() of the option's default value. If an option has no default value (or the default value is None), %default expands to none.

When dealing with many options, it is convenient to group these options for better help output. An OptionParser can contain several option groups, each of which can contain several options.

Continuing with the parser defined above, adding an OptionGroup to a parser is easy:

```python
group = OptionGroup(parser, "Dangerous Options", "Caution: use these options at your own risk. It is believed that some of them bite.")
group.add_option("-g", action="store_true", help="Group option.
parser.add_option_group(group)
```

This would result in the following help output:

```plaintext
usage: [options] arg1 arg2

options:
  -h, --help            show this help message and exit
  -v, --verbose         make lots of noise [default]
  -q, --quiet           be vewwy quiet (I'm hunting wabbits)
  -fFILE, --file=FILE   write output to FILE
  -mMODE, --mode=MODE   interaction mode: one of 'novice', 'intermediate'
                       [default], 'expert'

Dangerous Options:
  Caution: use of these options is at your own risk. It is b
  some of them bite.
  -g                     Group option.
```

Printing a version string

Similar to the brief usage string, optparse can also print a version
string for your program. You have to supply the string as the `version`
argument to OptionParser:

```python
parser = OptionParser(usage="%prog [-f] [-q]", version="%prog 1.0")
```

"%prog" is expanded just like it is in `usage`. Apart from that, `version`
can contain anything you like. When you supply it, `optparse`
automatically adds a "--version" option to your parser. If it
encounters this option on the command line, it expands your `version`
string (by replacing "%prog"), prints it to stdout, and exits.

For example, if your script is called `/usr/bin/foo`:

```
$ /usr/bin/foo --version
foo 1.0
```

**How `optparse` handles errors**

There are two broad classes of errors that `optparse` has to worry
about: programmer errors and user errors. Programmer errors are
usually erroneous calls to `parser.add_option()`, e.g. invalid option
strings, unknown option attributes, missing option attributes, etc.
These are dealt with in the usual way: raise an exception (either
`optparse.OptionError` or `TypeError`) and let the program crash.

Handling user errors is much more important, since they are
guaranteed to happen no matter how stable your code is. `optparse`
can automatically detect some user errors, such as bad option
arguments (passing "-n 4x" where `-n` takes an integer argument),
missing arguments ("-n" at the end of the command line, where `-n`
takes an argument of any type). Also, you can call `parser.error()` to
signal an application-defined error condition:
In either case, **optparse** handles the error the same way: it prints the program’s usage message and an error message to standard error and exits with error status 2.

Consider the first example above, where the user passes "4x" to an option that takes an integer:

```
$ /usr/bin/foo -n 4x
usage: foo [options]
foo: error: option -n: invalid integer value: '4x'
```

Or, where the user fails to pass a value at all:

```
$ /usr/bin/foo -n
usage: foo [options]
foo: error: -n option requires an argument
```

**optparse**-generated error messages take care always to mention the option involved in the error; be sure to do the same when calling `parser.error()` from your application code.

If **optparse**'s default error-handling behaviour does not suit your needs, you'll need to subclass `OptionParser` and override its `exit()` and/or `error()` methods.

**Putting it all together**

Here’s what **optparse**-based scripts usually look like:

```
from optparse import OptionParser
[...]
```
def main():
    usage = "usage: %prog [options] arg"
    parser = OptionParser(usage)
    parser.add_option("-f", "--file", dest="filename",
                      help="read data from FILENAME")
    parser.add_option("-v", "--verbose",
                      action="store_true", dest="verbose")
    parser.add_option("-q", "--quiet",
                      action="store_false", dest="verbose")

    [...]
    (options, args) = parser.parse_args()
    if len(args) != 1:
        parser.error("incorrect number of arguments")
    if options.verbose:
        print "reading %s..." % options.filename
    [...]

if __name__ == "__main__":
    main()
The first step in using `optparse` is to create an `OptionParser` instance:

```python
parser = OptionParser(...)  
```

The `OptionParser` constructor has no required arguments, but a number of optional keyword arguments. You should always pass them as keyword arguments, i.e. do not rely on the order in which the arguments are declared.

- **usage** (default: "%prog [options]"")
  The usage summary to print when your program is run incorrectly or with a help option. When `optparse` prints the usage string, it expands `%prog` to `os.path.basename(sys.argv[0])` (or to `prog` if you passed that keyword argument). To suppress a usage message, pass the special value `optparse.SUPPRESS_USAGE`.

- **option_list** (default: `[]`)
  A list of `Option` objects to populate the parser with. The options in `option_list` are added after any options in `standard_option_list` (a class attribute that may be set by `OptionParser` subclasses), but before any version or help options. Deprecated; use `add_option()` after creating the parser instead.

- **option_class** (default: `optparse.Option`)
  Class to use when adding options to the parser in `add_option()`.
version (default: None)

A version string to print when the user supplies a version option. If you supply a true value for version, optparse automatically adds a version option with the single option string "--version". The substring "%prog" is expanded the same as for usage.

conflict_handler (default: "error")

Specifies what to do when options with conflicting option strings are added to the parser; see section Conflicts between options.

description (default: None)

A paragraph of text giving a brief overview of your program. optparse reformats this paragraph to fit the current terminal width and prints it when the user requests help (after usage, but before the list of options).

formatter (default: a new IndentedHelpFormatter)

An instance of optparse.HelpFormatter that will be used for printing help text. optparse provides two concrete classes for this purpose: IndentedHelpFormatter and TitledHelpFormatter.

add_help_option (default: True)

If true, optparse will add a help option (with option strings "-h" and "--help") to the parser.

prog

The string to use when expanding "%prog" in usage and version instead of os.path.basename(sys.argv[0]).

Populating the parser

There are several ways to populate the parser with options. The preferred way is by using OptionParser.add_option(), as shown in
section Tutorial. `add_option()` can be called in one of two ways:

- pass it an Option instance (as returned by `make_option()`)
- pass it any combination of positional and keyword arguments that are acceptable to `make_option()` (i.e., to the Option constructor), and it will create the Option instance for you

The other alternative is to pass a list of pre-constructed Option instances to the OptionParser constructor, as in:

```python
option_list = [
    make_option("-f", "--filename",
                action="store", type="string", dest="filename")
    make_option("-q", "--quiet",
                action="store_false", dest="verbose"),
]
parsed = OptionParser(option_list=option_list)
```

(`make_option()` is a factory function for creating Option instances; currently it is an alias for the Option constructor. A future version of `optparse` may split Option into several classes, and `make_option()` will pick the right class to instantiate. Do not instantiate Option directly.)

### Defining options

Each Option instance represents a set of synonymous command-line option strings, e.g. `-f` and `--file`. You can specify any number of short or long option strings, but you must specify at least one overall option string.

The canonical way to create an Option instance is with the `add_option()` method of `OptionParser`:

```python
parser.add_option(opt_str[,...], attr=value, ...)
```
To define an option with only a short option string:

```python
caller.add_option("-f", attr=value, ...)
```

And to define an option with only a long option string:

```python
caller.add_option("--foo", attr=value, ...)
```

The keyword arguments define attributes of the new Option object. The most important option attribute is `action`, and it largely determines which other attributes are relevant or required. If you pass irrelevant option attributes, or fail to pass required ones, `optparse` raises an `OptionError` exception explaining your mistake.

An option’s `action` determines what `optparse` does when it encounters this option on the command-line. The standard option actions hard-coded into `optparse` are:

- `store`:
  - store this option’s argument (default)
- `store_const`:
  - store a constant value
- `store_true`:
  - store a true value
- `store_false`:
  - store a false value
- `append`:
  - append this option’s argument to a list
- `append_const`:
  - append a constant value to a list
- `count`:
  - increment a counter by one
- `callback`:
  - call a specified function
help

print a usage message including all options and the documentation for them

(If you don’t supply an action, the default is store. For this action, you may also supply type and dest option attributes; see below.)

As you can see, most actions involve storing or updating a value somewhere. optparse always creates a special object for this, conventionally called options (it happens to be an instance of optparse.Values). Option arguments (and various other values) are stored as attributes of this object, according to the dest (destination) option attribute.

For example, when you call

```
parser.parse_args()
```

one of the first things optparse does is create the options object:

```
options = Values()
```

If one of the options in this parser is defined with

```
parser.add_option("-f", "--file", action="store", type="string"
```

and the command-line being parsed includes any of the following:

```
-f foo
--file=foo
--file foo
```

then optparse, on seeing this option, will do the equivalent of

```
options.filename = "foo"
```
The type and dest option attributes are almost as important as action, but action is the only one that makes sense for all options.

## Standard option actions

The various option actions all have slightly different requirements and effects. Most actions have several relevant option attributes which you may specify to guide optparse's behaviour; a few have required attributes, which you must specify for any option using that action.

- **store** [relevant: type, dest, nargs, choices]

  The option must be followed by an argument, which is converted to a value according to type and stored in dest. If nargs > 1, multiple arguments will be consumed from the command line; all will be converted according to type and stored to dest as a tuple. See the “Option types” section below.

  If choices is supplied (a list or tuple of strings), the type defaults to choice.

  If type is not supplied, it defaults to string.

  If dest is not supplied, optparse derives a destination from the first long option string (e.g., "--foo-bar" implies foo_bar). If there are no long option strings, optparse derives a destination from the first short option string (e.g., "-f" implies f).

Example:

```
parser.add_option("-f")
parser.add_option("-p", type="float", nargs=3, dest="point")
```
As it parses the command line

```
-f foo.txt -p 1 -3.5 4 -fbar.txt
```

```
optparse will set
```

```
options.f = "foo.txt"
options.point = (1.0, -3.5, 4.0)
options.f = "bar.txt"
```

- **store_const** [required: const; relevant: dest]

  The value const is stored in dest.

  Example:

  ```
  parser.add_option("-q", "--quiet",
      action="store_const", const=0, dest="verbose"
  parser.add_option("-v", "--verbose",
      action="store_const", const=1, dest="verbose"
  parser.add_option("--noisy",
      action="store_const", const=2, dest="verbose"
  ```

  If "--noisy" is seen, optparse will set

  ```
  options.verbose = 2
  ```

- **store_true** [relevant: dest]

  A special case of **store_const** that stores a true value to dest.

- **store_false** [relevant: dest]

  Like **store_true**, but stores a false value.
Example:

```python
parser.add_option("--clobber", action="store_true", dest="c"
parser.add_option("--no-clobber", action="store_false", des
```

- **append** [relevant: `type`, `dest`, `nargs`, `choices`]

The option must be followed by an argument, which is appended to the list in `dest`. If no default value for `dest` is supplied, an empty list is automatically created when `optparse` first encounters this option on the command-line. If `nargs > 1`, multiple arguments are consumed, and a tuple of length `nargs` is appended to `dest`.

The defaults for `type` and `dest` are the same as for the `store` action.

Example:

```python
parser.add_option("-t", "--tracks", action="append", type="
```

If `-t3` is seen on the command-line, `optparse` does the equivalent of:

```python
options.tracks = []
options.tracks.append(int("3"))
```

If, a little later on, `--tracks=4` is seen, it does:

```python
options.tracks.append(int("4"))
```

- **append_const** [required: `const`; relevant: `dest`]

Like `store_const`, but the value `const` is appended to `dest`; as with `append`, `dest` defaults to `None`, and an empty list is automatically created the first time the option is encountered.

- **count** [relevant: `dest`]

  Increment the integer stored at `dest`. If no default value is supplied, `dest` is set to zero before being incremented the first time.

  Example:

  ```
  parser.add_option("-v", action="count", dest="verbosity")
  ```

  The first time `-v` is seen on the command line, `optparse` does the equivalent of:

  ```
  options.verbosity = 0
  options.verbosity += 1
  ```

  Every subsequent occurrence of `-v` results in

  ```
  options.verbosity += 1
  ```

- **callback** [required: `callback`; relevant: `type`, `nargs`, `callback_args`, `callback_kwargs`]

  Call the function specified by `callback`, which is called as

  ```
  func(option, opt_str, value, parser, *args, **kwargs)
  ```

  See section *Option Callbacks* for more detail.

- **help**
Prints a complete help message for all the options in the current option parser. The help message is constructed from the `usage` string passed to `OptionParser`'s constructor and the `help` string passed to every option.

If no `help` string is supplied for an option, it will still be listed in the help message. To omit an option entirely, use the special value `optparse.SUPPRESS_HELP`.

`optparse` automatically adds a `help` option to all `OptionParsers`, so you do not normally need to create one.

Example:

```python
from optparse import OptionParser, SUPPRESS_HELP

parser = OptionParser()
parser.add_option("-h", "--help", action="help"),
parser.add_option("-v", action="store_true", dest="verbose"
    help="Be moderately verbose")
parser.add_option("--file", dest="filename",
    help="Input file to read data from"),
parser.add_option("--secret", help=SUPPRESS_HELP)
```

If `optparse` sees either `"-h"` or `"--help"` on the command line, it will print something like the following help message to stdout (assuming `sys.argv[0]` is "foo.py"):

```
usage: foo.py [options]

options:
  -h, --help            Show this help message and exit
  -v                    Be moderately verbose
```
After printing the help message, `optparse` terminates your process with `sys.exit(0)`.

- **version**

  Prints the version number supplied to the OptionParser to stdout and exits. The version number is actually formatted and printed by the `print_version()` method of OptionParser. Generally only relevant if the `version` argument is supplied to the OptionParser constructor. As with `help` options, you will rarely create `version` options, since `optparse` automatically adds them when needed.

### Option attributes

The following option attributes may be passed as keyword arguments to `parser.add_option()`. If you pass an option attribute that is not relevant to a particular option, or fail to pass a required option attribute, `optparse` raises `OptionError`.

- **action** (default: "store")

  Determines `optparse`'s behaviour when this option is seen on the command line; the available options are documented above.

- **type** (default: "string")

  The argument type expected by this option (e.g., "string" or "int"); the available option types are documented below.

- **dest** (default: derived from option strings)

  If the option's action implies writing or modifying a value
somewhere, this tells optparse where to write it: dest names an attribute of the options object that optparse builds as it parses the command line.

- **default** (deprecated)

  The value to use for this option’s destination if the option is not seen on the command line. Deprecated; use parser.set_defaults() instead.

- **nargs** (default: 1)

  How many arguments of type type should be consumed when this option is seen. If > 1, optparse will store a tuple of values to dest.

- **const**

  For actions that store a constant value, the constant value to store.

- **choices**

  For options of type "choice", the list of strings the user may choose from.

- **callback**

  For options with action "callback", the callable to call when this option is seen. See section Option Callbacks for detail on the arguments passed to callable.

- **callback_args, callback_kwargs**

  Additional positional and keyword arguments to pass to
callback after the four standard callback arguments.

- **help**

Help text to print for this option when listing all available options after the user supplies a help option (such as "--help"). If no help text is supplied, the option will be listed without help text. To hide this option, use the special value SUPPRESS_HELP.

- **metavar** (default: derived from option strings)

Stand-in for the option argument(s) to use when printing help text. See section Tutorial for an example.

---

**Standard option types**

**optparse** has six built-in option types: string, int, long, choice, float and complex. If you need to add new option types, see section Extending optparse.

Arguments to string options are not checked or converted in any way: the text on the command line is stored in the destination (or passed to the callback) as-is.

Integer arguments (type int or long) are parsed as follows:

- if the number starts with 0x, it is parsed as a hexadecimal number
- if the number starts with 0, it is parsed as an octal number
- if the number starts with 0b, it is parsed as a binary number
- otherwise, the number is parsed as a decimal number

The conversion is done by calling either int() or long() with the appropriate base (2, 8, 10, or 16). If this fails, so will optparse,
although with a more useful error message.

`float` and `complex` option arguments are converted directly with `float()` and `complex()`, with similar error-handling.

`choice` options are a subtype of `string` options. The `choices` option attribute (a sequence of strings) defines the set of allowed option arguments. `optparse.check_choice()` compares user-supplied option arguments against this master list and raises `OptionValueError` if an invalid string is given.

### Parsing arguments

The whole point of creating and populating an OptionParser is to call its `parse_args()` method:

```python
(options, args) = parser.parse_args(args=None, values=None)
```

where the input parameters are

- `args` the list of arguments to process (default: `sys.argv[1:]`)
- `values` object to store option arguments in (default: a new instance of `optparse.Values`)

and the return values are

- `options` the same object that was passed in as `options`, or the `optparse.Values` instance created by `optparse`
- `args` the leftover positional arguments after all options have been processed
The most common usage is to supply neither keyword argument. If you supply options, it will be modified with repeated setattr() calls (roughly one for every option argument stored to an option destination) and returned by parse_args().

If parse_args() encounters any errors in the argument list, it calls the OptionParser’s error() method with an appropriate end-user error message. This ultimately terminates your process with an exit status of 2 (the traditional Unix exit status for command-line errors).

Querying and manipulating your option parser

The default behavior of the option parser can be customized slightly, and you can also poke around your option parser and see what’s there. OptionParser provides several methods to help you out:

code

```python
disable_interspersed_args()
    Set parsing to stop on the first non-option. Use this if you have a command processor which runs another command which has options of its own and you want to make sure these options don’t get confused. For example, each command might have a different set of options.

enable_interspersed_args()
    Set parsing to not stop on the first non-option, allowing interspersing switches with command arguments. For example, "-s arg1 --long arg2" would return ["arg1", "arg2"] as the command arguments and -s, --long as options. This is the default behavior.

get_option(opt_str)
    Returns the Option instance with the option string opt_str, or None if no options have that option string.

has_option(opt_str)
    Return true if the OptionParser has an option with option string
```
remove_option(opt_str)

If the OptionParser has an option corresponding to `opt_str`, that option is removed. If that option provided any other option strings, all of those option strings become invalid. If `opt_str` does not occur in any option belonging to this OptionParser, raises ValueError.

Conflicts between options

If you’re not careful, it’s easy to define options with conflicting option strings:

```python
parser.add_option("-n", "--dry-run", ...)  
[...]  
parser.add_option("-n", "--noisy", ...)  
```

(This is particularly true if you’ve defined your own OptionParser subclass with some standard options.)

Every time you add an option, optparse checks for conflicts with existing options. If it finds any, it invokes the current conflict-handling mechanism. You can set the conflict-handling mechanism either in the constructor:

```python
parser = OptionParser(..., conflict_handler=handler)  
```

or with a separate call:

```python
parser.set_conflict_handler(handler)  
```

The available conflict handlers are:

- error (default)
  - assume option conflicts are a programming error and raise
OptionConflictError

resolve

resolve option conflicts intelligently (see below)

As an example, let's define an OptionParser that resolves conflicts intelligently and add conflicting options to it:

```python
parser = OptionParser(conflict_handler="resolve")
parser.add_option("-n", "--dry-run", ..., help="do no harm")
parser.add_option("-n", "--noisy", ..., help="be noisy")
```

At this point, optparse detects that a previously-added option is already using the "-n" option string. Since conflict_handler is "resolve", it resolves the situation by removing "-n" from the earlier option's list of option strings. Now "--dry-run" is the only way for the user to activate that option. If the user asks for help, the help message will reflect that:

```plaintext
options:
    --dry-run    do no harm
    [...]        
    -n, --noisy  be noisy
```

It's possible to whittle away the option strings for a previously-added option until there are none left, and the user has no way of invoking that option from the command-line. In that case, optparse removes that option completely, so it doesn't show up in help text or anywhere else. Carrying on with our existing OptionParser:

```python
parser.add_option("--dry-run", ..., help="new dry-run option")
```

At this point, the original -n/--dry-run option is no longer accessible, so optparse removes it, leaving this help text:

```plaintext
options:
    [...]        
    -n, --noisy  be noisy
```
OptionParser instances have several cyclic references. This should not be a problem for Python’s garbage collector, but you may wish to break the cyclic references explicitly by calling `destroy()` on your OptionParser once you are done with it. This is particularly useful in long-running applications where large object graphs are reachable from your OptionParser.

### Other methods

OptionParser supports several other public methods:

- **set_usage(usage)**

  Set the usage string according to the rules described above for the `usage` constructor keyword argument. Passing `None` sets the default usage string; use `SUPPRESS_USAGE` to suppress a usage message.

- **enable_interspersed_args(), disable_interspersed_args()**

  Enable/disable positional arguments interspersed with options, similar to GNU getopt (enabled by default). For example, if `-a` and `-b` are both simple options that take no arguments, `optparse` normally accepts this syntax:

  ```plaintext
  prog -a arg1 -b arg2
  ```

  and treats it as equivalent to

  ```plaintext
  prog -a -b arg1 arg2
  ```
To disable this feature, call `disable_interspersed_args()`. This restores traditional Unix syntax, where option parsing stops with the first non-option argument.

- `set_defaults(dest=value, ...)`

Set default values for several option destinations at once. Using `set_defaults()` is the preferred way to set default values for options, since multiple options can share the same destination. For example, if several “mode” options all set the same destination, any one of them can set the default, and the last one wins:

```python
parser.add_option("--advanced", action="store_const",
    dest="mode", const="advanced",
    default="novice")  # overridden below
parser.add_option("--novice", action="store_const",
    dest="mode", const="novice",
    default="advanced")  # overrides above setting
```

To avoid this confusion, use `set_defaults()`:

```python
parser.set_defaults(mode="advanced")
parser.add_option("--advanced", action="store_const",
    dest="mode", const="advanced")
parser.add_option("--novice", action="store_const",
    dest="mode", const="novice")
```
Option Callbacks

When `optparse`'s built-in actions and types aren't quite enough for your needs, you have two choices: extend `optparse` or define a callback option. Extending `optparse` is more general, but overkill for a lot of simple cases. Quite often a simple callback is all you need.

There are two steps to defining a callback option:

- define the option itself using the `callback` action
- write the callback; this is a function (or method) that takes at least four arguments, as described below

Defining a callback option

As always, the easiest way to define a callback option is by using the `parser.add_option()` method. Apart from `action`, the only option attribute you must specify is `callback`, the function to call:

```python
parser.add_option("-c", action="callback", callback=my_callback)
```

`callback` is a function (or other callable object), so you must have already defined `my_callback()` when you create this callback option. In this simple case, `optparse` doesn't even know if `-c` takes any arguments, which usually means that the option takes no arguments —the mere presence of `-c` on the command-line is all it needs to know. In some circumstances, though, you might want your callback to consume an arbitrary number of command-line arguments. This is where writing callbacks gets tricky; it's covered later in this section.

`optparse` always passes four particular arguments to your callback, and it will only pass additional arguments if you specify them via
callback_args and callback_kwargs. Thus, the minimal callback function signature is:

```python
def my_callback(option, opt, value, parser):
```

The four arguments to a callback are described below.

There are several other option attributes that you can supply when you define a callback option:

- **type**
  - has its usual meaning: as with the store or append actions, it instructs optparse to consume one argument and convert it to type. Rather than storing the converted value(s) anywhere, though, optparse passes it to your callback function.

- **nargs**
  - also has its usual meaning: if it is supplied and > 1, optparse will consume nargs arguments, each of which must be convertible to type. It then passes a tuple of converted values to your callback.

- **callback_args**
  - a tuple of extra positional arguments to pass to the callback

- **callback_kwargs**
  - a dictionary of extra keyword arguments to pass to the callback

### How callbacks are called

All callbacks are called as follows:

```python
func(option, opt_str, value, parser, *args, **kwargs)
```

where

- **option**
  - is the Option instance that's calling the callback
opt_str

is the option string seen on the command-line that's triggering the callback. (If an abbreviated long option was used, opt_str will be the full, canonical option string—e.g. if the user puts "--foo" on the command-line as an abbreviation for "--foobar", then opt_str will be "--foobar".)

value

is the argument to this option seen on the command-line. optparse will only expect an argument if type is set; the type of value will be the type implied by the option's type. If type for this option is None (no argument expected), then value will be None. If nargs > 1, value will be a tuple of values of the appropriate type.

parser

is the OptionParser instance driving the whole thing, mainly useful because you can access some other interesting data through its instance attributes:

parser.largs

the current list of leftover arguments, ie. arguments that have been consumed but are neither options nor option arguments. Feel free to modify parser.largs, e.g. by adding more arguments to it. (This list will become args, the second return value of parse_args().)

parser.rargs

the current list of remaining arguments, ie. with opt_str and value (if applicable) removed, and only the arguments following them still there. Feel free to modify parser.rargs, e.g. by consuming more arguments.

parser.values

the object where option values are by default stored (an instance of optparse.OptionValues). This lets callbacks use
the same mechanism as the rest of *optparse* for storing option values; you don't need to mess around with globals or closures. You can also access or modify the value(s) of any options already encountered on the command-line.

**args**

is a tuple of arbitrary positional arguments supplied via the `callback_args` option attribute.

**kwargs**

is a dictionary of arbitrary keyword arguments supplied via `callback_kwargs`.

### Raising errors in a callback

The callback function should raise `OptionValueError` if there are any problems with the option or its argument(s). *optparse* catches this and terminates the program, printing the error message you supply to stderr. Your message should be clear, concise, accurate, and mention the option at fault. Otherwise, the user will have a hard time figuring out what he did wrong.

### Callback example 1: trivial callback

Here's an example of a callback option that takes no arguments, and simply records that the option was seen:

```python
def record_foo_seen(option, opt_str, value, parser):
    parser.saw_foo = True
parser.add_option("--foo", action="callback", callback=record_foo_seen)
```

Of course, you could do that with the `store_true` action.

### Callback example 2: check option order
Here's a slightly more interesting example: record the fact that "-a" is seen, but blow up if it comes after "-b" in the command-line.

```python
def check_order(option, opt_str, value, parser):
    if parser.values.b:
        raise OptionValueError("can't use -a after -b")
    parser.values.a = 1
parser.add_option("-a", action="callback", callback=check_order)
```

Callback example 3: check option order (generalized)

If you want to re-use this callback for several similar options (set a flag, but blow up if "-b" has already been seen), it needs a bit of work: the error message and the flag that it sets must be generalized.

```python
def check_order(option, opt_str, value, parser):
    if parser.values.b:
        raise OptionValueError("can't use %s after -b" % opt_str)
    setattr(parser.values, option.dest, 1)
parser.add_option("-a", action="callback", callback=check_order)
parser.add_option("-b", action="store_true", dest="b")
parser.add_option("-c", action="callback", callback=check_order)
```

Callback example 4: check arbitrary condition

Of course, you could put any condition in there—you’re not limited to checking the values of already-defined options. For example, if you have options that should not be called when the moon is full, all you have to do is this:

```python
def check_moon(option, opt_str, value, parser):
    if is_moon_full():
```
raise OptionValueError("%s option invalid when moon is % opt_str")
setattr(parser.values, option.dest, 1)

parser.add_option("--foo",
    action="callback",
    callback=check_moon,
    dest="foo")

(The definition of is_moon_full() is left as an exercise for the reader.)

Callback example 5: fixed arguments

Things get slightly more interesting when you define callback options that take a fixed number of arguments. Specifying that a callback option takes arguments is similar to defining a store or append option: if you define type, then the option takes one argument that must be convertible to that type; if you further define nargs, then the option takes nargs arguments.

Here's an example that just emulates the standard store action:

def store_value(option, opt_str, value, parser):
    setattr(parser.values, option.dest, value)

parser.add_option("--foo",
    action="callback",
    callback=store_value,
    type="int", nargs=3, dest="foo")

Note that optparse takes care of consuming 3 arguments and converting them to integers for you; all you have to do is store them. (Or whatever; obviously you don’t need a callback for this example.)

Callback example 6: variable arguments

Things get hairy when you want an option to take a variable number of arguments. For this case, you must write a callback, as optparse
doesn’t provide any built-in capabilities for it. And you have to deal with certain intricacies of conventional Unix command-line parsing that optparse normally handles for you. In particular, callbacks should implement the conventional rules for bare "--" and "-" arguments:

- either "--" or "-" can be option arguments
- bare "--" (if not the argument to some option): halt command-line processing and discard the "--"
- bare "-" (if not the argument to some option): halt command-line processing but keep the "-" (append it to parser.largs)

If you want an option that takes a variable number of arguments, there are several subtle, tricky issues to worry about. The exact implementation you choose will be based on which trade-offs you’re willing to make for your application (which is why optparse doesn’t support this sort of thing directly).

Nevertheless, here’s a stab at a callback for an option with variable arguments:

```python
def vararg_callback(option, opt_str, value, parser):
    assert value is None
    done = 0
    value = []
    rargs = parser.rargs
    while rargs:
        arg = rargs[0]

        # Stop if we hit an arg like "--foo", "-a", "-fx", "-f", or etc. Note that this also stops on "-3" or "-3.0", so
        # your option takes numeric values, you will need to handle this.
        if ((arg[2:] == "--" and len(arg) > 2) or
             (arg[1:] == "-" and len(arg) > 1 and arg[1] != "-"))
            break
        else:
            value.append(arg)
            del rargs[0]
```
The main weakness with this particular implementation is that negative numbers in the arguments following "-c" will be interpreted as further options (probably causing an error), rather than as arguments to "-c". Fixing this is left as an exercise for the reader.
Extending \texttt{optparse}

Since the two major controlling factors in how \texttt{optparse} interprets command-line options are the action and type of each option, the most likely direction of extension is to add new actions and new types.

Adding new types

To add new types, you need to define your own subclass of \texttt{optparse}'s Option class. This class has a couple of attributes that define \texttt{optparse}'s types: \texttt{TYPES} and \texttt{TYPE\_CHECKER}.

\texttt{TYPES} is a tuple of type names; in your subclass, simply define a new tuple \texttt{TYPES} that builds on the standard one.

\texttt{TYPE\_CHECKER} is a dictionary mapping type names to type-checking functions. A type-checking function has the following signature:

\begin{verbatim}
    def check_mytype(option, opt, value)
\end{verbatim}

where \texttt{option} is an \texttt{Option} instance, \texttt{opt} is an option string (e.g., "-f"), and \texttt{value} is the string from the command line that must be checked and converted to your desired type. \texttt{check_mytype()} should return an object of the hypothetical type \texttt{mytype}. The value returned by a type-checking function will wind up in the OptionValues instance returned by \texttt{OptionParser.parse_args()}, or be passed to a callback as the \texttt{value} parameter.

Your type-checking function should raise \texttt{OptionValueError} if it encounters any problems. \texttt{OptionValueError} takes a single string argument, which is passed as-is to \texttt{OptionParser}’s \texttt{error()} method,
which in turn prepends the program name and the string "error:", and prints everything to stderr before terminating the process.

Here's a silly example that demonstrates adding a `complex` option type to parse Python-style complex numbers on the command line. (This is even sillier than it used to be, because `optparse` 1.3 added built-in support for complex numbers, but never mind.)

First, the necessary imports:

```python
from copy import copy
from optparse import Option, OptionValueError
```

You need to define your type-checker first, since it's referred to later (in the `TYPE_CHECKER` class attribute of your Option subclass):

```python
def check_complex(option, opt, value):
    try:
        return complex(value)
    except ValueError:
        raise OptionValueError("option %s: invalid complex value: %r" % (opt, value))
```

Finally, the Option subclass:

```python
class MyOption(Option):
    TYPES = Option.TYPES + ("complex",)
    TYPE_CHECKER = copy(Option.TYPE_CHECKER)
    TYPE_CHECKER["complex"] = check_complex
```

(If we didn't make a `copy()` of `Option.TYPE_CHECKER`, we would end up modifying the `TYPE_CHECKER` attribute of `optparse`'s Option class. This being Python, nothing stops you from doing that except good manners and common sense.)

That's it! Now you can write a script that uses the new option type just like any other `optparse`-based script, except you have to instruct
your OptionParser to use MyOption instead of Option:

```python
parser = OptionParser(option_class=MyOption)
parsed.add_option("-c", type="complex")
```

Alternately, you can build your own option list and pass it to OptionParser; if you don’t use `add_option()` in the above way, you don’t need to tell OptionParser which option class to use:

```python
option_list = [MyOption("-c", action="store", type="complex",...
parsed = OptionParser(option_list=option_list)
```

## Adding new actions

Adding new actions is a bit trickier, because you have to understand that `optparse` has a couple of classifications for actions:

- **“store” actions**
  - actions that result in `optparse` storing a value to an attribute of the current OptionValues instance; these options require a `dest` attribute to be supplied to the Option constructor

- **“typed” actions**
  - actions that take a value from the command line and expect it to be of a certain type; or rather, a string that can be converted to a certain type. These options require a `type` attribute to the Option constructor.

These are overlapping sets: some default “store” actions are `store`, `store_const`, `append`, and `count`, while the default “typed” actions are `store`, `append`, and `callback`.

When you add an action, you need to categorize it by listing it in at least one of the following class attributes of Option (all are lists of strings):
ACTIONS
   all actions must be listed in ACTIONS
STORE_ACTIONS
   “store” actions are additionally listed here
TYPED_ACTIONS
   “typed” actions are additionally listed here
ALWAYS_TYPED_ACTIONS
   actions that always take a type (i.e. whose options always take a value) are additionally listed here. The only effect of this is that optparse assigns the default type, string, to options with no explicit type whose action is listed in ALWAYS_TYPED_ACTIONS.

In order to actually implement your new action, you must override Option’s take_action() method and add a case that recognizes your action.

For example, let’s add an extend action. This is similar to the standard append action, but instead of taking a single value from the command-line and appending it to an existing list, extend will take multiple values in a single comma-delimited string, and extend an existing list with them. That is, if --names is an extend option of type string, the command line

```
--names=foo,bar --names blah --names ding,dong
```

would result in a list

```
["foo", "bar", "blah", "ding", "dong"]
```

Again we define a subclass of Option:

```python
class MyOption (Option):
    ACTIONS = Option.ACTIONS + ("extend",)
    STORE_ACTIONS = Option.STORE_ACTIONS + ("extend",)
```
TYPED_ACTIONS = Option.TYPED_ACTIONS + ("extend",)
ALWAYS_TYPED_ACTIONS = Option.ALWAYS_TYPED_ACTIONS + ("extend",)

```python
def take_action(self, action, dest, opt, value, values, parser):
    if action == "extend":
        lvalue = value.split(",")
        values.ensure_value(dest, []).extend(lvalue)
    else:
        Option.take_action(self, action, dest, opt, value, values, parser)
```

Features of note:

- `extend` both expects a value on the command-line and stores that value somewhere, so it goes in both `STORE_ACTIONS` and `TYPED_ACTIONS`.

- To ensure that `optparse` assigns the default type of `string` to `extend` actions, we put the `extend` action in `ALWAYS_TYPED_ACTIONS` as well.

- `MyOption.take_action()` implements just this one new action, and passes control back to `Option.take_action()` for the standard `optparse` actions.

- `values` is an instance of the `optparse_parser.Values` class, which provides the very useful `ensure_value()` method. `ensure_value()` is essentially `getattr()` with a safety valve; it is called as

  ```python
  values.ensure_value(attr, value)
  ```

If the `attr` attribute of `values` doesn’t exist or is `None`, then `ensure_value()` first sets it to `value`, and then returns `value`. This is very handy for actions like `extend`, `append`, and `count`, all of which accumulate data in a variable and expect that variable to
be of a certain type (a list for the first two, an integer for the latter). Using `ensure_value()` means that scripts using your action don’t have to worry about setting a default value for the option destinations in question; they can just leave the default as None and `ensure_value()` will take care of getting it right when it’s needed.
getopt — Parser for command line options

This module helps scripts to parse the command line arguments in `sys.argv`. It supports the same conventions as the Unix `getopt` function (including the special meanings of arguments of the form `'- '` and ` '--'`). Long options similar to those supported by GNU software may be used as well via an optional third argument.

A more convenient, flexible, and powerful alternative is the `optparse` module.

This module provides two functions and an exception:

```python
gopt.getopt(args, options[, long_options])
```

Parses command line options and parameter list. `args` is the argument list to be parsed, without the leading reference to the running program. Typically, this means `sys.argv[1:]`. `options` is the string of option letters that the script wants to recognize, with options that require an argument followed by a colon (`':'`; i.e., the same format that Unix `getopt` uses).

**Note:** Unlike GNU `getopt`, after a non-option argument, all further arguments are considered also non-options. This is similar to the way non-GNU Unix systems work.

