    Return the next value from the iteration o. If the object is an iterator, this retrieves the next value from the iteration, and returns NULL with no exception set if there are no remaining items. If the object is not an iterator, TypeError is raised, or if there is an error in retrieving the item, returns NULL and passes along the exception.
```

To write a loop which iterates over an iterator, the C code should look something like this:

```c
PyObject *iterator = PyObject_GetIter(obj);
PyObject *item;

if (iterator == NULL) {
    /* propagate error */
}

while (item = PyIter_Next(iterator)) {
    /* do something with item */
    ...
    /* release reference when done */
    Py_DECREF(item);
}

Py_DECREF(iterator);

if (PyErr_Occurred()) {
```
/* propagate error */
}
else {
    /* continue doing useful work */
}
Buffer Protocol

```c
int PyObject_AsCharBuffer(PyObject *obj, const char **buffer, Py_ssize_t *buffer_len)

Returns a pointer to a read-only memory location usable as character-based input. The obj argument must support the single-segment character buffer interface. On success, returns 0, sets buffer to the memory location and buffer_len to the buffer length. Returns -1 and sets a TypeError on error.

New in version 1.6.
```

```c
int PyObject_AsReadBuffer(PyObject *obj, const void **buffer, Py_ssize_t *buffer_len)

Returns a pointer to a read-only memory location containing arbitrary data. The obj argument must support the single-segment readable buffer interface. On success, returns 0, sets buffer to the memory location and buffer_len to the buffer length. Returns -1 and sets a TypeError on error.

New in version 1.6.
```

```c
int PyObject_CheckReadBuffer(PyObject *o)

Returns 1 if o supports the single-segment readable buffer interface. Otherwise returns 0.

New in version 2.2.
```

```c
int PyObject_AsWriteBuffer(PyObject *obj, void **buffer, Py_ssize_t *buffer_len)

Returns a pointer to a writeable memory location. The obj argument must support the single-segment, character buffer interface. On success, returns 0, sets buffer to the memory
location and *buffer_len* to the buffer length. Returns -1 and sets a *TypeError* on error.

*New in version 1.6.*
Concrete Objects Layer

The functions in this chapter are specific to certain Python object types. Passing them an object of the wrong type is not a good idea; if you receive an object from a Python program and you are not sure that it has the right type, you must perform a type check first; for example, to check that an object is a dictionary, use \texttt{PyDict\_Check}. The chapter is structured like the “family tree” of Python object types.

\textbf{Warning:} While the functions described in this chapter carefully check the type of the objects which are passed in, many of them do not check for \texttt{NULL} being passed instead of a valid object. Allowing \texttt{NULL} to be passed in can cause memory access violations and immediate termination of the interpreter.
Fundamental Objects

This section describes Python type objects and the singleton object \texttt{None}.

- Type Objects
- The None Object
Numeric Objects

- Plain Integer Objects
- Boolean Objects
- Long Integer Objects
- Floating Point Objects
- Complex Number Objects
  - Complex Numbers as C Structures
  - Complex Numbers as Python Objects
Sequence Objects

Generic operations on sequence objects were discussed in the previous chapter; this section deals with the specific kinds of sequence objects that are intrinsic to the Python language.

- Byte Array Objects

- String/Bytes Objects

- Unicode Objects and Codecs
  - Unicode Objects
  - Built-in Codecs
  - Methods and Slot Functions

- Buffer Objects

- Tuple Objects

- List Objects
Mapping Objects

- Dictionary Objects
Other Objects

- Class and Instance Objects
- Function Objects
- Method Objects
- File Objects
- Module Objects
- Iterator Objects
- Descriptor Objects
- Slice Objects
- Weak Reference Objects
- CObjects
- Cell Objects
- Generator Objects
- DateTime Objects
- Set Objects
Type Objects

**PyTypeObject**
The C structure of the objects used to describe built-in types.

**PyObject** *PyType_Type**
This is the type object for type objects; it is the same object as `type` and `types.TypeType` in the Python layer.

```c
int PyType_Check(PyObject *o)
```
Return true if the object `o` is a type object, including instances of types derived from the standard type object. Return false in all other cases.

```c
int PyType_CheckExact(PyObject *o)
```
Return true if the object `o` is a type object, but not a subtype of the standard type object. Return false in all other cases.

*New in version 2.2.*

```c
unsigned int PyType_ClearCache(void)
```
Clear the internal lookup cache. Return the current version tag.

*New in version 2.6.*

```c
void PyType_Modified(PyTypeObject *type)
```
Invalidate the internal lookup cache for the type and all of its subtypes. This function must be called after any manual modification of the attributes or base classes of the type.

*New in version 2.6.*

```c
int PyType_HasFeature(PyObject *o, int feature)
```
Return true if the type object `o` sets the feature `feature`. Type
features are denoted by single bit flags.

int **PyType_IS_GC**(PyObject *o)

Return true if the type object includes support for the cycle detector; this tests the type flag **Py_TPFLAGS_HAVE_GC**.

*New in version 2.0.*

int **PyType_IsSubtype**(PyTypeObject *a, PyTypeObject *b)

Return true if a is a subtype of b.

*New in version 2.2.*

PyObject* **PyType_GenericAlloc**(PyTypeObject *type, Py_ssize_t nitems)

*Return value: New reference.*

*New in version 2.2.*

PyObject* **PyType_GenericNew**(PyTypeObject *type, PyObject *args, PyObject *kwds)

*Return value: New reference.*

*New in version 2.2.*

int **PyType_Ready**(PyTypeObject *type)

Finalize a type object. This should be called on all type objects to finish their initialization. This function is responsible for adding inherited slots from a type's base class. Return 0 on success, or return -1 and sets an exception on error.

*New in version 2.2.*
The None Object

Note that the PyTypeObject for None is not directly exposed in the Python/C API. Since None is a singleton, testing for object identity (using == in C) is sufficient. There is no PyNone_Check function for the same reason.

PyObject* Py_None

The Python None object, denoting lack of value. This object has no methods. It needs to be treated just like any other object with respect to reference counts.

Py_RETURN_NONE

Properly handle returning Py_None from within a C function.

New in version 2.4.
Plain Integer Objects

**PyIntObject**
This subtype of **PyObject** represents a Python integer object.

**PyTypeObject PyInt_Type**
This instance of **PyTypeObject** represents the Python plain integer type. This is the same object as **int** and **types.IntType**.

**int PyInt_Check(PyObject *o)**
Return true if o is of type **PyInt_Type** or a subtype of **PyInt_Type**.

*Changed in version 2.2:* Allowed subtypes to be accepted.

**int PyInt_CheckExact(PyObject *o)**
Return true if o is of type **PyInt_Type**, but not a subtype of **PyInt_Type**.

*New in version 2.2.*

**PyObject* PyInt_FromString(char *str, char **pend, int base)**

*Return value: New reference.*

Return a new **PyIntObject** or **PyLongObject** based on the string value in str, which is interpreted according to the radix in base. If pend is non-**NULL**, *pend will point to the first character in str which follows the representation of the number. If base is 0, the radix will be determined based on the leading characters of str: if str starts with '0x' or '0X', radix 16 will be used; if str starts with '0', radix 8 will be used; otherwise radix 10 will be used. If base is not 0, it must be between 2 and 36, inclusive. Leading spaces are ignored. If there are no digits, **ValueError** will be raised. If the string represents a number too large to be contained within the machine’s **long int** type and overflow warnings are being
suppressed, a PyLongObject will be returned. If overflow warnings are not being suppressed, NULL will be returned in this case.

PyObject* PyInt_FromLong(long ival)

Create a new integer object with a value of ival.

The current implementation keeps an array of integer objects for all integers between -5 and 256, when you create an int in that range you actually just get back a reference to the existing object. So it should be possible to change the value of 1. I suspect the behaviour of Python in this case is undefined. :-)

PyObject* PyInt_FromSsize_t(Py_ssize_t ival)

Create a new integer object with a value of ival. If the value exceeds LONG_MAX, a long integer object is returned.

New in version 2.5.

long PyInt_AsLong(PyObject *io)

Will first attempt to cast the object to a PyIntObject, if it is not already one, and then return its value. If there is an error, -1 is returned, and the caller should check PyErr_Occurred() to find out whether there was an error, or whether the value just happened to be -1.

long PyInt_AS_LONG(PyObject *io)

Return the value of the object io. No error checking is performed.

unsigned long PyInt_AsUnsignedLongMask(PyObject *io)

Will first attempt to cast the object to a PyIntObject or PyLongObject, if it is not already one, and then return its value as unsigned long. This function does not check for overflow.
unsigned PY_LONG_LONG

**PyInt.AsUnsignedLongLongMask**(*PyObject *io*)

Will first attempt to cast the object to a **PyIntObject** or **PyLongObject**, if it is not already one, and then return its value as unsigned long long, without checking for overflow.

**New in version 2.3.**

**Py_ssize_t PyInt.AsSsize_t**(*PyObject *io*)

Will first attempt to cast the object to a **PyIntObject** or **PyLongObject**, if it is not already one, and then return its value as **Py_ssize_t**.

**New in version 2.3.**

**long PyInt.GetMax**()

Return the system’s idea of the largest integer it can handle (**LONG_MAX**, as defined in the system header files).

**int PyInt.ClearFreeList**(void)

Clear the integer free list. Return the number of items that could not be freed.

**New in version 2.5.**

**New in version 2.6.**
Boolean Objects

Booleans in Python are implemented as a subclass of integers. There are only two booleans, `Py_False` and `Py_True`. As such, the normal creation and deletion functions don’t apply to booleans. The following macros are available, however.

```
int PyBool_Check(PyObject *o)
    Return true if o is of type PyBool_Type.

New in version 2.3.
```

```
PyObject* Py_False
    The Python False object. This object has no methods. It needs to be treated just like any other object with respect to reference counts.

PyObject* Py_True
    The Python True object. This object has no methods. It needs to be treated just like any other object with respect to reference counts.
```

```
Py_RETURN_FALSE
    Return Py_False from a function, properly incrementing its reference count.

New in version 2.4.
```

```
Py_RETURN_TRUE
    Return Py_True from a function, properly incrementing its reference count.

New in version 2.4.
```

```
PyObject* PyBool_FromLong(long v)
```
Return a new reference to `Py_True` or `Py_False` depending on the truth value of `v`.

New in version 2.3.
Long Integer Objects

**PyLongObject**
This subtype of **PyObject** represents a Python long integer object.

**PyTypeObject** **PyLong_Type**
This instance of **PyTypeObject** represents the Python long integer type. This is the same object as `long` and `types.LongType`.

```c
int PyLong_Check(PyObject *p)
    Return true if its argument is a PyLongObject or a subtype of PyLongObject.
```

*Changed in version 2.2: Allowed subtypes to be accepted.*

```c
int PyLong_CheckExact(PyObject *p)
    Return true if its argument is a PyLongObject, but not a subtype of PyLongObject.
```

*New in version 2.2.*

```c
PyObject* PyLong_FromLong(long v)
    Return a new PyLongObject object from v, or NULL on failure.
```

```c
PyObject* PyLong_FromUnsignedLong(unsigned long v)
    Return a new PyLongObject object from a C unsigned long, or NULL on failure.
```

```c
PyObject* PyLong_FromSsize_t(Py_ssize_t v)
    Return a new PyLongObject object from a C Py_ssize_t, or NULL on failure.
```
New in version 2.5.

PyObject* PyLong_FromSize_t(size_t v)
Return a new PyLongObject object from a C size_t, or NULL on failure.

New in version 2.5.

PyObject* PyLong_FromLongLong(PY_LONG_LONG v)
Return a new PyLongObject object from a C long long, or NULL on failure.

PyObject* PyLong_FromUnsignedLongLong(unsigned PY_LONG_LONG v)
Return a new PyLongObject object from a C unsigned long long, or NULL on failure.

PyObject* PyLong_FromDouble(double v)
Return a new PyLongObject object from the integer part of v, or NULL on failure.

PyObject* PyLong_FromString(char *str, char **pend, int base)
Return a new PyLongObject based on the string value in str, which is interpreted according to the radix in base. If pend is non-
NULL, *pend will point to the first character in str which follows
the representation of the number. If base is 0, the radix will be
determined based on the leading characters of str: if str starts
with '0x' or '0X', radix 16 will be used; if str starts with '0', radix
8 will be used; otherwise radix 10 will be used. If base is not 0, it
must be between 2 and 36, inclusive. Leading spaces are
ignored. If there are no digits, `ValueError` will be raised.

`PyObject* PyLong_FromUnicode(Py_UNICODE *u, Py_ssize_t length, int base)`

*Return value: New reference.*

Convert a sequence of Unicode digits to a Python long integer value. The first parameter, `u`, points to the first character of the Unicode string, `length` gives the number of characters, and `base` is the radix for the conversion. The radix must be in the range [2, 36]; if it is out of range, `ValueError` will be raised.

*New in version 1.6.*

`PyObject* PyLong_FromVoidPtr(void *p)`  

*Return value: New reference.*

Create a Python integer or long integer from the pointer `p`. The pointer value can be retrieved from the resulting value using `PyLong_AsVoidPtr`.

*New in version 1.5.2.*

*Changed in version 2.5:* If the integer is larger than `LONG_MAX`, a positive long integer is returned.

`long PyLong_AsLong(PyObject *pylong)`

Return a C `long` representation of the contents of `pylong`. If `pylong` is greater than `LONG_MAX`, an `OverflowError` is raised and `-1` will be returned.

`Py_ssize_t PyLong_AsSsize_t(PyObject *pylong)`

Return a C `Py_ssize_t` representation of the contents of `pylong`. If `pylong` is greater than `PY_SSIZE_T_MAX`, an `OverflowError` is raised and `-1` will be returned.
**New in version 2.5.**

unsigned long **PyLong_AsUnsignedLong**(*PyObject *pylong*)

Return a C unsigned long representation of the contents of `pylong`. If `pylong` is greater than **ULONG_MAX**, an **OverflowError** is raised.

**PY_LONG_LONG** **PyLong_AsLongLong**(*PyObject *pylong*)

Return a C long long from a Python long integer. If `pylong` cannot be represented as a long long, an **OverflowError** will be raised.

**New in version 2.2.**

unsigned **PY_LONG_LONG**

**PyLong_AsUnsignedLongLong**(*PyObject *pylong*)

Return a C unsigned long long from a Python long integer. If `pylong` cannot be represented as an unsigned long long, an **OverflowError** will be raised if the value is positive, or a **TypeError** will be raised if the value is negative.

**New in version 2.2.**

unsigned long **PyLong_AsUnsignedLongMask**(*PyObject *io*)

Return a C unsigned long from a Python long integer, without checking for overflow.

**New in version 2.3.**

unsigned **PY_LONG_LONG**

**PyLong_AsUnsignedLongLongMask**(*PyObject *io*)

Return a C unsigned long long from a Python long integer, without checking for overflow.

**New in version 2.3.**
double `PyLong_AsDouble(PyObject *pylong)`

Return a C `double` representation of the contents of `pylong`. If `pylong` cannot be approximately represented as a `double`, an `OverflowError` exception is raised and `-1.0` will be returned.

```c
void* `PyLong_AsVoidPtr(PyObject *pylong)`
```

Convert a Python integer or long integer `pylong` to a C `void` pointer. If `pylong` cannot be converted, an `OverflowError` will be raised. This is only assured to produce a usable `void` pointer for values created with `PyLong_FromVoidPtr`.

New in version 1.5.2.

Changed in version 2.5: For values outside 0..LONG_MAX, both signed and unsigned integers are accepted.
Floating Point Objects

**PyFloatObject**
This subtype of **PyObject** represents a Python floating point object.

**PyTypeObject PyFloat_Type**
This instance of **PyTypeObject** represents the Python floating point type. This is the same object as `float` and `types.FloatType`.

```c
int PyFloat_Check(PyObject *p)
```
Return true if its argument is a **PyFloatObject** or a subtype of **PyFloatObject**.

*Changed in version 2.2: Allowed subtypes to be accepted.*

```c
int PyFloat_CheckExact(PyObject *p)
```
Return true if its argument is a **PyFloatObject**, but not a subtype of **PyFloatObject**.

*New in version 2.2.*

```c
PyObject* PyFloat_FromString(PyObject *str, char **pend)
```
*Return value: New reference.*
Create a **PyFloatObject** object based on the string value in `str`, or `NULL` on failure. The `pend` argument is ignored. It remains only for backward compatibility.

```c
PyObject* PyFloat_FromDouble(double v)
```
*Return value: New reference.*
Create a **PyFloatObject** object from `v`, or `NULL` on failure.
double PyFloat_AsDouble(PyObject *pyfloat)
Return a C double representation of the contents of pyfloat. If pyfloat is not a Python floating point object but has a __float__() method, this method will first be called to convert pyfloat into a float.

double PyFloat_AS_DOUBLE(PyObject *pyfloat)
Return a C double representation of the contents of pyfloat, but without error checking.

PyObject* PyFloat_GetInfo(void)
Return a structseq instance which contains information about the precision, minimum and maximum values of a float. It's a thin wrapper around the header file float.h.

    New in version 2.6.

double PyFloat_GetMax(void)
Return the maximum representable finite float DBL_MAX as C double.

    New in version 2.6.

double PyFloat_GetMin(void)
Return the minimum normalized positive float DBL_MIN as C double.

    New in version 2.6.

int PyFloat_ClearFreeList(void)
Clear the float free list. Return the number of items that could not be freed.

    New in version 2.6.
Complex Number Objects

Python’s complex number objects are implemented as two distinct types when viewed from the C API: one is the Python object exposed to Python programs, and the other is a C structure which represents the actual complex number value. The API provides functions for working with both.
Complex Numbers as C Structures

Note that the functions which accept these structures as parameters and return them as results do so by value rather than dereferencing them through pointers. This is consistent throughout the API.

Py_complex

The C structure which corresponds to the value portion of a Python complex number object. Most of the functions for dealing with complex number objects use structures of this type as input or output values, as appropriate. It is defined as:

```c
typedef struct {
    double real;
    double imag;
} Py_complex;
```

Py_complex __Py_c_sum(Py_complex left, Py_complex right)
Return the sum of two complex numbers, using the C Py_complex representation.

Py_complex __Py_c_diff(Py_complex left, Py_complex right)
Return the difference between two complex numbers, using the C Py_complex representation.

Py_complex __Py_c_neg(Py_complex complex)
Return the negation of the complex number complex, using the C Py_complex representation.

Py_complex __Py_c_prod(Py_complex left, Py_complex right)
Return the product of two complex numbers, using the C Py_complex representation.
Py_complex _Py_c_quot(Py_complex dividend, Py_complex divisor)

    Return the quotient of two complex numbers, using the C Py_complex representation.

Py_complex _Py_c_pow(Py_complex num, Py_complex exp)

    Return the exponentiation of num by exp, using the C Py_complex representation.
Complex Numbers as Python Objects

**PyComplexObject**

This subtype of **PyObject** represents a Python complex number object.

**PyTypeObject** **PyComplex_Type**

This instance of **PyTypeObject** represents the Python complex number type. It is the same object as `complex` and `types.ComplexType`.

```python
int PyComplex_Check(PyObject *p)
```

Return true if its argument is a **PyComplexObject** or a subtype of **PyComplexObject**.

*Changed in version 2.2*: Allowed subtypes to be accepted.

```python
int PyComplex_CheckExact(PyObject *p)
```

Return true if its argument is a **PyComplexObject**, but not a subtype of **PyComplexObject**.