`long_options`, if specified, must be a list of strings with the names of the long options which should be supported. The leading `'- '` characters should not be included in the option name. Long options which require an argument should be followed by an equal sign (`'='`). To accept only long options, `options` should be an empty string. Long options on the command line can be
recognized so long as they provide a prefix of the option name that matches exactly one of the accepted options. For example, if `long_options` is `['foo', 'frob']`, the option `--fo` will match as `--foo`, but `--f` will not match uniquely, so `GetoptError` will be raised.

The return value consists of two elements: the first is a list of `(option, value)` pairs; the second is the list of program arguments left after the option list was stripped (this is a trailing slice of `args`). Each option-and-value pair returned has the option as its first element, prefixed with a hyphen for short options (e.g., `-x`) or two hyphens for long options (e.g., `--long-option`), and the option argument as its second element, or an empty string if the option has no argument. The options occur in the list in the same order in which they were found, thus allowing multiple occurrences. Long and short options may be mixed.

```python
gnu_getopt(args, options[, long_options])
```

This function works like `getopt()`, except that GNU style scanning mode is used by default. This means that option and non-option arguments may be intermixed. The `getopt()` function stops processing options as soon as a non-option argument is encountered.

If the first character of the option string is `+`, or if the environment variable `POSIXLY_CORRECT` is set, then option processing stops as soon as a non-option argument is encountered.

`New in version 2.3.`

```python
GetoptError
```

This is raised when an unrecognized option is found in the argument list or when an option requiring an argument is given none. The argument to the exception is a string indicating the
cause of the error. For long options, an argument given to an option which does not require one will also cause this exception to be raised. The attributes msg and opt give the error message and related option; if there is no specific option to which the exception relates, opt is an empty string.

*Changed in version 1.6:* Introduced `GetoptError` as a synonym for `error`.

```python
exception getopt.error

   Alias for GetoptError; for backward compatibility.
```

An example using only Unix style options:

```python
>>> import getopt
>>> args = '-a -b -cfoo -d bar a1 a2'.split()
>>> args
['-a', '-b', '-cfoo', '-d', 'bar', 'a1', 'a2']
>>> optlist, args = getopt.getopt(args, 'abc:d:')
>>> optlist
[('-a', ''), ('-b', ''), ('-c', 'foo'), ('-d', 'bar')]
>>> args
['a1', 'a2']
```

Using long option names is equally easy:

```python
>>> s = '--condition=foo --testing --output-file abc.def -x a1
>>> args = s.split()
>>> args
['--condition=foo', '--testing', '--output-file', 'abc.def', '--output-file', 'abc.def', '-x', 'a1']
>>> optlist, args = getopt.getopt(args, 'x', ['condition=', 'output-file=', 'testing'])
>>> optlist
[('--condition', 'foo'), ('--testing', ''), ('--output-file', 'abc.def'), ('--output-file', 'abc.def'), ('--output-file', 'abc.def')]  
>>> args
['a1', 'a2']
```

In a script, typical usage is something like this:

```python
import getopt, sys
```
def main():
    try:
        opts, args = getopt.getopt(sys.argv[1:], "ho:v", ["help"])
    except getopt.GetoptError, err:
        # print help information and exit:
        print str(err)  # will print something like "option -a not recognized"
        usage()
        sys.exit(2)
    output = None
    verbose = False
    for o, a in opts:
        if o == "-v":
            verbose = True
        elif o in ("-h", "--help"):
            usage()
            sys.exit()
        elif o in ("-o", "--output"):
            output = a
        else:
            assert False, "unhandled option"
    # ...

if __name__ == "__main__":
    main()

Module optparse

More object-oriented command line option parsing.
logging — Logging facility for Python

New in version 2.3.

This module defines functions and classes which implement a flexible error logging system for applications.

Logging is performed by calling methods on instances of the `Logger` class (hereafter called `loggers`). Each instance has a name, and they are conceptually arranged in a namespace hierarchy using dots (periods) as separators. For example, a logger named “scan” is the parent of loggers “scan.text”, “scan.html” and “scan.pdf”. Logger names can be anything you want, and indicate the area of an application in which a logged message originates.

Logged messages also have levels of importance associated with them. The default levels provided are `DEBUG`, `INFO`, `WARNING`, `ERROR` and `CRITICAL`. As a convenience, you indicate the importance of a logged message by calling an appropriate method of `Logger`. The methods are `debug()`, `info()`, `warning()`, `error()` and `critical()`, which mirror the default levels. You are not constrained to use these levels: you can specify your own and use a more general `Logger` method, `log()`, which takes an explicit level argument.
Logging tutorial

The key benefit of having the logging API provided by a standard library module is that all Python modules can participate in logging, so your application log can include messages from third-party modules.

It is, of course, possible to log messages with different verbosity levels or to different destinations. Support for writing log messages to files, HTTP GET/POST locations, email via SMTP, generic sockets, or OS-specific logging mechanisms are all supported by the standard module. You can also create your own log destination class if you have special requirements not met by any of the built-in classes.

Simple examples

Most applications are probably going to want to log to a file, so let's start with that case. Using the `basicConfig()` function, we can set up the default handler so that debug messages are written to a file:

```python
import logging
LOG_FILENAME = '/tmp/logging_example.out'
logging.basicConfig(filename=LOG_FILENAME, level=logging.DEBUG,)
logging.debug('This message should go to the log file')
```

And now if we open the file and look at what we have, we should find the log message:

```
DEBUG:root:This message should go to the log file
```

If you run the script repeatedly, the additional log messages are appended to the file. To create a new file each time, you can pass a
filemode argument to `basicConfig()` with a value of `'w'`. Rather than managing the file size yourself, though, it is simpler to use a `RotatingFileHandler`:

```python
import glob
import logging
import logging.handlers

LOG_FILENAME = '/tmp/logging_rotatingfile_example.out'

# Set up a specific logger with our desired output level
my_logger = logging.getLogger('MyLogger')
my_logger.setLevel(logging.DEBUG)

# Add the log message handler to the logger
handler = logging.handlers.RotatingFileHandler(
    LOG_FILENAME, maxBytes=20, backupCount=5)

my_logger.addHandler(handler)

# Log some messages
for i in range(20):
    my_logger.debug('i = %d' % i)

# See what files are created
logfiles = glob.glob('%s*' % LOG_FILENAME)

for filename in logfiles:
    print filename
```

The result should be 6 separate files, each with part of the log history for the application:

```
/tmp/logging_rotatingfile_example.out
/tmp/logging_rotatingfile_example.out.1
/tmp/logging_rotatingfile_example.out.2
/tmp/logging_rotatingfile_example.out.3
/tmp/logging_rotatingfile_example.out.4
/tmp/logging_rotatingfile_example.out.5
```

The most current file is always `/tmp/logging_rotatingfile_example.out`, and each time it reaches the size limit it is renamed with the suffix `.1`. Each of the existing
backup files is renamed to increment the suffix (.1 becomes .2, etc.) and the .5 file is erased.

Obviously this example sets the log length much much too small as an extreme example. You would want to set maxBytes to an appropriate value.

Another useful feature of the logging API is the ability to produce different messages at different log levels. This allows you to instrument your code with debug messages, for example, but turning the log level down so that those debug messages are not written for your production system. The default levels are CRITICAL, ERROR, WARNING, INFO, DEBUG and UNSET.

The logger, handler, and log message call each specify a level. The log message is only emitted if the handler and logger are configured to emit messages of that level or lower. For example, if a message is CRITICAL, and the logger is set to ERROR, the message is emitted. If a message is a WARNING, and the logger is set to produce only ERRORS, the message is not emitted:

```python
import logging
import sys

LEVELS = {'debug': logging.DEBUG,
          'info': logging.INFO,
          'warning': logging.WARNING,
          'error': logging.ERROR,
          'critical': logging.CRITICAL}

if len(sys.argv) > 1:
    level_name = sys.argv[1]
    level = LEVELS.get(level_name, logging.NOTSET)
    logging.basicConfig(level=level)

logging.debug('This is a debug message')
logging.info('This is an info message')
logging.warning('This is a warning message')
logging.error('This is an error message')
logging.critical('This is a critical error message')
```
Run the script with an argument like ‘debug’ or ‘warning’ to see which messages show up at different levels:

```
$ python logging_level_example.py debug
DEBUG:root:This is a debug message
INFO:root:This is an info message
WARNING:root:This is a warning message
ERROR:root:This is an error message
CRITICAL:root:This is a critical error message
```

```
$ python logging_level_example.py info
INFO:root:This is an info message
WARNING:root:This is a warning message
ERROR:root:This is an error message
CRITICAL:root:This is a critical error message
```

You will notice that these log messages all have root embedded in them. The logging module supports a hierarchy of loggers with different names. An easy way to tell where a specific log message comes from is to use a separate logger object for each of your modules. Each new logger “inherits” the configuration of its parent, and log messages sent to a logger include the name of that logger. Optionally, each logger can be configured differently, so that messages from different modules are handled in different ways. Let’s look at a simple example of how to log from different modules so it is easy to trace the source of the message:

```python
import logging

logging.basicConfig(level=logging.WARNING)

logger1 = logging.getLogger('package1.module1')
logger2 = logging.getLogger('package2.module2')

logger1.warning('This message comes from one module')
logger2.warning('And this message comes from another module')
```

And the output:

```
$ python logging_modules_example.py
WARNING:package1.module1:This message comes from one module
```
There are many more options for configuring logging, including different log message formatting options, having messages delivered to multiple destinations, and changing the configuration of a long-running application on the fly using a socket interface. All of these options are covered in depth in the library module documentation.

Loggers

The logging library takes a modular approach and offers the several categories of components: loggers, handlers, filters, and formatters. Loggers expose the interface that application code directly uses. Handlers send the log records to the appropriate destination. Filters provide a finer grained facility for determining which log records to send on to a handler. Formatters specify the layout of the resultant log record.

Logger objects have a threefold job. First, they expose several methods to application code so that applications can log messages at runtime. Second, logger objects determine which log messages to act upon based upon severity (the default filtering facility) or filter objects. Third, logger objects pass along relevant log messages to all interested log handlers.

The most widely used methods on logger objects fall into two categories: configuration and message sending.

- **Logger.setLevel()** specifies the lowest-severity log message a logger will handle, where debug is the lowest built-in severity level and critical is the highest built-in severity. For example, if the severity level is info, the logger will handle only info, warning, error, and critical messages and will ignore debug messages.
- `Logger.addFilter()` and `Logger.removeFilter()` add and remove filter objects from the logger object. This tutorial does not address filters.

With the logger object configured, the following methods create log messages:

- `Logger.debug()`, `Logger.info()`, `Logger.warning()`, `Logger.error()`, and `Logger.critical()` all create log records with a message and a level that corresponds to their respective method names. The message is actually a format string, which may contain the standard string substitution syntax of `%s`, `%d`, `%f`, and so on. The rest of their arguments is a list of objects that correspond with the substitution fields in the message. With regard to `**kwargs`, the logging methods care only about a keyword of `exc_info` and use it to determine whether to log exception information.

- `Logger.exception()` creates a log message similar to `Logger.error()`. The difference is that `Logger.exception()` dumps a stack trace along with it. Call this method only from an exception handler.

- `Logger.log()` takes a log level as an explicit argument. This is a little more verbose for logging messages than using the log level convenience methods listed above, but this is how to log at custom log levels.

`getLogger()` returns a reference to a logger instance with the specified if it it is provided, or `root` if not. The names are period-separated hierarchical structures. Multiple calls to `getLogger()` with the same name will return a reference to the same logger object. Loggers that are further down in the hierarchical list are children of loggers higher up in the list. For example, given a logger with a name of `foo`, loggers with names of `foo.bar`, `foo.bar.baz`, and
foo.bam are all children of foo. Child loggers propagate messages up to their parent loggers. Because of this, it is unnecessary to define and configure all the loggers an application uses. It is sufficient to configure a top-level logger and create child loggers as needed.

Handlers

Handler objects are responsible for dispatching the appropriate log messages (based on the log messages' severity) to the handler's specified destination. Logger objects can add zero or more handler objects to themselves with an addHandler() method. As an example scenario, an application may want to send all log messages to a log file, all log messages of error or higher to stdout, and all messages of critical to an email address. This scenario requires three individual handlers where each handler is responsible for sending messages of a specific severity to a specific location.

The standard library includes quite a few handler types; this tutorial uses only StreamHandler and FileHandler in its examples.

There are very few methods in a handler for application developers to concern themselves with. The only handler methods that seem relevant for application developers who are using the built-in handler objects (that is, not creating custom handlers) are the following configuration methods:

- The Handler.setLevel() method, just as in logger objects, specifies the lowest severity that will be dispatched to the appropriate destination. Why are there two setLevel() methods? The level set in the logger determines which severity of messages it will pass to its handlers. The level set in each handler determines which messages that handler will send on. setFormatter() selects a Formatter object for this handler to
use.
- `addFilter()` and `removeFilter()` respectively configure and deconfigure filter objects on handlers.

Application code should not directly instantiate and use handlers. Instead, the `Handler` class is a base class that defines the interface that all Handlers should have and establishes some default behavior that child classes can use (or override).

### Formatters

Formatter objects configure the final order, structure, and contents of the log message. Unlike the base `logging.Handler` class, application code may instantiate formatter classes, although you could likely subclass the formatter if your application needs special behavior. The constructor takes two optional arguments: a message format string and a date format string. If there is no message format string, the default is to use the raw message. If there is no date format string, the default date format is:

```plaintext
%Y-%m-%d %H:%M:%S
```

with the milliseconds tacked on at the end.

The message format string uses `%(<dictionary key>)s` styled string substitution; the possible keys are documented in `Formatter Objects`.

The following message format string will log the time in a human-readable format, the severity of the message, and the contents of the message, in that order:

```
"%(asctime)s - %(levelname)s - %(message)s"
```

### Configuring Logging
Programmers can configure logging either by creating loggers, handlers, and formatters explicitly in a main module with the configuration methods listed above (using Python code), or by creating a logging config file. The following code is an example of configuring a very simple logger, a console handler, and a simple formatter in a Python module:

```python
import logging

# create logger
logger = logging.getLogger("simple_example")
logger.setLevel(logging.DEBUG)
# create console handler and set level to debug
ch = logging.StreamHandler()
ch.setLevel(logging.DEBUG)
# create formatter
formatter = logging.Formatter("%(asctime)s - %(name)s - %(levelname)s - %(message)s")
# add formatter to ch
ch.setFormatter(formatter)
# add ch to logger
logger.addHandler(ch)

# "application" code
logger.debug("debug message")
logger.info("info message")
logger.warn("warn message")
logger.error("error message")
logger.critical("critical message")
```

Running this module from the command line produces the following output:

```
$ python simple_logging_module.py
2005-03-19 15:10:26,618 - simple_example - DEBUG - debug message
2005-03-19 15:10:26,620 - simple_example - INFO - info message
2005-03-19 15:10:26,695 - simple_example - WARNING - warn message
2005-03-19 15:10:26,697 - simple_example - ERROR - error message
2005-03-19 15:10:26,773 - simple_example - CRITICAL - critical message
```

The following Python module creates a logger, handler, and formatter nearly identical to those in the example listed above, with
the only difference being the names of the objects:

```python
import logging
import logging.config

logging.config.fileConfig("logging.conf")

# create logger
logger = logging.getLogger("simpleExample")

# "application" code
logger.debug("debug message")
logger.info("info message")
logger.warn("warn message")
logger.error("error message")
logger.critical("critical message")
```

Here is the logging.conf file:

```
[loggers]
keys=root,simpleExample

[handlers]
keys=consoleHandler

[formatters]
keys=simpleFormatter

[logger_root]
level=DEBUG
handlers=consoleHandler

[logger_simpleExample]
level=DEBUG
handlers=consoleHandler
qualname=simpleExample
propagate=0

[handler_consoleHandler]
class=StreamHandler
level=DEBUG
formatter=simpleFormatter
args=(sys.stdout,)

[formatter_simpleFormatter]
format=%(asctime)s - %(name)s - %(levelname)s - %(message)s
datefmt=
```
The output is nearly identical to that of the non-config-file-based example:

```
$ python simple_logging_config.py
2005-03-19 15:38:55,977 - simpleExample - DEBUG - debug message
2005-03-19 15:38:55,979 - simpleExample - INFO - info message
2005-03-19 15:38:56,054 - simpleExample - WARNING - warn message
2005-03-19 15:38:56,055 - simpleExample - ERROR - error message
2005-03-19 15:38:56,130 - simpleExample - CRITICAL - critical message
```

You can see that the config file approach has a few advantages over the Python code approach, mainly separation of configuration and code and the ability of noncoders to easily modify the logging properties.

**Configuring Logging for a Library**

When developing a library which uses logging, some consideration needs to be given to its configuration. If the using application does not use logging, and library code makes logging calls, then a one-off message “No handlers could be found for logger X.Y.Z” is printed to the console. This message is intended to catch mistakes in logging configuration, but will confuse an application developer who is not aware of logging by the library.

In addition to documenting how a library uses logging, a good way to configure library logging so that it does not cause a spurious message is to add a handler which does nothing. This avoids the message being printed, since a handler will be found: it just doesn’t produce any output. If the library user configures logging for application use, presumably that configuration will add some handlers, and if levels are suitably configured then logging calls made in library code will send output to those handlers, as normal.

A do-nothing handler can be simply defined as follows:
An instance of this handler should be added to the top-level logger of the logging namespace used by the library. If all logging by a library `foo` is done using loggers with names matching “foo.x.y”, then the code:

```python
import logging

h = NullHandler()
logging.getLogger("foo").addHandler(h)
```

should have the desired effect. If an organisation produces a number of libraries, then the logger name specified can be “orgname.foo” rather than just “foo”.

```python
import logging
class NullHandler(logging.Handler):
    def emit(self, record):
        pass
```
Logging Levels

The numeric values of logging levels are given in the following table. These are primarily of interest if you want to define your own levels, and need them to have specific values relative to the predefined levels. If you define a level with the same numeric value, it overwrites the predefined value; the predefined name is lost.

<table>
<thead>
<tr>
<th>Level</th>
<th>Numeric value</th>
</tr>
</thead>
<tbody>
<tr>
<td>CRITICAL</td>
<td>50</td>
</tr>
<tr>
<td>ERROR</td>
<td>40</td>
</tr>
<tr>
<td>WARNING</td>
<td>30</td>
</tr>
<tr>
<td>INFO</td>
<td>20</td>
</tr>
<tr>
<td>DEBUG</td>
<td>10</td>
</tr>
<tr>
<td>NOTSET</td>
<td>0</td>
</tr>
</tbody>
</table>

Levels can also be associated with loggers, being set either by the developer or through loading a saved logging configuration. When a logging method is called on a logger, the logger compares its own level with the level associated with the method call. If the logger’s level is higher than the method call’s, no logging message is actually generated. This is the basic mechanism controlling the verbosity of logging output.

Logging messages are encoded as instances of the `LogRecord` class. When a logger decides to actually log an event, a `LogRecord` instance is created from the logging message.

Logging messages are subjected to a dispatch mechanism through the use of `handlers`, which are instances of subclasses of the `Handler` class. Handlers are responsible for ensuring that a logged message (in the form of a `LogRecord`) ends up in a particular location
(or set of locations) which is useful for the target audience for that message (such as end users, support desk staff, system administrators, developers). Handlers are passed LogRecord instances intended for particular destinations. Each logger can have zero, one or more handlers associated with it (via the addHandler() method of Logger). In addition to any handlers directly associated with a logger, all handlers associated with all ancestors of the logger are called to dispatch the message.

Just as for loggers, handlers can have levels associated with them. A handler’s level acts as a filter in the same way as a logger’s level does. If a handler decides to actually dispatch an event, the emit() method is used to send the message to its destination. Most user-defined subclasses of Handler will need to override this emit().

In addition to the base Handler class, many useful subclasses are provided:

1. StreamHandler instances send error messages to streams (file-like objects).
2. FileHandler instances send error messages to disk files.
3. BaseRotatingHandler is the base class for handlers that rotate log files at a certain point. It is not meant to be instantiated directly. Instead, use RotatingFileHandler or TimedRotatingFileHandler.
4. RotatingFileHandler instances send error messages to disk files, with support for maximum log file sizes and log file rotation.
5. TimedRotatingFileHandler instances send error messages to disk files rotating the log file at certain timed intervals.
6. SocketHandler instances send error messages to TCP/IP sockets.
7. DatagramHandler instances send error messages to UDP sockets.
8. **SMTPHandler** instances send error messages to a designated email address.
9. **SysLogHandler** instances send error messages to a Unix syslog daemon, possibly on a remote machine.
10. **NTEventLogHandler** instances send error messages to a Windows NT/2000/XP event log.
11. **MemoryHandler** instances send error messages to a buffer in memory, which is flushed whenever specific criteria are met.
12. **HTTPHandler** instances send error messages to an HTTP server using either **GET** or **POST** semantics.

The **StreamHandler** and **FileHandler** classes are defined in the core logging package. The other handlers are defined in a sub-module, `logging.handlers`. (There is also another sub-module, `logging.config`, for configuration functionality.)

Logged messages are formatted for presentation through instances of the **Formatter** class. They are initialized with a format string suitable for use with the `%` operator and a dictionary.

For formatting multiple messages in a batch, instances of **BufferingFormatter** can be used. In addition to the format string (which is applied to each message in the batch), there is provision for header and trailer format strings.

When filtering based on logger level and/or handler level is not enough, instances of **Filter** can be added to both **Logger** and **Handler** instances (through their `addFilter()` method). Before deciding to process a message further, both loggers and handlers consult all their filters for permission. If any filter returns a false value, the message is not processed further.

The basic **Filter** functionality allows filtering by specific logger name. If this feature is used, messages sent to the named logger
and its children are allowed through the filter, and all others dropped.

In addition to the classes described above, there are a number of module- level functions.

**logging.getLogger([name])**

Return a logger with the specified name or, if no name is specified, return a logger which is the root logger of the hierarchy. If specified, the name is typically a dot-separated hierarchical name like “a”, “a.b” or “a.b.c.d”. Choice of these names is entirely up to the developer who is using logging.

All calls to this function with a given name return the same logger instance. This means that logger instances never need to be passed between different parts of an application.

**logging.getLoggerClass()**

Return either the standard Logger class, or the last class passed to setLoggerClass(). This function may be called from within a new class definition, to ensure that installing a customised Logger class will not undo customisations already applied by other code. For example:

```python
class MyLogger(logging.getLoggerClass()):
    # ... override behaviour here
```

**logging.debug(msg[, args[, **kwargs]])**

Logs a message with level DEBUG on the root logger. The msg is the message format string, and the args are the arguments which are merged into msg using the string formatting operator. (Note that this means that you can use keywords in the format string, together with a single dictionary argument.)

There are two keyword arguments in kwargs which are
inspected: `exc_info` which, if it does not evaluate as false, causes exception information to be added to the logging message. If an exception tuple (in the format returned by `sys.exc_info()`) is provided, it is used; otherwise, `sys.exc_info()` is called to get the exception information.

The other optional keyword argument is `extra` which can be used to pass a dictionary which is used to populate the `__dict__` of the LogRecord created for the logging event with user-defined attributes. These custom attributes can then be used as you like. For example, they could be incorporated into logged messages. For example:

```python
FORMAT = "%(asctime)-15s %(clientip)s %(user)-8s %(message)s"
logging.basicConfig(format=FORMAT)
d = {'clientip': '192.168.0.1', 'user': 'fbloggs'}
logging.warning("Protocol problem: %s", "connection reset",
                extra=d)
```

would print something like

```
2006-02-08 22:20:02,165 192.168.0.1 fbloggs Protocol problem: connection reset
```

The keys in the dictionary passed in `extra` should not clash with the keys used by the logging system. (See the `Formatter` documentation for more information on which keys are used by the logging system.)

If you choose to use these attributes in logged messages, you need to exercise some care. In the above example, for instance, the `Formatter` has been set up with a format string which expects ‘clientip’ and ‘user’ in the attribute dictionary of the LogRecord. If these are missing, the message will not be logged because a string formatting exception will occur. So in this case, you always
need to pass the extra dictionary with these keys.

While this might be annoying, this feature is intended for use in specialized circumstances, such as multi-threaded servers where the same code executes in many contexts, and interesting conditions which arise are dependent on this context (such as remote client IP address and authenticated user name, in the above example). In such circumstances, it is likely that specialized Formatters would be used with particular Handlers.

*Changed in version 2.5: extra was added.*

```python
logging.info(msg[, *args[, **kwargs]])
```

Logs a message with level INFO on the root logger. The arguments are interpreted as for `debug()`.

```python
logging.warning(msg[, *args[, **kwargs]])
```

Logs a message with level WARNING on the root logger. The arguments are interpreted as for `debug()`.

```python
logging.error(msg[, *args[, **kwargs]])
```

Logs a message with level ERROR on the root logger. The arguments are interpreted as for `debug()`.

```python
logging.critical(msg[, *args[, **kwargs]])
```

Logs a message with level CRITICAL on the root logger. The arguments are interpreted as for `debug()`.

```python
logging.exception(msg[, *args])
```

Logs a message with level ERROR on the root logger. The arguments are interpreted as for `debug()`. Exception info is added to the logging message. This function should only be called from an exception handler.
logging. `log(level, msg[, *args[, **kwargs]]])`
Logs a message with level `level` on the root logger. The other arguments are interpreted as for `debug()`.

logging. `disable(lvl)`
Provides an overriding level `lvl` for all loggers which takes precedence over the logger’s own level. When the need arises to temporarily throttle logging output down across the whole application, this function can be useful.

logging. `addLevelName(lvl, levelName)`
Associates level `lvl` with text `levelName` in an internal dictionary, which is used to map numeric levels to a textual representation, for example when a `Formatter` formats a message. This function can also be used to define your own levels. The only constraints are that all levels used must be registered using this function, levels should be positive integers and they should increase in increasing order of severity.

logging. `getLevelName(lvl)`
Returns the textual representation of logging level `lvl`. If the level is one of the predefined levels `CRITICAL`, `ERROR`, `WARNING`, `INFO` or `DEBUG` then you get the corresponding string. If you have associated levels with names using `addLevelName()` then the name you have associated with `lvl` is returned. If a numeric value corresponding to one of the defined levels is passed in, the corresponding string representation is returned. Otherwise, the string “Level %s” % `lvl` is returned.

logging. `makeLogRecord(attrdict)`
Creates and returns a new `LogRecord` instance whose attributes are defined by `attrdict`. This function is useful for taking a pickled `LogRecord` attribute dictionary, sent over a socket, and
reconstituting it as a `LogRecord` instance at the receiving end.

logging.**basicConfig([**kwargs])**

Does basic configuration for the logging system by creating a `StreamHandler` with a default `Formatter` and adding it to the root logger. The function does nothing if any handlers have been defined for the root logger. The functions `debug()`, `info()`, `warning()`, `error()` and `critical()` will call `basicConfig()` automatically if no handlers are defined for the root logger.

This function does nothing if the root logger already has handlers configured.

*Changed in version 2.4:* Formerly, `basicConfig()` did not take any keyword arguments.

The following keyword arguments are supported.

<table>
<thead>
<tr>
<th>Format</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>filename</code></td>
<td>Specifies that a FileHandler be created, using the specified filename, rather than a StreamHandler.</td>
</tr>
<tr>
<td><code>filemode</code></td>
<td>Specifies the mode to open the file, if filename is specified (if filemode is unspecified, it defaults to ‘a’).</td>
</tr>
<tr>
<td><code>format</code></td>
<td>Use the specified format string for the handler.</td>
</tr>
<tr>
<td><code>datefmt</code></td>
<td>Use the specified date/time format.</td>
</tr>
<tr>
<td><code>level</code></td>
<td>Set the root logger level to the specified level.</td>
</tr>
<tr>
<td><code>stream</code></td>
<td>Use the specified stream to initialize the StreamHandler. Note that this argument is incompatible with ‘filename’ - if both are present, ‘stream’ is ignored.</td>
</tr>
</tbody>
</table>

logging.**shutdown()**

Informs the logging system to perform an orderly shutdown by
flushing and closing all handlers. This should be called at application exit and no further use of the logging system should be made after this call.

**logging.setLoggerClass(klass)**

Tells the logging system to use the class `klass` when instantiating a logger. The class should define `__init__()` such that only a name argument is required, and the `__init__()` should call `Logger.__init__()`. This function is typically called before any loggers are instantiated by applications which need to use custom logger behavior.

**See also:**

**PEP 282 - A Logging System**

The proposal which described this feature for inclusion in the Python standard library.

**Original Python logging package**

This is the original source for the `logging` package. The version of the package available from this site is suitable for use with Python 1.5.2, 2.1.x and 2.2.x, which do not include the `logging` package in the standard library.
Logger Objects

Loggers have the following attributes and methods. Note that Loggers are never instantiated directly, but always through the module-level function `logging.getLogger(name)`.

Logger. **propagate**

If this evaluates to false, logging messages are not passed by this logger or by child loggers to higher level (ancestor) loggers. The constructor sets this attribute to 1.

Logger. **setLevel**(lvl)

Sets the threshold for this logger to `lvl`. Logging messages which are less severe than `lvl` will be ignored. When a logger is created, the level is set to **NOTSET** (which causes all messages to be processed when the logger is the root logger, or delegation to the parent when the logger is a non-root logger). Note that the root logger is created with level **WARNING**.

The term “delegation to the parent” means that if a logger has a level of NOTSET, its chain of ancestor loggers is traversed until either an ancestor with a level other than NOTSET is found, or the root is reached.

If an ancestor is found with a level other than NOTSET, then that ancestor's level is treated as the effective level of the logger where the ancestor search began, and is used to determine how a logging event is handled.

If the root is reached, and it has a level of NOTSET, then all messages will be processed. Otherwise, the root's level will be used as the effective level.

Logger. **isEnabledFor**(lvl)
Indicates if a message of severity \textit{lvl} would be processed by this logger. This method checks first the module-level level set by \texttt{logging.disable(lvl)} and then the logger's effective level as determined by \texttt{getEffectiveLevel()}.

\texttt{Logger.getEffectiveLevel()}

Indicates the effective level for this logger. If a value other than \texttt{NOTSET} has been set using \texttt{setLevel()}, it is returned. Otherwise, the hierarchy is traversed towards the root until a value other than \texttt{NOTSET} is found, and that value is returned.

\texttt{Logger.debug(msg[, \*args[, **kwargs]])}

Logs a message with level \texttt{DEBUG} on this logger. The \texttt{msg} is the message format string, and the \texttt{args} are the arguments which are merged into \texttt{msg} using the string formatting operator. (Note that this means that you can use keywords in the format string, together with a single dictionary argument.)

There are two keyword arguments in \texttt{kwargs} which are inspected: \texttt{exc_info} which, if it does not evaluate as false, causes exception information to be added to the logging message. If an exception tuple (in the format returned by \texttt{sys.exc_info()}) is provided, it is used; otherwise, \texttt{sys.exc_info()} is called to get the exception information.

The other optional keyword argument is \texttt{extra} which can be used to pass a dictionary which is used to populate the \texttt{__dict__} of the LogRecord created for the logging event with user-defined attributes. These custom attributes can then be used as you like. For example, they could be incorporated into logged messages.

For example:

\begin{verbatim}
FORMAT = "%(asctime)-15s %(clientip)s %(user)-8s %(message)s"
logging.basicConfig(format=FORMAT)
\end{verbatim}
d = { 'clientip' : '192.168.0.1', 'user' : 'fbloggs' }
logger = logging.getLogger("tcpserver")
logger.warning("Protocol problem: %s", "connection reset", e)

would print something like

```
2006-02-08 22:20:02,165 192.168.0.1 fbloggs Protocol problem: connection reset
```

The keys in the dictionary passed in `extra` should not clash with the keys used by the logging system. (See the `Formatter` documentation for more information on which keys are used by the logging system.)

If you choose to use these attributes in logged messages, you need to exercise some care. In the above example, for instance, the `Formatter` has been set up with a format string which expects ‘clientip’ and ‘user’ in the attribute dictionary of the LogRecord. If these are missing, the message will not be logged because a string formatting exception will occur. So in this case, you always need to pass the `extra` dictionary with these keys.

While this might be annoying, this feature is intended for use in specialized circumstances, such as multi-threaded servers where the same code executes in many contexts, and interesting conditions which arise are dependent on this context (such as remote client IP address and authenticated user name, in the above example). In such circumstances, it is likely that specialized `Formatters` would be used with particular `Handlers`.

*Changed in version 2.5: extra was added.*

```
Logger.info(msg[, *args[, **kwargs]])
```

Logs a message with level `INFO` on this logger. The arguments
are interpreted as for `debug()`.

Logger.

Logger. `warning`(*msg[, *args[, **kwargs]])
Logs a message with level `WARNING` on this logger. The arguments are interpreted as for `debug()`.

Logger. `error`(*msg[, *args[, **kwargs]])
Logs a message with level `ERROR` on this logger. The arguments are interpreted as for `debug()`.

Logger. `critical`(*msg[, *args[, **kwargs]])
Logs a message with level `CRITICAL` on this logger. The arguments are interpreted as for `debug()`.

Logger. `log`(*lvl, *msg[, *args[, **kwargs]])
Logs a message with integer level `lvl` on this logger. The other arguments are interpreted as for `debug()`.

Logger. `exception`(*msg[, *args])
Logs a message with level `ERROR` on this logger. The arguments are interpreted as for `debug()`. Exception info is added to the logging message. This method should only be called from an exception handler.

Logger. `addFilter`(*filt)
Adds the specified filter `filt` to this logger.

Logger. `removeFilter`(*filt)
Removes the specified filter `filt` from this logger.

Logger. `filter`(*record)
Applies this logger's filters to the record and returns a true value
if the record is to be processed.

Logger. **addHandler**(hdlr)

Adds the specified handler hdlr to this logger.

Logger. **removeHandler**(hdlr)

Removes the specified handler hdlr from this logger.

Logger. **findCaller**()

Finds the caller’s source filename and line number. Returns the filename, line number and function name as a 3-element tuple.

*Changed in version 2.4:* The function name was added. In earlier versions, the filename and line number were returned as a 2-element tuple.

Logger. **handle**(record)

Handles a record by passing it to all handlers associated with this logger and its ancestors (until a false value of *propagate* is found). This method is used for unpickled records received from a socket, as well as those created locally. Logger-level filtering is applied using **filter**().

Logger. **makeRecord**(name, lvl, fn, lno, msg, args, exc_info[, func, extra])

This is a factory method which can be overridden in subclasses to create specialized LogRecord instances.

*Changed in version 2.5:* func and extra were added.
Basic example

Changed in version 2.4: formerly `basicConfig()` did not take any keyword arguments.

The `logging` package provides a lot of flexibility, and its configuration can appear daunting. This section demonstrates that simple use of the logging package is possible.

The simplest example shows logging to the console:

```python
import logging

logging.debug('A debug message')
logging.info('Some information')
logging.warning('A shot across the bows')
```

If you run the above script, you'll see this:

```
WARNING:root:A shot across the bows
```

Because no particular logger was specified, the system used the root logger. The debug and info messages didn’t appear because by default, the root logger is configured to only handle messages with a severity of WARNING or above. The message format is also a configuration default, as is the output destination of the messages - `sys.stderr`. The severity level, the message format and destination can be easily changed, as shown in the example below:

```python
import logging

logging.basicConfig(level=logging.DEBUG,  
                    format='%(asctime)s %(levelname)s %(message)s',  
                    filename='/tmp/myapp.log',  
                    filemode='w')

logging.debug('A debug message')
logging.info('Some information')
logging.warning('A shot across the bows')
```
The `basicConfig()` method is used to change the configuration defaults, which results in output (written to `/tmp/myapp.log`) which should look something like the following:

```
2004-07-02 13:00:08,743 DEBUG A debug message
2004-07-02 13:00:08,743 INFO Some information
2004-07-02 13:00:08,743 WARNING A shot across the bows
```

This time, all messages with a severity of DEBUG or above were handled, and the format of the messages was also changed, and output went to the specified file rather than the console.

Formatting uses standard Python string formatting - see section *String Formatting Operations*. The format string takes the following common specifiers. For a complete list of specifiers, consult the `Formatter` documentation.

<table>
<thead>
<tr>
<th>Format</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>%s</code></td>
<td>Name of the logger (logging channel).</td>
</tr>
<tr>
<td><code>%s</code></td>
<td>Text logging level for the message (<code>'DEBUG'</code>, <code>'INFO'</code>, <code>'WARNING'</code>, <code>'ERROR'</code>, <code>'CRITICAL'</code>).</td>
</tr>
<tr>
<td><code>%s</code></td>
<td>Human-readable time when the <code>LogRecord</code> was created. By default this is of the form “2003-07-08 16:49:45,896” (the numbers after the comma are millisecond portion of the time).</td>
</tr>
<tr>
<td><code>%s</code></td>
<td>The logged message.</td>
</tr>
</tbody>
</table>

To change the date/time format, you can pass an additional keyword parameter, `datefmt`, as in the following:

```
import logging
logging.basicConfig(level=logging.DEBUG,
                     format='%(asctime)s %(levelname)-8s %(message)s',
                     datefmt='%a, %d %b %Y %H:%M:%S',
                     filename='/tmp/myapp.log',
```
import logging

logging.basicConfig(level=logging.DEBUG,
    format='%(asctime)s %(levelname)-8s %(message)s',
    datefmt='%a, %d %b %Y %H:%M:%S',
    filename='/temp/myapp.log',
    filemode='w')

logging.error('Pack my box with %d dozen %s', 5, 'liquor jugs')

which would result in

Wed, 21 Jul 2004 15:35:16 ERROR Pack my box with 5 dozen liquor jugs
Logging to multiple destinations

Let's say you want to log to console and file with different message formats and in differing circumstances. Say you want to log messages with levels of DEBUG and higher to file, and those messages at level INFO and higher to the console. Let's also assume that the file should contain timestamps, but the console messages should not. Here's how you can achieve this:

```python
import logging

# set up logging to file - see previous section for more details
logging.basicConfig(level=logging.DEBUG,
    format='%(asctime)s (%name)-12s %(levelname)-8s
    datefmt='%m-%d %H:%M',
    filename='/temp/myapp.log',
    filemode='w')

# define a Handler which writes INFO messages or higher to the console
console = logging.StreamHandler()
console.setLevel(logging.INFO)
# set a format which is simpler for console use
formatter = logging.Formatter('%(name)-12s: %(levelname)-8s
# tell the handler to use this format
console.setFormatter(formatter)
# add the handler to the root logger
logging.getLogger('').addHandler(console)

# Now, we can log to the root logger, or any other logger. First...
logging.info('Jackdaws love my big sphinx of quartz. ')

# Now, define a couple of other loggers which might represent a
# application:

logger1 = logging.getLogger('myapp.area1')
logger2 = logging.getLogger('myapp.area2')

logger1.debug('Quick zephyrs blow, vexing daft Jim.')
logger1.info('How quickly daft jumping zebras vex.')
logger2.warning('Jail zesty vixen who grabbed pay from quack.')
logger2.error('The five boxing wizards jump quickly.')
```

When you run this, on the console you will see
and in the file you will see something like

As you can see, the DEBUG message only shows up in the file. The other messages are sent to both destinations.

This example uses console and file handlers, but you can use any number and combination of handlers you choose.
Adding contextual information to your logging output

Sometimes you want logging output to contain contextual information in addition to the parameters passed to the logging call. For example, in a networked application, it may be desirable to log client-specific information in the log (e.g. remote client's username, or IP address). Although you could use the extra parameter to achieve this, it’s not always convenient to pass the information in this way. While it might be tempting to create Logger instances on a per-connection basis, this is not a good idea because these instances are not garbage collected. While this is not a problem in practice, when the number of Logger instances is dependent on the level of granularity you want to use in logging an application, it could be hard to manage if the number of Logger instances becomes effectively unbounded.

An easy way in which you can pass contextual information to be output along with logging event information is to use the LoggerAdapter class. This class is designed to look like a Logger, so that you can call debug(), info(), warning(), error(), exception(), critical() and log(). These methods have the same signatures as their counterparts in Logger, so you can use the two types of instances interchangeably.

When you create an instance of LoggerAdapter, you pass it a Logger instance and a dict-like object which contains your contextual information. When you call one of the logging methods on an instance of LoggerAdapter, it delegates the call to the underlying instance of Logger passed to its constructor, and arranges to pass the contextual information in the delegated call. Here's a snippet from the code of LoggerAdapter:
def debug(self, msg, *args, **kwargs):  
    """  
    Delegate a debug call to the underlying logger, after adding  
    contextual information from this adapter instance.  
    """  
    msg, kwargs = self.process(msg, kwargs)  
    self.logger.debug(msg, *args, **kwargs)

The process() method of LoggerAdapter is where the contextual information is added to the logging output. It’s passed the message and keyword arguments of the logging call, and it passes back (potentially) modified versions of these to use in the call to the underlying logger. The default implementation of this method leaves the message alone, but inserts an “extra” key in the keyword argument whose value is the dict-like object passed to the constructor. Of course, if you had passed an “extra” keyword argument in the call to the adapter, it will be silently overwritten.

The advantage of using “extra” is that the values in the dict-like object are merged into the LogRecord instance’s __dict__, allowing you to use customized strings with your Formatter instances which know about the keys of the dict-like object. If you need a different method, e.g. if you want to prepend or append the contextual information to the message string, you just need to subclass LoggerAdapter and override process() to do what you need. Here’s an example script which uses this class, which also illustrates what dict-like behaviour is needed from an arbitrary “dict-like” object for use in the constructor:

import logging

class ConnInfo:  
    """  
    An example class which shows how an arbitrary class can be  
    the 'extra' context information repository passed to a Logg  
    """
def __getitem__(self, name):
    """To allow this instance to look like a dict. """
    from random import choice
    if name == "ip":
        result = choice(["127.0.0.1", "192.168.0.1" Brom
    elif name == "user":
        result = choice(["jim", "fred", "sheila"])
    else:
        result = self.__dict__.get(name, "?")
    return result

def __iter__(self):
    """To allow iteration over keys, which will be merged into the LogRecord dict before formatting and output. """
    keys = ["ip", "user"]
    keys.extend(self.__dict__.keys())
    return keys.__iter__()

if __name__ == "__main__":
    from random import choice
    levels = (logging.DEBUG, logging.INFO, logging.WARNING, logging.ERROR)
    a1 = logging.LoggerAdapter(logging.getLogger("a.b.c"),
                      { "ip" : "123.231.231.123", "user": "jim"})
    logging.basicConfig(level=logging.DEBUG,
                        format="%(asctime)-15s %(name)-5s %(levelname)-8s %(message)s"
                      )
    a1.debug("A debug message")
    a1.info("An info message with %s", "some parameters")
    a2 = logging.LoggerAdapter(logging.getLogger("d.e.f"), Conn
    for x in range(10):
        lvl = choice(levels)
        lvlname = logging.getLevelName(lvl)
        a2.log(lvl, "A message at %s level with %d %s", lvlname, x, "args")

When this script is run, the output should look something like this:
New in version 2.6.

The **LoggerAdapter** class was not present in previous versions.
Sending and receiving logging events across a network

Let's say you want to send logging events across a network, and handle them at the receiving end. A simple way of doing this is attaching a `SocketHandler` instance to the root logger at the sending end:

```python
import logging, logging.handlers

rootLogger = logging.getLogger('')
rootLogger.setLevel(logging.DEBUG)
socketHandler = logging.handlers.SocketHandler('localhost',
                                               logging.handlers.DEFAULT_TCP_LOGGING_PORT)

# don't bother with a formatter, since a socket handler sends t
# an unformatted pickle
rootLogger.addHandler(socketHandler)

# Now, we can log to the root logger, or any other logger. First
logging.info('Jackdaws love my big sphinx of quartz.

# Now, define a couple of other loggers which might represent a
# application:

logger1 = logging.getLogger('myapp.area1')
logger2 = logging.getLogger('myapp.area2')

logger1.debug('Quick zephyrs blow, vexing daft Jim.
logger1.info('How quickly daft jumping zebras vex.
logger2.warning('Jail zesty vixen who grabbed pay from quack.
logger2.error('The five boxing wizards jump quickly.
```

At the receiving end, you can set up a receiver using the `SocketServer` module. Here is a basic working example:

```python
import cPickle
import logging
import logging.handlers
import SocketServer
import struct
```
class LogRecordStreamHandler(SocketServer.StreamRequestHandler):
    """Handler for a streaming logging request.
    This basically logs the record using whatever logging policy is configured locally.
    """
    def handle(self):
        """Handle multiple requests - each expected to be a 4-byte length, followed by the LogRecord in pickle format. Logs the record according to whatever policy is configured locally.
        """
        while 1:
            chunk = self.connection.recv(4)
            if len(chunk) < 4:
                break
            slen = struct.unpack(">L", chunk)[0]
            chunk = self.connection.recv(slen)
            while len(chunk) < slen:
                chunk = chunk + self.connection.recv(slen - len(chunk))
            obj = self.unPickle(chunk)
            record = logging.makeLogRecord(obj)
            self.handleLogRecord(record)

    def unPickle(self, data):
        return cPickle.loads(data)

    def handleLogRecord(self, record):
        # if a name is specified, we use the named logger rather than the one implied by the record.
        if self.server.logname is not None:
            name = self.server.logname
        else:
            name = record.name
        logger = logging.getLogger(name)
        # N.B. EVERY record gets logged. This is because Logger.handle is normally called AFTER logger-level filtering. If you want to do filtering, do it at the client end to save wasted cycles and network bandwidth!
        logger.handle(record)

class LogRecordSocketReceiver(SocketServer.ThreadingTCPServer):
    """""""simple TCP socket-based logging receiver suitable for testing"""
    allow_reuse_address = 1
def __init__(self, host='localhost',
            port=logging.handlers.DEFAULT_TCP_LOGGING_PORT
            handler=LogRecordStreamHandler):
    SocketServer.ThreadingTCPServer.__init__(self, (host, p
self.abort = 0
self.timeout = 1
self.logname = None

def serve_until_stopped(self):
    import select
abort = 0
while not abort:
    rd, wr, ex = select.select([self.socket.fileno()],
                               [], [],
                        self.timeout)

    if rd:
        self.handle_request()
    abort = self.abort

def main():
    logging.basicConfig(format="%(
        relativeCreated)5d %(name)-15s %(levelname)-8s'
tcpserver = LogRecordSocketReceiver()
print "About to start TCP server..."
tcpserver.serve_until_stopped()

if __name__ == "__main__":
    main()

First run the server, and then the client. On the client side, nothing is
printed on the console; on the server side, you should see something
like:

About to start TCP server...
59 root INFO Jackdaws love my big sphinx of quartz.
59 myapp.area1 DEBUG Quick zephyrs blow, vexing daft Jim.
69 myapp.area1 INFO How quickly daft jumping zebras vex.
69 myapp.area2 WARNING Jail zesty vixen who grabbed pay
69 myapp.area2 ERROR The five boxing wizards jump quickly.
**Handler Objects**

Handlers have the following attributes and methods. Note that **Handler** is never instantiated directly; this class acts as a base for more useful subclasses. However, the `__init__()` method in subclasses needs to call `Handler.__init__()`.

**Handler.** __init__**(level=NOTSET)**  
Initializes the **Handler** instance by setting its level, setting the list of filters to the empty list and creating a lock (using `createLock()`) for serializing access to an I/O mechanism.

**Handler.** createLock**( )**  
Initializes a thread lock which can be used to serialize access to underlying I/O functionality which may not be threadsafe.

**Handler.** acquire**( )**  
Acquires the thread lock created with `createLock()`.

**Handler.** release**( )**  
Releases the thread lock acquired with `acquire()`.

**Handler.** setLevel**(lvl)**  
Sets the threshold for this handler to `lvl`. Logging messages which are less severe than `lvl` will be ignored. When a handler is created, the level is set to `NOTSET` (which causes all messages to be processed).

**Handler.** setFormatter**(form)**  
Sets the **Formatter** for this handler to `form`.

**Handler.** addFilter**(filt)**
Adds the specified filter \textit{filt} to this handler.

\texttt{Handler.removeFilter(filt)}

Removes the specified filter \textit{filt} from this handler.

\texttt{Handler.filter(record)}

Applies this handler's filters to the record and returns a true value if the record is to be processed.

\texttt{Handler.flush()}

Ensure all logging output has been flushed. This version does nothing and is intended to be implemented by subclasses.

\texttt{Handler.close()}

Tidy up any resources used by the handler. This version does no output but removes the handler from an internal list of handlers which is closed when \texttt{shutdown()} is called. Subclasses should ensure that this gets called from overridden \texttt{close()} methods.

\texttt{Handler.handle(record)}

Conditionally emits the specified logging record, depending on filters which may have been added to the handler. Wraps the actual emission of the record with acquisition/release of the I/O thread lock.

\texttt{Handler.handleError(record)}

This method should be called from handlers when an exception is encountered during an \texttt{emit()} call. By default it does nothing, which means that exceptions get silently ignored. This is what is mostly wanted for a logging system - most users will not care about errors in the logging system, they are more interested in application errors. You could, however, replace this with a custom handler if you wish. The specified record is the one which was being processed when the exception occurred.
Handler. **format**(*record*)

Do formatting for a record - if a formatter is set, use it. Otherwise, use the default formatter for the module.

Handler. **emit**(*record*)

Do whatever it takes to actually log the specified logging record. This version is intended to be implemented by subclasses and so raises a `NotImplementedError`.

### StreamHandler

The **StreamHandler** class, located in the core **logging** package, sends logging output to streams such as `sys.stdout`, `sys.stderr` or any file-like object (or, more precisely, any object which supports `write()` and `flush()` methods).

```python
class logging.StreamHandler([strm])
    Returns a new instance of the **StreamHandler** class. If `strm` is specified, the instance will use it for logging output; otherwise, `sys.stderr` will be used.

    **emit**(*record*)
        If a formatter is specified, it is used to format the record. The record is then written to the stream with a trailing newline. If exception information is present, it is formatted using `traceback.print_exception()` and appended to the stream.

    **flush**()
        Flushes the stream by calling its `flush()` method. Note that the `close()` method is inherited from **Handler** and so does no output, so an explicit `flush()` call may be needed at times.
```

### FileHandler
The FileHandler class, located in the core logging package, sends logging output to a disk file. It inherits the output functionality from StreamHandler.

class logging.FileHandler(filename[, mode[, encoding[, delay]]])

Returns a new instance of the FileHandler class. The specified file is opened and used as the stream for logging. If mode is not specified, 'a' is used. If encoding is not None, it is used to open the file with that encoding. If delay is true, then file opening is deferred until the first call to emit(). By default, the file grows indefinitely.

close()

Closes the file.

emit(record)

Outputs the record to the file.

WatchedFileHandler

New in version 2.6.

The WatchedFileHandler class, located in the logging.handlers module, is a FileHandler which watches the file it is logging to. If the file changes, it is closed and reopened using the file name.

A file change can happen because of usage of programs such as newsyslog and logrotate which perform log file rotation. This handler, intended for use under Unix/Linux, watches the file to see if it has changed since the last emit. (A file is deemed to have changed if its device or inode have changed.) If the file has changed, the old file stream is closed, and the file opened to get a new stream.

This handler is not appropriate for use under Windows, because
under Windows open log files cannot be moved or renamed - logging opens the files with exclusive locks - and so there is no need for such a handler. Furthermore, ST_INO is not supported under Windows; stat() always returns zero for this value.

```python
class logging.WatchedFileHandler(filename[, mode[, encoding[, delay]]])
```

Returns a new instance of the `WatchedFileHandler` class. The specified file is opened and used as the stream for logging. If `mode` is not specified, 'a' is used. If `encoding` is not `None`, it is used to open the file with that encoding. If `delay` is true, then file opening is deferred until the first call to `emit()`. By default, the file grows indefinitely.

```python
class logging.RotatingFileHandler(filename[, mode[, maxBytes[, backupCount[, encoding[, delay]]]]])
```

Returns a new instance of the `RotatingFileHandler` class. The specified file is opened and used as the stream for logging. If `mode` is not specified, 'a' is used. If `encoding` is not `None`, it is used to open the file with that encoding. If `delay` is true, then file opening is deferred until the first call to `emit()`. By default, the file...
grows indefinitely.

You can use the `maxBytes` and `backupCount` values to allow the file to rollover at a predetermined size. When the size is about to be exceeded, the file is closed and a new file is silently opened for output. Rollover occurs whenever the current log file is nearly `maxBytes` in length; if `maxBytes` is zero, rollover never occurs. If `backupCount` is non-zero, the system will save old log files by appending the extensions “.1”, “.2” etc., to the filename. For example, with a `backupCount` of 5 and a base file name of `app.log`, you would get `app.log`, `app.log.1`, `app.log.2`, up to `app.log.5`. The file being written to is always `app.log`. When this file is filled, it is closed and renamed to `app.log.1`, and if files `app.log.1`, `app.log.2`, etc. exist, then they are renamed to `app.log.2`, `app.log.3` etc. respectively.

**doRollover()**

Does a rollover, as described above.

**emit(record)**

Outputs the record to the file, catering for rollover as described previously.

---

**TimedRotatingFileHandler**

The `TimedRotatingFileHandler` class, located in the `logging.handlers` module, supports rotation of disk log files at certain timed intervals.

```python
class logging.TimedRotatingFileHandler(filename[, when[, interval[, backupCount[, encoding[, delay[, utc]]]]]])
```

Returns a new instance of the `TimedRotatingFileHandler` class. The specified file is opened and used as the stream for logging.
On rotating it also sets the filename suffix. Rotating happens based on the product of \textit{when} and \textit{interval}.

You can use the \textit{when} to specify the type of \textit{interval}. The list of possible values is below. Note that they are not case sensitive.

<table>
<thead>
<tr>
<th>Value</th>
<th>Type of interval</th>
</tr>
</thead>
<tbody>
<tr>
<td>'S'</td>
<td>Seconds</td>
</tr>
<tr>
<td>'M'</td>
<td>Minutes</td>
</tr>
<tr>
<td>'H'</td>
<td>Hours</td>
</tr>
<tr>
<td>'D'</td>
<td>Days</td>
</tr>
<tr>
<td>'W'</td>
<td>Week day (0=Monday)</td>
</tr>
<tr>
<td>'midnight'</td>
<td>Roll over at midnight</td>
</tr>
</tbody>
</table>

The system will save old log files by appending extensions to the filename. The extensions are date-and-time based, using the \texttt{strftime} format \texttt{%Y-%m-%d\_%H-%M-%S} or a leading portion thereof, depending on the rollover interval. If the \texttt{utc} argument is true, times in UTC will be used; otherwise local time is used.

If \texttt{backupCount} is nonzero, at most \texttt{backupCount} files will be kept, and if more would be created when rollover occurs, the oldest one is deleted. The deletion logic uses the interval to determine which files to delete, so changing the interval may leave old files lying around.

\texttt{doRollover()}

Does a rollover, as described above.

\texttt{emit(record)}

Outputs the record to the file, catering for rollover as described above.

\textbf{SocketHandler}
The **SocketHandler** class, located in the `logging.handlers` module, sends logging output to a network socket. The base class uses a TCP socket.

```python
class logging.SocketHandler(host, port)
    Returns a new instance of the SocketHandler class intended to communicate with a remote machine whose address is given by `host` and `port`.

close()
    Closes the socket.

emit()
    Pickles the record’s attribute dictionary and writes it to the socket in binary format. If there is an error with the socket, silently drops the packet. If the connection was previously lost, re-establishes the connection. To unpickle the record at the receiving end into a LogRecord, use the makeLogRecord() function.

handleError()
    Handles an error which has occurred during `emit()`. The most likely cause is a lost connection. Closes the socket so that we can retry on the next event.

makeSocket()
    This is a factory method which allows subclasses to define the precise type of socket they want. The default implementation creates a TCP socket (socket.SOCK_STREAM).

makePickle(record)
    Pickles the record’s attribute dictionary in binary format with a length prefix, and returns it ready for transmission across the socket.
```
**send**(*packet*)  
Send a pickled string *packet* to the socket. This function allows for partial sends which can happen when the network is busy.

### DatagramHandler

The **DatagramHandler** class, located in the `logging.handlers` module, inherits from `SocketHandler` to support sending logging messages over UDP sockets.

```python
class logging.DatagramHandler(host, port):
    Returns a new instance of the DatagramHandler class intended to communicate with a remote machine whose address is given by host and port.
```

**emit()**  
Pickles the record’s attribute dictionary and writes it to the socket in binary format. If there is an error with the socket, silently drops the packet. To unpickle the record at the receiving end into a LogRecord, use the `makeLogRecord()` function.

**makeSocket()**  
The factory method of `SocketHandler` is here overridden to create a UDP socket (`socket.SOCK_DGRAM`).

**send(s)**  
Send a pickled string to a socket.

### SysLogHandler

The **SysLogHandler** class, located in the `logging.handlers` module, supports sending logging messages to a remote or local Unix syslog.
class logging.SysLogHandler([address[, facility]])

Returns a new instance of the SysLogHandler class intended to communicate with a remote Unix machine whose address is given by address in the form of a (host, port) tuple. If address is not specified, ('localhost', 514) is used. The address is used to open a UDP socket. An alternative to providing a (host, port) tuple is providing an address as a string, for example “/dev/log”. In this case, a Unix domain socket is used to send the message to the syslog. If facility is not specified, LOG_USER is used.

close()

Closes the socket to the remote host.

emit(record)

The record is formatted, and then sent to the syslog server. If exception information is present, it is not sent to the server.

encodePriority(facility, priority)

Encodes the facility and priority into an integer. You can pass in strings or integers - if strings are passed, internal mapping dictionaries are used to convert them to integers.

NTEventLogHandler

The NTEventLogHandler class, located in the logging.handlers module, supports sending logging messages to a local Windows NT, Windows 2000 or Windows XP event log. Before you can use it, you need Mark Hammond’s Win32 extensions for Python installed.

class logging.NTEventLogHandler(appname[, dllname[, logtype]])

Returns a new instance of the NTEventLogHandler class. The appname is used to define the application name as it appears in the event log. An appropriate registry entry is created using this
name. The \textit{dllname} should give the fully qualified pathname of a .dll or .exe which contains message definitions to hold in the log (if not specified, \texttt{\textquotesingle}win32service.pyd\textquotesingle{} is used - this is installed with the Win32 extensions and contains some basic placeholder message definitions. Note that use of these placeholders will make your event logs big, as the entire message source is held in the log. If you want slimmer logs, you have to pass in the name of your own .dll or .exe which contains the message definitions you want to use in the event log). The \textit{logtype} is one of \texttt{\textquotesingle}Application\textquotesingle{}, \texttt{\textquotesingle}System\textquotesingle{} or \texttt{\textquotesingle}Security\textquotesingle{}, and defaults to \texttt{\textquotesingle}Application\textquotesingle{}.

\texttt{close()}  
At this point, you can remove the application name from the registry as a source of event log entries. However, if you do this, you will not be able to see the events as you intended in the Event Log Viewer - it needs to be able to access the registry to get the .dll name. The current version does not do this.

\texttt{emit(record)}
Determines the message ID, event category and event type, and then logs the message in the NT event log.

\texttt{getEventCategory(record)}
Returns the event category for the record. Override this if you want to specify your own categories. This version returns 0.

\texttt{getEventType(record)}
Returns the event type for the record. Override this if you want to specify your own types. This version does a mapping using the handler's typemap attribute, which is set up in \texttt{\_\_init\_()} to a dictionary which contains mappings for \texttt{DEBUG}, \texttt{INFO}, \texttt{WARNING}, \texttt{ERROR} and \texttt{CRITICAL}. If you are using your own
levels, you will either need to override this method or place a suitable dictionary in the handler’s typemap attribute.

**getMessageID(record)**

Returns the message ID for the record. If you are using your own messages, you could do this by having the `msg` passed to the logger being an ID rather than a format string. Then, in here, you could use a dictionary lookup to get the message ID. This version returns 1, which is the base message ID in `win32service.pyd`.

### SMTPHandler

The **SMTPHandler** class, located in the `logging.handlers` module, supports sending logging messages to an email address via SMTP.

```python
class logging.SMTPHandler(mailhost, fromaddr, toaddrs, subject[, credentials])
```

Returns a new instance of the `SMTPHandler` class. The instance is initialized with the from and to addresses and subject line of the email. The `toaddrs` should be a list of strings. To specify a non-standard SMTP port, use the (host, port) tuple format for the `mailhost` argument. If you use a string, the standard SMTP port is used. If your SMTP server requires authentication, you can specify a (username, password) tuple for the `credentials` argument.

*Changed in version 2.6: credentials was added.*

**emit(record)**

Formats the record and sends it to the specified addressees.

**getSubject(record)**

If you want to specify a subject line which is record-
dependent, override this method.

## MemoryHandler

The *MemoryHandler* class, located in the *logging.handlers* module, supports buffering of logging records in memory, periodically flushing them to a *target* handler. Flushing occurs whenever the buffer is full, or when an event of a certain severity or greater is seen.

*MemoryHandler* is a subclass of the more general *BufferingHandler*, which is an abstract class. This buffers logging records in memory. Whenever each record is added to the buffer, a check is made by calling *shouldFlush()* to see if the buffer should be flushed. If it should, then *flush()* is expected to do the needful.

```python
class logging.BufferingHandler(capacity):
    Initializes the handler with a buffer of the specified capacity.

    emit(record)
    Appends the record to the buffer. If *shouldFlush()* returns true, calls *flush()* to process the buffer.

    flush()
    You can override this to implement custom flushing behavior. This version just zaps the buffer to empty.

    shouldFlush(record)
    Returns true if the buffer is up to capacity. This method can be overridden to implement custom flushing strategies.
```

```python
class logging.MemoryHandler(capacity[, flushLevel[, target]])
    Returns a new instance of the *MemoryHandler* class. The instance is initialized with a buffer size of *capacity*. If *flushLevel* is not specified, *ERROR* is used. If no *target* is specified, the target will
need to be set using `setTarget()` before this handler does anything useful.

`close()`
Calls `flush()`, sets the target to `None` and clears the buffer.

`flush()`
For a `MemoryHandler`, flushing means just sending the buffered records to the target, if there is one. Override if you want different behavior.

`setTarget(target)`
Sets the target handler for this handler.

`shouldFlush(record)`
Checks for buffer full or a record at the `flushLevel` or higher.

**HTTPHandler**

The `HTTPHandler` class, located in the `logging.handlers` module, supports sending logging messages to a Web server, using either GET or POST semantics.

```python
class logging.HTTPHandler(host, url[, method])
```
Returns a new instance of the `HTTPHandler` class. The instance is initialized with a host address, url and HTTP method. The `host` can be of the form `host:port`, should you need to use a specific port number. If no `method` is specified, `GET` is used.

`emit(record)`
Sends the record to the Web server as an URL-encoded dictionary.
Formatter Objects

Formatters have the following attributes and methods. They are responsible for converting a LogRecord to (usually) a string which can be interpreted by either a human or an external system. The base Formatter allows a formatting string to be specified. If none is supplied, the default value of '%(message)s' is used.

A Formatter can be initialized with a format string which makes use of knowledge of the LogRecord attributes - such as the default value mentioned above making use of the fact that the user’s message and arguments are pre-formatted into a LogRecord’s message attribute. This format string contains standard python %-style mapping keys. See section String Formatting Operations for more information on string formatting.

Currently, the useful mapping keys in a LogRecord are:

<table>
<thead>
<tr>
<th>Format</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>%(name)s</td>
<td>Name of the logger (logging channel).</td>
</tr>
<tr>
<td>%(levelname)s</td>
<td>Text logging level for the message ('DEBUG', 'INFO', 'WARNING', 'ERROR', 'CRITICAL').</td>
</tr>
<tr>
<td>%(pathname)s</td>
<td>Full pathname of the source file where the logging call was issued (if available).</td>
</tr>
<tr>
<td>%(filename)s</td>
<td>Filename portion of pathname.</td>
</tr>
<tr>
<td>%(module)s</td>
<td>Module (name portion of filename).</td>
</tr>
<tr>
<td>%(funcName)s</td>
<td>Name of function containing the logging call.</td>
</tr>
<tr>
<td>%(lineno)d</td>
<td>Source line number where the logging call was issued (if available).</td>
</tr>
<tr>
<td>Format</td>
<td>Description</td>
</tr>
<tr>
<td>---------------</td>
<td>----------------------------------------------------------------------------------------------</td>
</tr>
<tr>
<td>%(created)f</td>
<td>Time when the LogRecord was created (as returned by <code>time.time()</code>).</td>
</tr>
<tr>
<td>%(relativeCreated)d</td>
<td>Time in milliseconds when the LogRecord was created, relative to the time the logging module was loaded.</td>
</tr>
<tr>
<td>%(asctime)s</td>
<td>Human-readable time when the LogRecord was created. By default this is of the form “2003-07-08 16:49:45,896” (the numbers after the comma are millisecond portion of the time).</td>
</tr>
<tr>
<td>%(msecs)d</td>
<td>Millisecond portion of the time when the LogRecord was created.</td>
</tr>
<tr>
<td>%(thread)d</td>
<td>Thread ID (if available).</td>
</tr>
<tr>
<td>%(threadName)s</td>
<td>Thread name (if available).</td>
</tr>
<tr>
<td>%(process)d</td>
<td>Process ID (if available).</td>
</tr>
<tr>
<td>%(message)s</td>
<td>The logged message, computed as <code>msg % args</code>.</td>
</tr>
</tbody>
</table>

*Changed in version 2.5: `funcName` was added.*

```python
class logging.Formatter([fmt[, datefmt]])
```

Returns a new instance of the `Formatter` class. The instance is initialized with a format string for the message as a whole, as well as a format string for the date/time portion of a message. If no `fmt` is specified, `'%(message)s'` is used. If no `datefmt` is specified, the ISO8601 date format is used.

```python
format(record)
```

The record’s attribute dictionary is used as the operand to a string formatting operation. Returns the resulting string. Before formatting the dictionary, a couple of preparatory steps are carried out. The `message` attribute of the record is computed using `msg % args`. If the formatting string contains `'%(asctime)'`, `formatTime()` is called to format the event time.
If there is exception information, it is formatted using `formatException()` and appended to the message. Note that the formatted exception information is cached in attribute `exc_text`. This is useful because the exception information can be pickled and sent across the wire, but you should be careful if you have more than one `Formatter` subclass which customizes the formatting of exception information. In this case, you will have to clear the cached value after a formatter has done its formatting, so that the next formatter to handle the event doesn’t use the cached value but recalculates it afresh.

`formatTime(record[, datefmt])`

This method should be called from `format()` by a formatter which wants to make use of a formatted time. This method can be overridden in formatters to provide for any specific requirement, but the basic behavior is as follows: if `datefmt` (a string) is specified, it is used with `time.strftime()` to format the creation time of the record. Otherwise, the ISO8601 format is used. The resulting string is returned.

`formatException(exc_info)`

Formats the specified exception information (a standard exception tuple as returned by `sys.exc_info()`) as a string. This default implementation just uses `traceback.print_exception()`. The resulting string is returned.
Filter Objects

Filters can be used by Handlers and Loggers for more sophisticated filtering than is provided by levels. The base filter class only allows events which are below a certain point in the logger hierarchy. For example, a filter initialized with “A.B” will allow events logged by loggers “A.B”, “A.B.C”, “A.B.C.D”, “A.B.D” etc. but not “A.BB”, “B.A.B” etc. If initialized with the empty string, all events are passed.

class logging.Filter([name])

Returns an instance of the Filter class. If name is specified, it names a logger which, together with its children, will have its events allowed through the filter. If no name is specified, allows every event.

filter(record)

Is the specified record to be logged? Returns zero for no, nonzero for yes. If deemed appropriate, the record may be modified in-place by this method.
LogRecord Objects

LogRecord instances are created every time something is logged. They contain all the information pertinent to the event being logged. The main information passed in is in msg and args, which are combined using msg % args to create the message field of the record. The record also includes information such as when the record was created, the source line where the logging call was made, and any exception information to be logged.

class logging. LogRecord(name, lvl, pathname, lineno, msg, args, exc_info[, func])

Returns an instance of LogRecord initialized with interesting information. The name is the logger name; lvl is the numeric level; pathname is the absolute pathname of the source file in which the logging call was made; lineno is the line number in that file where the logging call is found; msg is the user-supplied message (a format string); args is the tuple which, together with msg, makes up the user message; and exc_info is the exception tuple obtained by calling sys.exc_info() (or None, if no exception information is available). The func is the name of the function from which the logging call was made. If not specified, it defaults to None.

Changed in version 2.5: func was added.

getMessage()

Returns the message for this LogRecord instance after merging any user-supplied arguments with the message.
LoggerAdapter Objects

New in version 2.6.

LoggerAdapter instances are used to conveniently pass contextual information into logging calls. For a usage example, see the section on adding contextual information to your logging output.

class logging.LoggerAdapter(logger, extra)

Returns an instance of LoggerAdapter initialized with an underlying Logger instance and a dict-like object.

process(msg, kwargs)

Modifies the message and/or keyword arguments passed to a logging call in order to insert contextual information. This implementation takes the object passed as extra to the constructor and adds it to kwargs using key ‘extra’. The return value is a (msg, kwargs) tuple which has the (possibly modified) versions of the arguments passed in.

In addition to the above, LoggerAdapter supports all the logging methods of Logger, i.e. debug(), info(), warning(), error(), exception(), critical() and log(). These methods have the same signatures as their counterparts in Logger, so you can use the two types of instances interchangeably.
Thread Safety

The logging module is intended to be thread-safe without any special work needing to be done by its clients. It achieves this though using threading locks; there is one lock to serialize access to the module's shared data, and each handler also creates a lock to serialize access to its underlying I/O.
Configuration

Configuration functions

The following functions configure the logging module. They are located in the `logging.config` module. Their use is optional — you can configure the logging module using these functions or by making calls to the main API (defined in `logging` itself) and defining handlers which are declared either in `logging` or `logging.handlers`.

`logging.fileConfig(fname[, defaults])`

Reads the logging configuration from a ConfigParser-format file named `fname`. This function can be called several times from an application, allowing an end user the ability to select from various pre-canned configurations (if the developer provides a mechanism to present the choices and load the chosen configuration). Defaults to be passed to ConfigParser can be specified in the `defaults` argument.

`logging.listen([port])`

Starts up a socket server on the specified port, and listens for new configurations. If no port is specified, the module's default `DEFAULT_LOGGING_CONFIG_PORT` is used. Logging configurations will be sent as a file suitable for processing by `fileConfig()`. Returns a `Thread` instance on which you can call `start()` to start the server, and which you can `join()` when appropriate. To stop the server, call `stopListening()`.

To send a configuration to the socket, read in the configuration file and send it to the socket as a string of bytes preceded by a four-byte length string packed in binary using `struct.pack('>L',
logging.stopListening()

Stops the listening server which was created with a call to listen(). This is typically called before calling join() on the return value from listen().

Configuration file format

The configuration file format understood by fileConfig() is based on ConfigParser functionality. The file must contain sections called [loggers], [handlers] and [formatters] which identify by name the entities of each type which are defined in the file. For each such entity, there is a separate section which identified how that entity is configured. Thus, for a logger named log01 in the [loggers] section, the relevant configuration details are held in a section [logger_log01]. Similarly, a handler called hand01 in the [handlers] section will have its configuration held in a section called [handler_hand01], while a formatter called form01 in the [formatters] section will have its configuration specified in a section called [formatter_form01]. The root logger configuration must be specified in a section called [logger_root].

Examples of these sections in the file are given below.

```
[loggers]
keys=root,log02,log03,log04,log05,log06,log07

[handlers]
keys=hand01,hand02,hand03,hand04,hand05,hand06,hand07,hand08,ha

[formatters]
keys=form01/form02/form03/form04/form05/form06/form07/form08,fo
```

The root logger must specify a level and a list of handlers. An
example of a root logger section is given below.