*New in version 2.2.*

```python
PyObject* PyComplex_FromCComplex(Py_complex v)
```

*Return value: New reference.*

Create a new Python complex number object from a C `Py_complex` value.

```python
PyObject* PyComplex_FromDoubles(double real, double imag)
```

*Return value: New reference.*

Return a new **PyComplexObject** object from `real` and `imag`.

```python
double PyComplex_RealAsDouble(PyObject *op)
```
Return the real part of `op` as a C `double`.

double `PyComplex_ImagAsDouble(PyObject *op)`
Return the imaginary part of `op` as a C `double`.

`Py_complex PyComplex_AsCComplex(PyObject *op)`
Return the `Py_complex` value of the complex number `op`.

*Changed in version 2.6:* If `op` is not a Python complex number object but has a `__complex__()` method, this method will first be called to convert `op` to a Python complex number object.
Byte Array Objects

New in version 2.6.

**PyByteArrayObject**
This subtype of PyObject represents a Python bytearray object.

**PyTypeObject PyByteArray_Type**
This instance of PyTypeObject represents the Python bytearray type; it is the same object as bytearray in the Python layer.

```
int PyByteArray_Check(PyObject *o)
Return true if the object o is a bytearray object or an instance of a subtype of the bytearray type.
```

```
int PyByteArray_CheckExact(PyObject *o)
Return true if the object o is a bytearray object, but not an instance of a subtype of the bytearray type.
```

```
PyObject* PyByteArray_FromObject(PyObject *o)
Return a new bytearray object from any object, o, that implements the buffer protocol.
```

```
PyObject* PyByteArray_FromStringAndSize(const char *string, Py_ssize_t len)
Create a new bytearray object from string and its length, len. On failure, NULL is returned.
```

```
Py_ssize_t PyByteArray_Size(PyObject *bytearray)
Return the size of bytearray after checking for a NULL pointer.
```

```
Py_ssize_t PyByteArray_GET_SIZE(PyObject *bytearray)
Macro version of PyByteArray_Size that doesn’t do pointer checking.
```
char* **PyByteArray_AsString**(PyObject *bytearray)

Return the contents of `bytearray` as a char array after checking for a `NULL` pointer.

char* **PyByteArray_AS_STRING**(PyObject *bytearray)

Macro version of `PyByteArray_AsString` that doesn't check pointers.

**PyObject** *PyByteArray_Concat**(PyObject *a, PyObject *b)

Concat bytearrays `a` and `b` and return a new bytearray with the result.

**PyObject** *PyByteArray_Resize**(PyObject *bytearray, Py_ssize_t len)

Resize the internal buffer of `bytearray` to `len`.
String/Bytes Objects

These functions raise `TypeError` when expecting a string parameter and are called with a non-string parameter.

**Note:** These functions have been renamed to `PyBytes_*` in Python 3.x. The PyBytes names are also available in 2.6.

**PyStringObject**
This subtype of `PyObject` represents a Python string object.

**PyTypeObject PyString_Type**
This instance of `PyTypeObject` represents the Python string type; it is the same object as `str` and `types.StringType` in the Python layer.

```c
int PyString_Check(PyObject *o)
```
Return true if the object `o` is a string object or an instance of a subtype of the string type.

*Changed in version 2.2:* Allowed subtypes to be accepted.

```c
int PyString_CheckExact(PyObject *o)
```
Return true if the object `o` is a string object, but not an instance of a subtype of the string type.

*New in version 2.2.*

```c
PyObject* PyString_FromString(const char *v)
```
*Return value: New reference.*
Return a new string object with a copy of the string `v` as value on success, and `NULL` on failure. The parameter `v` must not be `NULL`; it will not be checked.
PyObject* **PyString_FromStringAndSize** (const char *v, Py_ssize_t len)

*Return value: New reference.*
Return a new string object with a copy of the string `v` as value and length `len` on success, and `NULL` on failure. If `v` is `NULL`, the contents of the string are uninitialized.

PyObject* **PyString_FromFormat** (const char *format, ...)

*Return value: New reference.*
Take a C `printf`-style `format` string and a variable number of arguments, calculate the size of the resulting Python string and return a string with the values formatted into it. The variable arguments must be C types and must correspond exactly to the format characters in the `format` string. The following format characters are allowed:

<table>
<thead>
<tr>
<th>Format Characters</th>
<th>Type</th>
<th>Comment</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>%</code></td>
<td>n/a</td>
<td>The literal <code>%</code> character.</td>
</tr>
<tr>
<td><code>%c</code></td>
<td>int</td>
<td>A single character, represented as an C int.</td>
</tr>
<tr>
<td><code>%d</code></td>
<td>int</td>
<td>Exactly equivalent to <code>printf(&quot;%d&quot;)</code>.</td>
</tr>
<tr>
<td><code>%u</code></td>
<td>unsigned int</td>
<td>Exactly equivalent to <code>printf(&quot;%u&quot;)</code>.</td>
</tr>
<tr>
<td><code>%ld</code></td>
<td>long</td>
<td>Exactly equivalent to <code>printf(&quot;%ld&quot;)</code>.</td>
</tr>
<tr>
<td><code>%lu</code></td>
<td>unsigned long</td>
<td>Exactly equivalent to <code>printf(&quot;%lu&quot;)</code>.</td>
</tr>
<tr>
<td><code>%zd</code></td>
<td>Py_ssize_t</td>
<td>Exactly equivalent to <code>printf(&quot;%zd&quot;)</code>.</td>
</tr>
<tr>
<td><code>%zu</code></td>
<td>size_t</td>
<td>Exactly equivalent to <code>printf(&quot;%zu&quot;)</code>.</td>
</tr>
<tr>
<td><code>%i</code></td>
<td></td>
<td>Exactly equivalent to <code>printf(&quot;%i&quot;)</code>.</td>
</tr>
</tbody>
</table>
An unrecognized format character causes all the rest of the format string to be copied as-is to the result string, and any extra arguments discarded.

**PyObject** *PyString_FromFormatV*(const char *format, va_list vargs)

*Return value: New reference.*

Identical to *PyString_FromFormat* except that it takes exactly two arguments.

**Py_ssize_t** *PyString_Size*(PyObject *string)

Return the length of the string in string object *string*.

**Py_ssize_t** *PyString_GET_SIZE*(PyObject *string)

Macro form of *PyString_Size* but without error checking.

**char** *PyString_AsString*(PyObject *string)

Return a NUL-terminated representation of the contents of *string*. The pointer refers to the internal buffer of *string*, not a copy. The data must not be modified in any way, unless the string was just created using *PyString_FromStringAndSize*(NULL, size). It must not be deallocated. If *string* is a Unicode object, this function
computes the default encoding of string and operates on that. If string is not a string object at all, PyString_AsString returns NULL and raises TypeError.

char* PyString_AS_STRING(PyObject *string)
Macro form of PyString_AsString but without error checking. Only string objects are supported; no Unicode objects should be passed.

int PyString_AsStringAndSize(PyObject *obj, char **buffer, Py_ssize_t *length)
Return a NUL-terminated representation of the contents of the object obj through the output variables buffer and length.

The function accepts both string and Unicode objects as input. For Unicode objects it returns the default encoded version of the object. If length is NULL, the resulting buffer may not contain NULL characters; if it does, the function returns -1 and a TypeError is raised.

The buffer refers to an internal string buffer of obj, not a copy. The data must not be modified in any way, unless the string was just created using PyString_FromStringAndSize(NULL, size). It must not be deallocated. If string is a Unicode object, this function computes the default encoding of string and operates on that. If string is not a string object at all, PyString_AsStringAndSize returns -1 and raises TypeError.

void PyString_Concat(PyObject **string, PyObject *newpart)
Create a new string object in *string containing the contents of newpart appended to string; the caller will own the new reference. The reference to the old value of string will be stolen. If the new string cannot be created, the old reference to string will still be discarded and the value of *string will be set to NULL; the
appropriate exception will be set.

```c
void PyString_ConcatAndDel(PyObject **string, PyObject *newpart)

Create a new string object in *string containing the contents of newpart appended to string. This version decrements the reference count of newpart.
```

```c
int _PyString.Resize(PyObject **string, Py_ssize_t newsize)

A way to resize a string object even though it is “immutable”. Only use this to build up a brand new string object; don’t use this if the string may already be known in other parts of the code. It is an error to call this function if the refcount on the input string object is not one. Pass the address of an existing string object as an lvalue (it may be written into), and the new size desired. On success, *string holds the resized string object and 0 is returned; the address in *string may differ from its input value. If the reallocation fails, the original string object at *string is deallocated, *string is set to NULL, a memory exception is set, and -1 is returned.
```

```c
PyObject* PyString_Format(PyObject *format, PyObject *args)

Return a new string object from format and args. Analogous to format % args. The args argument must be a tuple.
```

```c
void PyString_InternInPlace(PyObject **string)

Intern the argument *string in place. The argument must be the address of a pointer variable pointing to a Python string object. If there is an existing interned string that is the same as *string, it sets *string to it (decrementing the reference count of the old string object and incrementing the reference count of the interned string object), otherwise it leaves *string alone and interns it (incrementing its reference count). (Clarification: even though
there is a lot of talk about reference counts, think of this function as reference-count-neutral; you own the object after the call if and only if you owned it before the call.)

PyObject* PyString_InternFromString(const char *v)

A combination of PyString_FromString and PyString_InternInPlace, returning either a new string object that has been interned, or a new (“owned”) reference to an earlier interned string object with the same value.

PyObject* PyString_Decode(const char *s, Py_ssize_t size, const char *encoding, const char *errors)

Create an object by decoding size bytes of the encoded buffer s using the codec registered for encoding. encoding and errors have the same meaning as the parameters of the same name in the unicode() built-in function. The codec to be used is looked up using the Python codec registry. Return NULL if an exception was raised by the codec.

PyObject* PyString_AsDecodedObject(PyObject *str, const char *encoding, const char *errors)

Decode a string object by passing it to the codec registered for encoding and return the result as Python object. encoding and errors have the same meaning as the parameters of the same name in the string encode() method. The codec to be used is looked up using the Python codec registry. Return NULL if an exception was raised by the codec.

PyObject* PyString_Encode(const char *s, Py_ssize_t size, const char *encoding, const char *errors)

Encode the char buffer of the given size by passing it to the codec registered for encoding and return a Python object. encoding and errors have the same meaning as the parameters of the same name in the string encode() method. The codec to be used is looked up using the Python codec registry. Return NULL if an exception was raised by the codec.

PyObject* PyString_AsEncodedObject(PyObject *str, const char *encoding, const char *errors)

Encode a string object using the codec registered for encoding and return the result as Python object. encoding and errors have the same meaning as the parameters of the same name in the string encode() method. The codec to be used is looked up using the Python codec registry. Return NULL if an exception was raised by the codec.
Unicode Objects and Codecs
Unicode Objects

These are the basic Unicode object types used for the Unicode implementation in Python:

**Py_UNICODE**

This type represents the storage type which is used by Python internally as basis for holding Unicode ordinals. Python’s default builds use a 16-bit type for `Py_UNICODE` and store Unicode values internally as UCS2. It is also possible to build a UCS4 version of Python (most recent Linux distributions come with UCS4 builds of Python). These builds then use a 32-bit type for `Py_UNICODE` and store Unicode data internally as UCS4. On platforms where `wchar_t` is available and compatible with the chosen Python Unicode build variant, `Py_UNICODE` is a typedef alias for `wchar_t` to enhance native platform compatibility. On all other platforms, `Py_UNICODE` is a typedef alias for either `unsigned short` (UCS2) or `unsigned long` (UCS4).

Note that UCS2 and UCS4 Python builds are not binary compatible. Please keep this in mind when writing extensions or interfaces.

**PyUnicodeObject**

This subtype of `PyObject` represents a Python Unicode object.

**PyTypeObject PyUnicode_Type**

This instance of `PyTypeObject` represents the Python Unicode type. It is exposed to Python code as `unicode` and `types.UnicodeType`.

The following APIs are really C macros and can be used to do fast checks and to access internal read-only data of Unicode objects:
int PyUnicode_Check(PyObject *o)
    Return true if the object o is a Unicode object or an instance of a Unicode subtype.

    *Changed in version 2.2:* Allowed subtypes to be accepted.

int PyUnicode_CheckExact(PyObject *o)
    Return true if the object o is a Unicode object, but not an instance of a subtype.

    *New in version 2.2.*

Py_ssize_t PyUnicode_GET_SIZE(PyObject *o)
    Return the size of the object. o has to be a PyUnicodeObject (not checked).

Py_ssize_t PyUnicode_GET_DATA_SIZE(PyObject *o)
    Return the size of the object's internal buffer in bytes. o has to be a PyUnicodeObject (not checked).

Py_UNICODE* PyUnicode_AS_UNICODE(PyObject *o)
    Return a pointer to the internal Py_UNICODE buffer of the object. o has to be a PyUnicodeObject (not checked).

const char* PyUnicode_AS_DATA(PyObject *o)
    Return a pointer to the internal buffer of the object. o has to be a PyUnicodeObject (not checked).

int PyUnicode_ClearFreeList(void)
    Clear the free list. Return the total number of freed items.

    *New in version 2.6.*

Unicode provides many different character properties. The most often needed ones are available through these macros which are
mapped to C functions depending on the Python configuration.

int Py_UNICODE_ISSPACE(Py_UNICODE ch)
    Return 1 or 0 depending on whether ch is a whitespace character.

int Py_UNICODE_ISLOWER(Py_UNICODE ch)
    Return 1 or 0 depending on whether ch is a lowercase character.

int Py_UNICODE_ISUPPER(Py_UNICODE ch)
    Return 1 or 0 depending on whether ch is an uppercase character.

int Py_UNICODE_ISTITLE(Py_UNICODE ch)
    Return 1 or 0 depending on whether ch is a titlecase character.

int Py_UNICODE_ISLINEBREAK(Py_UNICODE ch)
    Return 1 or 0 depending on whether ch is a linebreak character.

int Py_UNICODE_ISDECIMAL(Py_UNICODE ch)
    Return 1 or 0 depending on whether ch is a decimal character.

int Py_UNICODE_ISDIGIT(Py_UNICODE ch)
    Return 1 or 0 depending on whether ch is a digit character.

int Py_UNICODE_ISNUMERIC(Py_UNICODE ch)
    Return 1 or 0 depending on whether ch is a numeric character.

int Py_UNICODE_ISALPHA(Py_UNICODE ch)
    Return 1 or 0 depending on whether ch is an alphabetic character.

int Py_UNICODE_ISALNUM(Py_UNICODE ch)
    Return 1 or 0 depending on whether ch is an alphanumeric character.
These APIs can be used for fast direct character conversions:

\texttt{Py\_UNICODE Py\_UNICODE\_TOLower(Py\_UNICODE ch)}

Return the character \textit{ch} converted to lower case.

\texttt{Py\_UNICODE Py\_UNICODE\_Toupper(Py\_UNICODE ch)}

Return the character \textit{ch} converted to upper case.

\texttt{Py\_UNICODE Py\_UNICODE\_Totitle(Py\_UNICODE ch)}

Return the character \textit{ch} converted to title case.

\texttt{int Py\_UNICODE\_ToDecimal(Py\_UNICODE ch)}

Return the character \textit{ch} converted to a decimal positive integer. Return \texttt{-1} if this is not possible. This macro does not raise exceptions.

\texttt{int Py\_UNICODE\_ToDigit(Py\_UNICODE ch)}

Return the character \textit{ch} converted to a single digit integer. Return \texttt{-1} if this is not possible. This macro does not raise exceptions.

\texttt{double Py\_UNICODE\_ToNumeric(Py\_UNICODE ch)}

Return the character \textit{ch} converted to a double. Return \texttt{-1.0} if this is not possible. This macro does not raise exceptions.

To create Unicode objects and access their basic sequence properties, use these APIs:

\texttt{PyObject* PyUnicode\_FromUnicode(const Py\_UNICODE *u, Py\_ssize\_t size)}

\textit{Return value: New reference.}

Create a Unicode Object from the Py\_UNICODE buffer \textit{u} of the given size. \textit{u} may be \textit{NULL} which causes the contents to be undefined. It is the user’s responsibility to fill in the needed data. The buffer is copied into the new object. If the buffer is not \textit{NULL}, the return value might be a shared object. Therefore, modification
of the resulting Unicode object is only allowed when \( u \) is \texttt{NULL}.

**Py_UNICODE**\* \texttt{PyUnicode_AsUnicode(PyObject \*unicode)}

Return a read-only pointer to the Unicode object's internal \texttt{Py_UNICODE} buffer, \texttt{NULL} if \texttt{unicode} is not a Unicode object.

\texttt{Py_ssize_t PyUnicode_GetSize(PyObject \*unicode)}

Return the length of the Unicode object.

**PyObject**\* \texttt{PyUnicode_FromEncodedObject(PyObject \*obj, const char \*encoding, const char \*errors)}

*Return value: New reference.*

Coerce an encoded object \texttt{obj} to an Unicode object and return a reference with incremented refcount.

String and other char buffer compatible objects are decoded according to the given encoding and using the error handling defined by \texttt{errors}. Both can be \texttt{NULL} to have the interface use the default values (see the next section for details).

All other objects, including Unicode objects, cause a \texttt{TypeError} to be set.

The API returns \texttt{NULL} if there was an error. The caller is responsible for decref'ing the returned objects.

**PyObject**\* \texttt{PyUnicode_FromObject(PyObject \*obj)}

*Return value: New reference.*

Shortcut for \texttt{PyUnicode_FromEncodedObject(obj, NULL, "strict")} which is used throughout the interpreter whenever coercion to Unicode is needed.

If the platform supports \texttt{wchar_t} and provides a header file \texttt{wchar.h}, Python can interface directly to this type using the following functions. Support is optimized if Python's own \texttt{Py_UNICODE} type is
identical to the system's `wchar_t`.

**PyObject* PyUnicode_FromWideChar(const wchar_t *w, Py_ssize_t size)**

*Return value: New reference.*

Create a Unicode object from the `wchar_t` buffer `w` of the given size. Return `NULL` on failure.

**Py_ssize_t PyUnicode_AsWideChar(PyUnicodeObject *unicode, wchar_t *w, Py_ssize_t size)**

Copy the Unicode object contents into the `wchar_t` buffer `w`. At most `size` `wchar_t` characters are copied (excluding a possibly trailing 0-termination character). Return the number of `wchar_t` characters copied or -1 in case of an error. Note that the resulting `wchar_t` string may or may not be 0-terminated. It is the responsibility of the caller to make sure that the `wchar_t` string is 0-terminated in case this is required by the application.
Built-in Codecs

Python provides a set of built-in codecs which are written in C for speed. All of these codecs are directly usable via the following functions.

Many of the following APIs take two arguments encoding and errors. These parameters encoding and errors have the same semantics as the ones of the built-in `unicode()` Unicode object constructor.

Setting encoding to `NULL` causes the default encoding to be used which is ASCII. The file system calls should use `Py_FileSystemDefaultEncoding` as the encoding for file names. This variable should be treated as read-only: On some systems, it will be a pointer to a static string, on others, it will change at run-time (such as when the application invokes `setlocale`).

Error handling is set by errors which may also be set to `NULL` meaning to use the default handling defined for the codec. Default error handling for all built-in codecs is “strict” (`ValueError` is raised).

The codecs all use a similar interface. Only deviation from the following generic ones are documented for simplicity.

These are the generic codec APIs:

```c
PyObject* PyUnicode_Decode(const char *s, Py_ssize_t size, const char *encoding, const char *errors)
```

*Return value: New reference.*

Create a Unicode object by decoding `size` bytes of the encoded string `s`. `encoding` and `errors` have the same meaning as the parameters of the same name in the `unicode()` built-in function. The codec to be used is looked up using the Python codec registry. Return `NULL` if an exception was raised by the codec.
PyObject* PyUnicode_Encode(const Py_UNICODE *s, Py_ssize_t size, const char *encoding, const char *errors)

Encode the Py_UNICODE buffer of the given size and return a Python string object. encoding and errors have the same meaning as the parameters of the same name in the Unicode encode() method. The codec to be used is looked up using the Python codec registry. Return NULL if an exception was raised by the codec.

PyObject* PyUnicode_AsEncodedString(PyObject *unicode, const char *encoding, const char *errors)

Encode a Unicode object and return the result as Python string object. encoding and errors have the same meaning as the parameters of the same name in the Unicode encode() method. The codec to be used is looked up using the Python codec registry. Return NULL if an exception was raised by the codec.

These are the UTF-8 codec APIs:

PyObject* PyUnicode_DecodeUTF8(const char *s, Py_ssize_t size, const char *errors)

Create a Unicode object by decoding size bytes of the UTF-8 encoded string s. Return NULL if an exception was raised by the codec.

PyObject* PyUnicode_DecodeUTF8Stateful(const char *s, Py_ssize_t size, const char *errors, Py_ssize_t *consumed)

If consumed is NULL, behave like PyUnicode_DecodeUTF8. If consumed is not NULL, trailing incomplete UTF-8 byte sequences will not be treated as an error. Those bytes will not be
decoded and the number of bytes that have been decoded will be stored in *consumed*.

*New in version 2.4.*

**PyObject* PyUnicode_EncodeUTF8**(const *Py_UNICODE* *s*, *Py_ssize_t* *size*, const char *errors*)

*Return value: New reference.*

Encode the *Py_UNICODE* buffer of the given size using UTF-8 and return a Python string object. Return *NULL* if an exception was raised by the codec.

**PyObject* PyUnicode_AsUTF8String**(PyObject *unicode*)

*Return value: New reference.*

Encode a Unicode object using UTF-8 and return the result as Python string object. Error handling is “strict”. Return *NULL* if an exception was raised by the codec.

These are the UTF-32 codec APIs:

**PyObject* PyUnicode_DecodeUTF32**(const char *s*, *Py_ssize_t* *size*, const char *errors*, int *byteorder*)

Decode length bytes from a UTF-32 encoded buffer string and return the corresponding Unicode object. *errors* (if non-*NULL*) defines the error handling. It defaults to “strict”.

If *byteorder* is non-*NULL*, the decoder starts decoding using the given byte order:

*byteorder == -1*: little endian  
*byteorder == 0*: native order  
*byteorder == 1*: big endian

and then switches if the first four bytes of the input data are a byte order mark (BOM) and the specified byte order is native...
order. This BOM is not copied into the resulting Unicode string. After completion, *byteorder* is set to the current byte order at the end of input data.

In a narrow build codepoints outside the BMP will be decoded as surrogate pairs.

If *byteorder* is *NULL*, the codec starts in native order mode.

Return *NULL* if an exception was raised by the codec.

*New in version 2.6.*

```c
PyObject* PyUnicode_DecodeUTF32Stateful(const char *s, Py_ssize_t size, const char *errors, int *byteorder, Py_ssize_t *consumed)
```

If *consumed* is *NULL*, behave like *PyUnicode_DecodeUTF32*. If *consumed* is not *NULL*, *PyUnicode_DecodeUTF32Stateful* will not treat trailing incomplete UTF-32 byte sequences (such as a number of bytes not divisible by four) as an error. Those bytes will not be decoded and the number of bytes that have been decoded will be stored in *consumed*.

*New in version 2.6.*

```c
PyObject* PyUnicode_EncodeUTF32(const Py_UNICODE *s, Py_ssize_t size, const char *errors, int byteorder)
```

Return a Python bytes object holding the UTF-32 encoded value of the Unicode data in *s*. If *byteorder* is not 0, output is written according to the following byte order:

<table>
<thead>
<tr>
<th>byteorder</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>-1</td>
<td>little endian</td>
</tr>
<tr>
<td>0</td>
<td>native byte order (writes a BOM mark)</td>
</tr>
<tr>
<td>1</td>
<td>big endian</td>
</tr>
</tbody>
</table>
If byteorder is 0, the output string will always start with the Unicode BOM mark (U+FEFF). In the other two modes, no BOM mark is prepended.

If Py_UNICODE_WIDE is not defined, surrogate pairs will be output as a single codepoint.

Return NULL if an exception was raised by the codec.

New in version 2.6.

PyObject* PyUnicode_AsUTF32String(PyObject *unicode)
Return a Python string using the UTF-32 encoding in native byte order. The string always starts with a BOM mark. Error handling is “strict”. Return NULL if an exception was raised by the codec.

New in version 2.6.

These are the UTF-16 codec APIs:

PyObject* PyUnicode_DecodeUTF16(const char *s, Py_ssize_t size, const char *errors, int *byteorder)
Decode length bytes from a UTF-16 encoded buffer string and return the corresponding Unicode object. errors (if non-NULL) defines the error handling. It defaults to “strict”.

If byteorder is non-NULL, the decoder starts decoding using the given byte order:

*byteorder == -1: little endian
*byteorder == 0: native order
*byteorder == 1: big endian

and then switches if the first two bytes of the input data are a byte order mark (BOM) and the specified byte order is native order.
This BOM is not copied into the resulting Unicode string. After completion, *byteorder* is set to the current byte order at the.

If *byteorder* is *NULL*, the codec starts in native order mode.

Return *NULL* if an exception was raised by the codec.

```py
PyObject* PyUnicode_DecodeUTF16Stateful(const char *s, Py_ssize_t size, const char *errors, int *byteorder, Py_ssize_t *consumed)
```

*Return value: New reference.*

If *consumed* is *NULL*, behave like PyUnicode_DecodeUTF16. If *consumed* is not *NULL*, PyUnicode_DecodeUTF16Stateful will not treat trailing incomplete UTF-16 byte sequences (such as an odd number of bytes or a split surrogate pair) as an error. Those bytes will not be decoded and the number of bytes that have been decoded will be stored in *consumed*.

*New in version 2.4.*

```py
PyObject* PyUnicode_EncodeUTF16(const Py_UNICODE *s, Py_ssize_t size, const char *errors, int byteorder)
```

*Return value: New reference.*

Return a Python string object holding the UTF-16 encoded value of the Unicode data in *s*. If *byteorder* is not 0, output is written according to the following byte order:

- `byteorder == -1`: little endian
- `byteorder == 0`: native byte order (writes a BOM mark)
- `byteorder == 1`: big endian

If *byteorder* is 0, the output string will always start with the Unicode BOM mark (U+FEFF). In the other two modes, no BOM mark is prepended.
If `Py_UNICODE_WIDE` is defined, a single `Py_UNICODE` value may get represented as a surrogate pair. If it is not defined, each `Py_UNICODE` values is interpreted as an UCS-2 character.

Return `NULL` if an exception was raised by the codec.

**PyObject* `PyUnicode_AsUTF16String`**(PyObject *unicode)

*Return value: New reference.*

Return a Python string using the UTF-16 encoding in native byte order. The string always starts with a BOM mark. Error handling is “strict”. Return `NULL` if an exception was raised by the codec.

These are the “Unicode Escape” codec APIs:

**PyObject* `PyUnicode_DecodeUnicodeEscape`**(const char *s, Py_ssize_t size, const char *errors)

*Return value: New reference.*

Create a Unicode object by decoding `size` bytes of the Unicode-Escape encoded string `s`. Return `NULL` if an exception was raised by the codec.

**PyObject* `PyUnicode_EncodeUnicodeEscape`**(const Py_UNICODE *s, Py_ssize_t size)

*Return value: New reference.*

Encode the `Py_UNICODE` buffer of the given size using Unicode-Escape and return a Python string object. Return `NULL` if an exception was raised by the codec.

**PyObject* `PyUnicode_AsUnicodeEscapeString`**(PyObject *unicode)

*Return value: New reference.*

Encode a Unicode object using Unicode-Escape and return the result as Python string object. Error handling is “strict”. Return `NULL` if an exception was raised by the codec.
These are the "Raw Unicode Escape" codec APIs:

**PyObject** PyUnicode_DecodeRawUnicodeEscape(const char *s, Py_ssize_t size, const char *errors)

*Return value: New reference.*
Create a Unicode object by decoding size bytes of the Raw-Unicode-Escape encoded string s. Return NULL if an exception was raised by the codec.

**PyObject** PyUnicode_EncodeRawUnicodeEscape(const Py_UNICODE *s, Py_ssize_t size, const char *errors)

*Return value: New reference.*
Encode the Py_UNICODE buffer of the given size using Raw-Unicode-Escape and return a Python string object. Return NULL if an exception was raised by the codec.

**PyObject** PyUnicode_AsRawUnicodeEscapeString(PyObject *unicode)

*Return value: New reference.*
Encode a Unicode object using Raw-Unicode-Escape and return the result as Python string object. Error handling is “strict”. Return NULL if an exception was raised by the codec.

These are the Latin-1 codec APIs: Latin-1 corresponds to the first 256 Unicode ordinals and only these are accepted by the codecs during encoding.

**PyObject** PyUnicode_DecodeLatin1(const char *s, Py_ssize_t size, const char *errors)

*Return value: New reference.*
Create a Unicode object by decoding size bytes of the Latin-1 encoded string s. Return NULL if an exception was raised by the codec.

**PyObject** PyUnicode_EncodeLatin1(const Py_UNICODE *s,
Py_ssize_t size, const char *errors)

*Return value: New reference.*
Encode the Py_UNICODE buffer of the given size using Latin-1 and return a Python string object. Return NULL if an exception was raised by the codec.

PyObject* PyUnicode_AsLatin1String(PyObject *unicode)

*Return value: New reference.*
Encode a Unicode object using Latin-1 and return the result as Python string object. Error handling is “strict”. Return NULL if an exception was raised by the codec.

These are the ASCII codec APIs. Only 7-bit ASCII data is accepted. All other codes generate errors.

PyObject* PyUnicode_DecodeASCII(const char *s, Py_ssize_t size, const char *errors)

*Return value: New reference.*
Create a Unicode object by decoding size bytes of the ASCII encoded string s. Return NULL if an exception was raised by the codec.

PyObject* PyUnicode_EncodeASCII(const Py_UNICODE *s, Py_ssize_t size, const char *errors)

*Return value: New reference.*
Encode the Py_UNICODE buffer of the given size using ASCII and return a Python string object. Return NULL if an exception was raised by the codec.

PyObject* PyUnicode_AsASCIIString(PyObject *unicode)

*Return value: New reference.*
Encode a Unicode object using ASCII and return the result as Python string object. Error handling is “strict”. Return NULL if an exception was raised by the codec.
These are the mapping codec APIs:

This codec is special in that it can be used to implement many different codecs (and this is in fact what was done to obtain most of the standard codecs included in the `encodings` package). The codec uses mapping to encode and decode characters.

Decoding mappings must map single string characters to single Unicode characters, integers (which are then interpreted as Unicode ordinals) or None (meaning “undefined mapping” and causing an error).

Encoding mappings must map single Unicode characters to single string characters, integers (which are then interpreted as Latin-1 ordinals) or None (meaning “undefined mapping” and causing an error).

The mapping objects provided must only support the `__getitem__` mapping interface.

If a character lookup fails with a LookupError, the character is copied as-is meaning that its ordinal value will be interpreted as Unicode or Latin-1 ordinal resp. Because of this, mappings only need to contain those mappings which map characters to different code points.

```
PyObject* PyUnicode_DecodeCharmap(const char *s, Py_ssize_t size, PyObject *mapping, const char *errors)
```

*Return value: New reference.*

Create a Unicode object by decoding `size` bytes of the encoded string `s` using the given `mapping` object. Return `NULL` if an exception was raised by the codec. If `mapping` is `NULL` latin-1 decoding will be done. Else it can be a dictionary mapping byte or a unicode string, which is treated as a lookup table. Byte values greater that the length of the string and U+FFFE “characters” are treated as “undefined mapping”.
Changed in version 2.4: Allowed unicode string as mapping argument.

PyObject* PyUnicode_EncodeCharmap(const Py_UNICODE*s, Py_ssize_t size, PyObject *mapping, const char *errors)

Encode the Py_UNICODE buffer of the given size using the given mapping object and return a Python string object. Return NULL if an exception was raised by the codec.

PyObject* PyUnicode_AsCharmapString(PyObject *unicode, PyObject *mapping)

Encode a Unicode object using the given mapping object and return the result as Python string object. Error handling is “strict”. Return NULL if an exception was raised by the codec.

The following codec API is special in that maps Unicode to Unicode.

PyObject* PyUnicode_TranslateCharmap(const Py_UNICODE*s, Py_ssize_t size, PyObject *table, const char *errors)

Translate a Py_UNICODE buffer of the given length by applying a character mapping table to it and return the resulting Unicode object. Return NULL when an exception was raised by the codec.

The mapping table must map Unicode ordinal integers to Unicode ordinal integers or None (causing deletion of the character).

Mapping tables need only provide the __getitem__() interface; dictionaries and sequences work well. Unmapped character ordinals (ones which cause a LookupError) are left untouched and are copied as-is.
These are the MBCS codec APIs. They are currently only available on Windows and use the Win32 MBCS converters to implement the conversions. Note that MBCS (or DBCS) is a class of encodings, not just one. The target encoding is defined by the user settings on the machine running the codec.

**PyObject** `PyUnicode_DecodeMBCS(const char *s, Py_ssize_t size, const char *errors)`

*Return value: New reference.*

Create a Unicode object by decoding size bytes of the MBCS encoded string `s`. Return `NULL` if an exception was raised by the codec.

**PyObject** `PyUnicode_DecodeMBCSStateful(const char *s, int size, const char *errors, int *consumed)`

If `consumed` is `NULL`, behave like `PyUnicode_DecodeMBCS`. If `consumed` is not `NULL`, `PyUnicode_DecodeMBCSStateful` will not decode trailing lead byte and the number of bytes that have been decoded will be stored in `consumed`.

*New in version 2.5.*

**PyObject** `PyUnicode_EncodeMBCS(const Py_UNICODE *s, Py_ssize_t size, const char *errors)`

*Return value: New reference.*

Encode the `Py_UNICODE` buffer of the given size using MBCS and return a Python string object. Return `NULL` if an exception was raised by the codec.

**PyObject** `PyUnicode_AsMBCSString(PyObject *unicode)`

*Return value: New reference.*

Encode a Unicode object using MBCS and return the result as Python string object. Error handling is “strict”. Return `NULL` if an exception was raised by the codec.
The following APIs are capable of handling Unicode objects and strings on input (we refer to them as strings in the descriptions) and return Unicode objects or integers as appropriate.

They all return NULL or -1 if an exception occurs.

**PyObject* PyUnicode_Concat**(PyObject *left, PyObject *right)

*Return value: New reference.*
Concat two strings giving a new Unicode string.

**PyObject* PyUnicode_Split**(PyObject *s, PyObject *sep, Py_ssize_t maxsplit)

*Return value: New reference.*
Split a string giving a list of Unicode strings. If sep is NULL, splitting will be done at all whitespace substrings. Otherwise, splits occur at the given separator. At most maxsplit splits will be done. If negative, no limit is set. Separators are not included in the resulting list.

**PyObject* PyUnicode_Splitlines**(PyObject *s, int keepend)

*Return value: New reference.*
Split a Unicode string at line breaks, returning a list of Unicode strings. CRLF is considered to be one line break. If keepend is 0, the Line break characters are not included in the resulting strings.

**PyObject* PyUnicode_Translate**(PyObject *str, PyObject *table, const char *errors)

*Return value: New reference.*
Translate a string by applying a character mapping table to it and return the resulting Unicode object.
The mapping table must map Unicode ordinal integers to Unicode ordinal integers or None (causing deletion of the character).

Mapping tables need only provide the \texttt{\_\_getitem\_()} interface; dictionaries and sequences work well. Unmapped character ordinals (ones which cause a \texttt{LookupError}) are left untouched and are copied as-is.

\texttt{errors} has the usual meaning for codecs. It may be \texttt{NULL} which indicates to use the default error handling.

\begin{verbatim}
PyObject* \texttt{PyUnicode Join}(PyObject *separator, PyObject *seq)
  \textit{Return value: New reference.}
  Join a sequence of strings using the given separator and return the resulting Unicode string.
\end{verbatim}

\begin{verbatim}
int \texttt{PyUnicode Tailmatch}(PyObject *str, PyObject *substr,
Py_ssize_t start, Py_ssize_t end, int direction)
  \textit{Return value: New reference.}
  Return 1 if \texttt{substr} matches \texttt{str[\*start:end]} at the given tail end
  (\texttt{direction} == -1 means to do a prefix match, \texttt{direction} == 1 a suffix match),
  0 otherwise. Return \texttt{-1} if an error occurred.
\end{verbatim}

\begin{verbatim}
Py_ssize_t \texttt{PyUnicode Find}(PyObject *str, PyObject *substr,
Py_ssize_t start, Py_ssize_t end, int direction)
  \textit{Return value: New reference.}
  Return the first position of \texttt{substr} in \texttt{str[\*start:end]} using the given \texttt{direction}
  (\texttt{direction} == 1 means to do a forward search, \texttt{direction} == -1 a backward search).
  The return value is the index of the first match; a value of \texttt{-1} indicates that no match was
  found, and \texttt{-2} indicates that an error occurred and an exception has been set.
\end{verbatim}

\begin{verbatim}
Py_ssize_t \texttt{PyUnicode Count}(PyObject *str, PyObject *substr,
Py_ssize_t start, Py_ssize_t end, int direction)
  \textit{Return value: New reference.}
  Return the first position of \texttt{substr} in \texttt{str[\*start:end]} using the given \texttt{direction}
  (\texttt{direction} == 1 means to do a forward search, \texttt{direction} == -1 a backward search).
  The return value is the index of the first match; a value of \texttt{-1} indicates that no match was
  found, and \texttt{-2} indicates that an error occurred and an exception has been set.
\end{verbatim}
Py_ssize_t start, Py_ssize_t end)
   Return the number of non-overlapping occurrences of \texttt{substr} in \texttt{str[start:end]}. Return \texttt{-1} if an error occurred.

\textbf{PyObject* PyUnicode\textunderscore Replace} (PyObject *\texttt{str}, PyObject *\texttt{substr}, PyObject *\texttt{replstr}, Py_ssize_t \texttt{maxcount})
   \textit{Return value: New reference.}
   Replace at most \texttt{maxcount} occurrences of \texttt{substr} in \texttt{str} with \texttt{replstr} and return the resulting Unicode object. \texttt{maxcount} == \texttt{-1} means replace all occurrences.

int PyUnicode\textunderscore Compare (PyObject *\texttt{left}, PyObject *\texttt{right})
   Compare two strings and return \texttt{-1}, \texttt{0}, \texttt{1} for less than, equal, and greater than, respectively.

int PyUnicode\textunderscore RichCompare (PyObject *\texttt{left}, PyObject *\texttt{right}, int \texttt{op})
   Rich compare two unicode strings and return one of the following:

   \begin{itemize}
   \item \texttt{NULL} in case an exception was raised
   \item \texttt{Py_True} or \texttt{Py_False} for successful comparisons
   \item \texttt{Py_NotImplemented} in case the type combination is unknown
   \end{itemize}

   Note that \texttt{Py_EQ} and \texttt{Py_NE} comparisons can cause a \texttt{UnicodeWarning} in case the conversion of the arguments to Unicode fails with a \texttt{UnicodeDecodeError}.

   Possible values for \texttt{op} are \texttt{Py_GT}, \texttt{Py GE}, \texttt{Py_EQ}, \texttt{Py_NE}, \texttt{Py_LT}, and \texttt{Py_LE}.

\textbf{PyObject* PyUnicode\textunderscore Format} (PyObject *\texttt{format}, PyObject *\texttt{args})
   \textit{Return value: New reference.}
   Return a new string object from \texttt{format} and \texttt{args}; this is analogous to \texttt{format \% args}. The \texttt{args} argument must be a tuple.
int PyUnicode_Contains(PyObject *container, PyObject *element)

Check whether element is contained in container and return true or false accordingly.

element has to coerce to a one element Unicode string. -1 is returned if there was an error.
Buffer Objects

Python objects implemented in C can export a group of functions called the “buffer interface.” These functions can be used by an object to expose its data in a raw, byte-oriented format. Clients of the object can use the buffer interface to access the object data directly, without needing to copy it first.

Two examples of objects that support the buffer interface are strings and arrays. The string object exposes the character contents in the buffer interface’s byte-oriented form. An array can also expose its contents, but it should be noted that array elements may be multi-byte values.

An example user of the buffer interface is the file object's `write()` method. Any object that can export a series of bytes through the buffer interface can be written to a file. There are a number of format codes to `PyArg_ParseTuple` that operate against an object’s buffer interface, returning data from the target object.

More information on the buffer interface is provided in the section *Buffer Object Structures*, under the description for `PyBufferProcs`.

A “buffer object” is defined in the `bufferobject.h` header (included by `Python.h`). These objects look very similar to string objects at the Python programming level: they support slicing, indexing, concatenation, and some other standard string operations. However, their data can come from one of two sources: from a block of memory, or from another object which exports the buffer interface.

Buffer objects are useful as a way to expose the data from another object’s buffer interface to the Python programmer. They can also be used as a zero-copy slicing mechanism. Using their ability to reference a block of memory, it is possible to expose any data to the
Python programmer quite easily. The memory could be a large, constant array in a C extension, it could be a raw block of memory for manipulation before passing to an operating system library, or it could be used to pass around structured data in its native, in-memory format.

**PyBufferObject**

This subtype of `PyObject` represents a buffer object.

**PyTypeObject PyBuffer_Type**

The instance of `PyTypeObject` which represents the Python buffer type; it is the same object as `buffer` and `types.BufferType` in the Python layer.