```ini
[logger_root]
level=NOTSET
handlers=hand01
```

The `level` entry can be one of `DEBUG`, `INFO`, `WARNING`, `ERROR`, `CRITICAL` or `NOTSET`. For the root logger only, `NOTSET` means that all messages will be logged. Level values are `eval()`uated in the context of the `logging` package’s namespace.

The `handlers` entry is a comma-separated list of handler names, which must appear in the `[handlers]` section. These names must appear in the `[handlers]` section and have corresponding sections in the configuration file.

For loggers other than the root logger, some additional information is required. This is illustrated by the following example.

```ini
[logger_parser]
level=DEBUG
handlers=hand01
propagate=1
qualname=compiler.parser
```

The `level` and `handlers` entries are interpreted as for the root logger, except that if a non-root logger’s level is specified as `NOTSET`, the system consults loggers higher up the hierarchy to determine the effective level of the logger. The `propagate` entry is set to 1 to indicate that messages must propagate to handlers higher up the logger hierarchy from this logger, or 0 to indicate that messages are not propagated to handlers up the hierarchy. The `qualname` entry is the hierarchical channel name of the logger, that is to say the name used by the application to get the logger.

Sections which specify handler configuration are exemplified by the
following.

The `class` entry indicates the handler’s class (as determined by `eval()` in the `logging` package’s namespace). The `level` is interpreted as for loggers, and `NOTSET` is taken to mean “log everything”.

*Changed in version 2.6:* Added support for resolving the handler’s class as a dotted module and class name.

The `formatter` entry indicates the key name of the formatter for this handler. If blank, a default formatter (`logging._defaultFormatter`) is used. If a name is specified, it must appear in the `[formatters]` section and have a corresponding section in the configuration file.

The `args` entry, when `eval()`uated in the context of the `logging` package’s namespace, is the list of arguments to the constructor for the handler class. Refer to the constructors for the relevant handlers, or to the examples below, to see how typical entries are constructed.
Sections which specify formatter configuration are typified by the following.

```
[formatter_form01]
format=F1 (%(asctime)s (%levelname)s (%message)s
datetime=
class=logging.Formatter
```

The `format` entry is the overall format string, and the `datetime` entry is the `strftime()`-compatible date/time format string. If empty, the
package substitutes ISO8601 format date/times, which is almost equivalent to specifying the date format string "%Y-%m-%d %H:%M:%S". The ISO8601 format also specifies milliseconds, which are appended to the result of using the above format string, with a comma separator. An example time in ISO8601 format is 2003-01-23 00:29:50,411.

The class entry is optional. It indicates the name of the formatter's class (as a dotted module and class name.) This option is useful for instantiating a Formatter subclass. Subclasses of Formatter can present exception tracebacks in an expanded or condensed format.

**Configuration server example**

Here is an example of a module using the logging configuration server:

```python
import logging
import logging.config
import time
import os

# read initial config file
logging.config.fileConfig("logging.conf")

# create and start listener on port 9999
t = logging.config.listen(9999)
t.start()

logger = logging.getLogger("simpleExample")

try:
    # loop through logging calls to see the difference
    # new configurations make, until Ctrl+C is pressed
    while True:
        logger.debug("debug message")
        logger.info("info message")
        logger.warn("warn message")
        logger.error("error message")
        logger.critical("critical message")
        time.sleep(5)
```
except KeyboardInterrupt:
    # cleanup
    logging.config.stopListening()
t.join()

And here is a script that takes a filename and sends that file to the server, properly preceded with the binary-encoded length, as the new logging configuration:

```python
#!/usr/bin/env python
import socket, sys, struct

data_to_send = open(sys.argv[1], "r").read()

HOST = 'localhost'
PORT = 9999
s = socket.socket(socket.AF_INET, socket.SOCK_STREAM)
print "connecting..."
s.connect((HOST, PORT))
print "sending config..."
s.send(struct.pack(">L", len(data_to_send)))
s.send(data_to_send)
s.close()
print "complete"
```
More examples

Multiple handlers and formatters

Loggers are plain Python objects. The `addHandler()` method has no minimum or maximum quota for the number of handlers you may add. Sometimes it will be beneficial for an application to log all messages of all severities to a text file while simultaneously logging errors or above to the console. To set this up, simply configure the appropriate handlers. The logging calls in the application code will remain unchanged. Here is a slight modification to the previous simple module-based configuration example:

```python
import logging

logger = logging.getLogger("simple_example")
logger.setLevel(logging.DEBUG)

# create file handler which logs even debug messages
fh = logging.FileHandler("spam.log")
fh.setLevel(logging.DEBUG)

# create console handler with a higher log level
ch = logging.StreamHandler()
ch.setLevel(logging.ERROR)

# create formatter and add it to the handlers
formatter = logging.Formatter("%(asctime)s - %(name)s - %(levelname)s -
%(message)s")
ch.setFormatter(formatter)
fh.setFormatter(formatter)

# add the handlers to logger
logger.addHandler(ch)
logger.addHandler(fh)

# "application" code
logger.debug("debug message")
logger.info("info message")
logger.warn("warn message")
logger.error("error message")
logger.critical("critical message")
```

Notice that the “application” code does not care about multiple
handlers. All that changed was the addition and configuration of a new handler named \textit{fh}.

The ability to create new handlers with higher- or lower-severity filters can be very helpful when writing and testing an application. Instead of using many \texttt{print} statements for debugging, use \texttt{logger.debug}: Unlike the print statements, which you will have to delete or comment out later, the logger.debug statements can remain intact in the source code and remain dormant until you need them again. At that time, the only change that needs to happen is to modify the severity level of the logger and/or handler to debug.

Using logging in multiple modules

It was mentioned above that multiple calls to \texttt{logging.getLogger('someLogger')} return a reference to the same logger object. This is true not only within the same module, but also across modules as long as it is in the same Python interpreter process. It is true for references to the same object; additionally, application code can define and configure a parent logger in one module and create (but not configure) a child logger in a separate module, and all logger calls to the child will pass up to the parent. Here is a main module:

```python
import logging
import auxiliary_module

# create logger with "spam_application"
logger = logging.getLogger("spam_application")
logger.setLevel(logging.DEBUG)

# create file handler which logs even debug messages
fh = logging.FileHandler("spam.log")
fh.setLevel(logging.DEBUG)

# create console handler with a higher log level
ch = logging.StreamHandler()
ch.setLevel(logging.ERROR)

# create formatter and add it to the handlers
formatter = logging.Formatter(
    "%(asctime)s - %(name)s - %(levelname)s - %(message)s")

fh.setFormatter(formatter)
```
ch.setFormatter(formatter)

# add the handlers to the logger
logger.addHandler(fh)
logger.addHandler(ch)

logger.info("creating an instance of auxiliary_module.Auxiliary")
logger.info("created an instance of auxiliary_module.Auxiliary")
logger.info("calling auxiliary_module.Auxiliary.do_something")
a.do_something()
logger.info("finished auxiliary_module.Auxiliary.do_something")
logger.info("calling auxiliary_module.some_function()")
auxiliary_module.some_function()
logger.info("done with auxiliary_module.some_function()")

Here is the auxiliary module:

```python
import logging

# create logger
module_logger = logging.getLogger("spam_application.auxiliary")

class Auxiliary:
    def __init__(self):
        self.logger = logging.getLogger("spam_application.auxiliary")
        self.logger.info("creating an instance of Auxiliary")

    def do_something(self):
        self.logger.info("doing something")
        a = 1 + 1
        self.logger.info("done doing something")

    def some_function():
        module_logger.info("received a call to \"some_function\"")
```

The output looks like this:

```
```
doing something
done doing something
2005-03-23 23:47:11,670 - spam_application - INFO -
finished auxiliary_module.Auxiliary.do_something
2005-03-23 23:47:11,671 - spam_application - INFO -
calling auxiliary_module.some_function()
2005-03-23 23:47:11,672 - spam_application.auxiliary - INFO -
received a call to "some_function"
2005-03-23 23:47:11,673 - spam_application - INFO -
done with auxiliary_module.some_function()
The `getpass` module provides two functions:

`getpass.getpass([prompt[, stream]])`

Prompt the user for a password without echoing. The user is prompted using the string `prompt`, which defaults to `'Password:'`. On Unix, the prompt is written to the file-like object `stream`. `stream` defaults to the controlling terminal (`/dev/tty`) or if that is unavailable to `sys.stderr` (this argument is ignored on Windows).

If echo free input is unavailable `getpass()` falls back to printing a warning message to `stream` and reading from `sys.stdin` and issuing a `GetPassWarning`.

Availability: Macintosh, Unix, Windows.

*Changed in version 2.5:* The `stream` parameter was added.

*Changed in version 2.6:* On Unix it defaults to using `/dev/tty` before falling back to `sys.stdin` and `sys.stderr`.

**Note:** If you call `getpass` from within IDLE, the input may be done in the terminal you launched IDLE from rather than the idle window itself.

`GetPassWarning`

A `UserWarning` subclass issued when password input may be echoed.

`getpass.getuser()`

Return the “login name” of the user. Availability: Unix, Windows.
This function checks the environment variables **LOGNAME**, **USER**, **LNAME** and **USERNAME**, in order, and returns the value of the first one which is set to a non-empty string. If none are set, the login name from the password database is returned on systems which support the `pwd` module, otherwise, an exception is raised.
curses — Terminal handling for character-cell displays

*Changed in version 1.6:* Added support for the `ncurses` library and converted to a package.

The `curses` module provides an interface to the curses library, the de-facto standard for portable advanced terminal handling.

While curses is most widely used in the Unix environment, versions are available for DOS, OS/2, and possibly other systems as well. This extension module is designed to match the API of `ncurses`, an open-source curses library hosted on Linux and the BSD variants of Unix.

**Note:** Since version 5.4, the `ncurses` library decides how to interpret non-ASCII data using the `nl_langinfo` function. That means that you have to call `locale.setlocale()` in the application and encode Unicode strings using one of the system’s available encodings. This example uses the system’s default encoding:

```python
import locale
locale.setlocale(locale.LC_ALL, '')
code = locale.getpreferredencoding()
```

Then use `code` as the encoding for `str.encode()` calls.

**See also:**

- **Module** `curses.ascii`  
  Utilities for working with ASCII characters, regardless of your locale settings.

- **Module** `curses.panel`
A panel stack extension that adds depth to curses windows.

**Module curses.textpad**

Editable text widget for curses supporting *Emacs*-like bindings.

**Module curses.wrapper**

Convenience function to ensure proper terminal setup and resetting on application entry and exit.

**Curses Programming with Python**

Tutorial material on using curses with Python, by Andrew Kuchling and Eric Raymond.

The Demo/curses/ directory in the Python source distribution contains some example programs using the curses bindings provided by this module.
Functions

The module `curses` defines the following exception:

```
exception curses.error

Exception raised when a curses library function returns an error.
```

**Note:** Whenever `x` or `y` arguments to a function or a method are optional, they default to the current cursor location. Whenever `attr` is optional, it defaults to `A_NORMAL`.

The module `curses` defines the following functions:

```
curses.baudrate()

Returns the output speed of the terminal in bits per second. On software terminal emulators it will have a fixed high value. Included for historical reasons; in former times, it was used to write output loops for time delays and occasionally to change interfaces depending on the line speed.
```

```
curses.beep()

Emit a short attention sound.
```

```
curses.can_change_color()

Returns true or false, depending on whether the programmer can change the colors displayed by the terminal.
```

```
curses.cbreak()

Enter cbreak mode. In cbreak mode (sometimes called "rare" mode) normal tty line buffering is turned off and characters are available to be read one by one. However, unlike raw mode, special characters (interrupt, quit, suspend, and flow control) retain their effects on the tty driver and calling program. Calling
first `raw()` then `cbreak()` leaves the terminal in cbreak mode.

curses.**color_content**(color_number)
Returns the intensity of the red, green, and blue (RGB) components in the color `color_number`, which must be between \( \emptyset \) and `COLORS`. A 3-tuple is returned, containing the R,G,B values for the given color, which will be between \( \emptyset \) (no component) and `1000` (maximum amount of component).

curses.**color_pair**(color_number)
Returns the attribute value for displaying text in the specified color. This attribute value can be combined with `A_STANDOUT`, `A_REVERSE`, and the other `A_*` attributes. `pair_number()` is the counterpart to this function.

curses.**curs_set**(visibility)
Sets the cursor state. `visibility` can be set to 0, 1, or 2, for invisible, normal, or very visible. If the terminal supports the visibility requested, the previous cursor state is returned; otherwise, an exception is raised. On many terminals, the “visible” mode is an underline cursor and the “very visible” mode is a block cursor.

curses.**def_prog_mode()**
Saves the current terminal mode as the “program” mode, the mode when the running program is using curses. (Its counterpart is the “shell” mode, for when the program is not in curses.) Subsequent calls to `reset_prog_mode()` will restore this mode.

curses.**def_shell_mode()**
Saves the current terminal mode as the “shell” mode, the mode when the running program is not using curses. (Its counterpart is the “program” mode, when the program is using curses
(capabilities.) Subsequent calls to `reset_shell_mode()` will restore this mode.

**curses.** delay_output(ms)

Inserts an `ms` millisecond pause in output.

**curses.** doupdate()

Update the physical screen. The curses library keeps two data structures, one representing the current physical screen contents and a virtual screen representing the desired next state. The `doupdate()` ground updates the physical screen to match the virtual screen.

The virtual screen may be updated by a `noutrefresh()` call after write operations such as `addstr()` have been performed on a window. The normal `refresh()` call is simply `noutrefresh()` followed by `doupdate()`; if you have to update multiple windows, you can speed performance and perhaps reduce screen flicker by issuing `noutrefresh()` calls on all windows, followed by a single `doupdate()`.

**curses.** echo()

Enter echo mode. In echo mode, each character input is echoed to the screen as it is entered.

**curses.** endwin()

De-initialize the library, and return terminal to normal status.

**curses.** erasechar()

Returns the user’s current erase character. Under Unix operating systems this is a property of the controlling tty of the curses program, and is not set by the curses library itself.

**curses.** filter()
The `filter()` routine, if used, must be called before `initscr()` is called. The effect is that, during those calls, LINES is set to 1; the capabilities clear, cup, cud, cud1, cuu1, cuu, vpa are disabled; and the home string is set to the value of cr. The effect is that the cursor is confined to the current line, and so are screen updates. This may be used for enabling character-at-a-time line editing without touching the rest of the screen.

**curses.** `flash()`

Flash the screen. That is, change it to reverse-video and then change it back in a short interval. Some people prefer such as ‘visible bell’ to the audible attention signal produced by `beep()`.

**curses.** `flushinp()`

Flush all input buffers. This throws away any typeahead that has been typed by the user and has not yet been processed by the program.

**curses.** `getmouse()`

After `getch()` returns `KEY_MOUSE` to signal a mouse event, this method should be call to retrieve the queued mouse event, represented as a 5-tuple `(id, x, y, z, bstate). `id` is an ID value used to distinguish multiple devices, and `x, y, z` are the event's coordinates. (z is currently unused.). `bstate` is an integer value whose bits will be set to indicate the type of event, and will be the bitwise OR of one or more of the following constants, where `n` is the button number from 1 to 4: `BUTTONn_PRESSED`, `BUTTONn_RELEASED`, `BUTTONn_CLICKED`, `BUTTONn_DOUBLE_CLICKED`, `BUTTONn_TRIPLE_CLICKED`, `BUTTON_SHIFT`, `BUTTON_CTRL`, `BUTTON_ALT`.

**curses.** `getsyx()`

Returns the current coordinates of the virtual screen cursor in y and x. If `leaveok` is currently true, then -1,-1 is returned.
curses.getwin(file)
Reads window related data stored in the file by an earlier putwin() call. The routine then creates and initializes a new window using that data, returning the new window object.

curses.has_colors()
Returns true if the terminal can display colors; otherwise, it returns false.

curses.has_ic()
Returns true if the terminal has insert- and delete- character capabilities. This function is included for historical reasons only, as all modern software terminal emulators have such capabilities.

curses.has_il()
Returns true if the terminal has insert- and delete-line capabilities, or can simulate them using scrolling regions. This function is included for historical reasons only, as all modern software terminal emulators have such capabilities.

curses.has_key(ch)
Takes a key value ch, and returns true if the current terminal type recognizes a key with that value.

curses.halfdelay(tenths)
Used for half-delay mode, which is similar to cbreak mode in that characters typed by the user are immediately available to the program. However, after blocking for tenths tenths of seconds, an exception is raised if nothing has been typed. The value of tenths must be a number between 1 and 255. Use nocbreak() to leave half-delay mode.

curses.init_color(color_number, r, g, b)
Changes the definition of a color, taking the number of the color
to be changed followed by three RGB values (for the amounts of red, green, and blue components). The value of color_number must be between $0$ and COLORS. Each of $r, g, b$, must be a value between $0$ and $1000$. When init_color() is used, all occurrences of that color on the screen immediately change to the new definition. This function is a no-op on most terminals; it is active only if can_change_color() returns 1.

curses. init_pair(pair_number, fg, bg)
Changes the definition of a color-pair. It takes three arguments: the number of the color-pair to be changed, the foreground color number, and the background color number. The value of pair_number must be between 1 and COLOR_PAIRS - 1 (the 0 color pair is wired to white on black and cannot be changed). The value of fg and bg arguments must be between 0 and COLORS. If the color-pair was previously initialized, the screen is refreshed and all occurrences of that color-pair are changed to the new definition.

curses. initscr()
Initialize the library. Returns a WindowObject which represents the whole screen.

**Note:** If there is an error opening the terminal, the underlying curses library may cause the interpreter to exit.

curses. isendwin()
Returns true if endwin() has been called (that is, the curses library has been deinitialized).

curses. keyname(k)
Return the name of the key numbered $k$. The name of a key generating printable ASCII character is the key's character. The
name of a control-key combination is a two-character string consisting of a caret followed by the corresponding printable ASCII character. The name of an alt-key combination (128-255) is a string consisting of the prefix ‘M-‘ followed by the name of the corresponding ASCII character.

curses.\texttt{killchar()}\texttt{\texttt{\texttt{\texttt{\texttt{(}}}\texttt{}}}\texttt{\texttt{\texttt{\texttt{\texttt{)}}\texttt{}}}}
Returns the user’s current line kill character. Under Unix operating systems this is a property of the controlling tty of the curses program, and is not set by the curses library itself.

curses.\texttt{longname()}\texttt{\texttt{\texttt{\texttt{\texttt{(}}}\texttt{}}}\texttt{\texttt{\texttt{\texttt{\texttt{)}}\texttt{}}}}
Returns a string containing the terminfo long name field describing the current terminal. The maximum length of a verbose description is 128 characters. It is defined only after the call to \texttt{initscr()}.

curses.\texttt{meta(}}\texttt{yes}\texttt{)}\texttt{\texttt{\texttt{\texttt{\texttt{(}}}\texttt{}}}\texttt{\texttt{\texttt{\texttt{\texttt{)}}\texttt{}}}}
If \texttt{yes} is 1, allow 8-bit characters to be input. If \texttt{yes} is 0, allow only 7-bit chars.

curses.\texttt{mouseinterval(}}\texttt{interval}\texttt{)}\texttt{\texttt{\texttt{\texttt{\texttt{(}}}\texttt{}}}\texttt{\texttt{\texttt{\texttt{\texttt{)}}\texttt{}}}}
Sets the maximum time in milliseconds that can elapse between press and release events in order for them to be recognized as a click, and returns the previous interval value. The default value is 200 msec, or one fifth of a second.

curses.\texttt{mousemask(}}\texttt{mousemask}\texttt{)}\texttt{\texttt{\texttt{\texttt{\texttt{(}}}\texttt{}}}\texttt{\texttt{\texttt{\texttt{\texttt{)}}\texttt{}}}}
Sets the mouse events to be reported, and returns a tuple \texttt{(availmask, oldmask)}. \texttt{availmask} indicates which of the specified mouse events can be reported; on complete failure it returns 0. \texttt{oldmask} is the previous value of the given window’s mouse event mask. If this function is never called, no mouse events are ever reported.
curses. **napms**(*ms*)

Sleep for *ms* milliseconds.

curses. **newpad**(*nlines*, *ncols*)

Creates and returns a pointer to a new pad data structure with the given number of lines and columns. A pad is returned as a window object.

A pad is like a window, except that it is not restricted by the screen size, and is not necessarily associated with a particular part of the screen. Pads can be used when a large window is needed, and only a part of the window will be on the screen at one time. Automatic refreshes of pads (such as from scrolling or echoing of input) do not occur. The `refresh()` and `noutrefresh()` methods of a pad require 6 arguments to specify the part of the pad to be displayed and the location on the screen to be used for the display. The arguments are pminrow, pmincol, sminrow, smincol, smaxrow, smaxcol; the p arguments refer to the upper left corner of the pad region to be displayed and the s arguments define a clipping box on the screen within which the pad region is to be displayed.

curses. **newwin**([*nlines*, *ncols*], *begin_y*, *begin_x*)

Return a new window, whose left-upper corner is at (*begin_y*, *begin_x*), and whose height/width is *nlines/ncols*.

By default, the window will extend from the specified position to the lower right corner of the screen.

curses. **nl**()

Enter newline mode. This mode translates the return key into newline on input, and translates newline into return and line-feed on output. Newline mode is initially on.
curses.\texttt{nocbreak()}

Leave \texttt{cbreak} mode. Return to normal “cooked” mode with line buffering.

curses.\texttt{noecho()}

Leave echo mode. Echoing of input characters is turned off.

curses.\texttt{nonl()}

Leave newline mode. Disable translation of return into newline on input, and disable low-level translation of newline into newline/return on output (but this does not change the behavior of \texttt{addch(‘\n’)}, which always does the equivalent of return and line feed on the virtual screen). With translation off, curses can sometimes speed up vertical motion a little; also, it will be able to detect the return key on input.

curses.\texttt{noqiflush()}

When the \texttt{noqiflush} routine is used, normal flush of input and output queues associated with the INTR, QUIT and SUSP characters will not be done. You may want to call \texttt{noqiflush()} in a signal handler if you want output to continue as though the interrupt had not occurred, after the handler exits.

curses.\texttt{noraw()}

Leave raw mode. Return to normal “cooked” mode with line buffering.

curses.\texttt{pair\_content(pair\_number)}

Returns a tuple (\texttt{fg, bg}) containing the colors for the requested color pair. The value of \texttt{pair\_number} must be between 1 and \texttt{COLOR\_PAIRS - 1}.

curses.\texttt{pair\_number(attr)}

Returns the number of the color-pair set by the attribute value
attr. color_pair() is the counterpart to this function.

curses. putp(string)
Equivalent to puts(str, 1, putchar); emits the value of a
specified terminfo capability for the current terminal. Note that the
output of putp always goes to standard output.

curses. qiflush([flag])
If flag is false, the effect is the same as calling noqiflush(). If flag
is true, or no argument is provided, the queues will be flushed
when these control characters are read.

curses. raw()
Enter raw mode. In raw mode, normal line buffering and
processing of interrupt, quit, suspend, and flow control keys are
turned off; characters are presented to curses input functions one
by one.

curses. reset_prog_mode()
Restores the terminal to “program” mode, as previously saved by
def_prog_mode().

curses. reset_shell_mode()
Restores the terminal to “shell” mode, as previously saved by
def_shell_mode().

curses. setsyx(y, x)
Sets the virtual screen cursor to y, x. If y and x are both -1, then
leaveok is set.

curses. setupterm([termstr, fd])
Initializes the terminal. termstr is a string giving the terminal
name; if omitted, the value of the TERM environment variable will
be used. fd is the file descriptor to which any initialization
sequences will be sent; if not supplied, the file descriptor for
\texttt{sys.stdout} will be used.

curses.\texttt{start\_color()}
Must be called if the programmer wants to use colors, and before
any other color manipulation routine is called. It is good practice
to call this routine right after \texttt{initscr()}.

\texttt{start\_color()} initializes eight basic colors (black, red, green,
yellow, blue, magenta, cyan, and white), and two global variables
in the \texttt{curses} module, \texttt{COLORS} and \texttt{COLOR\_PAIRS}, containing the
maximum number of colors and color-pairs the terminal can
support. It also restores the colors on the terminal to the values
they had when the terminal was just turned on.

curses.\texttt{termattrs()}
Returns a logical OR of all video attributes supported by the
terminal. This information is useful when a curses program needs
complete control over the appearance of the screen.

curses.\texttt{termname()}
Returns the value of the environment variable TERM, truncated
to 14 characters.

curses.\texttt{tigetflag(capname)}
Returns the value of the Boolean capability corresponding to the
terminfo capability name \texttt{capname}. The value \texttt{-1} is returned if
\texttt{capname} is not a Boolean capability, or \texttt{0} if it is canceled or
absent from the terminal description.

curses.\texttt{tigetnum(capname)}
Returns the value of the numeric capability corresponding to the
terminfo capability name \texttt{capname}. The value \texttt{-2} is returned if
\texttt{capname} is not a numeric capability, or \texttt{-1} if it is canceled or
absent from the terminal description.

**curses.tigetstr(capname)**

Returns the value of the string capability corresponding to the terminfo capability name `capname`. `None` is returned if `capname` is not a string capability, or is canceled or absent from the terminal description.

**curses.tparm(str[, ...])**

Instantiates the string `str` with the supplied parameters, where `str` should be a parameterized string obtained from the terminfo database. E.g. `tparm(tigetstr("cup"), 5, 3)` could result in `'\033[6;4H'`, the exact result depending on terminal type.

**curses.typeahead(fd)**

Specifies that the file descriptor `fd` be used for typeahead checking. If `fd` is `-1`, then no typeahead checking is done.

The curses library does “line-breakout optimization” by looking for typeahead periodically while updating the screen. If input is found, and it is coming from a tty, the current update is postponed until refresh or doupdate is called again, allowing faster response to commands typed in advance. This function allows specifying a different file descriptor for typeahead checking.

**curses.unctrl(ch)**

Returns a string which is a printable representation of the character `ch`. Control characters are displayed as a caret followed by the character, for example as `^C`. Printing characters are left as they are.

**curses.ungetch(ch)**

Push `ch` so the next `getch()` will return it.
**Note:** Only one `ch` can be pushed before `getch()` is called.

```c
ungetmouse(id, x, y, z, bstate)
```

Push a `KEY_MOUSE` event onto the input queue, associating the given state data with it.

```c
use_env(flag)
```

If used, this function should be called before `initscr()` or `newterm` are called. When `flag` is false, the values of lines and columns specified in the terminfo database will be used, even if environment variables `LINES` and `COLUMNS` (used by default) are set, or if curses is running in a window (in which case default behavior would be to use the window size if `LINES` and `COLUMNS` are not set).

```c
use_default_colors()
```

Allow use of default values for colors on terminals supporting this feature. Use this to support transparency in your application. The default color is assigned to the color number -1. After calling this function, `init_pair(x, curses.COLOR_RED, -1)` initializes, for instance, color pair `x` to a red foreground color on the default background.
Window Objects

Window objects, as returned by `initscr()` and `newwin()` above, have the following methods:

```c
window.addch([y, x], ch[, attr])
```

**Note:** A character means a C character (an ASCII code), rather than a Python character (a string of length 1). (This note is true whenever the documentation mentions a character.) The builtin `ord()` is handy for conveying strings to codes.

Paint character `ch` at `(y, x)` with attributes `attr`, overwriting any character previously painter at that location. By default, the character position and attributes are the current settings for the window object.

```c
window.addnstr([y, x], str, n[, attr])
```

Paint at most `n` characters of the string `str` at `(y, x)` with attributes `attr`, overwriting anything previously on the display.

```c
window.addstr([y, x], str[, attr])
```

Paint the string `str` at `(y, x)` with attributes `attr`, overwriting anything previously on the display.

```c
window.attroff(attr)
```

Remove attribute `attr` from the “background” set applied to all writes to the current window.

```c
window.attron(attr)
```

Add attribute `attr` from the “background” set applied to all writes to the current window.
**window.\texttt{attrset}(attr)**

Set the “background” set of attributes to \texttt{attr}. This set is initially 0 (no attributes).

**window.\texttt{bkgd}(ch[, attr])**

Sets the background property of the window to the character \texttt{ch}, with attributes \texttt{attr}. The change is then applied to every character position in that window:

- The attribute of every character in the window is changed to the new background attribute.
- Wherever the former background character appears, it is changed to the new background character.

**window.\texttt{bkgdset}(ch[, attr])**

Sets the window’s background. A window's background consists of a character and any combination of attributes. The attribute part of the background is combined (OR’ed) with all non-blank characters that are written into the window. Both the character and attribute parts of the background are combined with the blank characters. The background becomes a property of the character and moves with the character through any scrolling and insert/delete line/character operations.

**window.\texttt{border}([ls[, rs[, ts[, bs[, tl[, tr[, bl[, br]]]]]]]])**

Draw a border around the edges of the window. Each parameter specifies the character to use for a specific part of the border; see the table below for more details. The characters can be specified as integers or as one-character strings.

\textbf{Note:} A \texttt{0} value for any parameter will cause the default character to be used for that parameter. Keyword parameters can \textit{not} be used. The defaults are listed in this table:
<table>
<thead>
<tr>
<th>Parameter</th>
<th>Description</th>
<th>Default value</th>
</tr>
</thead>
<tbody>
<tr>
<td><em>ls</em></td>
<td>Left side</td>
<td>ACS_VLINE</td>
</tr>
<tr>
<td><em>rs</em></td>
<td>Right side</td>
<td>ACS_VLINE</td>
</tr>
<tr>
<td><em>ts</em></td>
<td>Top</td>
<td>ACS_HLINE</td>
</tr>
<tr>
<td><em>bs</em></td>
<td>Bottom</td>
<td>ACS_HLINE</td>
</tr>
<tr>
<td><em>tl</em></td>
<td>Upper-left corner</td>
<td>ACS_ULCORNER</td>
</tr>
<tr>
<td><em>tr</em></td>
<td>Upper-right corner</td>
<td>ACS_URCORNER</td>
</tr>
<tr>
<td><em>bl</em></td>
<td>Bottom-left corner</td>
<td>ACS_LLCORNER</td>
</tr>
<tr>
<td><em>br</em></td>
<td>Bottom-right corner</td>
<td>ACS_LRCORNER</td>
</tr>
</tbody>
</table>

**window.box([vertch, horch])**

Similar to `border()`, but both *ls* and *rs* are `vertch` and both *ts* and *bs* are `horch`. The default corner characters are always used by this function.

**window.chgat([y, x][, num], attr)**

Sets the attributes of `num` characters at the current cursor position, or at position `(y, x)` if supplied. If no value of `num` is given or `num` = -1, the attribute will be set on all the characters to the end of the line. This function does not move the cursor. The changed line will be touched using the `touchline()` method so that the contents will be redisplayed by the next window refresh.

**window.clear()**

Like `erase()`, but also causes the whole window to be repainted upon next call to `refresh()`.

**window.clearok(yes)**

If `yes` is 1, the next call to `refresh()` will clear the window completely.

**window.clrtobot()**

Erase from cursor to the end of the window: all lines below the
cursor are deleted, and then the equivalent of \texttt{clrtoeol()} is performed.

\texttt{window.clrtoeol()}
Erase from cursor to the end of the line.

\texttt{window.cursyncup()}
Updates the current cursor position of all the ancestors of the window to reflect the current cursor position of the window.

\texttt{window.delch([y, x])}
delete any character at \((y, x)\).

\texttt{window.delete1n()}
delete the line under the cursor. All following lines are moved up by 1 line.

\texttt{window.derwin([nlines, ncols], begin_y, begin_x)}
An abbreviation for “derive window”, \texttt{derwin()} is the same as calling \texttt{subwin()}, except that \texttt{begin_y} and \texttt{begin_x} are relative to the origin of the window, rather than relative to the entire screen. Returns a window object for the derived window.

\texttt{window.echochar(ch[, attr])}
Add character \texttt{ch} with attribute \texttt{attr}, and immediately call \texttt{refresh()} on the window.

\texttt{window.enclose(y, x)}
Tests whether the given pair of screen-relative character-cell coordinates are enclosed by the given window, returning true or false. It is useful for determining what subset of the screen windows enclose the location of a mouse event.

\texttt{window.erase()}
Clear the window.

window. getbegyx()
Return a tuple \((y, x)\) of co-ordinates of upper-left corner.

window. getch([y, x])
Get a character. Note that the integer returned does \textit{not} have to be in ASCII range: function keys, keypad keys and so on return numbers higher than 256. In no-delay mode, -1 is returned if there is no input.

window. getkey([y, x])
Get a character, returning a string instead of an integer, as \texttt{getch()} does. Function keys, keypad keys and so on return a multibyte string containing the key name. In no-delay mode, an exception is raised if there is no input.

window. getmaxyx()
Return a tuple \((y, x)\) of the height and width of the window.

window. getparyx()
Returns the beginning coordinates of this window relative to its parent window into two integer variables \(y\) and \(x\). Returns \(-1, -1\) if this window has no parent.

window. getstr([y, x])
Read a string from the user, with primitive line editing capacity.

window. getyx()
Return a tuple \((y, x)\) of current cursor position relative to the window's upper-left corner.

window. hline([y, x], ch, n)
Display a horizontal line starting at $(y, x)$ with length $n$ consisting of the character $ch$.

**window. idcok(flag)**

If flag is false, curses no longer considers using the hardware insert/delete character feature of the terminal; if flag is true, use of character insertion and deletion is enabled. When curses is first initialized, use of character insert/delete is enabled by default.

**window. idlok(yes)**

If called with yes equal to 1, *curses* will try and use hardware line editing facilities. Otherwise, line insertion/deletion are disabled.

**window. immedok(flag)**

If flag is true, any change in the window image automatically causes the window to be refreshed; you no longer have to call refresh() yourself. However, it may degrade performance considerably, due to repeated calls to wrefresh. This option is disabled by default.

**window. inch([y, x])**

Return the character at the given position in the window. The bottom 8 bits are the character proper, and upper bits are the attributes.

**window. insch([y, x], ch[, attr])**

Paint character $ch$ at $(y, x)$ with attributes $attr$, moving the line from position $x$ right by one character.

**window. insdelln(nlines)**

Inserts $nlines$ lines into the specified window above the current line. The $nlines$ bottom lines are lost. For negative $nlines$, delete $nlines$ lines starting with the one under the cursor, and move the
remaining lines up. The bottom \textit{nlines} lines are cleared. The current cursor position remains the same.

\texttt{window.insertln()}

Insert a blank line under the cursor. All following lines are moved down by 1 line.

\texttt{window.insnstr([y, x], str[n, attr])}

Insert a character string (as many characters as will fit on the line) before the character under the cursor, up to \textit{n} characters. If \textit{n} is zero or negative, the entire string is inserted. All characters to the right of the cursor are shifted right, with the rightmost characters on the line being lost. The cursor position does not change (after moving to \textit{y, x}, if specified).

\texttt{window.instr([y, x][, n])}

Returns a string of characters, extracted from the window starting at the current cursor position, or at \textit{y, x} if specified. Attributes are stripped from the characters. If \textit{n} is specified, \texttt{instr()} returns return a string at most \textit{n} characters long (exclusive of the trailing NUL).

\texttt{window.is_linetouched(line)}

Returns true if the specified line was modified since the last call to \texttt{refresh()}; otherwise returns false. Raises a \texttt{curses.error} exception if \textit{line} is not valid for the given window.
window. is_wintouched()
    Returns true if the specified window was modified since the last call to refresh(); otherwise returns false.

window. keypad(yes)
    If yes is 1, escape sequences generated by some keys (keypad, function keys) will be interpreted by curses. If yes is 0, escape sequences will be left as is in the input stream.

window. leaveok(yes)
    If yes is 1, cursor is left where it is on update, instead of being at “cursor position.” This reduces cursor movement where possible. If possible the cursor will be made invisible.

    If yes is 0, cursor will always be at “cursor position” after an update.

window. move(new_y, new_x)
    Move cursor to (new_y, new_x).

window. mvderwin(y, x)
    Moves the window inside its parent window. The screen-relative parameters of the window are not changed. This routine is used to display different parts of the parent window at the same physical position on the screen.

window. mvwin(new_y, new_x)
    Move the window so its upper-left corner is at (new_y, new_x).

window. nodelay(yes)
    If yes is 1, getch() will be non-blocking.

window. notimeout(yes)
    If yes is 1, escape sequences will not be timed out.
If yes is 0, after a few milliseconds, an escape sequence will not be interpreted, and will be left in the input stream as is.

`window.noutrefresh()`
Mark for refresh but wait. This function updates the data structure representing the desired state of the window, but does not force an update of the physical screen. To accomplish that, call `doupdate()`.

`window.overlay(destwin[, sminrow, smincol, dminrow, dmincol, dmaxrow, dmaxcol])`
Overlay the window on top of `destwin`. The windows need not be the same size, only the overlapping region is copied. This copy is non-destructive, which means that the current background character does not overwrite the old contents of `destwin`.

To get fine-grained control over the copied region, the second form of `overlay()` can be used. `sminrow` and `smincol` are the upper-left coordinates of the source window, and the other variables mark a rectangle in the destination window.

`window.overwrite(destwin[, sminrow, smincol, dminrow, dmincol, dmaxrow, dmaxcol])`
Overwrite the window on top of `destwin`. The windows need not be the same size, in which case only the overlapping region is copied. This copy is destructive, which means that the current background character overwrites the old contents of `destwin`.

To get fine-grained control over the copied region, the second form of `overwrite()` can be used. `sminrow` and `smincol` are the upper-left coordinates of the source window, the other variables mark a rectangle in the destination window.

`window.putwin(file)`
Writes all data associated with the window into the provided file object. This information can be later retrieved using the `getwin()` function.

```
window.redrawln(beg, num)
```
Indicates that the `num` screen lines, starting at line `beg`, are corrupted and should be completely redrawn on the next `refresh()` call.

```
window.redrawwin()
```
Touches the entire window, causing it to be completely redrawn on the next `refresh()` call.

```
window.refresh([pminrow, pmincol, sminrow, smincol, smaxrow, smaxcol])
```
Update the display immediately (sync actual screen with previous drawing/deleting methods).

The 6 optional arguments can only be specified when the window is a pad created with `newpad()`. The additional parameters are needed to indicate what part of the pad and screen are involved. `pminrow` and `pmincol` specify the upper left-hand corner of the rectangle to be displayed in the pad. `sminrow`, `smincol`, `smaxrow`, and `smaxcol` specify the edges of the rectangle to be displayed on the screen. The lower right-hand corner of the rectangle to be displayed in the pad is calculated from the screen coordinates, since the rectangles must be the same size. Both rectangles must be entirely contained within their respective structures. Negative values of `pminrow`, `pmincol`, `sminrow`, or `smincol` are treated as if they were zero.

```
window.scroll([lines=1])
```
Scroll the screen or scrolling region upward by `lines` lines.
**window. scrollok(flag)**

Controls what happens when the cursor of a window is moved off the edge of the window or scrolling region, either as a result of a newline action on the bottom line, or typing the last character of the last line. If flag is false, the cursor is left on the bottom line. If flag is true, the window is scrolled up one line. Note that in order to get the physical scrolling effect on the terminal, it is also necessary to call idlok().

**window. setscrreg(top, bottom)**

Set the scrolling region from line top to line bottom. All scrolling actions will take place in this region.

**window. standend()**

Turn off the standout attribute. On some terminals this has the side effect of turning off all attributes.

**window. standout()**

Turn on attribute A_STANDOUT.

**window. subpad([nlines, ncols], begin_y, begin_x)**

Return a sub-window, whose upper-left corner is at (begin_y, begin_x), and whose width/height is ncols/nlines.

**window. subwin([nlines, ncols], begin_y, begin_x)**

Return a sub-window, whose upper-left corner is at (begin_y, begin_x), and whose width/height is ncols/nlines.

By default, the sub-window will extend from the specified position to the lower right corner of the window.

**window. syncdown()**

Touches each location in the window that has been touched in any of its ancestor windows. This routine is called by refresh().
so it should almost never be necessary to call it manually.

window. **`syncok(flag)`**

If called with `flag` set to true, then `syncup()` is called automatically whenever there is a change in the window.

window. **`syncup()`**

Touches all locations in ancestors of the window that have been changed in the window.

window. **`timeout(delay)`**

Sets blocking or non-blocking read behavior for the window. If `delay` is negative, blocking read is used (which will wait indefinitely for input). If `delay` is zero, then non-blocking read is used, and -1 will be returned by `getch()` if no input is waiting. If `delay` is positive, then `getch()` will block for `delay` milliseconds, and return -1 if there is still no input at the end of that time.

window. **`touchline(start, count[, changed])`**

Pretend `count` lines have been changed, starting with line `start`. If `changed` is supplied, it specifies whether the affected lines are marked as having been changed (`changed`=1) or unchanged (`changed`=0).

window. **`touchwin()`**

Pretend the whole window has been changed, for purposes of drawing optimizations.

window. **`untouchwin()`**

Marks all lines in the window as unchanged since the last call to `refresh()`.

window. **`vline([y, x], ch, n)`**

Display a vertical line starting at `(y, x)` with length `n` consisting
of the character \textit{ch}.
The `curses` module defines the following data members:

`curses.ERR`
Some curses routines that return an integer, such as `getch()`, return `ERR` upon failure.

`curses.OK`
Some curses routines that return an integer, such as `napms()`, return `OK` upon success.

`curses.version`
A string representing the current version of the module. Also available as `__version__`.

Several constants are available to specify character cell attributes:

<table>
<thead>
<tr>
<th>Attribute</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>A_ALTCHARSET</td>
<td>Alternate character set mode.</td>
</tr>
<tr>
<td>A_BLINK</td>
<td>Blink mode.</td>
</tr>
<tr>
<td>A_BOLD</td>
<td>Bold mode.</td>
</tr>
<tr>
<td>A_DIM</td>
<td>Dim mode.</td>
</tr>
<tr>
<td>A_NORMAL</td>
<td>Normal attribute.</td>
</tr>
<tr>
<td>A_STANDOUT</td>
<td>Standout mode.</td>
</tr>
<tr>
<td>A_UNDERLINE</td>
<td>Underline mode.</td>
</tr>
</tbody>
</table>

Keys are referred to by integer constants with names starting with `KEY_`. The exact keycaps available are system dependent.

<table>
<thead>
<tr>
<th>Key constant</th>

</tbody>
</table>
On VT100s and their software emulations, such as X terminal emulators, there are normally at least four function keys (KEY_F1, KEY_F2, KEY_F3, KEY_F4) available, and the arrow keys mapped to KEY_UP, KEY_DOWN, KEY_LEFT and KEY_RIGHT in the obvious way. If your machine has a PC keyboard, it is safe to expect arrow keys and twelve function keys (older PC keyboards may have only ten function keys); also, the following keypad mappings are standard:

<table>
<thead>
<tr>
<th>Keycap</th>
<th>Constant</th>
</tr>
</thead>
<tbody>
<tr>
<td>Insert</td>
<td>KEY_IC</td>
</tr>
<tr>
<td>Delete</td>
<td>KEY_DC</td>
</tr>
<tr>
<td>Home</td>
<td>KEY_HOME</td>
</tr>
<tr>
<td>End</td>
<td>KEY_END</td>
</tr>
<tr>
<td>Page Up</td>
<td>KEY_NPAGE</td>
</tr>
<tr>
<td>Page Down</td>
<td>KEY_PPAGE</td>
</tr>
</tbody>
</table>

The following table lists characters from the alternate character set. These are inherited from the VT100 terminal, and will generally be available on software emulations such as X terminals. When there is no graphic available, curses falls back on a crude printable ASCII approximation.

Note: These are available only after initscr() has been called.

</tbody>
</table>
curses.textpad — Text input widget for curses programs

New in version 1.6.

The curses.textpad module provides a Textbox class that handles elementary text editing in a curses window, supporting a set of keybindings resembling those of Emacs (thus, also of Netscape Navigator, BBedit 6.x, FrameMaker, and many other programs). The module also provides a rectangle-drawing function useful for framing text boxes or for other purposes.

The module curses.textpad defines the following function:

curses.textpad.rectangle(win, uly, ulx, lry, lrx)

Draw a rectangle. The first argument must be a window object; the remaining arguments are coordinates relative to that window. The second and third arguments are the y and x coordinates of the upper left hand corner of the rectangle to be drawn; the fourth and fifth arguments are the y and x coordinates of the lower right hand corner. The rectangle will be drawn using VT100/IBM PC forms characters on terminals that make this possible (including xterm and most other software terminal emulators). Otherwise it will be drawn with ASCII dashes, vertical bars, and plus signs.
Textbox objects

You can instantiate a `Textbox` object as follows:

```python
class curses.textpad.Textbox(win)
```

Return a textbox widget object. The `win` argument should be a `curses WindowObject` in which the textbox is to be contained. The edit cursor of the textbox is initially located at the upper left hand corner of the containing window, with coordinates $(0, 0)$. The instance's `stripspaces` flag is initially on.

`Textbox` objects have the following methods:

`edit([validator])`

This is the entry point you will normally use. It accepts editing keystrokes until one of the termination keystrokes is entered. If `validator` is supplied, it must be a function. It will be called for each keystroke entered with the keystroke as a parameter; command dispatch is done on the result. This method returns the window contents as a string; whether blanks in the window are included is affected by the `stripspaces` member.

`do_command(ch)`

Process a single command keystroke. Here are the supported special keystrokes:

<table>
<thead>
<tr>
<th>Keystroke</th>
<th>Action</th>
</tr>
</thead>
<tbody>
<tr>
<td>Control-A</td>
<td>Go to left edge of window.</td>
</tr>
<tr>
<td>Control-B</td>
<td>Cursor left, wrapping to previous line if appropriate.</td>
</tr>
<tr>
<td>Control-D</td>
<td>Delete character under cursor.</td>
</tr>
<tr>
<td>Control-E</td>
<td>Go to right edge (stripspaces off) or end of line (stripspaces on).</td>
</tr>
</tbody>
</table>
Control-F | Cursor right, wrapping to next line when appropriate.
Control-G | Terminate, returning the window contents.
Control-H | Delete character backward.
Control-J | Terminate if the window is 1 line, otherwise insert newline.
Control-K | If line is blank, delete it, otherwise clear to end of line.
Control-L | Refresh screen.
Control-N | Cursor down; move down one line.
Control-O | Insert a blank line at cursor location.
Control-P | Cursor up; move up one line.

Move operations do nothing if the cursor is at an edge where the movement is not possible. The following synonyms are supported where possible:

<table>
<thead>
<tr>
<th>Constant</th>
<th>Keystroke</th>
</tr>
</thead>
<tbody>
<tr>
<td>KEY_LEFT</td>
<td>Control-B</td>
</tr>
<tr>
<td>KEY_RIGHT</td>
<td>Control-F</td>
</tr>
<tr>
<td>KEY_UP</td>
<td>Control-P</td>
</tr>
<tr>
<td>KEY_DOWN</td>
<td>Control-N</td>
</tr>
<tr>
<td>KEY_BACKSPACE</td>
<td>Control-h</td>
</tr>
</tbody>
</table>

All other keystrokes are treated as a command to insert the given character and move right (with line wrapping).

gather()
This method returns the window contents as a string; whether blanks in the window are included is affected by the stripspaces member.

stripspaces
This data member is a flag which controls the interpretation of blanks in the window. When it is on, trailing blanks on each line are ignored; any cursor motion that would land the cursor
on a trailing blank goes to the end of that line instead, and trailing blanks are stripped when the window contents are gathered.
**curses.wrapper — Terminal handler for curses programs**

*New in version 1.6.*

This module supplies one function, `wrapper()`, which runs another function which should be the rest of your curses-using application. If the application raises an exception, `wrapper()` will restore the terminal to a sane state before re-raising the exception and generating a traceback.

```
curses.wrapper(func, ...)
```

Wrapper function that initializes curses and calls another function, `func`, restoring normal keyboard/screen behavior on error. The callable object `func` is then passed the main window `‘stdscr’` as its first argument, followed by any other arguments passed to `wrapper()`.

Before calling the hook function, `wrapper()` turns on cbreak mode, turns off echo, enables the terminal keypad, and initializes colors if the terminal has color support. On exit (whether normally or by exception) it restores cooked mode, turns on echo, and disables the terminal keypad.
The `curses.ascii` module supplies name constants for ASCII characters and functions to test membership in various ASCII character classes. The constants supplied are names for control characters as follows:

<table>
<thead>
<tr>
<th>Name</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>NUL</td>
<td>Start of heading, console interrupt</td>
</tr>
<tr>
<td>SOH</td>
<td>Start of text</td>
</tr>
<tr>
<td>STX</td>
<td>End of text</td>
</tr>
<tr>
<td>ETX</td>
<td>End of transmission</td>
</tr>
<tr>
<td>EOT</td>
<td>Enquiry, goes with ACK flow control</td>
</tr>
<tr>
<td>ACK</td>
<td>Acknowledgement</td>
</tr>
<tr>
<td>BEL</td>
<td>Bell</td>
</tr>
<tr>

<td>Line feed</td>
</tr>
<tr>
<td>NL</td>
<td>Alias for LF: “New line”</td>
</tr>
<tr>
<td>VT</td>
<td>Vertical tab</td>
</tr>
<tr>
<td>FF</td>
<td>Form feed</td>
</tr>
<tr>
<td>CR</td>
<td>Carriage return</td>
</tr>
<tr>
<td>SO</td>
<td>Shift-out, begin alternate character set</td>
</tr>
<tr>
<td>SI</td>
<td>Shift-in, resume default character set</td>
</tr>
<tr>
<td>DLE</td>
<td>Data-link escape</td>
</tr>
<tr>
<td>DC1</td>
<td>XON, for flow control</td>
</tr>
<tr>
<td>DC2</td>
<td>Device control 2, block-mode flow control</td>
</tr>
<tr>
<td>-------</td>
<td>-------------------------------------------</td>
</tr>
<tr>
<td>DC3</td>
<td>XOFF, for flow control</td>
</tr>
<tr>
<td>DC4</td>
<td>Device control 4</td>
</tr>
<tr>
<td>NAK</td>
<td>Negative acknowledgement</td>
</tr>
<tr>
<td>SYN</td>
<td>Synchronous idle</td>
</tr>
<tr>
<td>ETB</td>
<td>End transmission block</td>
</tr>
<tr>
<td>CAN</td>
<td>Cancel</td>
</tr>
<tr>
<td>EM</td>
<td>End of medium</td>
</tr>
<tr>
<td>SUB</td>
<td>Substitute</td>
</tr>
<tr>
<td>ESC</td>
<td>Escape</td>
</tr>
<tr>
<td>FS</td>
<td>File separator</td>
</tr>
<tr>
<td>GS</td>
<td>Group separator</td>
</tr>
<tr>
<td>RS</td>
<td>Record separator, block-mode terminator</td>
</tr>
<tr>
<td>US</td>
<td>Unit separator</td>
</tr>
<tr>
<td>SP</td>
<td>Space</td>
</tr>
<tr>
<td>DEL</td>
<td>Delete</td>
</tr>
</tbody>
</table>

Note that many of these have little practical significance in modern usage. The mnemonics derive from teleprinter conventions that predate digital computers.

The module supplies the following functions, patterned on those in the standard C library:

```c
#include <curses.ascii>

// Checks for an ASCII alphanumeric character; it is equivalent to isalpha(c) or isdigit(c).

int isalnum(int c) { return isalpha(c) || isdigit(c); }

// Checks for an ASCII alphabetic character; it is equivalent to isupper(c) or islower(c).

int isalpha(int c) { return isupper(c) || islower(c); }
```
Checks for a character value that fits in the 7-bit ASCII set.

curses.ascii.isblank(c)
   Checks for an ASCII whitespace character.

curses.ascii.iscntrl(c)
   Checks for an ASCII control character (in the range 0x00 to 0x1f).

curses.ascii.isdigit(c)
   Checks for an ASCII decimal digit, '0' through '9'. This is equivalent to c in string.digits.

curses.ascii.isgraph(c)
   Checks for ASCII any printable character except space.

curses.ascii.islower(c)
   Checks for an ASCII lower-case character.

curses.ascii.isprint(c)
   Checks for any ASCII printable character including space.

curses.ascii.ispunct(c)
   Checks for any printable ASCII character which is not a space or an alphanumeric character.

curses.ascii.isspace(c)
   Checks for ASCII white-space characters; space, line feed, carriage return, form feed, horizontal tab, vertical tab.

curses.ascii.isupper(c)
   Checks for an ASCII uppercase letter.

curses.ascii.isxdigit(c)
   Checks for an ASCII hexadecimal digit. This is equivalent to c in
string.hexdigits.
curses.ascii.isctrl(c)
    Checks for an ASCII control character (ordinal values 0 to 31).
curses.ascii.ismeta(c)
    Checks for a non-ASCII character (ordinal values 0x80 and above).

These functions accept either integers or strings; when the argument is a string, it is first converted using the built-in function `ord()`.

Note that all these functions check ordinal bit values derived from the first character of the string you pass in; they do not actually know anything about the host machine's character encoding. For functions that know about the character encoding (and handle internationalization properly) see the string module.

The following two functions take either a single-character string or integer byte value; they return a value of the same type.

curses.ascii.ascii(c)
    Return the ASCII value corresponding to the low 7 bits of c.
curses.ascii.ctrl(c)
    Return the control character corresponding to the given character (the character bit value is bitwise-anded with 0x1f).
curses.ascii.alt(c)
    Return the 8-bit character corresponding to the given ASCII character (the character bit value is bitwise-ored with 0x80).

The following function takes either a single-character string or integer value; it returns a string.
curses.ascii.unctrl(c)

Return a string representation of the ASCII character c. If c is printable, this string is the character itself. If the character is a control character (0x00-0x1f) the string consists of a caret (‘^’) followed by the corresponding uppercase letter. If the character is an ASCII delete (0x7f) the string is ’^?’. If the character has its meta bit (0x80) set, the meta bit is stripped, the preceding rules applied, and ’!’ prepended to the result.

curses.ascii.controlnames

A 33-element string array that contains the ASCII mnemonics for the thirty-two ASCII control characters from 0 (NUL) to 0x1f (US), in order, plus the mnemonic SP for the space character.
Panels are windows with the added feature of depth, so they can be stacked on top of each other, and only the visible portions of each window will be displayed. Panels can be added, moved up or down in the stack, and removed.
Functions

The module `curses.panel` defines the following functions:

- `curses.panel.bottom_panel()`
  Returns the bottom panel in the panel stack.

- `curses.panel.new_panel(win)`
  Returns a panel object, associating it with the given window `win`. Be aware that you need to keep the returned panel object referenced explicitly. If you don't, the panel object is garbage collected and removed from the panel stack.

- `curses.panel.top_panel()`
  Returns the top panel in the panel stack.

- `curses.panel.update_panels()`
  Updates the virtual screen after changes in the panel stack. This does not call `curses.doupdate()`, so you'll have to do this yourself.
Panel Objects

Panel objects, as returned by `new_panel()` above, are windows with a stacking order. There's always a window associated with a panel which determines the content, while the panel methods are responsible for the window's depth in the panel stack.

Panel objects have the following methods:

**Panel.** `above()`
- Returns the panel above the current panel.

**Panel.** `below()`
- Returns the panel below the current panel.

**Panel.** `bottom()`
- Push the panel to the bottom of the stack.

**Panel.** `hidden()`
- Returns true if the panel is hidden (not visible), false otherwise.

**Panel.** `hide()`
- Hide the panel. This does not delete the object, it just makes the window on screen invisible.

**Panel.** `move(y, x)`
- Move the panel to the screen coordinates `(y, x)`.

**Panel.** `replace(win)`
- Change the window associated with the panel to the window `win`.

**Panel.** `set_userptr(obj)`
- Set the panel's user pointer to `obj`. This is used to associate an
arbitrary piece of data with the panel, and can be any Python object.

Panel. **show()**
Display the panel (which might have been hidden).

Panel. **top()**
Push panel to the top of the stack.

Panel. **userptr()**
Returns the user pointer for the panel. This might be any Python object.

Panel. **window()**
Returns the window object associated with the panel.
**platform** — Access to underlying platform’s identifying data.

*New in version 2.3.*

**Note:** Specific platforms listed alphabetically, with Linux included in the Unix section.
Cross Platform

platform.architecture(executable=sys.executable, bits='', linkage='')

Queries the given executable (defaults to the Python interpreter binary) for various architecture information.

Returns a tuple (bits, linkage) which contain information about the bit architecture and the linkage format used for the executable. Both values are returned as strings.

Values that cannot be determined are returned as given by the parameter presets. If bits is given as '', the sizeof(pointer) (or sizeof(long) on Python version < 1.5.2) is used as indicator for the supported pointer size.

The function relies on the system's file command to do the actual work. This is available on most if not all Unix platforms and some non-Unix platforms and then only if the executable points to the Python interpreter. Reasonable defaults are used when the above needs are not met.

platform.machine()

Returns the machine type, e.g. 'i386'. An empty string is returned if the value cannot be determined.

platform.node()

Returns the computer's network name (may not be fully qualified!). An empty string is returned if the value cannot be determined.

platform.platform(aliased=0, terse=0)

Returns a single string identifying the underlying platform with as
much useful information as possible.

The output is intended to be *human readable* rather than machine parseable. It may look different on different platforms and this is intended.

If *aliased* is true, the function will use aliases for various platforms that report system names which differ from their common names, for example SunOS will be reported as Solaris. The `system_alias()` function is used to implement this.

Setting *terse* to true causes the function to return only the absolute minimum information needed to identify the platform.

**platform.**`processor()`

Returns the (real) processor name, e.g. `'amdk6'`.

An empty string is returned if the value cannot be determined. Note that many platforms do not provide this information or simply return the same value as for `machine()`. NetBSD does this.

**platform.**`python_build()`

Returns a tuple `(buildno, builddate)` stating the Python build number and date as strings.

**platform.**`python_compiler()`

Returns a string identifying the compiler used for compiling Python.

**platform.**`python_branch()`

Returns a string identifying the Python implementation SCM branch.

*New in version 2.6.*
platform.python_implementation()
    Returns a string identifying the Python implementation. Possible return values are: ‘CPython’, ‘IronPython’, ‘Jython’

    New in version 2.6.

platform.python_revision()
    Returns a string identifying the Python implementation SCM revision.

    New in version 2.6.

platform.python_version()
    Returns the Python version as string 'major.minor.patchlevel'

    Note that unlike the Python sys.version, the returned value will always include the patchlevel (it defaults to 0).

platform.python_version_tuple()
    Returns the Python version as tuple (major, minor, patchlevel) of strings.

    Note that unlike the Python sys.version, the returned value will always include the patchlevel (it defaults to '0').

platform.release()
    Returns the system's release, e.g. '2.2.0' or 'NT'. An empty string is returned if the value cannot be determined.

platform.system()
    Returns the system/OS name, e.g. 'Linux', 'Windows', or 'Java'. An empty string is returned if the value cannot be determined.

platform.system_alias(system, release, version)
Returns \( (\text{system, release, version}) \) aliased to common marketing names used for some systems. It also does some reordering of the information in some cases where it would otherwise cause confusion.

**platform.version()**

Returns the system's release version, e.g. '3 on degas'. An empty string is returned if the value cannot be determined.

**platform.uname()**

Fairly portable uname interface. Returns a tuple of strings \( (\text{system, node, release, version, machine, processor}) \) identifying the underlying platform.

Note that unlike the \texttt{os.uname()} function this also returns possible processor information as additional tuple entry.

Entries which cannot be determined are set to ''. 
**Java Platform**

platform.java_ver(\texttt{release=\textasciitilde, vendor=\textasciitilde, vminfo=(\textasciitilde, \textasciitilde, \textasciitilde), osinfo=(\textasciitilde, \textasciitilde, \textasciitilde)})

Version interface for JPython.

Returns a tuple (\texttt{release, vendor, vminfo, osinfo}) with \texttt{vminfo} being a tuple (\texttt{vm\_name, vm\_release, vm\_vendor}) and \texttt{osinfo} being a tuple (\texttt{os\_name, os\_version, os\_arch}). Values which cannot be determined are set to the defaults given as parameters (which all default to \textasciitilde).
Windows Platform

platform.win32_ver(release='', version='', csd='', ptype='')

Get additional version information from the Windows Registry and return a tuple (version, csd, ptype) referring to version number, CSD level and OS type (multi/single processor).

As a hint: ptype is 'Uniprocessor Free' on single processor NT machines and 'Multiprocessor Free' on multi processor machines. The ‘Free’ refers to the OS version being free of debugging code. It could also state ‘Checked’ which means the OS version uses debugging code, i.e. code that checks arguments, ranges, etc.

Note: Note: this function works best with Mark Hammond's win32all package installed, but also on Python 2.3 and later (support for this was added in Python 2.6). It obviously only runs on Win32 compatible platforms.

Win95/98 specific

platform.popen(cmd, mode='r', bufsize=None)

Portable popen() interface. Find a working popen implementation preferring win32pipe.popen(). On Windows NT, win32pipe.popen() should work; on Windows 9x it hangs due to bugs in the MS C library.
platform.mac_ver(release='', versioninfo=('', '', ''), machine='')

Get Mac OS version information and return it as tuple (release, versioninfo, machine) with versioninfo being a tuple (version, dev_stage, non_release_version).

Entries which cannot be determined are set to ''. All tuple entries are strings.

Documentation for the underlying gestalt API is available online at http://www.rgaros.nl/gestalt/.
Unix Platforms

```python
platform.dist(distname='', version='', id='', supported_dists=('SuSE', 'debian', 'redhat', 'mandrake', ...))
```
This is another name for `linux_distribution()`.

```python
platform.linux_distribution(distname='', version='', id='', supported_dists=('SuSE', 'debian', 'redhat', 'mandrake', ...), full_distribution_name=1)
```
Tries to determine the name of the Linux OS distribution name.

- `supported_dists` may be given to define the set of Linux distributions to look for. It defaults to a list of currently supported Linux distributions identified by their release file name.

- If `full_distribution_name` is true (default), the full distribution read from the OS is returned. Otherwise the short name taken from `supported_dists` is used.

- Returns a tuple `(distname, version, id)` which defaults to the args given as parameters. `id` is the item in parentheses after the version number. It is usually the version codename.

```python
platform.libc_ver(executable=sys.executable, lib='', version='', chunksize=2048)
```
Tries to determine the libc version against which the file executable (defaults to the Python interpreter) is linked. Returns a tuple of strings `(lib, version)` which default to the given parameters in case the lookup fails.

- Note that this function has intimate knowledge of how different libc versions add symbols to the executable is probably only usable for executables compiled using `gcc`. 
The file is read and scanned in chunks of `chunksize` bytes.
This module makes available standard `errno` system symbols. The value of each symbol is the corresponding integer value. The names and descriptions are borrowed from `linux/include/errno.h`, which should be pretty all-inclusive.

`errno.errorcode`

Dictionary providing a mapping from the `errno` value to the string name in the underlying system. For instance, `errno.errorcode[errno.EPERM]` maps to 'EPERM'.

To translate a numeric error code to an error message, use `os.strerror()`.

Of the following list, symbols that are not used on the current platform are not defined by the module. The specific list of defined symbols is available as `errno.errorcode.keys()`. Symbols available can include:

`errno.EPERM`
   Operation not permitted

`errno.ENOENT`
   No such file or directory

`errno.ESRCH`
   No such process

`errno.EINTR`
   Interrupted system call

`errno.EIO`
I/O error

errno.**ENXIO**
No such device or address

errno.**E2BIG**
Arg list too long

errno.**ENOEXEC**
Exec format error

errno.**EBADF**
Bad file number

errno.**ECHILD**
No child processes

errno.**EAGAIN**
Try again

errno.**ENOMEM**
Out of memory

errno.**EACCES**
Permission denied

errno.**EFAULT**
Bad address

errno.**ENOTBLK**
Block device required

errno.**EBUSY**
Device or resource busy

errno.**EEXIST**
File exists
errno. **EXDEV**
   Cross-device link

errno. **ENODEV**
   No such device

errno. **ENOTDIR**
   Not a directory

errno. **EISDIR**
   Is a directory

errno. **EINVAL**
   Invalid argument

errno. **ENFILE**
   File table overflow

errno. **EMFILE**
   Too many open files

errno. **ENOTTY**
   Not a typewriter

errno. **ETXTBSY**
   Text file busy

errno. **EFBIG**
   File too large

errno. **ENOSPC**
   No space left on device

errno. **ESPIPE**
   Illegal seek

errno. **EROFS**
   Read-only file system
errno. **EMLINK**  
Too many links

errno. **EPIPE**  
Broken pipe

errno. **EDOM**  
Math argument out of domain of func

errno. **ERANGE**  
Math result not representable

errno. **EDEADLK**  
Resource deadlock would occur

errno. **ENAMETOOLONG**  
File name too long

errno. **ENOLCK**  
No record locks available

errno. **ENOSYS**  
Function not implemented

errno. **ENOTEMPTY**  
Directory not empty

errno. **ELOOP**  
Too many symbolic links encountered

errno. **EWOULDBLOCK**  
Operation would block

errno. **ENOMSG**  
No message of desired type

errno. **EIDRM**  
Identifier removed
errno. **ECHRTN**
Channel number out of range

erro. **EL2NSYNC**
Level 2 not synchronized

erro. **EL3HLT**
Level 3 halted

erro. **EL3RST**
Level 3 reset

erro. **ELNRNG**
Link number out of range

erro. **EUNATCH**
Protocol driver not attached

erro. **ENOCSI**
No CSI structure available

erro. **EL2HLT**
Level 2 halted

erro. **EBADE**
Invalid exchange

erro. **EBADR**
Invalid request descriptor

erro. **EXFULL**
Exchange full

erro. **ENOANO**
No anode

erro. **EBADRC**
Invalid request code
errno. **EBADSLT**
Invalid slot

errno. **EDEADLOCK**
File locking deadlock error

errno. **EBFONT**
Bad font file format

errno. **ENOSTR**
Device not a stream

errno. **ENODATA**
No data available

errno. **ETIME**
Timer expired

errno. **ENOSR**
Out of streams resources

errno. **ENONET**
Machine is not on the network

errno. **ENOPKG**
Package not installed

errno. **EREMOTE**
Object is remote

errno. **ENOLINK**
Link has been severed

errno. **EADV**
Advertise error

errno. **ESRMNT**
Srmount error
errno. **ECOMM**
Communication error on send

errno. **EPROTO**
Protocol error

errno. **EMULTIHOP**
Multihop attempted

errno. **EDOTDOT**
RFS specific error

errno. **EBADMSG**
Not a data message

errno. **EOVERFLOW**
Value too large for defined data type

errno. **ENOTUNIQ**
Name not unique on network

errno. **EBADFD**
File descriptor in bad state

errno. **EREMCHG**
Remote address changed

errno. **ELIBACC**
Can not access a needed shared library

errno. **ELIBBAD**
Accessing a corrupted shared library

errno. **ELIBSCN**
.lib section in a.out corrupted

errno. **ELIBMAX**
Attempting to link in too many shared libraries
errno. **ELIBEXEC**
Cannot exec a shared library directly

errno. **EILSEQ**
Illegal byte sequence

errno. **ERESTART**
Interrupted system call should be restarted

errno. **ESTRPIPE**
Streams pipe error

errno. **EUSERS**
Too many users

errno. **ENOTSOCK**
Socket operation on non-socket

errno. **EDESTADDRREQ**
Destination address required

errno. **EMSGSIZE**
Message too long

errno. **EPROTOTYPE**
Protocol wrong type for socket

errno. **ENOPROTOOPT**
Protocol not available

errno. **EPROTONOSUPPORT**
Protocol not supported

errno. **ESOCKTNOSUPPORT**
Socket type not supported

errno. **EOPNOTSUPP**
Operation not supported on transport endpoint
errno. **EPFNOSUPPORT**  
Protocol family not supported

errno. **EAFNOSUPPORT**  
Address family not supported by protocol

errno. **EADDRINUSE**  
Address already in use

errno. **EADDRNOTAVAIL**  
Cannot assign requested address

errno. **ENETDOWN**  
Network is down

errno. **ENETUNREACH**  
Network is unreachable

errno. **ENETRESET**  
Network dropped connection because of reset

errno. **ECONNABORTED**  
Software caused connection abort

errno. **ECONNRESET**  
Connection reset by peer

errno. **ENOBUSFS**  
No buffer space available

errno. **EISCONN**  
Transport endpoint is already connected

errno. **ENOTCONN**  
Transport endpoint is not connected

errno. **ESHUTDOWN**  
Cannot send after transport endpoint shutdown
errno. **ETOOMANYREFS**
   Too many references: cannot splice

errno. **ETIMEDOUT**
   Connection timed out

errno. **ECONNREFUSED**
   Connection refused

errno. **EHOSTDOWN**
   Host is down

errno. **EHOSTUNREACH**
   No route to host

errno. **EALREADY**
   Operation already in progress

errno. **EINPROGRESS**
   Operation now in progress

errno. **ESTALE**
   Stale NFS file handle

errno. **EUCLEAN**
   Structure needs cleaning

errno. **ENOTNAM**
   Not a XENIX named type file

errno. **ENAVAIL**
   No XENIX semaphores available

errno. **EISNAM**
   Is a named type file

errno. **EREMOTEIO**
   Remote I/O error

ctypes — A foreign function library for Python.

New in version 2.5.

`ctypes` is a foreign function library for Python. It provides C compatible data types, and allows calling functions in DLLs or shared libraries. It can be used to wrap these libraries in pure Python.
Note: The code samples in this tutorial use doctest to make sure that they actually work. Since some code samples behave differently under Linux, Windows, or Mac OS X, they contain doctest directives in comments.

Note: Some code samples reference the ctypes `c_int` type. This type is an alias for the `c_long` type on 32-bit systems. So, you should not be confused if `c_long` is printed if you would expect `c_int` — they are actually the same type.

### Loading dynamic link libraries

ctypes exports the `cdll`, and on Windows `windll` and `oledll` objects, for loading dynamic link libraries.

You load libraries by accessing them as attributes of these objects. `cdll` loads libraries which export functions using the standard cdecl calling convention, while `windll` libraries call functions using the stdcall calling convention. `oledll` also uses the stdcall calling convention, and assumes the functions return a Windows HRESULT error code. The error code is used to automatically raise a WindowsError exception when the function call fails.

Here are some examples for Windows. Note that `msvcrt` is the MS standard C library containing most standard C functions, and uses the cdecl calling convention:

```python
>>> from ctypes import *
>>> print windll.kernel32 # doctest: +WINDOWS
<WinDLL 'kernel32', handle ... at ...>
>>> print cdll.msvcrt # doctest: +WINDOWS
<CDLL 'msvcrt', handle ... at ...>
```
Windows appends the usual `.dll` file suffix automatically.

On Linux, it is required to specify the filename *including* the extension to load a library, so attribute access can not be used to load libraries. Either the `LoadLibrary()` method of the dll loaders should be used, or you should load the library by creating an instance of CDLL by calling the constructor:

```python
>>> cdll.LoadLibrary("libc.so.6") # doctest: +LINUX
<CDLL 'libc.so.6', handle ... at ...>
>>> libc = CDLL("libc.so.6")    # doctest: +LINUX
>>> libc                     # doctest: +LINUX
<CDLL 'libc.so.6', handle ... at ...>
>>>```

### Accessing functions from loaded dlls

Functions are accessed as attributes of dll objects:

```python
>>> from ctypes import *
>>> libc.printf
<_FuncPtr object at 0x...>
>>> print windll.kernel32.GetModuleHandleA # doctest: +WINDOWS
<_FuncPtr object at 0x...>
>>> print windll.kernel32.MyOwnFunction # doctest: +WINDOWS
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
    File "ctypes.py", line 239, in __getattr__
          func = _StdcallFuncPtr(name, self)
AttributeError: function 'MyOwnFunction' not found
>>>```

Note that win32 system dlls like `kernel32` and `user32` often export ANSI as well as UNICODE versions of a function. The UNICODE version is exported with an `W` appended to the name, while the ANSI version is exported with an `A` appended to the name. The win32 `GetModuleHandle` function, which returns a `module handle` for a given
module name, has the following C prototype, and a macro is used to expose one of them as `GetModuleHandle` depending on whether UNICODE is defined or not:

```c
/* ANSI version */
HMODULE GetModuleHandleA(LPCSTR lpModuleName);
/* UNICODE version */
HMODULE GetModuleHandleW(LPCWSTR lpModuleName);
```

`windll` does not try to select one of them by magic, you must access the version you need by specifying `GetModuleHandleA` or `GetModuleHandleW` explicitly, and then call it with strings or unicode strings respectively.