```c
int Py_END_OF_BUFFER
```

This constant may be passed as the size parameter to `PyBuffer_FromObject` or `PyBuffer_FromReadWriteObject`. It indicates that the new `PyBufferObject` should refer to base object from the specified offset to the end of its exported buffer. Using this enables the caller to avoid querying the base object for its length.

```c
int PyBuffer_Check(PyObject *p)
```

Return true if the argument has type `PyBuffer_Type`.

```c
PyObject* PyBuffer_FromObject(PyObject *base, PyObject *base, Py_ssize_t offset, Py_ssize_t size)
```

*Return value: New reference.*

Return a new read-only buffer object. This raises `TypeError` if `base` doesn’t support the read-only buffer protocol or doesn’t provide exactly one buffer segment, or it raises `ValueError` if `offset` is less than zero. The buffer will hold a reference to the base object, and the buffer’s contents will refer to the base object’s buffer interface, starting as position `offset` and extending
for size bytes. If size is \texttt{Py\_END\_OF\_BUFFER}, then the new buffer’s contents extend to the length of the base object’s exported buffer data.

\textbf{PyObject* \texttt{PyBuffer\_FromReadWriteObject}(PyObject *base, Py\_ssize\_t offset, Py\_ssize\_t size)}

\textit{Return value: New reference.}
Return a new writable buffer object. Parameters and exceptions are similar to those for \texttt{PyBuffer\_FromObject}. If the base object does not export the writeable buffer protocol, then \texttt{TypeError} is raised.

\textbf{PyObject* \texttt{PyBuffer\_FromMemory}(void *ptr, Py\_ssize\_t size)}

\textit{Return value: New reference.}
Return a new read-only buffer object that reads from a specified location in memory, with a specified size. The caller is responsible for ensuring that the memory buffer, passed in as \texttt{ptr}, is not deallocated while the returned buffer object exists. Raises \texttt{ValueError} if size is less than zero. Note that \texttt{Py\_END\_OF\_BUFFER} may not be passed for the size parameter; \texttt{ValueError} will be raised in that case.

\textbf{PyObject* \texttt{PyBuffer\_FromReadWriteMemory}(void *ptr, Py\_ssize\_t size)}

\textit{Return value: New reference.}
Similar to \texttt{PyBuffer\_FromMemory}, but the returned buffer is writable.

\textbf{PyObject* \texttt{PyBuffer\_New}(Py\_ssize\_t size)}

\textit{Return value: New reference.}
Return a new writable buffer object that maintains its own memory buffer of size bytes. \texttt{ValueError} is returned if size is not zero or positive. Note that the memory buffer (as returned by
PyObject_AsWriteBuffer) is not specifically aligned.
Tuple Objects

**PyTupleObject**
This subtype of `PyObject` represents a Python tuple object.

**PyTypeObject** **PyTuple_Type**
This instance of `PyTypeObject` represents the Python tuple type; it is the same object as `tuple` and `types.TupleType` in the Python layer.

```c
int PyTuple_Check(PyObject *p)
```
Return true if `p` is a tuple object or an instance of a subtype of the tuple type.

*Changed in version 2.2:* Allowed subtypes to be accepted.

```c
int PyTuple_CheckExact(PyObject *p)
```
Return true if `p` is a tuple object, but not an instance of a subtype of the tuple type.

*New in version 2.2.*

```c
PyObject* PyTuple_New(Py_ssize_t len)
```
*Return value: New reference.*
Return a new tuple object of size `len`, or `NULL` on failure.

```c
PyObject* PyTuple_Pack(Py_ssize_t n, ...)
```
*Return value: New reference.*
Return a new tuple object of size `n`, or `NULL` on failure. The tuple values are initialized to the subsequent `n` C arguments pointing to Python objects. `PyTuple_Pack(2, a, b)` is equivalent to `Py_BuildValue("(OO)", a, b)`.

*New in version 2.4.*
Py_ssize_t PyTuple_Size(PyObject *p)
    Take a pointer to a tuple object, and return the size of that tuple.

Py_ssize_t PyTuple_GET_SIZE(PyObject *p)
    Return the size of the tuple p, which must be non-NULL and point to a tuple; no error checking is performed.

PyObject* PyTuple_GetItem(PyObject *p, Py_ssize_t pos)
    Return value: Borrowed reference.
    Return the object at position pos in the tuple pointed to by p. If pos is out of bounds, return NULL and sets an IndexError exception.

PyObject* PyTuple_GET_ITEM(PyObject *p, Py_ssize_t pos)
    Return value: Borrowed reference.
    Like PyTuple_GetItem, but does no checking of its arguments.

PyObject* PyTuple_GetSlice(PyObject *p, Py_ssize_t low, Py_ssize_t high)
    Take a slice of the tuple pointed to by p from low to high and return it as a new tuple.

int PyTuple_SetItem(PyObject *p, Py_ssize_t pos, PyObject *o)
    Insert a reference to object o at position pos of the tuple pointed to by p. Return 0 on success.

    Note: This function “steals” a reference to o.

void PyTuple_SET_ITEM(PyObject *p, Py_ssize_t pos, PyObject *o)
    Like PyTuple_SetItem, but does no error checking, and should only be used to fill in brand new tuples.
Note: This function “steals” a reference to o.

```c
int _PyTuple_Resize(PyObject **p, Py_ssize_t newsize)
```
Can be used to resize a tuple. `newsize` will be the new length of the tuple. Because tuples are supposed to be immutable, this should only be used if there is only one reference to the object. Do not use this if the tuple may already be known to some other part of the code. The tuple will always grow or shrink at the end. Think of this as destroying the old tuple and creating a new one, only more efficiently. Returns 0 on success. Client code should never assume that the resulting value of p will be the same as before calling this function. If the object referenced by p is replaced, the original p is destroyed. On failure, returns -1 and sets p to NULL, and raises MemoryError or SystemError.

Changed in version 2.2: Removed unused third parameter, last_is_sticky.

```c
int PyTuple_ClearFreeList(void)
```
Clear the free list. Return the total number of freed items.

New in version 2.6.
**List Objects**

**PyListObject**
This subtype of PyObject represents a Python list object.

**PyTypeObject** PyList_Type
This instance of PyTypeObject represents the Python list type. This is the same object as list and types.ListType in the Python layer.

```c
int PyList_Check(PyObject *p)
```
Return true if p is a list object or an instance of a subtype of the list type.

*Changed in version 2.2: Allowed subtypes to be accepted.*

```c
int PyList_CheckExact(PyObject *p)
```
Return true if p is a list object, but not an instance of a subtype of the list type.

*New in version 2.2.*

```c
PyObject* PyList_New(Py_ssize_t len)
```
*Return value: New reference.*
Return a new list of length len on success, or NULL on failure.

**Note:** If length is greater than zero, the returned list object’s items are set to NULL. Thus you cannot use abstract API functions such as PySequence_SetItem or expose the object to Python code before setting all items to a real object with PyList_SetItem.

```c
Py_ssize_t PyList_Size(PyObject *list)
```
Return the length of the list object in \textit{list}; this is equivalent to \texttt{len(list)} on a list object.

\texttt{Py\_ssize\_t PyList\_GET\_SIZE(PyObject *list)}

Macro form of \texttt{PyList\_Size} without error checking.

\texttt{PyObject* PyList\_GetItem(PyObject *list, Py\_ssize\_t index)}

\textit{Return value: Borrowed reference.}

Return the object at position \textit{pos} in the list pointed to by \textit{p}. The position must be positive, indexing from the end of the list is not supported. If \textit{pos} is out of bounds, return \texttt{NULL} and set an \texttt{IndexError} exception.

\texttt{PyObject* PyList\_GET\_ITEM(PyObject *list, Py\_ssize\_t i)}

\textit{Return value: Borrowed reference.}

Macro form of \texttt{PyList\_GetItem} without error checking.

\texttt{int PyList\_SetItem(PyObject *list, Py\_ssize\_t index, PyObject *item)}

Set the item at index \textit{index} in list to \textit{item}. Return \texttt{0} on success or \texttt{-1} on failure.

\textbf{Note:} This function “steals” a reference to \textit{item} and discards a reference to an item already in the list at the affected position.

\texttt{void PyList\_SET\_ITEM(PyObject *list, Py\_ssize\_t i, PyObject *o)}

Macro form of \texttt{PyList\_SetItem} without error checking. This is normally only used to fill in new lists where there is no previous content.

\textbf{Note:} This function “steals” a reference to \textit{item}, and, unlike \texttt{PyList\_SetItem}, does \textit{not} discard a reference to any item that it being replaced; any reference in \textit{list} at position \textit{i} will be leaked.
int PyList_Insert(PyObject *list, Py_ssize_t index, PyObject *item)
Insert the item item into list list in front of index index. Return 0 if successful; return -1 and set an exception if unsuccessful. Analogous to list.insert(index, item).

int PyList_Append(PyObject *list, PyObject *item)
Append the object item at the end of list list. Return 0 if successful; return -1 and set an exception if unsuccessful. Analogous to list.append(item).

PyObject* PyList_GetSlice(PyObject *list, Py_ssize_t low, Py_ssize_t high)

Return a list of the objects in list containing the objects between low and high. Return NULL and set an exception if unsuccessful. Analogous to list[low:high].

int PyList_SetSlice(PyObject *list, Py_ssize_t low, Py_ssize_t high, PyObject *itemlist)
Set the slice of list between low and high to the contents of itemlist. Analogous to list[low:high] = itemlist. The itemlist may be NULL, indicating the assignment of an empty list (slice deletion). Return 0 on success, -1 on failure.

int PyList_Sort(PyObject *list)
Sort the items of list in place. Return 0 on success, -1 on failure. This is equivalent to list.sort().

int PyList.Reverse(PyObject *list)
Reverse the items of list in place. Return 0 on success, -1 on failure. This is the equivalent of list.reverse().

PyObject* PyList_AsTuple(PyObject *list)
Return a new tuple object containing the contents of list; equivalent to `tuple(list)`.
**Dictionary Objects**

**PyDictObject**
This subtype of **PyObject** represents a Python dictionary object.

**PyTypeObject** **PyDict_Type**
This instance of **PyTypeObject** represents the Python dictionary type. This is exposed to Python programs as `dict` and `types.DictType`.

```c
int PyDict_Check(PyObject *p)
```
Return true if `p` is a dict object or an instance of a subtype of the dict type.

*Changed in version 2.2:* Allowed subtypes to be accepted.

```c
int PyDict_CheckExact(PyObject *p)
```
Return true if `p` is a dict object, but not an instance of a subtype of the dict type.

*New in version 2.4.*

**PyObject**

**PyDict_New()**

*Return value: New reference.*
Return a new empty dictionary, or `NULL` on failure.

**PyObject**

**PyDictProxy_New(PyObject *dict)**

*Return value: New reference.*
Return a proxy object for a mapping which enforces read-only behavior. This is normally used to create a proxy to prevent modification of the dictionary for non-dynamic class types.

*New in version 2.2.*
void **PyDict_Clear***(PyObject *p)*

Empty an existing dictionary of all key-value pairs.

int **PyDict_Contains***(PyObject *p, PyObject *key)*

Determine if dictionary *p* contains *key*. If an item in *p* is matches *key*, return 1, otherwise return 0. On error, return -1. This is equivalent to the Python expression `key in p`.

*New in version 2.4.*

PyObject* **PyDict_Copy***(PyObject *p)*

*Return value: New reference.*

Return a new dictionary that contains the same key-value pairs as *p*.

*New in version 1.6.*

int **PyDict_SetItem***(PyObject *p, PyObject *key, PyObject *val)*

Insert *value* into the dictionary *p* with a key of *key*. *key* must be *hashable*; if it isn’t, *TypeError* will be raised. Return 0 on success or -1 on failure.

int **PyDict_SetItemString***(PyObject *p, const char *key, PyObject *val)*

Insert *value* into the dictionary *p* using *key* as a key. *key* should be a *char*. The key object is created using `PyString_FromString(key)`. Return 0 on success or -1 on failure.

int **PyDict_DelItem***(PyObject *p, PyObject *key)*

Remove the entry in dictionary *p* with key *key*. *key* must be hashable; if it isn’t, *TypeError* is raised. Return 0 on success or -1 on failure.

int **PyDict_DelItemString***(PyObject *p, char *key)*
Remove the entry in dictionary $p$ which has a key specified by the string $key$. Return 0 on success or -1 on failure.

**PyObject* **PyDict_GetItem**(PyObject *$p$, PyObject *key)

*Return value: Borrowed reference.*

Return the object from dictionary $p$ which has a key $key$. Return NULL if the key $key$ is not present, but without setting an exception.

**PyObject* **PyDict_GetItemString**(PyObject *$p$, const char *key)

*Return value: Borrowed reference.*

This is the same as PyDict_GetItem, but $key$ is specified as a char*, rather than a PyObject*.

**PyObject* **PyDict_Items**(PyObject *$p$)

*Return value: New reference.*

Return a PyListObject containing all the items from the dictionary, as in the dictionary method dict.items().

**PyObject* **PyDict_Keys**(PyObject *$p$)

*Return value: New reference.*

Return a PyListObject containing all the keys from the dictionary, as in the dictionary method dict.keys().

**PyObject* **PyDict.Values**(PyObject *$p$)

*Return value: New reference.*

Return a PyListObject containing all the values from the dictionary $p$, as in the dictionary method dict.values().

**Py_ssize_t** PyDict_Size**(PyObject *$p$)

Return the number of items in the dictionary. This is equivalent to len($p$) on a dictionary.

**int** PyDict.Next**(PyObject *$p$, Py_ssize_t *$pos$, PyObject **$pkey$,**
Iterate over all key-value pairs in the dictionary \( p \). The \texttt{int} referred to by \texttt{ppos} must be initialized to \texttt{0} prior to the first call to this function to start the iteration; the function returns true for each pair in the dictionary, and false once all pairs have been reported. The parameters \texttt{pkey} and \texttt{pvalue} should either point to \texttt{PyObject*} variables that will be filled in with each key and value, respectively, or may be \texttt{NULL}. Any references returned through them are borrowed. \texttt{ppos} should not be altered during iteration. Its value represents offsets within the internal dictionary structure, and since the structure is sparse, the offsets are not consecutive.

For example:

```c
PyObject *key, *value;
Py_ssize_t pos = 0;

while (PyDict_Next(self->dict, &pos, &key, &value)) {
    /* do something interesting with the values... */
    ...
}
```

The dictionary \( p \) should not be mutated during iteration. It is safe (since Python 2.1) to modify the values of the keys as you iterate over the dictionary, but only so long as the set of keys does not change. For example:

```c
PyObject *key, *value;
Py_ssize_t pos = 0;

while (PyDict_Next(self->dict, &pos, &key, &value)) {
    int i = PyInt_AS_LONG(value) + 1;
    PyObject *o = PyInt_FromLong(i);
    if (o == NULL)
```
return -1;
if (PyDict_SetItem(self->dict, key, o) < 0) {
    Py_XDECREF(o);
    return -1;
}
Py_XDECREF(o);  

int PyDict_Merge(PyObject *a, PyObject *b, int override)
    Iterate over mapping object b adding key-value pairs to dictionary a. b may be a dictionary, or any object supporting PyMapping_Keys() and PyObject_GetItem(). If override is true, existing pairs in a will be replaced if a matching key is found in b, otherwise pairs will only be added if there is not a matching key in a. Return 0 on success or -1 if an exception was raised.

New in version 2.2.

int PyDict_Update(PyObject *a, PyObject *b)
    This is the same as PyDict_Merge(a, b, 1) in C, or a.update(b) in Python. Return 0 on success or -1 if an exception was raised.

New in version 2.2.

int PyDict_MergeFromSeq2(PyObject *a, PyObject *seq2, int override)
    Update or merge into dictionary a, from the key-value pairs in seq2. seq2 must be an iterable object producing iterable objects of length 2, viewed as key-value pairs. In case of duplicate keys, the last wins if override is true, else the first wins. Return 0 on success or -1 if an exception was raised. Equivalent Python (except for the return value):

    def PyDict_MergeFromSeq2(a, seq2, override):
for key, value in seq2:
    if override or key not in a:
        a[key] = value

New in version 2.2.
Class and Instance Objects

Note that the class objects described here represent old-style classes, which will go away in Python 3. When creating new types for extension modules, you will want to work with type objects (section *Type Objects*).

**PyClassObject**

The C structure of the objects used to describe built-in classes.

**PyObject** *PyClass_Type*

This is the type object for class objects; it is the same object as `types.ClassType` in the Python layer.

```c
int PyClass_Check(PyObject *o)
```

Return true if the object `o` is a class object, including instances of types derived from the standard class object. Return false in all other cases.

```c
int PyClass_IsSubclass(PyObject *klass, PyObject *base)
```

Return true if `klass` is a subclass of `base`. Return false in all other cases.

There are very few functions specific to instance objects.

**PyTypeObject** *PyInstance_Type*

Type object for class instances.

```c
int PyInstance_Check(PyObject *obj)
```

Return true if `obj` is an instance.

```c
PyObject* PyInstance_New(PyObject *class, PyObject *arg, PyObject *kw)
```

*Return value: New reference.*
Create a new instance of a specific class. The parameters *arg* and *kw* are used as the positional and keyword parameters to the object's constructor.

**PyObject** * PyInstance_NewRaw(*PyObject* *class, PyObject *dict)  

*Return value: New reference.*

Create a new instance of a specific class without calling its constructor. *class* is the class of new object. The *dict* parameter will be used as the object's __dict__; if NULL, a new dictionary will be created for the instance.
Function Objects

There are a few functions specific to Python functions.

**PyFunctionObject**

The C structure used for functions.

**PyTypeObject** *PyFunction_Type*

This is an instance of *PyTypeObject* and represents the Python function type. It is exposed to Python programmers as *types.FunctionType*.

```c
int PyFunction_Check(PyObject *o)
```

Return true if *o* is a function object (has type *PyFunction_Type*). The parameter must not be *NULL*.

```c
PyObject* PyFunction_New(PyObject *code, PyObject *globals)
```

*Return value: New reference.*

Return a new function object associated with the code object *code*. *globals* must be a dictionary with the global variables accessible to the function.

The function's docstring, name and *__module__* are retrieved from the code object, the argument defaults and closure are set to *NULL*.

```c
PyObject* PyFunction_GetCode(PyObject *op)
```

*Return value: Borrowed reference.*

Return the code object associated with the function object *op*.

```c
PyObject* PyFunction_GetGlobals(PyObject *op)
```

*Return value: Borrowed reference.*

Return the globals dictionary associated with the function object *op*. 
PyObject* PyFunction_GetModule(PyObject *op)

Return value: Borrowed reference.

Return the __module__ attribute of the function object op. This is normally a string containing the module name, but can be set to any other object by Python code.

PyObject* PyFunction_GetDefaults(PyObject *op)

Return value: Borrowed reference.

Return the argument default values of the function object op. This can be a tuple of arguments or NULL.

int PyFunction_SetDefaults(PyObject *op, PyObject *defaults)

Set the argument default values for the function object op. defaults must be Py_None or a tuple.

Raises SystemError and returns -1 on failure.

PyObject* PyFunction_GetClosure(PyObject *op)

Return value: Borrowed reference.

Return the closure associated with the function object op. This can be NULL or a tuple of cell objects.

int PyFunction_SetClosure(PyObject *op, PyObject *closure)

Set the closure associated with the function object op. closure must be Py_None or a tuple of cell objects.

Raises SystemError and returns -1 on failure.
Method Objects

There are some useful functions that are useful for working with method objects.

**PyTypeObject PyMethod_Type**
This instance of `PyTypeObject` represents the Python method type. This is exposed to Python programs as `types.MethodType`.

`int PyMethod_Check(PyObject *o)`
Return true if `o` is a method object (has type `PyMethod_Type`). The parameter must not be `NULL`.

`PyObject* PyMethod_New(PyObject *func, PyObject *self, PyObject *class)`
*Return value: New reference.*
Return a new method object, with `func` being any callable object; this is the function that will be called when the method is called. If this method should be bound to an instance, `self` should be the instance and `class` should be the class of `self`, otherwise `self` should be `NULL` and `class` should be the class which provides the unbound method..

`PyObject* PyMethod_Class(PyObject *meth)`
*Return value: Borrowed reference.*
Return the class object from which the method `meth` was created; if this was created from an instance, it will be the class of the instance.

`PyObject* PyMethod_GET_CLASS(PyObject *meth)`
*Return value: Borrowed reference.*
Macro version of `PyMethod_Class` which avoids error checking.
PyObject* PyMethodFunction(PyObject* meth)

Return value: Borrowed reference.
Return the function object associated with the method meth.

PyObject* PyMethod_GET_FUNCTION(PyObject* meth)

Return value: Borrowed reference.
Macro version of PyMethodFunction which avoids error checking.

PyObject* PyMethod_Self(PyObject* meth)

Return value: Borrowed reference.
Return the instance associated with the method meth if it is bound, otherwise return NULL.

PyObject* PyMethod_GET_SELF(PyObject* meth)

Return value: Borrowed reference.
Macro version of PyMethod_Self which avoids error checking.

int PyMethod_ClearFreeList(void)

Clear the free list. Return the total number of freed items.

New in version 2.6.
File Objects

Python's built-in file objects are implemented entirely on the FILE* support from the C standard library. This is an implementation detail and may change in future releases of Python.

**PyFileObject**

This subtype of **PyObject** represents a Python file object.

**PyTypeObject PyFile_Type**

This instance of **PyTypeObject** represents the Python file type. This is exposed to Python programs as file and types.FileType.

```c
int PyFile_Check(PyObject *p)
    
Return true if its argument is a PyFileObject or a subtype of PyFileObject.

Changed in version 2.2: Allowed subtypes to be accepted.
```

```c
int PyFile_CheckExact(PyObject *p)
    
Return true if its argument is a PyFileObject, but not a subtype of PyFileObject.

New in version 2.2.
```

**PyObject* PyFile_FromString(char *filename, char *mode)**

*Return value: New reference.*

On success, return a new file object that is opened on the file given by filename, with a file mode given by mode, where mode has the same semantics as the standard C routine fopen. On failure, return NULL.

**PyObject* PyFile_FromFile(FILE *fp, char *name, char *mode, int (*close)(FILE*))**
**Return value:** New reference.
Create a new `PyFileObject` from the already-open standard C file pointer, `fp`. The function `close` will be called when the file should be closed. Return `NULL` on failure.

```c
FILE* PyFile_AsFile(PyObject *p)
```
Return the file object associated with `p` as a `FILE*`.

If the caller will ever use the returned `FILE*` object while the GIL is released it must also call the `PyFile_IncUseCount` and `PyFile_DecUseCount` functions described below as appropriate.

```c
void PyFile_IncUseCount(PyFileObject *p)
```
Increments the PyFileObject’s internal use count to indicate that the underlying `FILE*` is being used. This prevents Python from calling `f_close()` on it from another thread. Callers of this must call `PyFile_DecUseCount` when they are finished with the `FILE*`. Otherwise the file object will never be closed by Python.

The GIL must be held while calling this function.

The suggested use is to call this after `PyFile_AsFile` just before you release the GIL.

*New in version 2.6.*

```c
void PyFile_DecUseCount(PyFileObject *p)
```
Decrements the PyFileObject’s internal unlocked_count member to indicate that the caller is done with its own use of the `FILE*`. This may only be called to undo a prior call to `PyFile_IncUseCount`.

The GIL must be held while calling this function.

*New in version 2.6.*
PyObject* `PyFile_GetLine` (PyObject *p, int n)

*Return value: New reference.*
Equivalent to `p.readline([n])`, this function reads one line from the object `p`. `p` may be a file object or any object with a `readline()` method. If `n` is 0, exactly one line is read, regardless of the length of the line. If `n` is greater than 0, no more than `n` bytes will be read from the file; a partial line can be returned. In both cases, an empty string is returned if the end of the file is reached immediately. If `n` is less than 0, however, one line is read regardless of length, but `EOFError` is raised if the end of the file is reached immediately.

PyObject* `PyFile_Name` (PyObject *p)

*Return value: Borrowed reference.*
Return the name of the file specified by `p` as a string object.

void `PyFile_SetBufSize` (PyFileObject *p, int n)

Available on systems with `setvbuf` only. This should only be called immediately after file object creation.

int `PyFile_SetEncoding` (PyFileObject *p, const char *enc)

Set the file's encoding for Unicode output to `enc`. Return 1 on success and 0 on failure.

*New in version 2.3.*

int `PyFile_SetEncodingAndErrors` (PyFileObject *p, const char *enc, *errors)

Set the file's encoding for Unicode output to `enc`, and its error mode to `err`. Return 1 on success and 0 on failure.

*New in version 2.6.*

int `PyFile_SoftSpace` (PyObject *p, int newflag)
This function exists for internal use by the interpreter. Set the 
softspace attribute of \textit{p} to \textit{newflag} and return the previous value. \textit{p} does not have to be a file object for this function to work properly; any object is supported (thought its only interesting if the \textit{softspace} attribute can be set). This function clears any errors, and will return 0 as the previous value if the attribute either does not exist or if there were errors in retrieving it. There is no way to detect errors from this function, but doing so should not be needed.

\begin{verbatim}
int PyFile_WriteObject(PyObject *obj, PyObject *p, int flags)
    Write object \textit{obj} to file object \textit{p}. The only supported flag for \textit{flags} is \texttt{Py_PRINT_RAW}; if given, the \texttt{str()} of the object is written instead of the \texttt{repr()}. Return 0 on success or -1 on failure; the appropriate exception will be set.
\end{verbatim}

\begin{verbatim}
int PyFile_WriteString(const char *s, PyObject *p)
    Write string \textit{s} to file object \textit{p}. Return 0 on success or -1 on failure; the appropriate exception will be set.
\end{verbatim}
Module Objects

There are only a few functions special to module objects.

**PyTypeObject** **`PyModule_Type`**

This instance of `PyTypeObject` represents the Python module type. This is exposed to Python programs as `types.ModuleType`.

```
int PyModule_Check(PyObject *p)
```

Return true if `p` is a module object, or a subtype of a module object.

*Changed in version 2.2:* Allowed subtypes to be accepted.

```
int PyModule_CheckExact(PyObject *p)
```

Return true if `p` is a module object, but not a subtype of `PyModule_Type`.

*New in version 2.2.*

```
PyObject* PyModule_New(const char *name)
```

*Return value: New reference.*

Return a new module object with the `__name__` attribute set to `name`. Only the module's `__doc__` and `__name__` attributes are filled in; the caller is responsible for providing a `__file__` attribute.

```
PyObject* PyModule_GetDict(PyObject *module)
```

*Return value: Borrowed reference.*

Return the dictionary object that implements module's namespace; this object is the same as the `__dict__` attribute of the module object. This function never fails. It is recommended extensions use other `PyModule_*` and `PyObject_*` functions rather
than directly manipulate a module's __dict__.

char* PyModule_GetName(PyObject *module)
Return module's __name__ value. If the module does not provide one, or if it is not a string, SystemError is raised and NULL is returned.

char* PyModule_GetFilename(PyObject *module)
Return the name of the file from which module was loaded using module's __file__ attribute. If this is not defined, or if it is not a string, raise SystemError and return NULL.

int PyModule_AddObject(PyObject *module, const char *name, PyObject *value)
Add an object to module as name. This is a convenience function which can be used from the module's initialization function. This steals a reference to value. Return -1 on error, 0 on success.

New in version 2.0.

int PyModule_AddIntConstant(PyObject *module, const char *name, long value)
Add an integer constant to module as name. This convenience function can be used from the module's initialization function. Return -1 on error, 0 on success.

New in version 2.0.

int PyModule_AddStringConstant(PyObject *module, const char *name, const char *value)
Add a string constant to module as name. This convenience function can be used from the module's initialization function. The string value must be null-terminated. Return -1 on error, 0 on success.
New in version 2.0.

int PyModule_AddIntMacro(PyObject *module, macro)

Add an int constant to module. The name and the value are taken from macro. For example PyModule_AddConstant(module, AF_INET) adds the int constant AF_INET with the value of AF_INET to module. Return -1 on error, 0 on success.

New in version 2.6.

int PyModule_AddStringMacro(PyObject *module, macro)

Add a string constant to module.

New in version 2.6.
Iterator Objects

Python provides two general-purpose iterator objects. The first, a sequence iterator, works with an arbitrary sequence supporting the \_\_getitem\_\_() method. The second works with a callable object and a sentinel value, calling the callable for each item in the sequence, and ending the iteration when the sentinel value is returned.

PyTypeObject PySeqIter_Type
Type object for iterator objects returned by PySeqIter_New and the one-argument form of the iter() built-in function for built-in sequence types.

*New in version 2.2.*

int PySeqIter_Check(op)
Return true if the type of op is PySeqIter_Type.

*New in version 2.2.*

PyObject* PySeqIter_New(PyObject *seq)
*Return value: New reference.*
Return an iterator that works with a general sequence object, seq. The iteration ends when the sequence raises IndexError for the subscring operation.

*New in version 2.2.*

PyTypeObject PyCallIter_Type
Type object for iterator objects returned by PyCallIter_New and the two-argument form of the iter() built-in function.

*New in version 2.2.*
int PyCallIter_Check(op)
    Return true if the type of op is PyCallIter_Type.

    New in version 2.2.

PyObject* PyCallIter_New(PyObject *callable, PyObject *sentinel)
    Return a new iterator. The first parameter, callable, can be any Python callable object that can be called with no parameters; each call to it should return the next item in the iteration. When callable returns a value equal to sentinel, the iteration will be terminated.

    New in version 2.2.
“Descriptors” are objects that describe some attribute of an object. They are found in the dictionary of type objects.

**PyTypeObject PyProperty_Type**

The type object for the built-in descriptor types.

*New in version 2.2.*

**PyObject* PyDescr_NewGetSet(PyTypeObject *type, struct PyGetSetDef *getset)**

*Return value: New reference.*
*New in version 2.2.*

**PyObject* PyDescr_NewMember(PyTypeObject *type, struct PyMemberDef *meth)**

*Return value: New reference.*
*New in version 2.2.*

**PyObject* PyDescr_NewMethod(PyTypeObject *type, struct PyMethodDef *meth)**

*Return value: New reference.*
*New in version 2.2.*

**PyObject* PyDescr_NewWrapper(PyTypeObject *type, struct wrapperbase *wrapper, void *wrapped)**

*Return value: New reference.*
*New in version 2.2.*

**PyObject* PyDescr_NewClassMethod(PyTypeObject *type, PyMethodDef *method)**

*Return value: New reference.*
*New in version 2.3.*
int PyDescr_IsData(PyObject *descr)

Return true if the descriptor objects descr describes a data attribute, or false if it describes a method. descr must be a descriptor object; there is no error checking.

*New in version 2.2.*

PyObject* PyWrapper_New(PyObject *, PyObject *)

*Return value: New reference.*

*New in version 2.2.*
Slice Objects

PyTypeObject PySlice_Type
    The type object for slice objects. This is the same as slice and types.SliceType.

int PySlice_Check(PyObject *ob)
    Return true if ob is a slice object; ob must not be NULL.

PyObject* PySlice_New(PyObject *start, PyObject *stop, PyObject *step)
    \textit{Return value: New reference.}
    Return a new slice object with the given values. The \textit{start}, \textit{stop}, and \textit{step} parameters are used as the values of the slice object attributes of the same names. Any of the values may be \textit{NULL}, in which case the \textit{None} will be used for the corresponding attribute. Return \textit{NULL} if the new object could not be allocated.

int PySlice_GetIndices(PySliceObject *slice, Py_ssize_t length, Py_ssize_t *start, Py_ssize_t *stop, Py_ssize_t *step)
    Retrieve the start, stop and step indices from the slice object \textit{slice}, assuming a sequence of length \textit{length}. Treats indices greater than \textit{length} as errors.

    Returns 0 on success and -1 on error with no exception set (unless one of the indices was not \textit{None} and failed to be converted to an integer, in which case -1 is returned with an exception set).

You probably do not want to use this function. If you want to use slice objects in versions of Python prior to 2.3, you would probably do well to incorporate the source of PySlice_GetIndicesEx, suitably renamed, in the source of your
extension.

int **PySlice_GetIndicesEx**(**PySliceObject *slice**, **Py_ssize_t length**, **Py_ssize_t *start**, **Py_ssize_t *stop**, **Py_ssize_t *step**, **Py_ssize_t *slicelength**)

Usable replacement for **PySlice_GetIndices**. Retrieve the start, stop, and step indices from the slice object *slice* assuming a sequence of length *length*, and store the length of the slice in *slicelength*. Out of bounds indices are clipped in a manner consistent with the handling of normal slices.

Returns 0 on success and -1 on error with exception set.

*New in version 2.3.*
Weak Reference Objects

Python supports *weak references* as first-class objects. There are two specific object types which directly implement weak references. The first is a simple reference object, and the second acts as a proxy for the original object as much as it can.

```c
int PyWeakref_Check( obstruction )
    Return true if obstruction is either a reference or proxy object.

    *New in version 2.2.*
```

```c
int PyWeakref_CheckRef( obstruction )
    Return true if obstruction is a reference object.

    *New in version 2.2.*
```

```c
int PyWeakref_CheckProxy( obstruction )
    Return true if obstruction is a proxy object.

    *New in version 2.2.*
```

```c
PyObject* PyWeakref_NewRef( PyObject *ob, PyObject *callback )
    Return a weak reference object for the object ob. This will always return a new reference, but is not guaranteed to create a new object; an existing reference object may be returned. The second parameter, callback, can be a callable object that receives notification when ob is garbage collected; it should accept a single parameter, which will be the weak reference object itself. callback may also be None or NULL. If ob is not a weakly-referencable object, or if callback is not callable, None, or NULL, this will return NULL and raise TypeError.
```
New in version 2.2.

PyObject* **PyWeakref_NewProxy**(PyObject *ob, PyObject *callback)

*Return value: New reference.*

Return a weak reference proxy object for the object *ob*. This will always return a new reference, but is not guaranteed to create a new object; an existing proxy object may be returned. The second parameter, *callback*, can be a callable object that receives notification when *ob* is garbage collected; it should accept a single parameter, which will be the weak reference object itself. *callback* may also be **None** or **NULL**. If *ob* is not a weakly-referencable object, or if *callback* is not callable, **None**, or **NULL**, this will return **NULL** and raise **TypeError**.

New in version 2.2.

PyObject* **PyWeakref_GetObject**(PyObject *ref)

*Return value: Borrowed reference.*

Return the referenced object from a weak reference, *ref*. If the referent is no longer live, returns **None**.

New in version 2.2.

PyObject* **PyWeakref_GET_OBJECT**(PyObject *ref)

*Return value: Borrowed reference.*

Similar to **PyWeakref_GetObject**, but implemented as a macro that does no error checking.

New in version 2.2.
CObjects

Refer to *Providing a C API for an Extension Module* for more information on using these objects.

PyCObject

This subtype of *PyObject* represents an opaque value, useful for C extension modules who need to pass an opaque value (as a `void*` pointer) through Python code to other C code. It is often used to make a C function pointer defined in one module available to other modules, so the regular import mechanism can be used to access C APIs defined in dynamically loaded modules.

```c
int PyCObject_Check(PyObject *p)
    Return true if its argument is a PyCObject.

PyObject* PyCObject_FromVoidPtr(void* cobj, void (*destr)(void *))
    Create a PyCObject from the void * cobj. The destr function will be called when the object is reclaimed, unless it is NULL.

PyObject* PyCObject_FromVoidPtrAndDesc(void* cobj, void* desc, void (*destr)(void *, void *))
    Create a PyCObject from the void * cobj. The destr function will be called when the object is reclaimed. The desc argument can be used to pass extra callback data for the destructor function.

void* PyCObject_AsVoidPtr(PyObject* self)
    Return the object void * that the PyCObject self was created with.

void* PyCObject_GetDesc(PyObject* self)
```
Return the description `void *` that the `PyCObject self` was created with.