Sometimes, dlls export functions with names which aren't valid Python identifiers, like `"??2@YAPAXI@Z"`. In this case you have to use `getattr` to retrieve the function:

```python
>>> getattr(cdll.msvcr, "??2@YAPAXI@Z") # doctest: +WINDOWS
<_FuncPtr object at 0x...>

>>>  
```

On Windows, some dlls export functions not by name but by ordinal. These functions can be accessed by indexing the dll object with the ordinal number:

```python
>>> cdll.kernel32[1] # doctest: +WINDOWS
<_FuncPtr object at 0x...>
>>> cdll.kernel32[0] # doctest: +WINDOWS
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
  File "ctypes.py", line 310, in __getitem__
    func = _StdcallFuncPtr(name, self)
AttributeError: function ordinal 0 not found

>>>  
```

Calling functions
You can call these functions like any other Python callable. This
example uses the time() function, which returns system time in
seconds since the Unix epoch, and the GetModuleHandleA() function,
which returns a win32 module handle.
This example calls both functions with a NULL pointer ( None should
be used as the NULL pointer):
>>> print libc.time(None) # doctest: +SKIP
1150640792
>>> print hex(windll.kernel32.GetModuleHandleA(None)) # doctest: +WINDOWS
0x1d000000
>>>

tries to protect you from calling functions with the wrong
number of arguments or the wrong calling convention. Unfortunately
this only works on Windows. It does this by examining the stack after
the function returns, so although an error is raised the function has
been called:
ctypes

>>> windll.kernel32.GetModuleHandleA() # doctest: +WINDOWS
Traceback (most recent call last):
File "<stdin>", line 1, in ?
ValueError: Procedure probably called with not enough arguments (4 bytes mis
>>> windll.kernel32.GetModuleHandleA(0, 0) # doctest: +WINDOWS
Traceback (most recent call last):
File "<stdin>", line 1, in ?
ValueError: Procedure probably called with too many arguments (4 bytes in ex
>>>

The same exception is raised when you call an
the cdecl calling convention, or vice versa:

stdcall

function with

>>> cdll.kernel32.GetModuleHandleA(None) # doctest: +WINDOWS
Traceback (most recent call last):
File "<stdin>", line 1, in ?
ValueError: Procedure probably called with not enough arguments (4 bytes mis
>>>


To find out the correct calling convention you have to look into the C header file or the documentation for the function you want to call.

On Windows, ctypes uses win32 structured exception handling to prevent crashes from general protection faults when functions are called with invalid argument values:

There are, however, enough ways to crash Python with ctypes, so you should be careful anyway.

None, integers, longs, byte strings and unicode strings are the only native Python objects that can directly be used as parameters in these function calls. None is passed as a C NULL pointer, byte strings and unicode strings are passed as pointer to the memory block that contains their data (char * or wchar_t *). Python integers and Python longs are passed as the platforms default C int type, their value is masked to fit into the C type.

Before we move on calling functions with other parameter types, we have to learn more about ctypes data types.

Fundamental data types

cypes defines a number of primitive C compatible data types :
<table>
<thead>
<tr>
<th>ctypes type</th>
<th>C type</th>
<th>Python type</th>
</tr>
</thead>
<tbody>
<tr>
<td>c_char</td>
<td>char</td>
<td>1-character string</td>
</tr>
<tr>
<td>c_wchar</td>
<td>wchar_t</td>
<td>1-character unicode string</td>
</tr>
<tr>
<td>c_byte</td>
<td>char</td>
<td>int/long</td>
</tr>
<tr>
<td>c_ubyte</td>
<td>unsigned char</td>
<td>int/long</td>
</tr>
<tr>
<td>c_short</td>
<td>short</td>
<td>int/long</td>
</tr>
<tr>
<td>c_ushort</td>
<td>unsigned short</td>
<td>int/long</td>
</tr>
<tr>
<td>c_int</td>
<td>int</td>
<td>int/long</td>
</tr>
<tr>
<td>c_uint</td>
<td>unsigned int</td>
<td>int/long</td>
</tr>
<tr>
<td>c_long</td>
<td>long</td>
<td>int/long</td>
</tr>
<tr>
<td>c_ulong</td>
<td>unsigned long</td>
<td>int/long</td>
</tr>
<tr>
<td>c_longlong</td>
<td>__int64 or long long</td>
<td>int/long</td>
</tr>
<tr>
<td>c_ullonglong</td>
<td>unsigned __int64 or unsigned long long</td>
<td>int/long</td>
</tr>
<tr>
<td>c_float</td>
<td>float</td>
<td>float</td>
</tr>
<tr>
<td>c_double</td>
<td>double</td>
<td>float</td>
</tr>
<tr>
<td>c_longdouble</td>
<td>long double</td>
<td>float</td>
</tr>
<tr>
<td>c_char_p</td>
<td>char * (NUL terminated)</td>
<td>string or None</td>
</tr>
<tr>
<td>c_wchar_p</td>
<td>wchar_t * (NUL terminated)</td>
<td>unicode or None</td>
</tr>
<tr>
<td>c_void_p</td>
<td>void *</td>
<td>int/long or None</td>
</tr>
</tbody>
</table>

All these types can be created by calling them with an optional initializer of the correct type and value:

```python
c_int()
c_long(0)
c_char_p("Hello, World")
c_char_p('Hello, World')
c_ushort(-3)
c_ushort(65533)
```

Since these types are mutable, their value can also be changed...
afterwards:

```python
>>> i = c_int(42)
>>> print i
c_long(42)
>>> print i.value
42
>>> i.value = -99
>>> print i.value
-99
```

Assigning a new value to instances of the pointer types `c_char_p`, `c_wchar_p`, and `c_void_p` changes the *memory location* they point to, *not the contents* of the memory block (of course not, because Python strings are immutable):

```python
>>> s = "Hello, World"
>>> c_s = c_char_p(s)
>>> print c_s
c_char_p('Hello, World')
>>> c_s.value = 'Hi, there'
>>> print c_s
c_char_p('Hi, there')
>>> print s                         # first string is unchanged
Hello, World
```

You should be careful, however, not to pass them to functions expecting pointers to mutable memory. If you need mutable memory blocks, ctypes has a `create_string_buffer` function which creates these in various ways. The current memory block contents can be accessed (or changed) with the `raw` property; if you want to access it as NUL terminated string, use the `value` property:

```python
>>> from ctypes import *
>>> p = create_string_buffer(3)         # create a 3 byte buffer, 'a'
>>> print sizeof(p), repr(p.raw)
3 \x00\x00\x00
>>> p = create_string_buffer("Hello")  # create a buffer containing
>>> print sizeof(p), repr(p.raw)
6 'Hello\x00'
```
The `create_string_buffer` function replaces the `c_buffer` function (which is still available as an alias), as well as the `c_string` function from earlier ctypes releases. To create a mutable memory block containing unicode characters of the C type `wchar_t` use the `create_unicode_buffer` function.

Calling functions, continued

Note that printf prints to the real standard output channel, *not* to `sys.stdout`, so these examples will only work at the console prompt, not from within *IDLE* or *PythonWin*:

```
>>> printf = libc.printf
>>> printf("Hello, %s\n", "World!")
Hello, World!
14
>>> printf("Hello, %S", u"World!")
Hello, World!
13
>>> printf("%d bottles of beer\n", 42)
42 bottles of beer
19
>>> printf("%f bottles of beer\n", 42.5)
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
ArgumentError: argument 2: exceptions.TypeError: Don't know how
```
corresponding \texttt{ctypes} type, so that they can be converted to the required C data type:

\begin{verbatim}
>>> printf("An int \%d, a double \%f\n", 1234, c_double(3.14))
Integer 1234, double 3.1400001049
31

Calling functions with your own custom data types

You can also customize \texttt{ctypes} argument conversion to allow instances of your own classes be used as function arguments. \texttt{ctypes} looks for an \_as\_parameter\_ attribute and uses this as the function argument. Of course, it must be one of integer, string, or unicode:

\begin{verbatim}
>>> class Bottles(object):
...     def \_init\_(self, number):
...         self._as_parameter_ = number
... >>> bottles = Bottles(42)
... >>> printf("\%d bottles of beer\n", bottles)
42 bottles of beer
19

If you don’t want to store the instance’s data in the \_as\_parameter\_ instance variable, you could define a \texttt{property} which makes the data available.

Specifying the required argument types (function prototypes)

It is possible to specify the required argument types of functions exported from DLLs by setting the \texttt{argtypes} attribute.

\texttt{argtypes} must be a sequence of C data types (the \texttt{printf} function is
probably not a good example here, because it takes a variable number and different types of parameters depending on the format string, on the other hand this is quite handy to experiment with this feature):

```python
>>> printf.argtypes = [c_char_p, c_char_p, c_int, c_double]
>>> printf("String '%s', Int %d, Double %f\n", "Hi", 10, 2.2)
String 'Hi', Int 10, Double 2.200000
37
```

Specifying a format protects against incompatible argument types (just as a prototype for a C function), and tries to convert the arguments to valid types:

```python
>>> printf("%d %d %d", 1, 2, 3)
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
ArgumentError: argument 2: exceptions.TypeError: wrong type
>>> printf("%s %d %f", "X", 2, 3)
X 2 3.00000012
12
```

If you have defined your own classes which you pass to function calls, you have to implement a `from_param()` class method for them to be able to use them in the `argtypes` sequence. The `from_param()` class method receives the Python object passed to the function call, it should do a typecheck or whatever is needed to make sure this object is acceptable, and then return the object itself, its `__as_parameter__` attribute, or whatever you want to pass as the C function argument in this case. Again, the result should be an integer, string, unicode, a `ctypes` instance, or an object with an `__as_parameter__` attribute.

**Return types**
By default functions are assumed to return the \texttt{C int} type. Other return types can be specified by setting the \texttt{restype} attribute of the function object.

Here is a more advanced example, it uses the \texttt{strchr} function, which expects a string pointer and a char, and returns a pointer to a string:

```python
>>> strchr = libc.strchr
>>> strchr("abcdef", ord("d"))  # doctest: +SKIP
8059983
>>> strchr.retype = c_char_p  # \texttt{c_char_p} is a pointer to a string
>>> strchr("abcdef", ord("d"))
'def'
>>> print strchr("abcdef", ord("x"))
None

If you want to avoid the \texttt{ord("x")} calls above, you can set the \texttt{argtypes} attribute, and the second argument will be converted from a single character Python string into a C char:

```python
>>> strchr.retype = c_char_p
>>> strchr.argtypes = [c_char_p, c_char]
>>> strchr("abcdef", "d")
'def'
>>> strchr("abcdef", "def")
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
ArgumentError: argument 2: exceptions.TypeError: one character

You can also use a callable Python object (a function or a class for example) as the \texttt{restype} attribute, if the foreign function returns an integer. The callable will be called with the \texttt{integer} the C function returns, and the result of this call will be used as the result of your
function call. This is useful to check for error return values and automatically raise an exception:

```python
>>> GetModuleHandle = windll.kernel32.GetModuleHandleA  # doctest:
... def ValidHandle(value):
...     if value == 0:
...         raise WinError()
...     return value
...>>> GetModuleHandle().restype = ValidHandle  # doctest: +WINDOWS
>>> GetModuleHandle(None)  # doctest: +WINDOWS
486539264
>>> GetModuleHandle("something silly")  # doctest: +WINDOWS
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
  File "<stdin>", line 3, in ValidHandle
WindowsError: [Errno 126] The specified module could not be found.
```  

WinError is a function which will call Windows FormatMessage() api to get the string representation of an error code, and returns an exception. WinError takes an optional error code parameter, if no one is used, it calls GetLastError() to retrieve it.

Please note that a much more powerful error checking mechanism is available through the errcheck attribute; see the reference manual for details.

**Passing pointers (or: passing parameters by reference)**

Sometimes a C api function expects a pointer to a data type as parameter, probably to write into the corresponding location, or if the data is too large to be passed by value. This is also known as passing parameters by reference.

ctypes exports the byref() function which is used to pass
parameters by reference. The same effect can be achieved with the `pointer` function, although `pointer` does a lot more work since it constructs a real pointer object, so it is faster to use `byref()` if you don’t need the pointer object in Python itself:

```python
>>> i = c_int()
>>> f = c_float()
>>> s = create_string_buffer('\000' * 32)
>>> print i.value, f.value, repr(s.value)
0 0.0 ''
>>> libc sscanf("1 3.14 Hello", "%d %f %s", ...
   ... byref(i), byref(f), s)
3
>>> print i.value, f.value, repr(s.value)
1 3.1400000001049 'Hello'

Structures and unions

Structures and unions must derive from the `Structure` and `Union` base classes which are defined in the `ctypes` module. Each subclass must define a `_fields_` attribute. `_fields_` must be a list of 2-tuples, containing a field name and a field type.

The field type must be a `ctypes` type like `c_int`, or any other derived `ctypes` type: structure, union, array, pointer.

Here is a simple example of a POINT structure, which contains two integers named `x` and `y`, and also shows how to initialize a structure in the constructor:

```python
>>> from ctypes import *
>>> class POINT(Structure):
...     _fields_ = [("x", c_int),
...                 ("y", c_int)]
...
>>> point = POINT(10, 20)
>>> print point.x, point.y
10 20
>>> point = POINT(y=5)
```
You can, however, build much more complicated structures. Structures can itself contain other structures by using a structure as a field type.

Here is a RECT structure which contains two POINTs named `upperleft` and `lowerright`:

```python
>>> class RECT(Structure):
...     _fields_ = [('upperleft', POINT),
...                 ('lowerright', POINT)]
...     
>>> rc = RECT(point)
>>> print rc.upperleft.x, rc.upperleft.y
0 5
>>> print rc.lowerright.x, rc.lowerright.y
0 0
```
Structure/union alignment and byte order

By default, Structure and Union fields are aligned in the same way the C compiler does it. It is possible to override this behavior by specifying a _pack_ class attribute in the subclass definition. This must be set to a positive integer and specifies the maximum alignment for the fields. This is what `#pragma pack(n)` also does in MSVC.

`ctypes` uses the native byte order for Structures and Unions. To build structures with non-native byte order, you can use one of the `BigEndianStructure`, `LittleEndianStructure`, `BigEndianUnion`, and `LittleEndianUnion` base classes. These classes cannot contain pointer fields.

Bit fields in structures and unions

It is possible to create structures and unions containing bit fields. Bit fields are only possible for integer fields, the bit width is specified as the third item in the `_fields_` tuples:

```python
>>> class Int(Structure):
...     _fields_ = ["first_16", c_int, 16],
...                 ("second_16", c_int, 16)]
... >>> print Int.first_16
Field type=c_long, ofs=0:0, bits=16
>>> print Int.second_16
Field type=c_long, ofs=0:16, bits=16
```  

Arrays

Arrays are sequences, containing a fixed number of instances of the same type.
The recommended way to create array types is by multiplying a data type with a positive integer:

```python
TenPointsArrayType = POINT * 10
```

Here is an example of an somewhat artificial data type, a structure containing 4 POINTs among other stuff:

```python
>>> from ctypes import *

>>> class POINT(Structure):
...     _fields_ = ("x", c_int), ("y", c_int)
...

>>> class MyStruct(Structure):
...     _fields_ = [('a', c_int),
...                 ('b', c_float),
...                 ('point_array', POINT * 4)]

>>> print len(MyStruct().point_array)
4
```

Instances are created in the usual way, by calling the class:

```python
arr = TenPointsArrayType()
for pt in arr:
    print pt.x, pt.y
```

The above code print a series of 0 0 lines, because the array contents is initialized to zeros.

Initializers of the correct type can also be specified:

```python
>>> from ctypes import *

>>> TenIntegers = c_int * 10

>>> ii = TenIntegers(1, 2, 3, 4, 5, 6, 7, 8, 9, 10)

>>> print ii
<c_long_Array_10 object at 0x...>

>>> for i in ii: print i,
1 2 3 4 5 6 7 8 9 10
```
Pointers

Pointer instances are created by calling the `pointer` function on a `ctypes` type:

```python
>>> from ctypes import *
>>> i = c_int(42)
>>> pi = pointer(i)

>>> pi.contents
\c_long(42)
```

Pointer instances have a `contents` attribute which returns the object to which the pointer points, the `i` object above:

```python
>>> pi.contents
\c_long(42)
```

Note that `ctypes` does not have OOR (original object return), it constructs a new, equivalent object each time you retrieve an attribute:

```python
>>> pi.contents is i
False
>>> pi.contents is pi.contents
False
```

Assigning another `c_int` instance to the pointer’s contents attribute would cause the pointer to point to the memory location where this is stored:

```python
>>> i = c_int(99)
>>> pi.contents = i
>>> pi.contents
\c_long(99)
```

Pointer instances can also be indexed with integers:
Assigning to an integer index changes the pointed to value:

```python
>>> pi[0] = 22
>>> print c_long(22)
```

It is also possible to use indexes different from 0, but you must know what you're doing, just as in C: You can access or change arbitrary memory locations. Generally you only use this feature if you receive a pointer from a C function, and you know that the pointer actually points to an array instead of a single item.

Behind the scenes, the `pointer` function does more than simply create pointer instances, it has to create pointer `types` first. This is done with the `POINTER` function, which accepts any `ctypes` type, and returns a new type:

```python
>>> PI = POINTER(c_int)
>>> PI(42)
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
TypeError: expected c_long instead of int
>>> PI(c_int(42))
<ctypes.LP_c_long object at 0x...>
```

Calling the pointer type without an argument creates a **NULL** pointer. **NULL** pointers have a **False** boolean value:

```python
>>> null_ptr = POINTER(c_int)()
>>> print bool(null_ptr)
False
```
ctypes checks for NULL when dereferencing pointers (but dereferencing invalid non-NULL pointers would crash Python):

```python
>>> null_ptr[0]
Traceback (most recent call last):
  ....
ValueError: NULL pointer access
```

```python
>>> null_ptr[0] = 1234
Traceback (most recent call last):
  ....
ValueError: NULL pointer access
```

### Type conversions

Usually, ctypes does strict type checking. This means, if you have POINTER(c_int) in the argtypes list of a function or as the type of a member field in a structure definition, only instances of exactly the same type are accepted. There are some exceptions to this rule, where ctypes accepts other objects. For example, you can pass compatible array instances instead of pointer types. So, for POINTER(c_int), ctypes accepts an array of c_int:

```python
>>> class Bar(Structure):
...     _fields_ = ["count", c_int], ("values", POINTER(c_int))
...>>> bar = Bar()
>>> bar.values = (c_int * 3)(1, 2, 3)
>>> bar.count = 3
>>> for i in range(bar.count):
...     print bar.values[i]
...1
2
3
```
To set a POINTER type field to NULL, you can assign None:

```python
>>> bar.values = None
```
Incomplete Types

Incomplete Types are structures, unions or arrays whose members are not yet specified. In C, they are specified by forward declarations, which are defined later:

```c
struct cell; /* forward declaration */
struct {
    char *name;
    struct cell *next;
} cell;
```

The straightforward translation into ctypes code would be this, but it does not work:

```python
>>> class cell(Structure):
...     _fields_ = [('name', c_char_p),
...                 ('next', POINTER(cell))]
...
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
  File "<stdin>", line 2, in cell
NameError: name 'cell' is not defined
```

because the new class `cell` is not available in the class statement itself. In ctypes, we can define the `cell` class and set the `_fields_` attribute later, after the class statement:

```python
>>> from ctypes import *
>>> class cell(Structure):
...     pass
...     _fields_ = [('name', c_char_p),
...                 ('next', POINTER(cell))]
```

Let's try it. We create two instances of `cell`, and let them point to each other, and finally follow the pointer chain a few times:

```python
>>> c1 = cell()
>>> c1.name = "foo"
>>> c2 = cell()
>>> c2.name = "bar"
>>> c1.next = pointer(c2)
>>> c2.next = pointer(c1)
>>> p = c1
>>> for i in range(8):
...     print p.name,
...     p = p.next[0]
...foo bar foo bar foo bar foo bar
```
qsort() must be called with a pointer to the data to sort, the number of items in the data array, the size of one item, and a pointer to the comparison function, the callback. The callback will then be called with two pointers to items, and it must return a negative integer if the first item is smaller than the second, a zero if they are equal, and a positive integer else.

So our callback function receives pointers to integers, and must return an integer. First we create the type for the callback function:

```python
>>> CMPFUNC = CFUNCTYPE(c_int, POINTER(c_int), POINTER(c_int))
>>>```

For the first implementation of the callback function, we simply print the arguments we get, and return 0 (incremental development ;-):

```python
>>> def py_cmp_func(a, b):
...     print("py_cmp_func", a, b
...     return 0
... >>>
```

Create the C callable callback:

```python
>>> cmp_func = CMPFUNC(py_cmp_func)
>>>```

And we’re ready to go:

```python
>>> qsort(ia, len(ia), sizeof(c_int), cmp_func) # doctest: +WIN
py_cmp_func <types.LP_c_long object at 0x00...> <ctypes.LP_c_l
py_cmp_func <types.LP_c_long object at 0x00...> <ctypes.LP_c_l
py_cmp_func <types.LP_c_long object at 0x00...> <ctypes.LP_c_l
py_cmp_func <types.LP_c_long object at 0x00...> <ctypes.LP_c_l
```
We know how to access the contents of a pointer, so let's redefine our callback:

```python
>>> def py_cmp_func(a, b):
...     print("py_cmp_func", a[0], b[0])
...     return 0
... >>> cmp_func = CMPFUNC(py_cmp_func)
``` 

Here is what we get on Windows:

```python
>>> qsort(ia, len(ia), sizeof(c_int), cmp_func) # doctest: +WIN
py_cmp_func 7 1
py_cmp_func 33 1
py_cmp_func 99 1
py_cmp_func 5 1
py_cmp_func 7 5
py_cmp_func 33 5
py_cmp_func 99 5
py_cmp_func 7 99
py_cmp_func 33 99
py_cmp_func 7 33
>>> 
```

It is funny to see that on linux the sort function seems to work much more efficient, it is doing less comparisons:

```python
>>> qsort(ia, len(ia), sizeof(c_int), cmp_func) # doctest: +LIN
py_cmp_func 5 1
py_cmp_func 33 99
py_cmp_func 7 33
py_cmp_func 5 7
py_cmp_func 1 7
>>> 
```
Ah, we're nearly done! The last step is to actually compare the two items and return a useful result:

```python
def py_cmp_func(a, b):
    ...
    print "py_cmp_func", a[0], b[0]
    ...
    return a[0] - b[0]
```

Final run on Windows:

```python
>>> qsort(ia, len(ia), sizeof(c_int), CMPFUNC(py_cmp_func)) # doctest: +WINDOWS
py_cmp_func 33 7
py_cmp_func 99 33
py_cmp_func 5 99
py_cmp_func 1 99
py_cmp_func 33 7
py_cmp_func 1 33
py_cmp_func 5 33
py_cmp_func 5 7
py_cmp_func 1 7
py_cmp_func 5 1
```

and on Linux:

```python
>>> qsort(ia, len(ia), sizeof(c_int), CMPFUNC(py_cmp_func)) # doctest: +LINUX
py_cmp_func 5 1
py_cmp_func 33 99
py_cmp_func 7 33
py_cmp_func 1 7
py_cmp_func 5 7
```

It is quite interesting to see that the Windows `qsort()` function needs more comparisons than the linux version!

As we can easily check, our array is sorted now:
>>> for i in ia: print i,
...
1 5 7 33 99
>>> 

**Important note for callback functions:**

Make sure you keep references to CFUNCTYPE objects as long as they are used from C code. `ctypes` doesn’t, and if you don’t, they may be garbage collected, crashing your program when a callback is made.

### Accessing values exported from dlls

Some shared libraries not only export functions, they also export variables. An example in the Python library itself is the `Py_OptimizeFlag`, an integer set to 0, 1, or 2, depending on the `-O` or `-OO` flag given on startup.

`ctypes` can access values like this with the `in_dll()` class methods of the type. `pythonapi` is a predefined symbol giving access to the Python C api:

```python
>>> opt_flag = c_int.in_dll(pythonapi, "Py_OptimizeFlag")
>>> print opt_flag
c_long(0)
```  

If the interpreter would have been started with `-O`, the sample would have printed `c_long(1)`, or `c_long(2)` if `-OO` would have been specified.

An extended example which also demonstrates the use of pointers accesses the `PyImport_FrozenModules` pointer exported by Python.

Quoting the Python docs: *This pointer is initialized to point to an array of “struct _frozen” records, terminated by one whose members*
are all NULL or zero. When a frozen module is imported, it is searched in this table. Third-party code could play tricks with this to provide a dynamically created collection of frozen modules.

So manipulating this pointer could even prove useful. To restrict the example size, we show only how this table can be read with ctypes:

```python
>>> from ctypes import *

>>> class struct_frozen(Structure):
...     _fields_ = ["name", c_char_p],
...     ("code", POINTER(c_ubyte)),
...     ("size", c_int)

>>> FrozenTable = POINTER(struct_frozen)
>>> table = FrozenTable.in_dll(pythonapi, "PyImport_FrozenModules")

We have defined the struct_frozen data type, so we can get the pointer to the table:

>>> for item in table:
...     print item.name, item.size
...     if item.name is None:
...         break
...__hello__ 104
__phello__ -104
__phello__.spam 104
None 0

Since table is a pointer to the array of struct_frozen records, we can iterate over it, but we just have to make sure that our loop terminates, because pointers have no size. Sooner or later it would probably crash with an access violation or whatever, so it's better to break out of the loop when we hit the NULL entry:
The fact that standard Python has a frozen module and a frozen package (indicated by the negative size member) is not well known, it is only used for testing. Try it out with `import __hello__` for example.

**Surprises**

There are some edges in `ctypes` where you may be expect something else than what actually happens.

Consider the following example:

```python
>>> from ctypes import *
>>> class POINT(Structure):
...    _fields_ = ('x', c_int), ('y', c_int)
...>>> class RECT(Structure):
...    _fields_ = ('a', POINT), ('b', POINT)
...>>> p1 = POINT(1, 2)
>>> p2 = POINT(3, 4)
>>> rc = RECT(p1, p2)
>>> print rc.a.x, rc.a.y, rc.b.x, rc.b.y
1 2 3 4
>>> # now swap the two points
>>> rc.a, rc.b = rc.b, rc.a
>>> print rc.a.x, rc.a.y, rc.b.x, rc.b.y
3 4 3 4
```

Hm. We certainly expected the last statement to print 3 4 1 2. What happened? Here are the steps of the `rc.a, rc.b = rc.b, rc.a` line above:

```python
>>> temp0, temp1 = rc.b, rc.a
>>> rc.a = temp0
>>> rc.b = temp1
```

Note that `temp0` and `temp1` are objects still using the internal buffer of
the \texttt{rc} object above. So executing \texttt{rc.a = temp0} copies the buffer contents of \texttt{temp0} into \texttt{rc}'s buffer. This, in turn, changes the contents of \texttt{temp1}. So, the last assignment \texttt{rc.b = temp1}, doesn't have the expected effect.

Keep in mind that retrieving sub-objects from Structure, Unions, and Arrays doesn't \textit{copy} the sub-object, instead it retrieves a wrapper object accessing the root-object's underlying buffer.

Another example that may behave different from what one would expect is this:

```
>>> s = c_char_p()
>>> s.value = "abc def ghi"
>>> s.value
'abc def ghi'
>>> s.value is s.value
False
```  

Why is it printing \texttt{False}? ctypes instances are objects containing a memory block plus some \texttt{descriptors} accessing the contents of the memory. Storing a Python object in the memory block does not store the object itself, instead the \texttt{contents} of the object is stored. Accessing the contents again constructs a new Python object each time!

### Variable-sized data types

c\texttt{types} provides some support for variable-sized arrays and structures (this was added in version 0.9.9.7).

The \texttt{resize} function can be used to resize the memory buffer of an existing ctypes object. The function takes the object as first argument, and the requested size in bytes as the second argument. The memory block cannot be made smaller than the natural memory
block specified by the objects type, a `ValueError` is raised if this is tried:

```python
>>> short_array = (c_short * 4)()
>>> print sizeof(short_array)
8
>>> resize(short_array, 4)
Traceback (most recent call last):
...  
ValueError: minimum size is 8
>>> resize(short_array, 32)
>>> sizeof(short_array)
32
>>> sizeof(type(short_array))
8
>>> 
This is nice and fine, but how would one access the additional elements contained in this array? Since the type still only knows about 4 elements, we get errors accessing other elements:

```python
>>> short_array[:]
[0, 0, 0, 0]
>>> short_array[7]
Traceback (most recent call last):
...
IndexError: invalid index
>>> 
```  
Another way to use variable-sized data types with `ctypes` is to use the dynamic nature of Python, and (re-)define the data type after the required size is already known, on a case by case basis.
Finding shared libraries

When programming in a compiled language, shared libraries are accessed when compiling/linking a program, and when the program is run.

The purpose of the `find_library` function is to locate a library in a way similar to what the compiler does (on platforms with several versions of a shared library the most recent should be loaded), while the ctypes library loaders act like when a program is run, and call the runtime loader directly.

The `ctypes.util` module provides a function which can help to determine the library to load.

`ctypes.find_library(name)`

Try to find a library and return a pathname. `name` is the library name without any prefix like `lib`, suffix like `.so`, `.dylib` or version number (this is the form used for the posix linker option `-l`). If no library can be found, returns `None`.

The exact functionality is system dependent.

On Linux, `find_library` tries to run external programs (`/sbin/ldconfig`, `gcc`, and `objdump`) to find the library file. It returns the filename of the library file. Here are some examples:

```python
>>> from ctypes.util import find_library
>>> find_library("m")
'libm.so.6'
>>> find_library("c")
'libc.so.6'
>>> find_library("bz2")
```
On OS X, `find_library` tries several predefined naming schemes and paths to locate the library, and returns a full pathname if successful:

```python
>>> from ctypes.util import find_library
>>> find_library("c")
'/usr/lib/libc.dylib'
>>> find_library("m")
'/usr/lib/libm.dylib'
>>> find_library("bz2")
'/usr/lib/libbz2.dylib'
>>> find_library("AGL")
'/System/Library/Frameworks/AGL.framework/AGL'
```  

On Windows, `find_library` searches along the system search path, and returns the full pathname, but since there is no predefined naming scheme a call like `find_library("c")` will fail and return `None`.

If wrapping a shared library with `ctypes`, it may be better to determine the shared library name at development type, and hardcode that into the wrapper module instead of using `find_library` to locate the library at runtime.

### Loading shared libraries

There are several ways to loaded shared libraries into the Python process. One way is to instantiate one of the following classes:

```python
class ctypes.CDLL(name, mode=DEFAULT_MODE, handle=None, use_errno=False, use_last_error=False)
```  
Instances of this class represent loaded shared libraries. Functions in these libraries use the standard C calling
convention, and are assumed to return \texttt{int}.

\texttt{class \texttt{ctypes.OleDLL}(name, mode=DEFAULT\_MODE, handle=None, use\_errno=False, use\_last\_error=False)}

Windows only: Instances of this class represent loaded shared libraries, functions in these libraries use the \texttt{stdcall} calling convention, and are assumed to return the windows specific \texttt{HRESULT} code. \texttt{HRESULT} values contain information specifying whether the function call failed or succeeded, together with additional error code. If the return value signals a failure, an \texttt{WindowsError} is automatically raised.

\texttt{class \texttt{ctypes.WinDLL}(name, mode=DEFAULT\_MODE, handle=None, use\_errno=False, use\_last\_error=False)}

Windows only: Instances of this class represent loaded shared libraries, functions in these libraries use the \texttt{stdcall} calling convention, and are assumed to return \texttt{int} by default.

On Windows CE only the standard calling convention is used, for convenience the \texttt{WinDLL} and \texttt{OleDLL} use the standard calling convention on this platform.

The Python \textit{global interpreter lock} is released before calling any function exported by these libraries, and reacquired afterwards.

\texttt{class \texttt{ctypes.PyDLL}(name, mode=DEFAULT\_MODE, handle=None)}

Instances of this class behave like \texttt{CDLL} instances, except that the Python GIL is \textit{not} released during the function call, and after the function execution the Python error flag is checked. If the error flag is set, a Python exception is raised.

Thus, this is only useful to call Python C api functions directly.

All these classes can be instantiated by calling them with at least
one argument, the pathname of the shared library. If you have an existing handle to an already loaded shard library, it can be passed as the handle named parameter, otherwise the underlying platforms `dlopen` or `LoadLibrary()` function is used to load the library into the process, and to get a handle to it.

The *mode* parameter can be used to specify how the library is loaded. For details, consult the `dlopen(3)` manpage, on Windows, *mode* is ignored.

The *use_errno* parameter, when set to True, enables a ctypes mechanism that allows to access the system *errno* error number in a safe way. ctypes maintains a thread-local copy of the systems *errno* variable; if you call foreign functions created with *use_errno=True* then the *errno* value before the function call is swapped with the ctypes private copy, the same happens immediately after the function call.

The function `ctypes.get_errno()` returns the value of the ctypes private copy, and the function `ctypes.set_errno(value)` changes the ctypes private copy to *value* and returns the former value.

The *use_last_error* parameter, when set to True, enables the same mechanism for the Windows error code which is managed by the `GetLastError()` and `SetLastError()` Windows API functions; `ctypes.get_last_error()` and `ctypes.set_last_error(value)` are used to request and change the ctypes private copy of the windows error code.

_New in version 2.6:_ The *use_last_error* and *use_errno* optional parameters were added.

`ctypes.RTLD_GLOBAL`

Flag to use as *mode* parameter. On platforms where this flag is not available, it is defined as the integer zero.
ctypes. **RTLD_LOCAL**

Flag to use as *mode* parameter. On platforms where this is not available, it is the same as *RTLD_GLOBAL*.

ctypes. **DEFAULT_MODE**

The default mode which is used to load shared libraries. On OSX 10.3, this is *RTLD_GLOBAL*, otherwise it is the same as *RTLD_LOCAL*.

Instances of these classes have no public methods, however `__getattr__()` and `__getitem__()` have special behavior: functions exported by the shared library can be accessed as attributes of by index. Please note that both `__getattr__()` and `__getitem__()` cache their result, so calling them repeatedly returns the same object each time.

The following public attributes are available, their name starts with an underscore to not clash with exported function names:

**PyDLL. **_handle

The system handle used to access the library.

**PyDLL. **_name

The name of the library passed in the constructor.

Shared libraries can also be loaded by using one of the prefabricated objects, which are instances of the `LibraryLoader` class, either by calling the `LoadLibrary()` method, or by retrieving the library as attribute of the loader instance.

**class ctypes. **LibraryLoader(dlltype)

Class which loads shared libraries. `dlltype` should be one of the `CDLL`, `PyDLL`, `WinDLL`, or `OleDLL` types.

`__getattr__()` has special behavior: It allows to load a shared
library by accessing it as attribute of a library loader instance. The result is cached, so repeated attribute accesses return the same library each time.

**LoadLibrary**(name)

Load a shared library into the process and return it. This method always returns a new instance of the library.

These prefabricated library loaders are available:

- **ctypes.cdll**
  Creates **CDLL** instances.

- **ctypes.windll**
  Windows only: Creates **WinDLL** instances.

- **ctypes.oledll**
  Windows only: Creates **oleDLL** instances.

- **ctypes.pydll**
  Creates **PyDLL** instances.

For accessing the C Python api directly, a ready-to-use Python shared library object is available:

- **ctypes.pythonapi**
  An instance of **PyDLL** that exposes Python C api functions as attributes. Note that all these functions are assumed to return C **int**, which is of course not always the truth, so you have to assign the correct **restype** attribute to use these functions.

### Foreign functions

As explained in the previous section, foreign functions can be accessed as attributes of loaded shared libraries. The function
objects created in this way by default accept any number of arguments, accept any ctypes data instances as arguments, and return the default result type specified by the library loader. They are instances of a private class:

class ctypes._FuncPtr

    Base class for C callable foreign functions.

Instances of foreign functions are also C compatible data types; they represent C function pointers.

This behavior can be customized by assigning to special attributes of the foreign function object.

**restype**

Assign a ctypes type to specify the result type of the foreign function. Use `None` for `void` a function not returning anything.

It is possible to assign a callable Python object that is not a ctypes type, in this case the function is assumed to return a C `int`, and the callable will be called with this integer, allowing to do further processing or error checking. Using this is deprecated, for more flexible post processing or error checking use a ctypes data type as `restype` and assign a callable to the `errcheck` attribute.

**argtypes**

Assign a tuple of ctypes types to specify the argument types that the function accepts. Functions using the `stdcall` calling convention can only be called with the same number of arguments as the length of this tuple; functions using the C calling convention accept additional, unspecified arguments as well.

When a foreign function is called, each actual argument is
passed to the `from_param()` class method of the items in the `argtypes` tuple, this method allows to adapt the actual argument to an object that the foreign function accepts. For example, a `c_char_p` item in the `argtypes` tuple will convert a unicode string passed as argument into an byte string using ctypes conversion rules.

New: It is now possible to put items in `argtypes` which are not ctypes types, but each item must have a `from_param()` method which returns a value usable as argument (integer, string, ctypes instance). This allows to define adapters that can adapt custom objects as function parameters.

**errcheck**

Assign a Python function or another callable to this attribute. The callable will be called with three or more arguments:

```python
callable(result, func, arguments)
```

- `result` is what the foreign function returns, as specified by the `restype` attribute.

- `func` is the foreign function object itself, this allows to reuse the same callable object to check or post process the results of several functions.

- `arguments` is a tuple containing the parameters originally passed to the function call, this allows to specialize the behavior on the arguments used.

The object that this function returns will be returned from the foreign function call, but it can also check the result value and raise an exception if the foreign function call failed.