```
int PyCObject_SetVoidPtr(PyObject* self, void* cobj)
```

Set the void pointer inside `self` to `cobj`. The `PyCObject` must not have an associated destructor. Return true on success, false on failure.
Cell Objects

“Cell” objects are used to implement variables referenced by multiple scopes. For each such variable, a cell object is created to store the value; the local variables of each stack frame that references the value contains a reference to the cells from outer scopes which also use that variable. When the value is accessed, the value contained in the cell is used instead of the cell object itself. This de-referencing of the cell object requires support from the generated byte-code; these are not automatically de-referenced when accessed. Cell objects are not likely to be useful elsewhere.

**PyCellObject**

The C structure used for cell objects.

**PyTypeObject** **PyCell_Type**

The type object corresponding to cell objects.

int **PyCell_Check**(ob)

Return true if ob is a cell object; ob must not be NULL.

PyObject** PyCell_New**(PyObject *ob)

*Return value: New reference.*

Create and return a new cell object containing the value ob. The parameter may be NULL.

PyObject** PyCell_Get**(PyObject *cell)

*Return value: New reference.*

Return the contents of the cell cell.

PyObject** PyCell_GET**(PyObject *cell)

*Return value: Borrowed reference.*

Return the contents of the cell cell, but without checking that cell is non-NULL and a cell object.
int PyCell_Set(PyObject *cell, PyObject *value)

Set the contents of the cell object cell to value. This releases the reference to any current content of the cell. value may be NULL. cell must be non-NULL; if it is not a cell object, -1 will be returned. On success, 0 will be returned.

void PyCell_SET(PyObject *cell, PyObject *value)

Sets the value of the cell object cell to value. No reference counts are adjusted, and no checks are made for safety; cell must be non-NULL and must be a cell object.
Generator Objects

Generator objects are what Python uses to implement generator iterators. They are normally created by iterating over a function that yields values, rather than explicitly calling `PyGen_New`.

**PyGenObject**
The C structure used for generator objects.

**PyTypeObject** `PyGen_Type`
The type object corresponding to generator objects

```c
int PyGen_Check(ob)

  Return true if `ob` is a generator object; `ob` must not be `NULL`.
```

```c
int PyGen_CheckExact(ob)

  Return true if `ob`'s type is `PyGen_Type` is a generator object; `ob` must not be `NULL`.
```

```c
PyObject* PyGen_New(PyFrameObject *frame)

  Create and return a new generator object based on the `frame` object. A reference to `frame` is stolen by this function. The parameter must not be `NULL`.
```
Various date and time objects are supplied by the `datetime` module. Before using any of these functions, the header file `datetime.h` must be included in your source (note that this is not included by `Python.h`), and the macro `PyDateTime_IMPORT` must be invoked. The macro puts a pointer to a C structure into a static variable, `PyDateTimeAPI`, that is used by the following macros.

Type-check macros:

```c
int PyDate_Check(PyObject *ob)
    Return true if `ob` is of type `PyDateTime_DateType` or a subtype of `PyDateTime_DateType`. `ob` must not be `NULL`.

    New in version 2.4.

int PyDate_CheckExact(PyObject *ob)
    Return true if `ob` is of type `PyDateTime_DateType`. `ob` must not be `NULL`.

    New in version 2.4.

int PyDateTime_Check(PyObject *ob)
    Return true if `ob` is of type `PyDateTime_DateTimeType` or a subtype of `PyDateTime_DateTimeType`. `ob` must not be `NULL`.

    New in version 2.4.

int PyDateTime_CheckExact(PyObject *ob)
    Return true if `ob` is of type `PyDateTime_DateTimeType`. `ob` must not be `NULL`.

    New in version 2.4.
```
int PyTime_Check(PyObject *ob)
    Return true if ob is of type PyDateTime_TimeType or a subtype of PyDateTime_TimeType. ob must not be NULL.
    
    New in version 2.4.

int PyTime_CheckExact(PyObject *ob)
    Return true if ob is of type PyDateTime_TimeType. ob must not be NULL.
    
    New in version 2.4.

int PyDelta_Check(PyObject *ob)
    Return true if ob is of type PyDateTime_DeltaType or a subtype of PyDateTime_DeltaType. ob must not be NULL.
    
    New in version 2.4.

int PyDelta_CheckExact(PyObject *ob)
    Return true if ob is of type PyDateTime_DeltaType. ob must not be NULL.
    
    New in version 2.4.

int PyTZInfo_Check(PyObject *ob)
    Return true if ob is of type PyDateTime_TZInfoType or a subtype of PyDateTime_TZInfoType. ob must not be NULL.
    
    New in version 2.4.

int PyTZInfo_CheckExact(PyObject *ob)
    Return true if ob is of type PyDateTime_TZInfoType. ob must not be NULL.
    
    New in version 2.4.
Macros to create objects:

**PyObject** *PyDate_FromDate* (int *year*, int *month*, int *day*)

*Return value: New reference.*

Return a `datetime.date` object with the specified year, month and day.

*New in version 2.4.*

**PyObject** *PyDateTime_FromDateAndTime* (int *year*, int *month*, int *day*, int *hour*, int *minute*, int *second*, int *usecond*)

*Return value: New reference.*

Return a `datetime.datetime` object with the specified year, month, day, hour, minute, second and microsecond.

*New in version 2.4.*

**PyObject** *PyTime_FromTime* (int *hour*, int *minute*, int *second*, int *usecond*)

*Return value: New reference.*

Return a `datetime.time` object with the specified hour, minute, second and microsecond.

*New in version 2.4.*

**PyObject** *PyDelta_FromDSU* (int *days*, int *seconds*, int *useconds*)

*Return value: New reference.*

Return a `datetime.timedelta` object representing the given number of days, seconds and microseconds. Normalization is performed so that the resulting number of microseconds and seconds lie in the ranges documented for `datetime.timedelta` objects.

*New in version 2.4.*
Macros to extract fields from date objects. The argument must be an instance of `PyDateTime_Date`, including subclasses (such as `PyDateTime_DateTime`). The argument must not be `NULL`, and the type is not checked:

```c
int PyDateTime_GET_YEAR(PyDateTime_Date *o)
    Return the year, as a positive int.

    New in version 2.4.
```

```c
int PyDateTime_GET_MONTH(PyDateTime_Date *o)
    Return the month, as an int from 1 through 12.

    New in version 2.4.
```

```c
int PyDateTime_GET_DAY(PyDateTime_Date *o)
    Return the day, as an int from 1 through 31.

    New in version 2.4.
```

Macros to extract fields from datetime objects. The argument must be an instance of `PyDateTime_DateTime`, including subclasses. The argument must not be `NULL`, and the type is not checked:

```c
int PyDateTime_DATE_GET_HOUR(PyDateTime_DateTime *o)
    Return the hour, as an int from 0 through 23.

    New in version 2.4.
```

```c
int PyDateTime_DATE_GET_MINUTE(PyDateTime_DateTime *o)
    Return the minute, as an int from 0 through 59.

    New in version 2.4.
```

```c
int PyDateTime_DATE_GET_SECOND(PyDateTime_DateTime *o)
    Return the second, as an int from 0 through 59.
```
New in version 2.4.

```c
int PyDateTime_DATE_GET_MICROSECOND(PyDateTime_DateTime *o)
    Return the microsecond, as an int from 0 through 999999.
```

New in version 2.4.

Macros to extract fields from time objects. The argument must be an instance of `PyDateTime_Time`, including subclasses. The argument must not be `NULL`, and the type is not checked:

```c
int PyDateTime_TIME_GET_HOUR(PyDateTime_Time *o)
    Return the hour, as an int from 0 through 23.
```

New in version 2.4.

```c
int PyDateTime_TIME_GET_MINUTE(PyDateTime_Time *o)
    Return the minute, as an int from 0 through 59.
```

New in version 2.4.

```c
int PyDateTime_TIME_GET_SECOND(PyDateTime_Time *o)
    Return the second, as an int from 0 through 59.
```

New in version 2.4.

```c
int PyDateTime_TIME_GET_MICROSECOND(PyDateTime_Time *o)
    Return the microsecond, as an int from 0 through 999999.
```

New in version 2.4.

Macros for the convenience of modules implementing the DB API:

```c
PyObject* PyDateTime_FromTimestamp(PyObject *args)
    Create and return a new `datetime.datetime` object given an
argument tuple suitable for passing to `datetime.datetime.fromtimestamp()`.

New in version 2.4.

`PyObject* PyDate_FromTimestamp(PyObject *args)`

Create and return a new `datetime.date` object given an argument tuple suitable for passing to `datetime.date.fromtimestamp()`.

New in version 2.4.
Set Objects

New in version 2.5.

This section details the public API for `set` and `frozenset` objects. Any functionality not listed below is best accessed using the either the abstract object protocol (including `PyObject_CallMethod`, `PyObject_RichCompareBool`, `PyObject_Hash`, `PyObject_Repr`, `PyObject_IsTrue`, `PyObject_Print`, and `PyObject_GetIter`) or the abstract number protocol (including `PyNumber_And`, `PyNumber_Subtract`, `PyNumber_Or`, `PyNumber_Xor`, `PyNumber_InPlaceAnd`, `PyNumber_InPlaceSubtract`, `PyNumber_InPlaceOr`, and `PyNumber_InPlaceXor`).

**PySetObject**

This subtype of `PyObject` is used to hold the internal data for both `set` and `frozenset` objects. It is like a `PyDictObject` in that it is a fixed size for small sets (much like tuple storage) and will point to a separate, variable sized block of memory for medium and large sized sets (much like list storage). None of the fields of this structure should be considered public and are subject to change. All access should be done through the documented API rather than by manipulating the values in the structure.

**PyTypeObject PySet_Type**

This is an instance of `PyTypeObject` representing the Python `set` type.

**PyTypeObject PyFrozenSet_Type**

This is an instance of `PyTypeObject` representing the Python `frozenset` type.

The following type check macros work on pointers to any Python
object. Likewise, the constructor functions work with any iterable Python object.

```c
int PySet_Check(PyObject *p)
    Return true if p is a set object or an instance of a subtype.

    New in version 2.6.
```

```c
int PyFrozenSet_Check(PyObject *p)
    Return true if p is a frozenset object or an instance of a subtype.

    New in version 2.6.
```

```c
int PyAnySet_Check(PyObject *p)
    Return true if p is a set object, a frozenset object, or an instance of a subtype.
```

```c
int PyAnySet_CheckExact(PyObject *p)
    Return true if p is a set object or a frozenset object but not an instance of a subtype.
```

```c
int PyFrozenSet_CheckExact(PyObject *p)
    Return true if p is a frozenset object but not an instance of a subtype.
```

```c
PyObject* PySet_New(PyObject *iterable)
    Return a new set containing objects returned by the iterable. The iterable may be NULL to create a new empty set. Return the new set on success or NULL on failure. Raise TypeError if iterable is not actually iterable. The constructor is also useful for copying a set (c=set(s)).
```

```c
PyObject* PyFrozenSet_New(PyObject *iterable)
```
Return a new \texttt{frozenset} containing objects returned by the \textit{iterable}. The \textit{iterable} may be \texttt{NULL} to create a new empty frozenset. Return the new set on success or \texttt{NULL} on failure. Raise \texttt{TypeError} if \textit{iterable} is not actually iterable.

\textit{Changed in version 2.6}: Now guaranteed to return a brand-new \texttt{frozenset}. Formerly, frozensets of zero-length were a singleton. This got in the way of building-up new frozensets with \texttt{PySet\_Add(\)}.

The following functions and macros are available for instances of \texttt{set} or \texttt{frozenset} or instances of their subtypes.

\texttt{Py\_ssize\_t PySet\_Size(PyObject \*anyset)}
Return the length of a \texttt{set} or \texttt{frozenset} object. Equivalent to \texttt{len(anyset)}. Raises a \texttt{PyExc\_SystemError} if \textit{anyset} is not a \texttt{set}, \texttt{frozenset}, or an instance of a subtype.

\texttt{Py\_ssize\_t PySet\_GET\_SIZE(PyObject \*anyset)}
Macro form of \texttt{PySet\_Size} without error checking.

\texttt{int PySet\_Contains(PyObject \*anyset, PyObject \*key)}
Return 1 if found, 0 if not found, and -1 if an error is encountered. Unlike the Python \texttt{\_contains\_()} method, this function does not automatically convert unhashable sets into temporary frozensets. Raise a \texttt{TypeError} if the \texttt{key} is unhashable. Raise \texttt{PyExc\_SystemError} if \textit{anyset} is not a \texttt{set}, \texttt{frozenset}, or an instance of a subtype.

\texttt{int PySet\_Add(PyObject \*set, PyObject \*key)}
Add \texttt{key} to a \texttt{set} instance. Does not apply to \texttt{frozenset} instances. Return 0 on success or -1 on failure. Raise a
**TypeError** if the *key* is unhashable. Raise a **MemoryError** if there is no room to grow. Raise a **SystemError** if *set* is an not an instance of *set* or its subtype.

*Changed in version 2.6:* Now works with instances of *frozenset* or its subtypes. Like **PyTuple_SetItem** in that it can be used to fill-in the values of brand new frozensets before they are exposed to other code.

The following functions are available for instances of *set* or its subtypes but not for instances of *frozenset* or its subtypes.

```c
int PySet_Discard(PyObject *set, PyObject *key)
```
Return 1 if found and removed, 0 if not found (no action taken), and -1 if an error is encountered. Does not raise **KeyError** for missing keys. Raise a **TypeError** if the *key* is unhashable. Unlike the Python discard() method, this function does not automatically convert unhashable sets into temporary frozensets. Raise **PyExc_SystemError** if *set* is an not an instance of *set* or its subtype.

```c
PyObject* PySet_Pop(PyObject *set)
```
Return value: **New reference**.
Return a new reference to an arbitrary object in the *set*, and removes the object from the *set*. Return **NULL** on failure. Raise **KeyError** if the set is empty. Raise a **SystemError** if *set* is an not an instance of *set* or its subtype.

```c
int PySet_Clear(PyObject *set)
```
Empty an existing set of all elements.
Initialization, Finalization, and Threads

void Py_Initialize()

Initialize the Python interpreter. In an application embedding Python, this should be called before using any other Python/C API functions; with the exception of Py_SetProgramName, PyEval_InitThreads, PyEval_ReleaseLock, and PyEval_AcquireLock. This initializes the table of loaded modules (sys.modules), and creates the fundamental modules __builtin__, __main__ and sys. It also initializes the module search path (sys.path). It does not set sys.argv; use PySys_SetArgv for that. This is a no-op when called for a second time (without calling Py_Finalize first). There is no return value; it is a fatal error if the initialization fails.

void Py_InitializeEx(int initsigs)

This function works like Py_Initialize if initsigs is 1. If initsigs is 0, it skips initialization registration of signal handlers, which might be useful when Python is embedded.

New in version 2.4.

int Py_IsInitialized()

Return true (nonzero) when the Python interpreter has been initialized, false (zero) if not. After Py_Finalize is called, this returns false until Py_Initialize is called again.

void Py_Finalize()

Undo all initializations made by Py_Initialize and subsequent use of Python/C API functions, and destroy all sub-interpreters
(see `Py_NewInterpreter` below) that were created and not yet destroyed since the last call to `Py_Initialize`. Ideally, this frees all memory allocated by the Python interpreter. This is a no-op when called for a second time (without calling `Py_Initialize` again first). There is no return value; errors during finalization are ignored.

This function is provided for a number of reasons. An embedding application might want to restart Python without having to restart the application itself. An application that has loaded the Python interpreter from a dynamically loadable library (or DLL) might want to free all memory allocated by Python before unloading the DLL. During a hunt for memory leaks in an application a developer might want to free all memory allocated by Python before exiting from the application.

**Bugs and caveats:** The destruction of modules and objects in modules is done in random order; this may cause destructors (`__del__()`) methods) to fail when they depend on other objects (even functions) or modules. Dynamically loaded extension modules loaded by Python are not unloaded. Small amounts of memory allocated by the Python interpreter may not be freed (if you find a leak, please report it). Memory tied up in circular references between objects is not freed. Some memory allocated by extension modules may not be freed. Some extensions may not work properly if their initialization routine is called more than once; this can happen if an application calls `Py_Initialize` and `Py_Finalize` more than once.

`PyThreadState* Py_NewInterpreter()`  
Create a new sub-interpreter. This is an (almost) totally separate environment for the execution of Python code. In particular, the new interpreter has separate, independent versions of all imported modules, including the fundamental modules
__builtin__, __main__ and sys. The table of loaded modules (sys.modules) and the module search path (sys.path) are also separate. The new environment has no sys.argv variable. It has new standard I/O stream file objects sys.stdin, sys.stdout and sys.stderr (however these refer to the same underlying FILE structures in the C library).

The return value points to the first thread state created in the new sub-interpreter. This thread state is made in the current thread state. Note that no actual thread is created; see the discussion of thread states below. If creation of the new interpreter is unsuccessful, NULL is returned; no exception is set since the exception state is stored in the current thread state and there may not be a current thread state. (Like all other Python/C API functions, the global interpreter lock must be held before calling this function and is still held when it returns; however, unlike most other Python/C API functions, there needn’t be a current thread state on entry.)

Extension modules are shared between (sub-)interpreters as follows: the first time a particular extension is imported, it is initialized normally, and a (shallow) copy of its module’s dictionary is squirreled away. When the same extension is imported by another (sub-)interpreter, a new module is initialized and filled with the contents of this copy; the extension’s init function is not called. Note that this is different from what happens when an extension is imported after the interpreter has been completely re-initialized by calling Py_Finalize and Py_Initialize; in that case, the extension’s initmodule function is called again.

Bugs and caveats: Because sub-interpreters (and the main interpreter) are part of the same process, the insulation between them isn’t perfect — for example, using low-level file operations
like `os.close()` they can (accidentally or maliciously) affect each other’s open files. Because of the way extensions are shared between (sub-)interpreters, some extensions may not work properly; this is especially likely when the extension makes use of (static) global variables, or when the extension manipulates its module’s dictionary after its initialization. It is possible to insert objects created in one sub-interpreter into a namespace of another sub-interpreter; this should be done with great care to avoid sharing user-defined functions, methods, instances or classes between sub-interpreters, since import operations executed by such objects may affect the wrong (sub-)interpreter’s dictionary of loaded modules. (XXX This is a hard-to-fix bug that will be addressed in a future release.)

Also note that the use of this functionality is incompatible with extension modules such as PyObjC and ctypes that use the `PyGILState_*` APIs (and this is inherent in the way the `PyGILState_*` functions work). Simple things may work, but confusing behavior will always be near.

```c
void Py_EndInterpreter(PyThreadState *tstate)
```

Destroy the (sub-)interpreter represented by the given thread state. The given thread state must be the current thread state. See the discussion of thread states below. When the call returns, the current thread state is `NULL`. All thread states associated with this interpreter are destroyed. (The global interpreter lock must be held before calling this function and is still held when it returns.) `Py_Finalize` will destroy all sub-interpreters that haven’t been explicitly destroyed at that point.

```c
void Py_SetProgramName(char *name)
```

This function should be called before `Py_Initialize` is called for the first time, if it is called at all. It tells the interpreter the value of the `argv[0]` argument to the `main` function of the program. This is
used by `Py_GetPath` and some other functions below to find the Python run-time libraries relative to the interpreter executable. The default value is `"python"`. The argument should point to a zero-terminated character string in static storage whose contents will not change for the duration of the program’s execution. No code in the Python interpreter will change the contents of this storage.

```c
char* Py_GetProgramName()
```

Return the program name set with `Py_SetProgramName`, or the default. The returned string points into static storage; the caller should not modify its value.

```c
char* Py_GetPrefix()
```

Return the prefix for installed platform-independent files. This is derived through a number of complicated rules from the program name set with `Py_SetProgramName` and some environment variables; for example, if the program name is `/usr/local/bin/python`, the prefix is `/usr/local`. The returned string points into static storage; the caller should not modify its value. This corresponds to the :makevar:`prefix` variable in the top-level `Makefile` and the --prefix argument to the `configure` script at build time. The value is available to Python code as `sys.prefix`. It is only useful on Unix. See also the next function.

```c
char* Py_GetExecPrefix()
```

Return the exec-prefix for installed platform-dependent files. This is derived through a number of complicated rules from the program name set with `Py_SetProgramName` and some environment variables; for example, if the program name is `/usr/local/bin/python`, the exec-prefix is `/usr/local`. The returned string points into static storage; the caller should not
modify its value. This corresponds to the :makevar:`exec_prefix` variable in the top-level Makefile and the `--exec-prefix` argument to the configure script at build time. The value is available to Python code as `sys.exec_prefix`. It is only useful on Unix.

Background: The exec-prefix differs from the prefix when platform dependent files (such as executables and shared libraries) are installed in a different directory tree. In a typical installation, platform dependent files may be installed in the `/usr/local/plat` subtree while platform independent may be installed in `/usr/local`.

Generally speaking, a platform is a combination of hardware and software families, e.g. Sparc machines running the Solaris 2.x operating system are considered the same platform, but Intel machines running Solaris 2.x are another platform, and Intel machines running Linux are yet another platform. Different major revisions of the same operating system generally also form different platforms. Non-Unix operating systems are a different story; the installation strategies on those systems are so different that the prefix and exec-prefix are meaningless, and set to the empty string. Note that compiled Python bytecode files are platform independent (but not independent from the Python version by which they were compiled!).

System administrators will know how to configure the mount or automount programs to share `/usr/local` between platforms while having `/usr/local/plat` be a different filesystem for each platform.

```c
char* Py_GetProgramFullPath()
```

Return the full program name of the Python executable; this is computed as a side-effect of deriving the default module search path from the program name (set by `Py_SetProgramName` above).
The returned string points into static storage; the caller should not modify its value. The value is available to Python code as `sys.executable`.

`char* Py_GetPath()`
Return the default module search path; this is computed from the program name (set by `Py_SetProgramName` above) and some environment variables. The returned string consists of a series of directory names separated by a platform dependent delimiter character. The delimiter character is `:` on Unix and Mac OS X, `;` on Windows. The returned string points into static storage; the caller should not modify its value. The value is available to Python code as the list `sys.path`, which may be modified to change the future search path for loaded modules.

`const char* Py_GetVersion()`
Return the version of this Python interpreter. This is a string that looks something like

"1.5 (#67, Dec 31 1997, 22:34:28) [GCC 2.7.2.2]"

The first word (up to the first space character) is the current Python version; the first three characters are the major and minor version separated by a period. The returned string points into static storage; the caller should not modify its value. The value is available to Python code as `sys.version`.

`const char* Py_GetBuildNumber()`
Return a string representing the Subversion revision that this Python executable was built from. This number is a string because it may contain a trailing ‘M’ if Python was built from a mixed revision source tree.

_New in version 2.5._
const char* Py_GetPlatform()

Return the platform identifier for the current platform. On Unix, this is formed from the “official” name of the operating system, converted to lower case, followed by the major revision number; e.g., for Solaris 2.x, which is also known as SunOS 5.x, the value is 'sunos5'. On Mac OS X, it is 'darwin'. On Windows, it is 'win'. The returned string points into static storage; the caller should not modify its value. The value is available to Python code as sys.platform.

const char* Py_GetCopyright()

Return the official copyright string for the current Python version, for example

'Copyright 1991-1995 Stichting Mathematisch Centrum, Amsterdam'

The returned string points into static storage; the caller should not modify its value. The value is available to Python code as sys.copyright.

const char* Py_GetCompiler()

Return an indication of the compiler used to build the current Python version, in square brackets, for example:

"[GCC 2.7.2.2]"

The returned string points into static storage; the caller should not modify its value. The value is available to Python code as part of the variable sys.version.

const char* Py_GetBuildInfo()

Return information about the sequence number and build date and time of the current Python interpreter instance, for example
The returned string points into static storage; the caller should not modify its value. The value is available to Python code as part of the variable `sys.version`.

```c
void PySys_SetArgv(int argc, char **argv)
```

Set `sys.argv` based on `argc` and `argv`. These parameters are similar to those passed to the program's `main` function with the difference that the first entry should refer to the script file to be executed rather than the executable hosting the Python interpreter. If there isn't a script that will be run, the first entry in `argv` can be an empty string. If this function fails to initialize `sys.argv`, a fatal condition is signalled using `Py_FatalError`. 
Thread State and the Global Interpreter Lock

The Python interpreter is not fully thread safe. In order to support multi-threaded Python programs, there's a global lock that must be held by the current thread before it can safely access Python objects. Without the lock, even the simplest operations could cause problems in a multi-threaded program: for example, when two threads simultaneously increment the reference count of the same object, the reference count could end up being incremented only once instead of twice.

Therefore, the rule exists that only the thread that has acquired the global interpreter lock may operate on Python objects or call Python/C API functions. In order to support multi-threaded Python programs, the interpreter regularly releases and reacquires the lock — by default, every 100 bytecode instructions (this can be changed with `sys.setcheckinterval()`). The lock is also released and reacquired around potentially blocking I/O operations like reading or writing a file, so that other threads can run while the thread that requests the I/O is waiting for the I/O operation to complete.

The Python interpreter needs to keep some bookkeeping information separate per thread — for this it uses a data structure called `PyThreadState`. There's one global variable, however: the pointer to the current `PyThreadState` structure. While most thread packages have a way to store “per-thread global data,” Python’s internal platform independent thread abstraction doesn’t support this yet. Therefore, the current thread state must be manipulated explicitly.

This is easy enough in most cases. Most code manipulating the global interpreter lock has the following simple structure:
Save the thread state in a local variable. Release the interpreter lock.
...Do some blocking I/O operation...
Reacquire the interpreter lock.
Restore the thread state from the local variable.

This is so common that a pair of macros exists to simplify it:

```c
Py_BEGIN_ALLOW_THREADS
...Do some blocking I/O operation...
Py_END_ALLOW_THREADS
```

The **Py_BEGIN_ALLOW_THREADS** macro opens a new block and declares a hidden local variable; the **Py_END_ALLOW_THREADS** macro closes the block. Another advantage of using these two macros is that when Python is compiled without thread support, they are defined empty, thus saving the thread state and lock manipulations.

When thread support is enabled, the block above expands to the following code:

```c
PyThreadState *__save;
__save = PyEval_SaveThread();
...Do some blocking I/O operation...
PyEval_RestoreThread(__save);
```

Using even lower level primitives, we can get roughly the same effect as follows:

```c
PyThreadState *__save;
__save = PyThreadState_Swap(NULL);
PyEval_ReleaseLock();
...Do some blocking I/O operation...
PyEval_AcquireLock();
PyThreadState_Swap(__save);
```

There are some subtle differences; in particular, **PyEval_RestoreThread** saves and restores the value of the global
variable `errno`, since the lock manipulation does not guarantee that `errno` is left alone. Also, when thread support is disabled, `PyEval_SaveThread` and `PyEval_RestoreThread` don't manipulate the lock; in this case, `PyEval_ReleaseLock` and `PyEval_AcquireLock` are not available. This is done so that dynamically loaded extensions compiled with thread support enabled can be loaded by an interpreter that was compiled with disabled thread support.

The global interpreter lock is used to protect the pointer to the current thread state. When releasing the lock and saving the thread state, the current thread state pointer must be retrieved before the lock is released (since another thread could immediately acquire the lock and store its own thread state in the global variable). Conversely, when acquiring the lock and restoring the thread state, the lock must be acquired before storing the thread state pointer.

Why am I going on with so much detail about this? Because when threads are created from C, they don’t have the global interpreter lock, nor is there a thread state data structure for them. Such threads must bootstrap themselves into existence, by first creating a thread state data structure, then acquiring the lock, and finally storing their thread state pointer, before they can start using the Python/C API. When they are done, they should reset the thread state pointer, release the lock, and finally free their thread state data structure.

Beginning with version 2.3, threads can now take advantage of the `PyGILState_*` functions to do all of the above automatically. The typical idiom for calling into Python from a C thread is now:

```c
PyGILState_STATE gstate;
gstate = PyGILState_Ensure();

/* Perform Python actions here. */
result = CallSomeFunction();
/* evaluate result */

/* Release the thread. No Python API allowed beyond this point. */
```
Note that the PyGILState_* functions assume there is only one global interpreter (created automatically by Py_Initialize). Python still supports the creation of additional interpreters (using Py_NewInterpreter), but mixing multiple interpreters and the PyGILState_* API is unsupported.

PyInterpreterState

This data structure represents the state shared by a number of cooperating threads. Threads belonging to the same interpreter share their module administration and a few other internal items. There are no public members in this structure.

Threads belonging to different interpreters initially share nothing, except process state like available memory, open file descriptors and such. The global interpreter lock is also shared by all threads, regardless of to which interpreter they belong.

PyThreadState

This data structure represents the state of a single thread. The only public data member is PyInterpreterState *interp, which points to this thread's interpreter state.

void PyEval_InitThreads()

Initialize and acquire the global interpreter lock. It should be called in the main thread before creating a second thread or engaging in any other thread operations such as PyEval_ReleaseLock or PyEval_ReleaseThread(tstate). It is not needed before calling PyEval_SaveThread or PyEval_RestoreThread.

This is a no-op when called for a second time. It is safe to call this function before calling Py_Initialize.
When only the main thread exists, no lock operations are needed. This is a common situation (most Python programs do not use threads), and the lock operations slow the interpreter down a bit. Therefore, the lock is not created initially. This situation is equivalent to having acquired the lock: when there is only a single thread, all object accesses are safe. Therefore, when this function initializes the lock, it also acquires it. Before the Python thread module creates a new thread, knowing that either it has the lock or the lock hasn't been created yet, it calls `PyEval_InitThreads`. When this call returns, it is guaranteed that the lock has been created and that the calling thread has acquired it.

It is not safe to call this function when it is unknown which thread (if any) currently has the global interpreter lock.

This function is not available when thread support is disabled at compile time.

```c
int PyEval_ThreadsInitialized()
```

Returns a non-zero value if `PyEval_InitThreads` has been called. This function can be called without holding the lock, and therefore can be used to avoid calls to the locking API when running single-threaded. This function is not available when thread support is disabled at compile time.

*New in version 2.4.*

```c
void PyEval_AcquireLock()
```

Acquire the global interpreter lock. The lock must have been created earlier. If this thread already has the lock, a deadlock ensues. This function is not available when thread support is disabled at compile time.

```c
void PyEval_ReleaseLock()
```
Release the global interpreter lock. The lock must have been created earlier. This function is not available when thread support is disabled at compile time.

```c
void PyEval_AcquireThread(PyThreadState *tstate)
```

Acquire the global interpreter lock and set the current thread state to `tstate`, which should not be `NULL`. The lock must have been created earlier. If this thread already has the lock, deadlock ensues. This function is not available when thread support is disabled at compile time.

```c
void PyEval_ReleaseThread(PyThreadState *tstate)
```

Reset the current thread state to `NULL` and release the global interpreter lock. The lock must have been created earlier and must be held by the current thread. The `tstate` argument, which must not be `NULL`, is only used to check that it represents the current thread state — if it isn’t, a fatal error is reported. This function is not available when thread support is disabled at compile time.

```c
PyThreadState* PyEval_SaveThread()
```

Release the interpreter lock (if it has been created and thread support is enabled) and reset the thread state to `NULL`, returning the previous thread state (which is not `NULL`). If the lock has been created, the current thread must have acquired it. (This function is available even when thread support is disabled at compile time.)

```c
void PyEval_RestoreThread(PyThreadState *tstate)
```

Acquire the interpreter lock (if it has been created and thread support is enabled) and set the thread state to `tstate`, which must not be `NULL`. If the lock has been created, the current thread must not have acquired it, otherwise deadlock ensues. (This function is available even when thread support is disabled at compile time.)
compile time.)

void PyEval_ReInitThreads()
    This function is called from PyOS_AfterFork to ensure that newly
    created child processes don't hold locks referring to threads
    which are not running in the child process.

The following macros are normally used without a trailing semicolon;
look for example usage in the Python source distribution.

**Py_BEGIN_ALLOW_THREADS**
    This macro expands to `{ PyThreadState _save; _save = 
    PyEval_SaveThread();`. Note that it contains an opening brace; it
    must be matched with a following **Py_END_ALLOW_THREADS** macro.
    See above for further discussion of this macro. It is a no-op when
    thread support is disabled at compile time.

**Py_END_ALLOW_THREADS**
    This macro expands to **PyEval_RestoreThread(_save); }**. Note
    that it contains a closing brace; it must be matched with an earlier
    **Py_BEGIN_ALLOW_THREADS** macro. See above for further discussion
    of this macro. It is a no-op when thread support is disabled at compile time.

**Py_BLOCK_THREADS**
    This macro expands to **PyEval_RestoreThread(_save);**: it is
    equivalent to **Py_END_ALLOW_THREADS** without the closing brace. It
    is a no-op when thread support is disabled at compile time.

**Py_UNBLOCK_THREADS**
    This macro expands to `_save = PyEval_SaveThread();`: it is
    equivalent to **Py_BEGIN_ALLOW_THREADS** without the opening brace
    and variable declaration. It is a no-op when thread support is
    disabled at compile time.
All of the following functions are only available when thread support is enabled at compile time, and must be called only when the interpreter lock has been created.

**PyInterpreterState**\* PyInterpreterState\_New()

Create a new interpreter state object. The interpreter lock need not be held, but may be held if it is necessary to serialize calls to this function.

void PyInterpreterState\_Clear(PyInterpreterState \*interp)

Reset all information in an interpreter state object. The interpreter lock must be held.

void PyInterpreterState\_Delete(PyInterpreterState \*interp)

Destroy an interpreter state object. The interpreter lock need not be held. The interpreter state must have been reset with a previous call to **PyInterpreterState\_Clear**.

**PyThreadState**\* PyThreadState\_New(PyInterpreterState \*interp)

Create a new thread state object belonging to the given interpreter object. The interpreter lock need not be held, but may be held if it is necessary to serialize calls to this function.

void PyThreadState\_Clear(PyThreadState \*tstate)

Reset all information in a thread state object. The interpreter lock must be held.

void PyThreadState\_Delete(PyThreadState \*tstate)

Destroy a thread state object. The interpreter lock need not be held. The thread state must have been reset with a previous call to **PyThreadState\_Clear**.

**PyThreadState**\* PyThreadState\_Get()

Return the current thread state. The interpreter lock must be
When the current thread state is *NULL*, this issues a fatal error (so that the caller needn't check for *NULL*).

**PyThreadState**\(^*\) **PyThreadState_Swap**(*PyThreadState* \(^*\)\(tstate\))

Swap the current thread state with the thread state given by the argument \(tstate\), which may be *NULL*. The interpreter lock must be held.

**PyObject**\(^*\) **PyThreadState_GetDict**()

---

*Return value: Borrowed reference.*

Return a dictionary in which extensions can store thread-specific state information. Each extension should use a unique key to use to store state in the dictionary. It is okay to call this function when no current thread state is available. If this function returns *NULL*, no exception has been raised and the caller should assume no current thread state is available.

*Changed in version 2.3:* Previously this could only be called when a current thread is active, and *NULL* meant that an exception was raised.

**int** **PyThreadState_SetAsyncExc**(*long* \(id\), *PyObject* \(^*\)\(exc\))

Asynchronously raise an exception in a thread. The \(id\) argument is the thread id of the target thread; \(exc\) is the exception object to be raised. This function does not steal any references to \(exc\). To prevent naive misuse, you must write your own C extension to call this. Must be called with the GIL held. Returns the number of thread states modified; this is normally one, but will be zero if the thread id isn't found. If \(exc\) is *NULL*, the pending exception (if any) for the thread is cleared. This raises no exceptions.

*New in version 2.3.*

**PyGILState_STATE** **PyGILState_Ensure**()

Ensure that the current thread is ready to call the Python C API
regardless of the current state of Python, or of its thread lock. This may be called as many times as desired by a thread as long as each call is matched with a call to \texttt{PyGILState\_Release}. In general, other thread-related APIs may be used between \texttt{PyGILState\_Ensure} and \texttt{PyGILState\_Release} calls as long as the thread state is restored to its previous state before the Release(). For example, normal usage of the \texttt{Py\_BEGIN\_ALLOW\_THREADS} and \texttt{Py\_END\_ALLOW\_THREADS} macros is acceptable.

The return value is an opaque “handle” to the thread state when \texttt{PyGILState\_Acquire} was called, and must be passed to \texttt{PyGILState\_Release} to ensure Python is left in the same state. Even though recursive calls are allowed, these handles \textit{cannot} be shared - each unique call to \texttt{PyGILState\_Ensure} must save the handle for its call to \texttt{PyGILState\_Release}.

When the function returns, the current thread will hold the GIL. Failure is a fatal error.

\textit{New in version 2.3.}

\texttt{void PyGILState\_Release(PyGILState\_STATE)}

\begin{verbatim}
Release any resources previously acquired. After this call, Python's state will be the same as it was prior to the corresponding PyGILState\_Ensure call (but generally this state will be unknown to the caller, hence the use of the GILState API.)

Every call to \texttt{PyGILState\_Ensure} must be matched by a call to \texttt{PyGILState\_Release} on the same thread.

\textit{New in version 2.3.}
\end{verbatim}
Profiling and Tracing

The Python interpreter provides some low-level support for attaching profiling and execution tracing facilities. These are used for profiling, debugging, and coverage analysis tools.

Starting with Python 2.2, the implementation of this facility was substantially revised, and an interface from C was added. This C interface allows the profiling or tracing code to avoid the overhead of calling through Python-level callable objects, making a direct C function call instead. The essential attributes of the facility have not changed; the interface allows trace functions to be installed per-thread, and the basic events reported to the trace function are the same as had been reported to the Python-level trace functions in previous versions.

```
int (*Py_tracefunc)(PyObject *obj, PyFrameObject *frame, int what, PyObject *arg)
```

The type of the trace function registered using `PyEval_SetProfile` and `PyEval_SetTrace`. The first parameter is the object passed to the registration function as `obj`, `frame` is the frame object to which the event pertains, `what` is one of the constants `PyTrace_CALL`, `PyTrace_EXCEPTION`, `PyTrace_LINE`, `PyTrace_RETURN`, `PyTrace_C_CALL`, `PyTrace_C_EXCEPTION`, or `PyTrace_C_RETURN`, and `arg` depends on the value of `what`:

<table>
<thead>
<tr>
<th>Value of <code>what</code></th>
<th>Meaning of <code>arg</code></th>
</tr>
</thead>
<tbody>
<tr>
<td><code>PyTrace_CALL</code></td>
<td>Always <code>NULL</code>.</td>
</tr>
<tr>
<td><code>PyTrace_EXCEPTION</code></td>
<td>Exception information as returned by <code>sys.exc_info()</code></td>
</tr>
<tr>
<td><code>PyTrace_LINE</code></td>
<td>Always <code>NULL</code>.</td>
</tr>
<tr>
<td><code>PyTrace_RETURN</code></td>
<td>Value being returned to the caller.</td>
</tr>
</tbody>
</table>
### PyTrace_C_CALL
Name of function being called.

### PyTrace_C_EXCEPTION
Always NULL.

### PyTrace_C_RETURN
Always NULL.

**int PyTrace_CALL**
The value of the *what* parameter to a *Py_tracefunc* function when a new call to a function or method is being reported, or a new entry into a generator. Note that the creation of the iterator for a generator function is not reported as there is no control transfer to the Python bytecode in the corresponding frame.

**int PyTrace_EXCEPTION**
The value of the *what* parameter to a *Py_tracefunc* function when an exception has been raised. The callback function is called with this value for *what* when after any bytecode is processed after which the exception becomes set within the frame being executed. The effect of this is that as exception propagation causes the Python stack to unwind, the callback is called upon return to each frame as the exception propagates. Only trace functions receives these events; they are not needed by the profiler.

**int PyTrace_LINE**
The value passed as the *what* parameter to a trace function (but not a profiling function) when a line-number event is being reported.

**int PyTrace_RETURN**
The value for the *what* parameter to *Py_tracefunc* functions when a call is returning without propagating an exception.