```python
exception ctypes.ArgumentError
```

This exception is raised when a foreign function call cannot
Function prototypes

Foreign functions can also be created by instantiating function prototypes. Function prototypes are similar to function prototypes in C; they describe a function (return type, argument types, calling convention) without defining an implementation. The factory functions must be called with the desired result type and the argument types of the function.

```python
ctypes.CFUNCTYPE(restype, *argtypes, use_errno=False, use_last_error=False)
```

The returned function prototype creates functions that use the standard C calling convention. The function will release the GIL during the call. If `use_errno` is set to True, the ctypes private copy of the system `errno` variable is exchanged with the real `errno` value before and after the call; `use_last_error` does the same for the Windows error code.

*Changed in version 2.6:* The optional `use_errno` and `use_last_error` parameters were added.

```python
ctypes.WINFUNCTYPE(restype, *argtypes, use_errno=False, use_last_error=False)
```

Windows only: The returned function prototype creates functions that use the `stdcall` calling convention, except on Windows CE where `WINFUNCTYPE()` is the same as `CFUNCTYPE()`. The function will release the GIL during the call. `use_errno` and `use_last_error` have the same meaning as above.

```python
ctypes.PYFUNCTYPE(restype, *argtypes)
```

The returned function prototype creates functions that use the Python calling convention. The function will *not* release the GIL

convert one of the passed arguments.
during the call.

Function prototypes created by these factory functions can be instantiated in different ways, depending on the type and number of the parameters in the call:

**prototype**(address)

Returns a foreign function at the specified address which must be an integer.

**prototype**(callable)

Create a C callable function (a callback function) from a Python callable.

**prototype**(func_spec[, paramflags])

Returns a foreign function exported by a shared library. *func_spec* must be a 2-tuple (name_or_ordinal, library). The first item is the name of the exported function as string, or the ordinal of the exported function as small integer. The second item is the shared library instance.

**prototype**(vtbl_index, name[, paramflags[, iid]])

Returns a foreign function that will call a COM method. *vtbl_index* is the index into the virtual function table, a small non-negative integer. *name* is name of the COM method. *iid* is an optional pointer to the interface identifier which is used in extended error reporting.

COM methods use a special calling convention: They require a pointer to the COM interface as first argument, in addition to those parameters that are specified in the *argtypes* tuple.

The optional *paramflags* parameter creates foreign function wrappers with much more functionality than the features
paramflags must be a tuple of the same length as argtypes.

Each item in this tuple contains further information about a parameter, it must be a tuple containing one, two, or three items.

The first item is an integer containing a combination of direction flags for the parameter:

1  Specifies an input parameter to the function.
2  Output parameter. The foreign function fills in a value.
4  Input parameter which defaults to the integer zero.

The optional second item is the parameter name as string. If this is specified, the foreign function can be called with named parameters.

The optional third item is the default value for this parameter.

This example demonstrates how to wrap the Windows MessageBoxA function so that it supports default parameters and named arguments. The C declaration from the windows header file is this:

```
WINUSERAPI int WINAPI MessageBoxA( 
    HWND hWnd, 
    LPCSTR lpText, 
    LPCSTR lpCaption, 
    UINT uType);
```

Here is the wrapping with ctypes:

```
>>> from ctypes import c_int, WINFUNCTYPE, windll
```
The MessageBox foreign function can now be called in these ways:

```python
>>> MessageBox()
>>> MessageBox(text="Spam, spam, spam")
>>> MessageBox(flags=2, text="foo bar")
```

A second example demonstrates output parameters. The win32 GetWindowRect function retrieves the dimensions of a specified window by copying them into `RECT` structure that the caller has to supply. Here is the C declaration:

```c
WINUSERAPI BOOL WINAPI GetWindowRect(
    HWND hWnd,
    LPRECT lpRect);
```

Here is the wrapping with `ctypes`:

```python
>>> from ctypes import POINTER, WINFUNCTYPE, windll, WinError
>>> from ctypes.wintypes import BOOL, HWND, RECT
>>> prototype = WINFUNCTYPE(BOOL, HWND, POINTER(RECT))
>>> paramflags = (1, "hwnd"), (2, "lprect")
>>> GetWindowRect = prototype(("GetWindowRect", windll.user32), paramflags)
```

Functions with output parameters will automatically return the output parameter value if there is a single one, or a tuple containing the output parameter values when there are more than one, so the GetWindowRect function now returns a RECT instance, when called.

Output parameters can be combined with the `errcheck` protocol to do further output processing and error checking. The win32
GetWindowRect api function returns a BOOL to signal success or failure, so this function could do the error checking, and raises an exception when the api call failed:

```python
>>> def errcheck(result, func, args):
...     if not result:
...         raise WinError()
...     return args
...
>>> GetWindowRect.errcheck = errcheck

If the `errcheck` function returns the argument tuple it receives unchanged, ctypes continues the normal processing it does on the output parameters. If you want to return a tuple of window coordinates instead of a RECT instance, you can retrieve the fields in the function and return them instead, the normal processing will no longer take place:

```python
>>> def errcheck(result, func, args):
...     if not result:
...         raise WinError()
...     rc = args[1]
...     return rc.left, rc.top, rc.bottom, rc.right
...
>>> GetWindowRect.errcheck = errcheck

Utility functions

c ctypes. `addressof(obj)`
Returns the address of the memory buffer as integer. `obj` must be an instance of a ctypes type.

c ctypes. `alignment(obj_or_type)`
Returns the alignment requirements of a ctypes type. `obj_or_type` must be a ctypes type or instance.
**ctypes.byref(obj[, offset])**

Returns a light-weight pointer to `obj`, which must be an instance of a ctypes type. `offset` defaults to zero, and must be an integer that will be added to the internal pointer value.

`byref(obj, offset)` corresponds to this C code:

```c
(((char *)&obj) + offset)
```

The returned object can only be used as a foreign function call parameter. It behaves similar to `pointer(obj)`, but the construction is a lot faster.

*New in version 2.6:* The `offset` optional argument was added.

**ctypes.cast(obj, type)**

This function is similar to the cast operator in C. It returns a new instance of `type` which points to the same memory block as `obj`. `type` must be a pointer type, and `obj` must be an object that can be interpreted as a pointer.

**ctypes.create_string_buffer(init_or_size[, size])**

This function creates a mutable character buffer. The returned object is a ctypes array of `c_char`.

`init_or_size` must be an integer which specifies the size of the array, or a string which will be used to initialize the array items.

If a string is specified as first argument, the buffer is made one item larger than the length of the string so that the last element in the array is a NUL termination character. An integer can be passed as second argument which allows to specify the size of the array if the length of the string should not be used.
If the first parameter is a unicode string, it is converted into an 8-bit string according to ctypes conversion rules.

```python
ctypes.create_unicode_buffer(init_or_size[, size])
```

This function creates a mutable unicode character buffer. The returned object is a ctypes array of `c_wchar`.

`init_or_size` must be an integer which specifies the size of the array, or a unicode string which will be used to initialize the array items.

If a unicode string is specified as first argument, the buffer is made one item larger than the length of the string so that the last element in the array is a NUL termination character. An integer can be passed as second argument which allows to specify the size of the array if the length of the string should not be used.

If the first parameter is a 8-bit string, it is converted into an unicode string according to ctypes conversion rules.

```python
c ctypes.DllCanUnloadNow()
```

Windows only: This function is a hook which allows to implement in-process COM servers with ctypes. It is called from the DllCanUnloadNow function that the _ctypes extension dll exports.

```python
c ctypes.DllGetClassObject()
```

Windows only: This function is a hook which allows to implement in-process COM servers with ctypes. It is called from the DllGetClassObject function that the _ctypes extension dll exports.

```python
c ctypes.util.find_library(name)
```

Try to find a library and return a pathname. `name` is the library name without any prefix like `lib`, suffix like `.so`, `.dylib` or version number (this is the form used for the posix linker option `-l`). If no
library can be found, returns None.

The exact functionality is system dependent.

*Changed in version 2.6:* Windows only: `find_library("m")` or `find_library("c")` return the result of a call to `find_msvcrt()`.

cpus.util.find_msvcrt()

Windows only: return the filename of the VC runtype library used by Python, and by the extension modules. If the name of the library cannot be determined, None is returned.

If you need to free memory, for example, allocated by an extension module with a call to the `free(void*)`, it is important that you use the function in the same library that allocated the memory.

*New in version 2.6.*

cpus.FormatError([code])

Windows only: Returns a textual description of the error code. If no error code is specified, the last error code is used by calling the Windows api function GetLastError.

cpus GetLastError()

Windows only: Returns the last error code set by Windows in the calling thread. This function calls the Windows GetLastError() function directly, it does not return the ctypes-private copy of the error code.

cpus.get_errno()

Returns the current value of the ctypes-private copy of the system errno variable in the calling thread.

*New in version 2.6.*
ctypes.get_last_error()

Windows only: returns the current value of the ctypes-private copy of the system LastError variable in the calling thread.

New in version 2.6.

c types.memmove(dst, src, count)

Same as the standard C memmove library function: copies count bytes from src to dst. dst and src must be integers or ctypes instances that can be converted to pointers.

c types.memset(dst, c, count)

Same as the standard C memset library function: fills the memory block at address dst with count bytes of value c. dst must be an integer specifying an address, or a ctypes instance.

c types.POINTER(type)

This factory function creates and returns a new ctypes pointer type. Pointer types are cached and reused internally, so calling this function repeatedly is cheap. type must be a ctypes type.

c types.pointer(obj)

This function creates a new pointer instance, pointing to obj. The returned object is of the type POINTER(type(obj)).

Note: If you just want to pass a pointer to an object to a foreign function call, you should use byref(obj) which is much faster.

c types.resize(obj, size)

This function resizes the internal memory buffer of obj, which must be an instance of a ctypes type. It is not possible to make the buffer smaller than the native size of the objects type, as given by sizeof(type(obj)), but it is possible to enlarge the buffer.

c types.set_conversion_mode(encoding, errors)
This function sets the rules that ctypes objects use when converting between 8-bit strings and unicode strings. encoding must be a string specifying an encoding, like 'utf-8' or 'mbcs', errors must be a string specifying the error handling on encoding/decoding errors. Examples of possible values are "strict", "replace", or "ignore".

set_conversion_mode returns a 2-tuple containing the previous conversion rules. On windows, the initial conversion rules are ('mbcs', 'ignore'), on other systems ('ascii', 'strict').

ctypes.set_errno(value)
Set the current value of the ctypes-private copy of the system errno variable in the calling thread to value and return the previous value.

New in version 2.6.

c ctypes.set_last_error(value)
Windows only: set the current value of the ctypes-private copy of the system LastError variable in the calling thread to value and return the previous value.

New in version 2.6.

c ctypes.sizeof(obj_or_type)
Returns the size in bytes of a ctypes type or instance memory buffer. Does the same as the C sizeof() function.

c ctypes.string_at(address[, size])
This function returns the string starting at memory address address. If size is specified, it is used as size, otherwise the string is assumed to be zero-terminated.

c ctypes.WinError(code=None, descr=None)
Windows only: this function is probably the worst-named thing in ctypes. It creates an instance of WindowsError. If `code` is not specified, `GetLastError` is called to determine the error code. If `descr` is not specified, `FormatError()` is called to get a textual description of the error.

`ctypes.wstring_at(address)`
This function returns the wide character string starting at memory address `address` as unicode string. If `size` is specified, it is used as the number of characters of the string, otherwise the string is assumed to be zero-terminated.

### Data types

#### class `ctypes._CData`
This non-public class is the common base class of all ctypes data types. Among other things, all ctypes type instances contain a memory block that hold C compatible data; the address of the memory block is returned by the `addressof()` helper function. Another instance variable is exposed as `_objects`; this contains other Python objects that need to be kept alive in case the memory block contains pointers.

Common methods of ctypes data types, these are all class methods (to be exact, they are methods of the `metaclass`):

##### `from_buffer(source[, offset])`
This method returns a ctypes instance that shares the buffer of the `source` object. The `source` object must support the writeable buffer interface. The optional `offset` parameter specifies an offset into the source buffer in bytes; the default is zero. If the source buffer is not large enough a ValueError is raised.
New in version 2.6.

**from_buffer_copy**(*source[, offset]*)
This method creates a ctypes instance, copying the buffer from the source object buffer which must be readable. The optional `offset` parameter specifies an offset into the source buffer in bytes; the default is zero. If the source buffer is not large enough a ValueError is raised.

New in version 2.6.

**from_address**(*address*)
This method returns a ctypes type instance using the memory specified by address which must be an integer.

**from_param**(*obj*)
This method adapts `obj` to a ctypes type. It is called with the actual object used in a foreign function call when the type is present in the foreign function’s `argtypes` tuple; it must return an object that can be used as a function call parameter.

All ctypes data types have a default implementation of this classmethod that normally returns `obj` if that is an instance of the type. Some types accept other objects as well.

**in_dll**(*library, name*)
This method returns a ctypes type instance exported by a shared library. `name` is the name of the symbol that exports the data, `library` is the loaded shared library.

Common instance variables of ctypes data types:

__b_base__
Sometimes ctypes data instances do not own the memory block they contain, instead they share part of the memory
block of a base object. The _b_base_ read-only member is the root ctypes object that owns the memory block.

_b_needsfree_

This read-only variable is true when the ctypes data instance has allocated the memory block itself, false otherwise.

_objects

This member is either None or a dictionary containing Python objects that need to be kept alive so that the memory block contents is kept valid. This object is only exposed for debugging; never modify the contents of this dictionary.

**Fundamental data types**

class ctypes._SimpleCData

This non-public class is the base class of all fundamental ctypes data types. It is mentioned here because it contains the common attributes of the fundamental ctypes data types. _SimpleCData is a subclass of _CData, so it inherits their methods and attributes.

*Changed in version 2.6:* ctypes data types that are not and do not contain pointers can now be pickled.

Instances have a single attribute:

value

This attribute contains the actual value of the instance. For integer and pointer types, it is an integer, for character types, it is a single character string, for character pointer types it is a Python string or unicode string.

When the value attribute is retrieved from a ctypes instance, usually a new object is returned each time. ctypes does not implement original object return, always a new object is
constructed. The same is true for all other ctypes object instances.

Fundamental data types, when returned as foreign function call results, or, for example, by retrieving structure field members or array items, are transparently converted to native Python types. In other words, if a foreign function has a restype of `c_char_p`, you will always receive a Python string, *not* a `c_char_p` instance.

Subclasses of fundamental data types do *not* inherit this behavior. So, if a foreign functions restype is a subclass of `c_void_p`, you will receive an instance of this subclass from the function call. Of course, you can get the value of the pointer by accessing the `value` attribute.

These are the fundamental ctypes data types:

```python
class ctypes.c_byte
    Represents the C signed char datatype, and interprets the value as small integer. The constructor accepts an optional integer initializer; no overflow checking is done.

class ctypes.c_char
    Represents the C char datatype, and interprets the value as a single character. The constructor accepts an optional string initializer, the length of the string must be exactly one character.

class ctypes.c_char_p
    Represents the C char * datatype, which must be a pointer to a zero-terminated string. The constructor accepts an integer address, or a string.

class ctypes.c_double
    Represents the C double datatype. The constructor accepts an optional float initializer.
```
class ctypes.\texttt{c\_longdouble}

Represents the C long double datatype. The constructor accepts an optional float initializer. On platforms where $\text{sizeof(long double)} == \text{sizeof(double)}$ it is an alias to \texttt{c\_double}.

\textit{New in version 2.6.}

class ctypes.\texttt{c\_float}

Represents the C float datatype. The constructor accepts an optional float initializer.

class ctypes.\texttt{c\_int}

Represents the C signed int datatype. The constructor accepts an optional integer initializer; no overflow checking is done. On platforms where $\text{sizeof(int)} == \text{sizeof(long)}$ it is an alias to \texttt{c\_long}.

class ctypes.\texttt{c\_int8}

Represents the C 8-bit \texttt{signed int} datatype. Usually an alias for \texttt{c\_byte}.

class ctypes.\texttt{c\_int16}

Represents the C 16-bit signed int datatype. Usually an alias for \texttt{c\_short}.

class ctypes.\texttt{c\_int32}

Represents the C 32-bit signed int datatype. Usually an alias for \texttt{c\_int}.

class ctypes.\texttt{c\_int64}

Represents the C 64-bit \texttt{signed int} datatype. Usually an alias for \texttt{c\_longlong}.

class ctypes.\texttt{c\_long}
Represents the C `signed long` datatype. The constructor accepts an optional integer initializer; no overflow checking is done.

```python
class ctypes.c_longlong
    Represents the C `signed long` datatype. The constructor accepts an optional integer initializer; no overflow checking is done.
```

```python
class ctypes.c_short
    Represents the C `signed short` datatype. The constructor accepts an optional integer initializer; no overflow checking is done.
```

```python
class ctypes.c_size_t
    Represents the C `size_t` datatype.
```

```python
class ctypes.c_ubyte
    Represents the C `unsigned char` datatype, it interprets the value as small integer. The constructor accepts an optional integer initializer; no overflow checking is done.
```

```python
class ctypes.c_uint
    Represents the C `unsigned int` datatype. The constructor accepts an optional integer initializer; no overflow checking is done. On platforms where `sizeof(int) == sizeof(long)` it is an alias for `c_ulong`.
```

```python
class ctypes.c_uint8
    Represents the C 8-bit unsigned int datatype. Usually an alias for `c_ubyte`.
```

```python
class ctypes.c_uint16
    Represents the C 16-bit unsigned int datatype. Usually an alias for `c_ushort`.
```
class ctypes.\texttt{c\_uint32}

Represents the C 32-bit unsigned int datatype. Usually an alias for \texttt{c\_uint}.

class ctypes.\texttt{c\_uint64}

Represents the C 64-bit unsigned int datatype. Usually an alias for \texttt{c\_ulonglong}.

class ctypes.\texttt{c\_ulong}

Represents the C \texttt{unsigned long} datatype. The constructor accepts an optional integer initializer; no overflow checking is done.

class ctypes.\texttt{c\_ulonglong}

Represents the C \texttt{unsigned long long} datatype. The constructor accepts an optional integer initializer; no overflow checking is done.

class ctypes.\texttt{c\_ushort}

Represents the C \texttt{unsigned short} datatype. The constructor accepts an optional integer initializer; no overflow checking is done.

class ctypes.\texttt{c\_void\_p}

Represents the C \texttt{void} * type. The value is represented as integer. The constructor accepts an optional integer initializer.

class ctypes.\texttt{c\_wchar}

Represents the C \texttt{wchar\_t} datatype, and interprets the value as a single character unicode string. The constructor accepts an optional string initializer, the length of the string must be exactly one character.

class ctypes.\texttt{c\_wchar\_p}

Represents the C \texttt{wchar\_t} * datatype, which must be a pointer to
a zero-terminated wide character string. The constructor accepts an integer address, or a string.

class ctypes.c_bool

Represent the C bool datatype (more accurately, _Bool from C99). Its value can be True or False, and the constructor accepts any object that has a truth value.

New in version 2.6.

class ctypes.HRESULT

Windows only: Represents a HRESULT value, which contains success or error information for a function or method call.

class ctypes.py_object

Represents the C PyObject * datatype. Calling this without an argument creates a NULL PyObject * pointer.

The ctypes.wintypes module provides quite some other Windows specific data types, for example HWND, WPARAM, or DWORD. Some useful structures like MSG or RECT are also defined.

Structured data types

class ctypes.Union(*args, **kw)

Abstract base class for unions in native byte order.

class ctypes.BigEndianStructure(*args, **kw)

Abstract base class for structures in big endian byte order.

class ctypes.LittleEndianStructure(*args, **kw)

Abstract base class for structures in little endian byte order.

Structures with non-native byte order cannot contain pointer type fields, or any other data types containing pointer type fields.
class ctypes.Structure(*args, **kw)

Abstract base class for structures in native byte order.

Concrete structure and union types must be created by subclassing one of these types, and at least define a _fields_ class variable. ctypes will create descriptors which allow reading and writing the fields by direct attribute accesses. These are the _fields_

A sequence defining the structure fields. The items must be 2-tuples or 3-tuples. The first item is the name of the field, the second item specifies the type of the field; it can be any ctypes data type.

For integer type fields like c_int, a third optional item can be given. It must be a small positive integer defining the bit width of the field.

Field names must be unique within one structure or union. This is not checked, only one field can be accessed when names are repeated.

It is possible to define the _fields_ class variable after the class statement that defines the Structure subclass, this allows to create data types that directly or indirectly reference themselves:

```python
class List(Structure):
    pass
List._fields_ = ["pnext", POINTER(List)],
    ...
]
```

The _fields_ class variable must, however, be defined before
the type is first used (an instance is created, `sizeof()` is called on it, and so on). Later assignments to the `_fields_` class variable will raise an AttributeError.

Structure and union subclass constructors accept both positional and named arguments. Positional arguments are used to initialize the fields in the same order as they appear in the `_fields_` definition, named arguments are used to initialize the fields with the corresponding name.

It is possible to defined sub-subclasses of structure types, they inherit the fields of the base class plus the `_fields_` defined in the sub-subclass, if any.

`_pack_`
An optional small integer that allows to override the alignment of structure fields in the instance. `_pack_` must already be defined when `_fields_` is assigned, otherwise it will have no effect.

`_anonymous_`
An optional sequence that lists the names of unnamed (anonymous) fields. `_anonymous_` must be already defined when `_fields_` is assigned, otherwise it will have no effect.

The fields listed in this variable must be structure or union type fields. `ctypes` will create descriptors in the structure type that allows to access the nested fields directly, without the need to create the structure or union field.

Here is an example type (Windows):

```python
class _U(Union):
    _fields_ = [("lptdesc", POINTER(TYPEDESC)),
                ("lpadesc", POINTER(ARRAYDESC)),
```
class TYPEDESC(Structure):
    _fields_ = ["u", _U],
               ("vt", VARTYPE]

    _anonymous_ = ("u",)

The TYPEDESC structure describes a COM data type, the `vt` field specifies which one of the union fields is valid. Since the `u` field is defined as anonymous field, it is now possible to access the members directly off the TYPEDESC instance. `td.lptdesc` and `td.u.lptdesc` are equivalent, but the former is faster since it does not need to create a temporary union instance:

    td = TYPEDESC()
    td.vt = VT_PTR
    td.lptdesc = POINTER(some_type)
    td.u.lptdesc = POINTER(some_type)

It is possible to defined sub-subclasses of structures, they inherit the fields of the base class. If the subclass definition has a separate `_fields_` variable, the fields specified in this are appended to the fields of the base class.

Structure and union constructors accept both positional and keyword arguments. Positional arguments are used to initialize member fields in the same order as they are appear in `_fields_`. Keyword arguments in the constructor are interpreted as attribute assignments, so they will initialize `_fields_` with the same name, or create new attributes for names not present in `_fields_`.

Arrays and pointers
Not yet written - please see the sections *Pointers* and section *Arrays* in the tutorial.
Optional Operating System Services

The modules described in this chapter provide interfaces to operating system features that are available on selected operating systems only. The interfaces are generally modeled after the Unix or C interfaces but they are available on some other systems as well (e.g. Windows or NT). Here's an overview:

- **select** — Waiting for I/O completion
  - Edge and Level Trigger Polling (epoll) Objects
  - Polling Objects
  - Kqueue Objects
  - Kevent Objects

- **threading** — Higher-level threading interface
  - Lock Objects
  - RLock Objects
  - Condition Objects
  - Semaphore Objects
    - **Semaphore Example**
  - Event Objects
  - Thread Objects
  - Timer Objects
  - Using locks, conditions, and semaphores in the with statement
  - Importing in threaded code

- **thread** — Multiple threads of control

- **dummy_threading** — Drop-in replacement for the threading module
• **dummy_thread** — Drop-in replacement for the **thread** module

• **multiprocessing** — Process-based “threading” interface
  • Introduction

  • Examples
- `mmap` — Memory-mapped file support

- `readline` — GNU readline interface
  - Example

- `rlcompleter` — Completion function for GNU readline
  - Completer Objects
This module provides access to the `select` and `poll` functions available in most operating systems, `epoll` available on Linux 2.5+ and `kqueue` available on most BSD. Note that on Windows, it only works for sockets; on other operating systems, it also works for other file types (in particular, on Unix, it works on pipes). It cannot be used on regular files to determine whether a file has grown since it was last read.

The module defines the following:

**exception select.error**

The exception raised when an error occurs. The accompanying value is a pair containing the numeric error code from `errno` and the corresponding string, as would be printed by the C function `perror`.

**select.epoll([sizehint=-1])**

(Only supported on Linux 2.5.44 and newer.) Returns an edge polling object, which can be used as Edge or Level Triggered interface for I/O events; see section *Edge and Level Trigger Polling (epoll) Objects* below for the methods supported by epolling objects.

*New in version 2.6.*

**select.poll()**

(Not supported by all operating systems.) Returns a polling object, which supports registering and unregistering file descriptors, and then polling them for I/O events; see section *Polling Objects* below for the methods supported by polling objects.
select. kqueue()
(Only supported on BSD.) Returns a kernel queue object object; see section Kqueue Objects below for the methods supported by kqueue objects.

New in version 2.6.

select. kevent(ident, filter=KQ_FILTER_READ, flags=KQ_ADD, fflags=0, data=0, udata=0)
(Only supported on BSD.) Returns a kernel event object object; see section Kevent Objects below for the methods supported by kqueue objects.

New in version 2.6.

select. select(rlist, wlist, xlist[], timeout)
This is a straightforward interface to the Unix select system call. The first three arguments are sequences of 'waitable objects': either integers representing file descriptors or objects with a parameterless method named fileno() returning such an integer:

- rlist: wait until ready for reading
- wlist: wait until ready for writing
- xlist: wait for an “exceptional condition” (see the manual page for what your system considers such a condition)

Empty sequences are allowed, but acceptance of three empty sequences is platform-dependent. (It is known to work on Unix but not on Windows.) The optional timeout argument specifies a time-out as a floating point number in seconds. When the timeout argument is omitted the function blocks until at least one file descriptor is ready. A time-out value of zero specifies a poll and never blocks.
The return value is a triple of lists of objects that are ready: subsets of the first three arguments. When the time-out is reached without a file descriptor becoming ready, three empty lists are returned.

Among the acceptable object types in the sequences are Python file objects (e.g. `sys.stdin`, or objects returned by `open()` or `os.popen()`), socket objects returned by `socket.socket()`. You may also define a wrapper class yourself, as long as it has an appropriate `fileno()` method (that really returns a file descriptor, not just a random integer).

**Note:** File objects on Windows are not acceptable, but sockets are. On Windows, the underlying `select` function is provided by the WinSock library, and does not handle file descriptors that don't originate from WinSock.
Edge and Level Trigger Polling (epoll) Objects

</tr>
</tbody>
</table>

epoll.close()

Close the control file descriptor of the epoll object.

epoll.fileno()

Return the file descriptor number of the control fd.

epoll.fromfd(fd)

Create an epoll object from a given file descriptor.
epoll.register(fd[, eventmask])
   Register a fd descriptor with the epoll object.

epoll.modify(fd, eventmask)
   Modify a register file descriptor.

epoll.unregister(fd)
   Remove a registered file descriptor from the epoll object.

epoll.poll([timeout=-1[, maxevents=-1]])
   Wait for events. timeout in seconds (float)
Polling Objects

The poll system call, supported on most Unix systems, provides better scalability for network servers that service many, many clients at the same time. poll scales better because the system call only requires listing the file descriptors of interest, while select builds a bitmap, turns on bits for the fds of interest, and then afterward the whole bitmap has to be linearly scanned again. select is \(O\)(highest file descriptor), while poll is \(O\)(number of file descriptors).

**poll. register\((fd[, eventmask])\)**

Register a file descriptor with the polling object. Future calls to the `poll()` method will then check whether the file descriptor has any pending I/O events. \(fd\) can be either an integer, or an object with a `fileno()` method that returns an integer. File objects implement `fileno()`, so they can also be used as the argument.

*eventmask* is an optional bitmask describing the type of events you want to check for, and can be a combination of the constants `POLLIN`, `POLLPRI`, and `POLLOUT`, described in the table below. If not specified, the default value used will check for all 3 types of events.

<table>
<thead>
<tr>
<th>Constant</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>POLLIN</td>
<td>There is data to read</td>
</tr>
<tr>
<td>POLLPRI</td>
<td>There is urgent data to read</td>
</tr>
<tr>
<td>POLLOUT</td>
<td>Ready for output: writing will not block</td>
</tr>
<tr>
<td>POLLERR</td>
<td>Error condition of some sort</td>
</tr>
<tr>
<td>POLLHUP</td>
<td>Hung up</td>
</tr>
<tr>
<td>POLLNVAL</td>
<td>Invalid request: descriptor not open</td>
</tr>
</tbody>
</table>
Registering a file descriptor that’s already registered is not an error, and has the same effect as registering the descriptor exactly once.

**poll. modify**(*fd*, *eventmask*)

Modifies an already registered fd. This has the same effect as **register**(*fd*, *eventmask*)(). Attempting to modify a file descriptor that was never registered causes an **IOError** exception with **errno** **ENOENT** to be raised.

*New in version 2.6.*

**poll. unregister**(*fd*)

Remove a file descriptor being tracked by a polling object. Just like the **register**() method, *fd* can be an integer or an object with a **fileno**() method that returns an integer.

Attempting to remove a file descriptor that was never registered causes a **KeyError** exception to be raised.

**poll. poll**([*timeout*])

Polls the set of registered file descriptors, and returns a possibly-empty list containing (*fd*, *event*) 2-tuples for the descriptors that have events or errors to report. *fd* is the file descriptor, and *event* is a bitmask with bits set for the reported events for that descriptor — **POLLIN** for waiting input, **POLLOUT** to indicate that the descriptor can be written to, and so forth. An empty list indicates that the call timed out and no file descriptors had any events to report. If *timeout* is given, it specifies the length of time in milliseconds which the system will wait for events before returning. If *timeout* is omitted, negative, or **None**, the call will block until there is an event for this poll object.
Kqueue Objects

kqueue.close()
   Close the control file descriptor of the kqueue object.

kqueue.fileno()
   Return the file descriptor number of the control fd.

kqueue.fromfd(fd)
   Create a kqueue object from a given file descriptor.

kqueue.control(changelist, max_events[, timeout=None]) → eventlist
   Low level interface to kevent
      - changelist must be an iterable of kevent object or None
      - max_events must be 0 or a positive integer
      - timeout in seconds (floats possible)
Kevent Objects

http://www.freebsd.org/cgi/man.cgi?query=kqueue&sektion=2

**kevent**. **ident**
Value used to identify the event. The interpretation depends on the filter but it's usually the file descriptor. In the constructor ident can either be an int or an object with a fileno() function. kevent stores the integer internally.

**kevent**. **filter**
Name of the kernel filter

<table>

**kevent.data**  
Filter specific data

**kevent.udata**  
User defined value
This module constructs higher-level threading interfaces on top of the lower level \texttt{thread} module. See also the \texttt{mutex} and \texttt{Queue} modules.

The \texttt{dummy_threading} module is provided for situations where \texttt{threading} cannot be used because \texttt{thread} is missing.

\textbf{Note:} Starting with Python 2.6, this module provides PEP 8 compliant aliases and properties to replace the \texttt{camelCase} names that were inspired by Java's threading API. This updated API is compatible with that of the \texttt{multiprocessing} module. However, no schedule has been set for the deprecation of the \texttt{camelCase} names and they remain fully supported in both Python 2.x and 3.x.

This module defines the following functions and objects:

\begin{verbatim}
threading.active_count()
threading.activeCount()
    Return the number of \texttt{Thread} objects currently alive. The returned count is equal to the length of the list returned by \texttt{enumerate()}.

threading.Condition()
    A factory function that returns a new condition variable object. A condition variable allows one or more threads to wait until they are notified by another thread.

threading.current_thread()
threading.currentThread()
    Return the current \texttt{Thread} object, corresponding to the caller's
thread of control. If the caller’s thread of control was not created through the `threading` module, a dummy thread object with limited functionality is returned.

```python
threading.enumerate()
```

Return a list of all `Thread` objects currently alive. The list includes daemonic threads, dummy thread objects created by `current_thread()`, and the main thread. It excludes terminated threads and threads that have not yet been started.

```python
threading.Event()
```

A factory function that returns a new event object. An event manages a flag that can be set to true with the `set()` method and reset to false with the `clear()` method. The `wait()` method blocks until the flag is true.

```python
class threading.local
```

A class that represents thread-local data. Thread-local data are data whose values are thread specific. To manage thread-local data, just create an instance of `local` (or a subclass) and store attributes on it:

```python
mydata = threading.local()
mydata.x = 1
```

The instance's values will be different for separate threads.

For more details and extensive examples, see the documentation string of the `_threading_local` module.

*New in version 2.4.*

```python
threading.Lock()
```

A factory function that returns a new primitive lock object. Once a
thread has acquired it, subsequent attempts to acquire it block, until it is released; any thread may release it.

threading. **RLock()**
A factory function that returns a new reentrant lock object. A reentrant lock must be released by the thread that acquired it. Once a thread has acquired a reentrant lock, the same thread may acquire it again without blocking; the thread must release it once for each time it has acquired it.

threading. **Semaphore([value])**
A factory function that returns a new semaphore object. A semaphore manages a counter representing the number of release() calls minus the number of acquire() calls, plus an initial value. The acquire() method blocks if necessary until it can return without making the counter negative. If not given, value defaults to 1.

threading. **BoundedSemaphore([value])**
A factory function that returns a new bounded semaphore object. A bounded semaphore checks to make sure its current value doesn't exceed its initial value. If it does, ValueError is raised. In most situations semaphores are used to guard resources with limited capacity. If the semaphore is released too many times it's a sign of a bug. If not given, value defaults to 1.

class threading. **Thread**
A class that represents a thread of control. This class can be safely subclassed in a limited fashion.

class threading. **Timer**
A thread that executes a function after a specified interval has passed.
threading.settrace(func)
Set a trace function for all threads started from the threading module. The func will be passed to sys.settrace() for each thread, before its run() method is called.

New in version 2.3.

threading.setprofile(func)
Set a profile function for all threads started from the threading module. The func will be passed to sys.setprofile() for each thread, before its run() method is called.

New in version 2.3.

threading.stack_size([size])
Return the thread stack size used when creating new threads. The optional size argument specifies the stack size to be used for subsequently created threads, and must be 0 (use platform or configured default) or a positive integer value of at least 32,768 (32kB). If changing the thread stack size is unsupported, a TypeError is raised. If the specified stack size is invalid, a ValueError is raised and the stack size is unmodified. 32kB is currently the minimum supported stack size value to guarantee sufficient stack space for the interpreter itself. Note that some platforms may have particular restrictions on values for the stack size, such as requiring a minimum stack size > 32kB or requiring allocation in multiples of the system memory page size - platform documentation should be referred to for more information (4kB pages are common; using multiples of 4096 for the stack size is the suggested approach in the absence of more specific information). Availability: Windows, systems with POSIX threads.

New in version 2.5.
Detailed interfaces for the objects are documented below.

The design of this module is loosely based on Java’s threading model. However, where Java makes locks and condition variables basic behavior of every object, they are separate objects in Python. Python’s `Thread` class supports a subset of the behavior of Java’s Thread class; currently, there are no priorities, no thread groups, and threads cannot be destroyed, stopped, suspended, resumed, or interrupted. The static methods of Java’s Thread class, when implemented, are mapped to module-level functions.

All of the methods described below are executed atomically.
A primitive lock is a synchronization primitive that is not owned by a particular thread when locked. In Python, it is currently the lowest level synchronization primitive available, implemented directly by the thread extension module.

A primitive lock is in one of two states, “locked” or “unlocked”. It is created in the unlocked state. It has two basic methods, \texttt{acquire()} and \texttt{release()}. When the state is unlocked, \texttt{acquire()} changes the state to locked and returns immediately. When the state is locked, \texttt{acquire()} blocks until a call to \texttt{release()} in another thread changes it to unlocked, then the \texttt{acquire()} call resets it to locked and returns. The \texttt{release()} method should only be called in the locked state; it changes the state to unlocked and returns immediately. If an attempt is made to release an unlocked lock, a \texttt{RuntimeError} will be raised.

When more than one thread is blocked in \texttt{acquire()} waiting for the state to turn to unlocked, only one thread proceeds when a \texttt{release()} call resets the state to unlocked; which one of the waiting threads proceeds is not defined, and may vary across implementations.

All methods are executed atomically.

\texttt{Lock.\texttt{acquire}(blocking=1)}

Acquire a lock, blocking or non-blocking.

When invoked without arguments, block until the lock is unlocked, then set it to locked, and return true.

When invoked with the \texttt{blocking} argument set to true, do the same thing as when called without arguments, and return true.
When invoked with the *blocking* argument set to false, do not block. If a call without an argument would block, return false immediately; otherwise, do the same thing as when called without arguments, and return true.

**Lock**. `release()`
Release a lock.

When the lock is locked, reset it to unlocked, and return. If any other threads are blocked waiting for the lock to become unlocked, allow exactly one of them to proceed.

Do not call this method when the lock is unlocked.

There is no return value.
A reentrant lock is a synchronization primitive that may be acquired multiple times by the same thread. Internally, it uses the concepts of “owning thread” and “recursion level” in addition to the locked/unlocked state used by primitive locks. In the locked state, some thread owns the lock; in the unlocked state, no thread owns it.

To lock the lock, a thread calls its `acquire()` method; this returns once the thread owns the lock. To unlock the lock, a thread calls its `release()` method. `acquire()/release()` call pairs may be nested; only the final `release()` (the `release()` of the outermost pair) resets the lock to unlocked and allows another thread blocked in `acquire()` to proceed.

```
RLock.acquire([blocking=1])
```

Acquire a lock, blocking or non-blocking.

When invoked without arguments: if this thread already owns the lock, increment the recursion level by one, and return immediately. Otherwise, if another thread owns the lock, block until the lock is unlocked. Once the lock is unlocked (not owned by any thread), then grab ownership, set the recursion level to one, and return. If more than one thread is blocked waiting until the lock is unlocked, only one at a time will be able to grab ownership of the lock. There is no return value in this case.

When invoked with the `blocking` argument set to true, do the same thing as when called without arguments, and return true.

When invoked with the `blocking` argument set to false, do not block. If a call without an argument would block, return false immediately; otherwise, do the same thing as when called without
arguments, and return true.

**RLock.** release()

Release a lock, decrementing the recursion level. If after the decrement it is zero, reset the lock to unlocked (not owned by any thread), and if any other threads are blocked waiting for the lock to become unlocked, allow exactly one of them to proceed. If after the decrement the recursion level is still nonzero, the lock remains locked and owned by the calling thread.

Only call this method when the calling thread owns the lock. A **RuntimeError** is raised if this method is called when the lock is unlocked.

There is no return value.
A condition variable is always associated with some kind of lock; this can be passed in or one will be created by default. (Passing one in is useful when several condition variables must share the same lock.)

A condition variable has acquire() and release() methods that call the corresponding methods of the associated lock. It also has a wait() method, and notify() and notifyAll() methods. These three must only be called when the calling thread has acquired the lock, otherwise a RuntimeError is raised.

The wait() method releases the lock, and then blocks until it is awakened by a notify() or notifyAll() call for the same condition variable in another thread. Once awakened, it re-acquires the lock and returns. It is also possible to specify a timeout.

The notify() method wakes up one of the threads waiting for the condition variable, if any are waiting. The notifyAll() method wakes up all threads waiting for the condition variable.

Note: the notify() and notifyAll() methods don’t release the lock; this means that the thread or threads awakened will not return from their wait() call immediately, but only when the thread that called notify() or notifyAll() finally relinquishes ownership of the lock.

Tip: the typical programming style using condition variables uses the lock to synchronize access to some shared state; threads that are interested in a particular change of state call wait() repeatedly until they see the desired state, while threads that modify the state call notify() or notifyAll() when they change the state in such a way that it could possibly be a desired state for one of the waiters. For example, the following code is a generic producer-consumer
situation with unlimited buffer capacity:

```python
# Consume one item
cv.acquire()
while not an_item_is_available():
    cv.wait()
get_an_available_item()
   cv.release()

# Produce one item
   cv.acquire()
make_an_item_available()
   cv.notify()
   cv.release()
```

To choose between `notify()` and `notifyAll()`, consider whether one state change can be interesting for only one or several waiting threads. E.g. in a typical producer-consumer situation, adding one item to the buffer only needs to wake up one consumer thread.

class threading.Condition([lock])

- If the `lock` argument is given and not None, it must be a Lock or RLock object, and it is used as the underlying lock. Otherwise, a new RLock object is created and used as the underlying lock.

Condition.acquire(*args)

- Acquire the underlying lock. This method calls the corresponding method on the underlying lock; the return value is whatever that method returns.

Condition.release()

- Release the underlying lock. This method calls the corresponding method on the underlying lock; there is no return value.

Condition.wait([timeout])

- Wait until notified or until a timeout occurs. If the calling thread has not acquired the lock when this method is called, a
**RuntimeError** is raised.

This method releases the underlying lock, and then blocks until it is awakened by a *notify()* or *notifyAll()* call for the same condition variable in another thread, or until the optional timeout occurs. Once awakened or timed out, it re-acquires the lock and returns.

When the *timeout* argument is present and not *None*, it should be a floating point number specifying a timeout for the operation in seconds (or fractions thereof).

When the underlying lock is an *RLock*, it is not released using its *release()* method, since this may not actually unlock the lock when it was acquired multiple times recursively. Instead, an internal interface of the *RLock* class is used, which really unlocks it even when it has been recursively acquired several times. Another internal interface is then used to restore the recursion level when the lock is reacquired.

**Condition**. *notify()*

Wake up a thread waiting on this condition, if any. Wait until notified or until a timeout occurs. If the calling thread has not acquired the lock when this method is called, a **RuntimeError** is raised.

This method wakes up one of the threads waiting for the condition variable, if any are waiting; it is a no-op if no threads are waiting.

The current implementation wakes up exactly one thread, if any are waiting. However, it’s not safe to rely on this behavior. A future, optimized implementation may occasionally wake up more than one thread.
Note: the awakened thread does not actually return from its \texttt{wait()} call until it can reacquire the lock. Since \texttt{notify()} does not release the lock, its caller should.

\texttt{Condition.notify\_all()}
\texttt{Condition.notifyAll()}

Wake up all threads waiting on this condition. This method acts like \texttt{notify()}, but wakes up all waiting threads instead of one. If the calling thread has not acquired the lock when this method is called, a \texttt{RuntimeError} is raised.
Semaphore Objects

This is one of the oldest synchronization primitives in the history of computer science, invented by the early Dutch computer scientist Edsger W. Dijkstra (he used \( P() \) and \( V() \) instead of \texttt{acquire()} and \texttt{release()}).

A semaphore manages an internal counter which is decremented by each \texttt{acquire()} call and incremented by each \texttt{release()} call. The counter can never go below zero; when \texttt{acquire()} finds that it is zero, it blocks, waiting until some other thread calls \texttt{release()}.

```python
class threading.Semaphore([value])
```

The optional argument gives the initial \texttt{value} for the internal counter; it defaults to \texttt{1}. If the \texttt{value} given is less than \texttt{0}, \texttt{ValueError} is raised.

```python
Semaphore.acquire([blocking])
```

Acquire a semaphore.

When invoked without arguments: if the internal counter is larger than zero on entry, decrement it by one and return immediately. If it is zero on entry, block, waiting until some other thread has called \texttt{release()} to make it larger than zero. This is done with proper interlocking so that if multiple \texttt{acquire()} calls are blocked, \texttt{release()} will wake exactly one of them up. The implementation may pick one at random, so the order in which blocked threads are awakened should not be relied on. There is no return value in this case.

When invoked with \texttt{blocking} set to \texttt{true}, do the same thing as when called without arguments, and return \texttt{true}. 
When invoked with *blocking* set to false, do not block. If a call without an argument would block, return false immediately; otherwise, do the same thing as when called without arguments, and return true.

Semaphore.*release()*

Release a semaphore, incrementing the internal counter by one. When it was zero on entry and another thread is waiting for it to become larger than zero again, wake up that thread.

**Semaphore Example**

Semaphores are often used to guard resources with limited capacity, for example, a database server. In any situation where the size of the resource size is fixed, you should use a bounded semaphore. Before spawning any worker threads, your main thread would initialize the semaphore:

```python
maxconnections = 5
...
pool_sema = BoundedSemaphore(value=maxconnections)
```

Once spawned, worker threads call the semaphore’s acquire and release methods when they need to connect to the server:

```python
pool_sema.acquire()
conn = connectdb()
... use connection ...
conn.close()
pool_sema.release()
```

The use of a bounded semaphore reduces the chance that a programming error which causes the semaphore to be released more than it’s acquired will go undetected.
Event Objects

This is one of the simplest mechanisms for communication between threads: one thread signals an event and other threads wait for it.

An event object manages an internal flag that can be set to true with the `set()` method and reset to false with the `clear()` method. The `wait()` method blocks until the flag is true.

class threading.Event

    The internal flag is initially false.

    `Event.is_set()`
    `Event.isSet()`

    Return true if and only if the internal flag is true.

    `Event.set()`

    Set the internal flag to true. All threads waiting for it to become true are awakened. Threads that call `wait()` once the flag is true will not block at all.

    `Event.clear()`

    Reset the internal flag to false. Subsequently, threads calling `wait()` will block until `set()` is called to set the internal flag to true again.

    `Event.wait([timeout])`

    Block until the internal flag is true. If the internal flag is true on entry, return immediately. Otherwise, block until another thread calls `set()` to set the flag to true, or until the optional timeout occurs.

    When the timeout argument is present and not `None`, it should be
a floating point number specifying a timeout for the operation in seconds (or fractions thereof).
Thread Objects

This class represents an activity that is run in a separate thread of control. There are two ways to specify the activity: by passing a callable object to the constructor, or by overriding the `run()` method in a subclass. No other methods (except for the constructor) should be overridden in a subclass. In other words, only override the `__init__()` and `run()` methods of this class.

Once a thread object is created, its activity must be started by calling the thread’s `start()` method. This invokes the `run()` method in a separate thread of control.

Once the thread’s activity is started, the thread is considered ‘alive’. It stops being alive when its `run()` method terminates – either normally, or by raising an unhandled exception. The `is_alive()` method tests whether the thread is alive.

Other threads can call a thread’s `join()` method. This blocks the calling thread until the thread whose `join()` method is called is terminated.

A thread has a name. The name can be passed to the constructor, and read or changed through the `name` attribute.

A thread can be flagged as a “daemon thread”. The significance of this flag is that the entire Python program exits when only daemon threads are left. The initial value is inherited from the creating thread. The flag can be set through the `daemon` attribute.

There is a “main thread” object; this corresponds to the initial thread of control in the Python program. It is not a daemon thread.
There is the possibility that “dummy thread objects” are created. These are thread objects corresponding to “alien threads”, which are threads of control started outside the threading module, such as directly from C code. Dummy thread objects have limited functionality; they are always considered alive and daemonic, and cannot be `join()`ed. They are never deleted, since it is impossible to detect the termination of alien threads.

```python
class threading.Thread(
    group=None, target=None, name=None, args=(), kwargs={})
```

This constructor should always be called with keyword arguments. Arguments are:

- `group` should be `None`; reserved for future extension when a `ThreadGroup` class is implemented.

- `target` is the callable object to be invoked by the `run()` method. Defaults to `None`, meaning nothing is called.

- `name` is the thread name. By default, a unique name is constructed of the form “Thread-N” where N is a small decimal number.

- `args` is the argument tuple for the target invocation. Defaults to `()`. 

- `kwargs` is a dictionary of keyword arguments for the target invocation. Defaults to `{}`.

If the subclass overrides the constructor, it must make sure to invoke the base class constructor (`Thread.__init__()`) before doing anything else to the thread.

```python
Thread.start()
```
Start the thread’s activity.
It must be called at most once per thread object. It arranges for the object’s `run()` method to be invoked in a separate thread of control.

This method will raise a `RuntimeError` if called more than once on the same thread object.

**Thread. `run()`**

Method representing the thread's activity.

You may override this method in a subclass. The standard `run()` method invokes the callable object passed to the object’s constructor as the `target` argument, if any, with sequential and keyword arguments taken from the `args` and `kwargs` arguments, respectively.

**Thread. `join([timeout])`**

Wait until the thread terminates. This blocks the calling thread until the thread whose `join()` method is called terminates – either normally or through an unhandled exception – or until the optional timeout occurs.

When the `timeout` argument is present and not `None`, it should be a floating point number specifying a timeout for the operation in seconds (or fractions thereof). As `join()` always returns `None`, you must call `isAlive()` after `join()` to decide whether a timeout happened – if the thread is still alive, the `join()` call timed out.

When the `timeout` argument is not present or `None`, the operation will block until the thread terminates.

A thread can be `join()`ed many times.

`join()` raises a `RuntimeError` if an attempt is made to join the
current thread as that would cause a deadlock. It is also an error to `join()` a thread before it has been started and attempts to do so raises the same exception.

Thread. `getName()`
Thread. `setName()`
  Old API for `name`.

Thread. `getName()`

A string used for identification purposes only. It has no semantics. Multiple threads may be given the same name. The initial name is set by the constructor.

Thread. `ident`

The ‘thread identifier’ of this thread or `None` if the thread has not been started. This is a nonzero integer. See the `thread.get_ident()` function. Thread identifiers may be recycled when a thread exits and another thread is created. The identifier is available even after the thread has exited.

*New in version 2.6.*

Thread. `is_alive()`
Thread. `isAlive()`

Return whether the thread is alive.

Roughly, a thread is alive from the moment the `start()` method returns until its `run()` method terminates. The module function `enumerate()` returns a list of all alive threads.

Thread. `isDaemon()`
Thread. `setDaemon()`
  Old API for `daemon`.

Thread. `daemon`
The thread's daemon flag. This must be set before `start()` is called, otherwise `RuntimeError` is raised.

The initial value is inherited from the creating thread.

The entire Python program exits when no alive non-daemon threads are left.
Timer Objects

This class represents an action that should be run only after a certain amount of time has passed — a timer. `Timer` is a subclass of `Thread` and as such also functions as an example of creating custom threads.

Timers are started, as with threads, by calling their `start()` method. The timer can be stopped (before its action has begun) by calling the `cancel()` method. The interval the timer will wait before executing its action may not be exactly the same as the interval specified by the user.

For example:

```python
def hello():
    print "hello, world"

t = Timer(30.0, hello)
t.start()  # after 30 seconds, "hello, world" will be printed
```

```python
class threading.Timer(interval, function, args=[], kwargs={})
    Create a timer that will run function with arguments args and key
    word arguments kwargs, after interval seconds have passed.

Timer.cancel()
    Stop the timer, and cancel the execution of the timer's action.
    This will only work if the timer is still in its waiting stage.
```
Using locks, conditions, and semaphores in the with statement

All of the objects provided by this module that have `acquire()` and `release()` methods can be used as context managers for a `with` statement. The `acquire()` method will be called when the block is entered, and `release()` will be called when the block is exited.

Currently, `Lock`, `RLock`, `Condition`, `Semaphore`, and `BoundedSemaphore` objects may be used as `with` statement context managers. For example:

```python
import threading

some_rlock = threading.RLock()

with some_rlock:
    print "some_rlock is locked while this executes"
```
Importing in threaded code

While the import machinery is thread safe, there are two key restrictions on threaded imports due to inherent limitations in the way that thread safety is provided:

- Firstly, other than in the main module, an import should not have the side effect of spawning a new thread and then waiting for that thread in any way. Failing to abide by this restriction can lead to a deadlock if the spawned thread directly or indirectly attempts to import a module.
- Secondly, all import attempts must be completed before the interpreter starts shutting itself down. This can be most easily achieved by only performing imports from non-daemon threads created through the threading module. Daemon threads and threads created directly with the thread module will require some other form of synchronization to ensure they do not attempt imports after system shutdown has commenced. Failure to abide by this restriction will lead to intermittent exceptions and crashes during interpreter shutdown (as the late imports attempt to access machinery which is no longer in a valid state).
thread — Multiple threads of control

Note: The thread module has been renamed to _thread in Python 3.0. The 2to3 tool will automatically adapt imports when converting your sources to 3.0; however, you should consider using the high-level threading module instead.

This module provides low-level primitives for working with multiple threads (also called light-weight processes or tasks) — multiple threads of control sharing their global data space. For synchronization, simple locks (also called mutexes or binary semaphores) are provided. The threading module provides an easier to use and higher-level threading API built on top of this module.

The module is optional. It is supported on Windows, Linux, SGI IRIX, Solaris 2.x, as well as on systems that have a POSIX thread (a.k.a. “pthread”) implementation. For systems lacking the thread module, the dummy_thread module is available. It duplicates this module’s interface and can be used as a drop-in replacement.

It defines the following constant and functions:

exception thread.error
    Raised on thread-specific errors.

thread.LockType
    This is the type of lock objects.

thread.start_new_thread(function, args[, kwargs])
    Start a new thread and return its identifier. The thread executes the function function with the argument list args (which must be a tuple). The optional kwargs argument specifies a dictionary of
keyword arguments. When the function returns, the thread silently exits. When the function terminates with an unhandled exception, a stack trace is printed and then the thread exits (but other threads continue to run).

**thread.interrupt_main()**

Raise a `KeyboardInterrupt` exception in the main thread. A subthread can use this function to interrupt the main thread.

*New in version 2.3.*

**thread.exit()**

Raise the `SystemExit` exception. When not caught, this will cause the thread to exit silently.

**thread.allocate_lock()**

Return a new lock object. Methods of locks are described below. The lock is initially unlocked.

**thread.get_ident()**

Return the ‘thread identifier’ of the current thread. This is a nonzero integer. Its value has no direct meaning; it is intended as a magic cookie to be used e.g. to index a dictionary of thread-specific data. Thread identifiers may be recycled when a thread exits and another thread is created.

**thread.stack_size([size])**

Return the thread stack size used when creating new threads. The optional `size` argument specifies the stack size to be used for subsequently created threads, and must be 0 (use platform or configured default) or a positive integer value of at least 32,768 (32kB). If changing the thread stack size is unsupported, a `ThreadError` is raised. If the specified stack size is invalid, a `ValueError` is raised and the stack size is unmodified. 32kB is
currently the minimum supported stack size value to guarantee sufficient stack space for the interpreter itself. Note that some platforms may have particular restrictions on values for the stack size, such as requiring a minimum stack size > 32kB or requiring allocation in multiples of the system memory page size - platform documentation should be referred to for more information (4kB pages are common; using multiples of 4096 for the stack size is the suggested approach in the absence of more specific information). Availability: Windows, systems with POSIX threads.

New in version 2.5.

Lock objects have the following methods:

lock.\texttt{acquire()}\left[\texttt{waitflag}\right]

Without the optional argument, this method acquires the lock unconditionally, if necessary waiting until it is released by another thread (only one thread at a time can acquire a lock — that's their reason for existence). If the integer \texttt{waitflag} argument is present, the action depends on its value: if it is zero, the lock is only acquired if it can be acquired immediately without waiting, while if it is nonzero, the lock is acquired unconditionally as before. The return value is \texttt{True} if the lock is acquired successfully, \texttt{False} if not.

lock.\texttt{release()}

Releases the lock. The lock must have been acquired earlier, but not necessarily by the same thread.

lock.\texttt{locked()}

Return the status of the lock: \texttt{True} if it has been acquired by some thread, \texttt{False} if not.

In addition to these methods, lock objects can also be used via the
with statement, e.g.:

```python
import thread
a_lock = thread.allocate_lock()

with a_lock:
    print "a_lock is locked while this executes"
```

Caveats:

- Threads interact strangely with interrupts: the `KeyboardInterrupt` exception will be received by an arbitrary thread. (When the `signal` module is available, interrupts always go to the main thread.)

- Calling `sys.exit()` or raising the `SystemExit` exception is equivalent to calling `exit()`.

- Not all built-in functions that may block waiting for I/O allow other threads to run. (The most popular ones (`time.sleep()`, `file.read()`, `select.select()`) work as expected.)

- It is not possible to interrupt the `acquire()` method on a lock — the `KeyboardInterrupt` exception will happen after the lock has been acquired.

- When the main thread exits, it is system defined whether the other threads survive. On SGI IRIX using the native thread implementation, they survive. On most other systems, they are killed without executing `try ... finally` clauses or executing object destructors.

- When the main thread exits, it does not do any of its usual cleanup (except that `try ... finally` clauses are honored), and the standard I/O files are not flushed.
dummy_threading — Drop-in replacement for the threading module

This module provides a duplicate interface to the `threading` module. It is meant to be imported when the `thread` module is not provided on a platform.

Suggested usage is:

```python
try:
    import threading as _threading
except ImportError:
    import dummy_threading as _threading
```

Be careful to not use this module where deadlock might occur from a thread being created that blocks waiting for another thread to be created. This often occurs with blocking I/O.
dummy_thread — Drop-in replacement for the thread module

**Note:** The `dummy_thread` module has been renamed to `_dummy_thread` in Python 3.0. The `2to3` tool will automatically adapt imports when converting your sources to 3.0; however, you should consider using the high-lever `dummy_threading` module instead.

This module provides a duplicate interface to the `thread` module. It is meant to be imported when the `thread` module is not provided on a platform.

Suggested usage is:

```python
try:
    import thread as _thread
except ImportError:
    import dummy_thread as _thread
```

Be careful to not use this module where deadlock might occur from a thread being created that blocks waiting for another thread to be created. This often occurs with blocking I/O.
multiprocessing — Process-based “threading” interface

New in version 2.6.
Introduction

`multiprocessing` is a package that supports spawning processes using an API similar to the `threading` module. The `multiprocessing` package offers both local and remote concurrency, effectively side-stepping the *Global Interpreter Lock* by using subprocesses instead of threads. Due to this, the `multiprocessing` module allows the programmer to fully leverage multiple processors on a given machine. It runs on both Unix and Windows.

**Warning:** Some of this package's functionality requires a functioning shared semaphore implementation on the host operating system. Without one, the `multiprocessing.synchronize` module will be disabled, and attempts to import it will result in an `ImportError`. See issue 3770 for additional information.

The Process class

In `multiprocessing`, processes are spawned by creating a `Process` object and then calling its `start()` method. `Process` follows the API of `threading.Thread`. A trivial example of a multiprocess program is

```python
from multiprocessing import Process

def f(name):
    print('hello', name)

if __name__ == '__main__':
    p = Process(target=f, args=('bob',))
    p.start()
    p.join()
```

Here the function `f` is run in a child process.
For an explanation of why (on Windows) the `if __name__ == '__main__'` part is necessary, see Programming guidelines.

# Exchanging objects between processes

`multiprocessing` supports two types of communication channel between processes:

## Queues

The `Queue` class is a near clone of `Queue.Queue`. For example:

```python
from multiprocessing import Process, Queue

def f(q):
    q.put([42, None, 'hello'])

if __name__ == '__main__':
    q = Queue()
    p = Process(target=f, args=(q,))
    p.start()
    print(q.get()) # prints "[42, None, 'hello']"
    p.join()
```

Queues are thread and process safe.

## Pipes

The `Pipe()` function returns a pair of connection objects connected by a pipe which by default is duplex (two-way). For example:

```python
from multiprocessing import Process, Pipe

def f(conn):
    conn.send([42, None, 'hello'])
    conn.close()

if __name__ == '__main__':
    parent_conn, child_conn = Pipe()
    p = Process(target=f, args=(child_conn,))
The two connection objects returned by `Pipe()` represent the two ends of the pipe. Each connection object has `send()` and `recv()` methods (among others). Note that data in a pipe may become corrupted if two processes (or threads) try to read from or write to the same end of the pipe at the same time. Of course there is no risk of corruption from processes using different ends of the pipe at the same time.

### Synchronization between processes

`multiprocessing` contains equivalents of all the synchronization primitives from `threading`. For instance one can use a lock to ensure that only one process prints to standard output at a time:

```python
from multiprocessing import Process, Lock

def f(l, i):
    l.acquire()
    print 'hello world', i
    l.release()

if __name__ == '__main__':
    lock = Lock()

    for num in range(10):
        Process(target=f, args=(lock, num)).start()
```

Without using the lock output from the different processes is liable to get all mixed up.

### Sharing state between processes

As mentioned above, when doing concurrent programming it is
usually best to avoid using shared state as far as possible. This is particularly true when using multiple processes.

However, if you really do need to use some shared data then multiprocessing provides a couple of ways of doing so.

**Shared memory**

Data can be stored in a shared memory map using `value` or `Array`. For example, the following code

```python
from multiprocessing import Process, Value, Array

def f(n, a):
    n.value = 3.1415927
    for i in range(len(a)):
        a[i] = -a[i]

if __name__ == '__main__':
    num = Value('d', 0.0)
    arr = Array('i', range(10))

    p = Process(target=f, args=(num, arr))
    p.start()
    p.join()

    print(num.value)
    print(arr[:])
```

will print

```
3.1415927
[0, -1, -2, -3, -4, -5, -6, -7, -8, -9]
```

The 'd' and 'i' arguments used when creating `num` and `arr` are typecodes of the kind used by the `array` module: 'd' indicates a double precision float and 'i' indicates a signed integer. These shared objects will be process and thread safe.

For more flexibility in using shared memory one can use the
**multiprocessing.sharedctypes** module which supports the creation of arbitrary ctypes objects allocated from shared memory.

**Server process**

A manager object returned by `Manager()` controls a server process which holds Python objects and allows other processes to manipulate them using proxies.

A manager returned by `Manager()` will support types `list`, `dict`, `Namespace`, `Lock`, `RLock`, `Semaphore`, `BoundedSemaphore`, `Condition`, `Event`, `Queue`, `Value` and `Array`. For example,

```python
from multiprocessing import Process, Manager

def f(d, l):
    d[1] = '1'
    d['2'] = 2
    d[0.25] = None
    l.reverse()

if __name__ == '__main__':
    manager = Manager()

    d = manager.dict()
    l = manager.list(range(10))

    p = Process(target=f, args=(d, l))
    p.start()
    p.join()

    print d
    print l
```

will print

```python
{0.25: None, 1: '1', '2': 2}
[9, 8, 7, 6, 5, 4, 3, 2, 1, 0]
```

Server process managers are more flexible than using shared
memory objects because they can be made to support arbitrary object types. Also, a single manager can be shared by processes on different computers over a network. They are, however, slower than using shared memory.

Using a pool of workers

The `Pool` class represents a pool of worker processes. It has methods which allows tasks to be offloaded to the worker processes in a few different ways.

For example:

```python
from multiprocessing import Pool

def f(x):
    return x**x

if __name__ == '__main__':
    pool = Pool(processes=4)  # start 4 worker processes
    result = pool.applyAsync(f, [10])  # evaluate "f(10)" asynchronously
    print(result.get(timeout=1))  # prints "100" unless your computer is *very* slow
    print(pool.map(f, range(10)))  # prints ":[0, 1, 4,..., 81]"
```
The multiprocessing package mostly replicates the API of the threading module.

Process and exceptions

class multiprocessing.Process([group[, target[, name[, args[, kwargs]]]]])

Process objects represent activity that is run in a separate process. The Process class has equivalents of all the methods of threading.Thread.

The constructor should always be called with keyword arguments. group should always be None; it exists solely for compatibility with threading.Thread. target is the callable object to be invoked by the run() method. It defaults to None, meaning nothing is called. name is the process name. By default, a unique name is constructed of the form 'Process-N₁:N₂:...:Nₖ' where N₁,N₂,...,Nₖ is a sequence of integers whose length is determined by the generation of the process. args is the argument tuple for the target invocation. kwargs is a dictionary of keyword arguments for the target invocation. By default, no arguments are passed to target.

If a subclass overrides the constructor, it must make sure it invokes the base class constructor (Process.__init__()) before doing anything else to the process.

run()

Method representing the process’s activity.
You may override this method in a subclass. The standard \texttt{run()} method invokes the callable object passed to the object's constructor as the target argument, if any, with sequential and keyword arguments taken from the \texttt{args} and \texttt{kwargs} arguments, respectively.

\texttt{start()}
Start the process's activity.

This must be called at most once per process object. It arranges for the object's \texttt{run()} method to be invoked in a separate process.

\texttt{join([timeout])}
Block the calling thread until the process whose \texttt{join()} method is called terminates or until the optional timeout occurs.

If \texttt{timeout} is \texttt{None} then there is no timeout.

A process can be joined many times.

A process cannot join itself because this would cause a deadlock. It is an error to attempt to join a process before it has been started.

\texttt{name}
The process's name.

The name is a string used for identification purposes only. It has no semantics. Multiple processes may be given the same name. The initial name is set by the constructor.

\texttt{is\_alive()}
Return whether the process is alive.
Roughly, a process object is alive from the moment the `start()` method returns until the child process terminates.

**daemon**

The process’s daemon flag, a Boolean value. This must be called before `start()` is called.

The initial value is inherited from the creating process.

When a process exits, it attempts to terminate all of its daemonic child processes.

Note that a daemonic process is not allowed to create child processes. Otherwise a daemonic process would leave its children orphaned if it gets terminated when its parent process exits.

In addition to the `Threading.Thread` API, `Process` objects also support the following attributes and methods:

**pid**

Return the process ID. Before the process is spawned, this will be `None`.

**exitcode**

The child’s exit code. This will be `None` if the process has not yet terminated. A negative value `-N` indicates that the child was terminated by signal `N`.

**authkey**

The process’s authentication key (a byte string).

When `multiprocessing` is initialized the main process is assigned a random string using `os.random()`.

When a `Process` object is created, it will inherit the
authentication key of its parent process, although this may be changed by setting `authkey` to another byte string.

See Authentication keys.

**terminate()**

Terminate the process. On Unix this is done using the `SIGTERM` signal; on Windows `TerminateProcess` is used. Note that exit handlers and finally clauses, etc., will not be executed.

Note that descendant processes of the process will not be terminated – they will simply become orphaned.

**Warning:** If this method is used when the associated process is using a pipe or queue then the pipe or queue is liable to become corrupted and may become unusable by other process. Similarly, if the process has acquired a lock or semaphore etc. then terminating it is liable to cause other processes to deadlock.

Note that the `start()`, `join()`, `is_alive()` and `exit_code` methods should only be called by the process that created the process object.

Example usage of some of the methods of `Process`:

```python
>>> import processing, time, signal
>>> p = processing.Process(target=time.sleep, args=(1000,))
>>> print p, p.is_alive()
<Process(Process-1, initial)> False
>>> p.start()
>>> print p, p.is_alive()
<Process(Process-1, started)> True
>>> p.terminate()
```
exception multiprocessing.BufferTooShort

Exception raised by `Connection.recv_bytes_into()` when the supplied buffer object is too small for the message read.

If `e` is an instance of `BufferTooShort` then `e.args[0]` will give the message as a byte string.

**Pipes and Queues**

When using multiple processes, one generally uses message passing for communication between processes and avoids having to use any synchronization primitives like locks.

For passing messages one can use `Pipe()` (for a connection between two processes) or a queue (which allows multiple producers and consumers).

The `Queue` and `JoinableQueue` types are multi-producer, multi-consumer FIFO queues modelled on the `Queue.Queue` class in the standard library. They differ in that `Queue` lacks the `task_done()` and `join()` methods introduced into Python 2.5’s `Queue.Queue` class.

If you use `JoinableQueue` then you **must** call `JoinableQueue.task_done()` for each task removed from the queue or else the semaphore used to count the number of unfinished tasks may eventually overflow raising an exception.

Note that one can also create a shared queue by using a manager object – see `Managers`. 
**Note:** `multiprocessing` uses the usual `Queue.Empty` and `Queue.Full` exceptions to signal a timeout. They are not available in the `multiprocessing` namespace so you need to import them from `Queue`.

**Warning:** If a process is killed using `Process.terminate()` or `os.kill()` while it is trying to use a `Queue`, then the data in the queue is likely to become corrupted. This may cause any other processes to get an exception when it tries to use the queue later on.

**Warning:** As mentioned above, if a child process has put items on a queue (and it has not used `JoinableQueue.cancel_join_thread()`), then that process will not terminate until all buffered items have been flushed to the pipe. This means that if you try joining that process you may get a deadlock unless you are sure that all items which have been put on the queue have been consumed. Similarly, if the child process is non-daemonic then the parent process may hang on exit when it tries to join all its non-daemonic children. Note that a queue created using a manager does not have this issue. See *Programming guidelines*.

For an example of the usage of queues for interprocess communication see *Examples*.

```python
multiprocessing.Pipe([duplex])
```

Returns a pair `(conn1, conn2)` of `Connection` objects representing the ends of a pipe.

If `duplex` is `True` (the default) then the pipe is bidirectional. If `duplex` is `False` then the pipe is unidirectional: `conn1` can only be used for receiving messages and `conn2` can only be used for
sending messages.

class multiprocessing.Queue([maxsize])
Returns a process shared queue implemented using a pipe and a few locks/semaphores. When a process first puts an item on the queue a feeder thread is started which transfers objects from a buffer into the pipe.

The usual Queue.Empty and Queue.Full exceptions from the standard library’s Queue module are raised to signal timeouts.

Queue implements all the methods of Queue.Queue except for task_done() and join().

qsize()
Return the approximate size of the queue. Because of multithreading/multiprocessing semantics, this number is not reliable.