**int PyTrace_C_CALL**
The value for the *what* parameter to *Py_tracefunc* functions when a C function is about to be called.
int PyTrace_C_EXCEPTION
The value for the what parameter to Py_tracefunc functions when a C function has thrown an exception.

int PyTrace_C_RETURN
The value for the what parameter to Py_tracefunc functions when a C function has returned.

void PyEval_SetProfile(Py_tracefunc func, PyObject *obj)
Set the profiler function to func. The obj parameter is passed to the function as its first parameter, and may be any Python object, or NULL. If the profile function needs to maintain state, using a different value for obj for each thread provides a convenient and thread-safe place to store it. The profile function is called for all monitored events except the line-number events.

void PyEval_SetTrace(Py_tracefunc func, PyObject *obj)
Set the tracing function to func. This is similar to PyEval_SetProfile, except the tracing function does receive line-number events.

PyObject* PyEval_GetCallStats(PyObject *self)
Return a tuple of function call counts. There are constants defined for the positions within the tuple:

<table>
<thead>
<tr>
<th>Name</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>PCALL_ALL</td>
<td>0</td>
</tr>
<tr>

PCALL_GENERATOR 8
PCALL_OTHER 9
PCALL_POP 10

**PCALL_FAST_FUNCTION** means no argument tuple needs to be created. **PCALL_FASTER_FUNCTION** means that the fast-path frame setup code is used.

If there is a method call where the call can be optimized by changing the argument tuple and calling the function directly, it gets recorded twice.

This function is only present if Python is compiled with **CALL_PROFILE** defined.
Advanced Debugger Support

These functions are only intended to be used by advanced debugging tools.

**PyInterpreterState*** PyInterpreterState\_Head()  
Return the interpreter state object at the head of the list of all such objects.

*New in version 2.2.*

**PyInterpreterState*** PyInterpreterState\_Next(PyInterpreterState *interp)  
Return the next interpreter state object after interp from the list of all such objects.

*New in version 2.2.*

*PyThreadState *  
**PyInterpreterState\_ThreadHead(PyInterpreterState *interp)  
Return the a pointer to the first PyThreadState object in the list of threads associated with the interpreter interp.

*New in version 2.2.*

**PyThreadState*** PyThreadState\_Next(PyThreadState *tstate)  
Return the next thread state object after tstate from the list of all such objects belonging to the same PyInterpreterState object.

*New in version 2.2.*
using Sphinx 0.5.
Memory Management
Overview

Memory management in Python involves a private heap containing all Python objects and data structures. The management of this private heap is ensured internally by the Python memory manager. The Python memory manager has different components which deal with various dynamic storage management aspects, like sharing, segmentation, preallocation or caching.

At the lowest level, a raw memory allocator ensures that there is enough room in the private heap for storing all Python-related data by interacting with the memory manager of the operating system. On top of the raw memory allocator, several object-specific allocators operate on the same heap and implement distinct memory management policies adapted to the peculiarities of every object type. For example, integer objects are managed differently within the heap than strings, tuples or dictionaries because integers imply different storage requirements and speed/space tradeoffs. The Python memory manager thus delegates some of the work to the object-specific allocators, but ensures that the latter operate within the bounds of the private heap.

It is important to understand that the management of the Python heap is performed by the interpreter itself and that the user has no control over it, even if she regularly manipulates object pointers to memory blocks inside that heap. The allocation of heap space for Python objects and other internal buffers is performed on demand by the Python memory manager through the Python/C API functions listed in this document.

To avoid memory corruption, extension writers should never try to operate on Python objects with the functions exported by the C library: malloc, calloc, realloc and free. This will result in mixed
calls between the C allocator and the Python memory manager with fatal consequences, because they implement different algorithms and operate on different heaps. However, one may safely allocate and release memory blocks with the C library allocator for individual purposes, as shown in the following example:

```c
PyObject *res;
char *buf = (char *) malloc(BUFSIZ); /* for I/O */

if (buf == NULL)
    return PyErr_NoMemory();
...Do some I/O operation involving buf...
res = PyString_FromString(buf);
free(buf); /* malloc'ed */
return res;
```

In this example, the memory request for the I/O buffer is handled by the C library allocator. The Python memory manager is involved only in the allocation of the string object returned as a result.

In most situations, however, it is recommended to allocate memory from the Python heap specifically because the latter is under control of the Python memory manager. For example, this is required when the interpreter is extended with new object types written in C. Another reason for using the Python heap is the desire to inform the Python memory manager about the memory needs of the extension module. Even when the requested memory is used exclusively for internal, highly-specific purposes, delegating all memory requests to the Python memory manager causes the interpreter to have a more accurate image of its memory footprint as a whole. Consequently, under certain circumstances, the Python memory manager may or may not trigger appropriate actions, like garbage collection, memory compaction or other preventive procedures. Note that by using the C library allocator as shown in the previous example, the allocated memory for the I/O buffer escapes completely the Python memory manager.
Memory Interface

The following function sets, modeled after the ANSI C standard, but specifying behavior when requesting zero bytes, are available for allocating and releasing memory from the Python heap:

```c
void* PyMem_Malloc(size_t n)
Allocates n bytes and returns a pointer of type void* to the allocated memory, or NULL if the request fails. Requesting zero bytes returns a distinct non-NULL pointer if possible, as if PyMem_Malloc(1) had been called instead. The memory will not have been initialized in any way.
```

```c
void* PyMem_Realloc(void *p, size_t n)
Resizes the memory block pointed to by p to n bytes. The contents will be unchanged to the minimum of the old and the new sizes. If p is NULL, the call is equivalent to PyMem_Malloc(n); else if n is equal to zero, the memory block is resized but is not freed, and the returned pointer is non-NULL. Unless p is NULL, it must have been returned by a previous call to PyMem_Malloc or PyMem_Realloc. If the request fails, PyMem_Realloc returns NULL and p remains a valid pointer to the previous memory area.
```

```c
void PyMem_Free(void *p)
Frees the memory block pointed to by p, which must have been returned by a previous call to PyMem_Malloc or PyMem_Realloc. Otherwise, or if PyMem_Free(p) has been called before, undefined behavior occurs. If p is NULL, no operation is performed.
```

The following type-oriented macros are provided for convenience. Note that TYPE refers to any C type.

```c
TYPE* PyMem_New(TYPE, size_t n)
```
Same as `PyMem_Malloc`, but allocates \((n \times \text{sizeof}(\text{TYPE}))\) bytes of memory. Returns a pointer cast to `TYPE*`. The memory will not have been initialized in any way.

`TYPE* PyMem_Resize(void *p, TYPE, size_t n)`
Same as `PyMem_Realloc`, but the memory block is resized to \((n \times \text{sizeof}(\text{TYPE}))\) bytes. Returns a pointer cast to `TYPE*`. On return, \(p\) will be a pointer to the new memory area, or `NULL` in the event of failure. This is a C preprocessor macro; \(p\) is always reassigned. Save the original value of \(p\) to avoid losing memory when handling errors.

`void PyMem_Del(void *p)`
Same as `PyMem_Free`.

In addition, the following macro sets are provided for calling the Python memory allocator directly, without involving the C API functions listed above. However, note that their use does not preserve binary compatibility across Python versions and is therefore deprecated in extension modules.

`PyMem_MALLOC, PyMem_REALLOC, PyMem_FREE`.

`PyMem_NEW, PyMem_RESIZE, PyMem_DEL`. 
Examples

Here is the example from section *Overview*, rewritten so that the I/O buffer is allocated from the Python heap by using the first function set:

```c
PyObject *res;
char *buf = (char *) PyMem_Malloc(BUFSIZ); /* for I/O */

if (buf == NULL)
    return PyErr_NoMemory();
/* ...Do some I/O operation involving buf... */
res = PyString_FromString(buf);
PyMem_Free(buf); /* allocated with PyMem_Malloc */
return res;
```

The same code using the type-oriented function set:

```c
PyObject *res;
char *buf = PyMem_New(char, BUFSIZ); /* for I/O */

if (buf == NULL)
    return PyErr_NoMemory();
/* ...Do some I/O operation involving buf... */
res = PyString_FromString(buf);
PyMem_Del(buf); /* allocated with PyMem_New */
return res;
```

Note that in the two examples above, the buffer is always manipulated via functions belonging to the same set. Indeed, it is required to use the same memory API family for a given memory block, so that the risk of mixing different allocators is reduced to a minimum. The following code sequence contains two errors, one of which is labeled as *fatal* because it mixes two different allocators operating on different heaps.

```c
char *buf1 = PyMem_New(char, BUFSIZ);
char *buf2 = (char *) malloc(BUFSIZ);
char *buf3 = (char *) PyMem_Malloc(BUFSIZ);
...
PyMem_Del(buf3); /* Wrong -- should be PyMem_Free() */
free(buf2);    /* Right -- allocated via malloc() */
free(buf1);    /* Fatal -- should be PyMem_Del() */

In addition to the functions aimed at handling raw memory blocks from the Python heap, objects in Python are allocated and released with `PyObject_New`, `PyObject_NewVar` and `PyObject_Del`.

These will be explained in the next chapter on defining and implementing new object types in C.
Object Implementation Support

This chapter describes the functions, types, and macros used when defining new object types.

- Allocating Objects on the Heap
- Common Object Structures
- Type Objects
- Number Object Structures
- Mapping Object Structures
- Sequence Object Structures
- Buffer Object Structures
- Supporting Cyclic Garbage Collection
Allocating Objects on the Heap

PyObject* _PyObject_New(PyTypeObject *type)

*Return value: New reference.*

PyVarObject* _PyObject_NewVar(PyTypeObject *type, Py_ssize_t size)

*Return value: New reference.*

void _PyObject_Del(PyObject *op)

PyObject* PyObject_Init(PyObject *op, PyTypeObject *type)

*Return value: Borrowed reference.*

Initialize a newly-allocated object `op` with its type and initial reference. Returns the initialized object. If `type` indicates that the object participates in the cyclic garbage detector, it is added to the detector's set of observed objects. Other fields of the object are not affected.

PyVarObject* PyObject_InitVar(PyVarObject *op, PyTypeObject *type, Py_ssize_t size)

*Return value: Borrowed reference.*

This does everything `PyObject_Init` does, and also initializes the length information for a variable-size object.

TYPE* PyObject_New(TYPE, PyTypeObject *type)

*Return value: New reference.*

Allocate a new Python object using the C structure type `TYPE` and the Python type object `type`. Fields not defined by the Python object header are not initialized; the object's reference count will be one. The size of the memory allocation is determined from the `tp_basicsize` field of the type object.
TYPE* PyObject_NewVar(TYPE, PyTypeObject *type, Py_ssize_t size)

Allocate a new Python object using the C structure type TYPE and the Python type object type. Fields not defined by the Python object header are not initialized. The allocated memory allows for the TYPE structure plus size fields of the size given by the tp_itemsize field of type. This is useful for implementing objects like tuples, which are able to determine their size at construction time. Embedding the array of fields into the same allocation decreases the number of allocations, improving the memory management efficiency.

void PyObject_Del(PyObject *op)
Releases memory allocated to an object using PyObject_New or PyObject_NewVar. This is normally called from the tp_dealloc handler specified in the object's type. The fields of the object should not be accessed after this call as the memory is no longer a valid Python object.

PyObject* PyObject_InitModule(char *name, PyMethodDef *methods)
Return value: Borrowed reference.
Create a new module object based on a name and table of functions, returning the new module object.

Changed in version 2.3: Older versions of Python did not support NULL as the value for the methods argument.

PyObject* PyObject_InitModule3(char *name, PyMethodDef *methods, char *doc)
Return value: Borrowed reference.
Create a new module object based on a name and table of functions, returning the new module object. If doc is non-NULL, it will be used to define the docstring for the module.
Changed in version 2.3: Older versions of Python did not support NULL as the value for the methods argument.

PyObject* Py_InitModule4(char *name, PyMethodDef *methods, char *doc, PyObject *self, int apiver)

Return value: Borrowed reference.

Create a new module object based on a name and table of functions, returning the new module object. If doc is non-NULL, it will be used to define the docstring for the module. If self is non-NULL, it will passed to the functions of the module as their (otherwise NULL) first parameter. (This was added as an experimental feature, and there are no known uses in the current version of Python.) For apiver, the only value which should be passed is defined by the constant PYTHON_API_VERSION.

Note: Most uses of this function should probably be using the Py_InitModule3 instead; only use this if you are sure you need it.

Changed in version 2.3: Older versions of Python did not support NULL as the value for the methods argument.

PyObject _Py_NoneStruct

Object which is visible in Python as None. This should only be accessed using the Py_None macro, which evaluates to a pointer to this object.
Common Object Structures

There are a large number of structures which are used in the definition of object types for Python. This section describes these structures and how they are used.

All Python objects ultimately share a small number of fields at the beginning of the object's representation in memory. These are represented by the `PyObject` and `PyVarObject` types, which are defined, in turn, by the expansions of some macros also used, whether directly or indirectly, in the definition of all other Python objects.

**PyObject**

All object types are extensions of this type. This is a type which contains the information Python needs to treat a pointer to an object as an object. In a normal “release” build, it contains only the object’s reference count and a pointer to the corresponding type object. It corresponds to the fields defined by the expansion of the `PyObject_HEAD` macro.

**PyVarObject**

This is an extension of `PyObject` that adds the `ob_size` field. This is only used for objects that have some notion of `length`. This type does not often appear in the Python/C API. It corresponds to the fields defined by the expansion of the `PyObject_VAR_HEAD` macro.

These macros are used in the definition of `PyObject` and `PyVarObject`:

**PyObject_HEAD**

This is a macro which expands to the declarations of the fields of the `PyObject` type; it is used when declaring new types which represent objects without a varying length. The specific fields it
expands to depend on the definition of `Py_TRACE_REFS`. By default, that macro is not defined, and `PyObject_HEAD` expands to:

```c
Py_ssize_t ob_refcnt;
PyTypeObject *ob_type;
```

When `Py_TRACE_REFS` is defined, it expands to:

```c
PyObject *__ob_next, *__ob_prev;
Py_ssize_t ob_refcnt;
PyTypeObject *ob_type;
```

**PyObject_VAR_HEAD**

This is a macro which expands to the declarations of the fields of the `PyVarObject` type; it is used when declaring new types which represent objects with a length that varies from instance to instance. This macro always expands to:

```c
PyObject_HEAD
Py_ssize_t ob_size;
```

Note that `PyObject_HEAD` is part of the expansion, and that its own expansion varies depending on the definition of `Py_TRACE_REFS`.

**PyObject_HEAD_INIT**

**PyCFunction**

Type of the functions used to implement most Python callables in C. Functions of this type take two `PyObject*` parameters and return one such value. If the return value is `NULL`, an exception shall have been set. If not `NULL`, the return value is interpreted as the return value of the function as exposed in Python. The function must return a new reference.

**PyMethodDef**
Structure used to describe a method of an extension type. This structure has four fields:

<table>
<thead>
<tr>
<th>Field</th>
<th>C Type</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>ml_name</td>
<td>char *</td>
<td>name of the method</td>
</tr>
<tr>
<td>ml_meth</td>
<td>PyCFunction</td>
<td>pointer to the C implementation</td>
</tr>
<tr>
<td>ml_flags</td>
<td>int</td>
<td>flag bits indicating how the call should be constructed</td>
</tr>
<tr>
<td>ml_doc</td>
<td>char *</td>
<td>points to the contents of the docstring</td>
</tr>
</tbody>
</table>

The `ml_meth` is a C function pointer. The functions may be of different types, but they always return `PyObject*`. If the function is not of the `PyCFunction`, the compiler will require a cast in the method table. Even though `PyCFunction` defines the first parameter as `PyObject*`, it is common that the method implementation uses a the specific C type of the `self` object.

The `ml_flags` field is a bitfield which can include the following flags. The individual flags indicate either a calling convention or a binding convention. Of the calling convention flags, only `METH_VARARGS` and `METH_KEYWORDS` can be combined (but note that `METH_KEYWORDS` alone is equivalent to `METH_VARARGS | METH_KEYWORDS`). Any of the calling convention flags can be combined with a binding flag.

**METH_VARARGS**

This is the typical calling convention, where the methods have the type `PyCFunction`. The function expects two `PyObject*` values. The first one is the `self` object for methods; for module functions, it has the value given to `Py_InitModule4` (or `NULL` if `Py_InitModule` was used). The second parameter (often called `args`) is a tuple object representing all arguments. This parameter is typically processed using `PyArg_ParseTuple` or
**PyArg_UnpackTuple.**

**METH_KEYWORDS**
Methods with these flags must be of type `PyCFunctionWithKeywords`. The function expects three parameters: `self`, `args`, and a dictionary of all the keyword arguments. The flag is typically combined with `METH_VARARGS`, and the parameters are typically processed using `PyArg_ParseTupleAndKeywords`.

**METH_NOARGS**
Methods without parameters don’t need to check whether arguments are given if they are listed with the `METH_NOARGS` flag. They need to be of type `PyCFunction`. When used with object methods, the first parameter is typically named `self` and will hold a reference to the object instance. In all cases the second parameter will be `NULL`.

**METH_O**
Methods with a single object argument can be listed with the `METH_O` flag, instead of invoking `PyArg_ParseTuple` with a "O" argument. They have the type `PyCFunction`, with the `self` parameter, and a `PyObject*` parameter representing the single argument.

**METH_OLDARGS**
This calling convention is deprecated. The method must be of type `PyCFunction`. The second argument is `NULL` if no arguments are given, a single object if exactly one argument is given, and a tuple of objects if more than one argument is given. There is no way for a function using this convention to distinguish between a call with multiple arguments and a call with a tuple as the only argument.
These two constants are not used to indicate the calling convention but the binding when use with methods of classes. These may not be used for functions defined for modules. At most one of these flags may be set for any given method.

**METH_CLASS**

The method will be passed the type object as the first parameter rather than an instance of the type. This is used to create *class methods*, similar to what is created when using the `classmethod()` built-in function.

*New in version 2.3.*

**METH_STATIC**

The method will be passed `NULL` as the first parameter rather than an instance of the type. This is used to create *static methods*, similar to what is created when using the `staticmethod()` built-in function.

*New in version 2.3.*

One other constant controls whether a method is loaded in place of another definition with the same method name.

**METH_COEXIST**

The method will be loaded in place of existing definitions. Without `METH_COEXIST`, the default is to skip repeated definitions. Since slot wrappers are loaded before the method table, the existence of a `sq_contains` slot, for example, would generate a wrapped method named `__contains__()` and preclude the loading of a corresponding PyCFunction with the same name. With the flag defined, the PyCFunction will be loaded in place of the wrapper object and will co-exist with the slot. This is helpful because calls to PyCFunctions are optimized more than wrapper object calls.
New in version 2.4.

PyObject* Py_FindMethod(PyMethodDef table[], PyObject *ob, char *name)

Return a bound method object for an extension type implemented in C. This can be useful in the implementation of a tp_getattro or tp_getattr handler that does not use the PyObject_GenericGetAttr function.
Type Objects

Perhaps one of the most important structures of the Python object system is the structure that defines a new type: the \texttt{PyTypeObject} structure. Type objects can be handled using any of the \texttt{PyObject_*} or \texttt{PyType_*} functions, but do not offer much that’s interesting to most Python applications. These objects are fundamental to how objects behave, so they are very important to the interpreter itself and to any extension module that implements new types.

Type objects are fairly large compared to most of the standard types. The reason for the size is that each type object stores a large number of values, mostly C function pointers, each of which implements a small part of the type’s functionality. The fields of the type object are examined in detail in this section. The fields will be described in the order in which they occur in the structure.

Typedefns: unaryfunc, binaryfunc, ternaryfunc, inquiry, coercion, intargfunc, intintargfunc, intobjargproc, intintobjargproc, objobjargproc, destructor, freefunc, printfunc, getattrofunc, getattrofunc, setattrofunc, setattrofunc, cmpfunc, reprfunc, hashfunc

The structure definition for \texttt{PyTypeObject} can be found in \texttt{Include/object.h}. For convenience of reference, this repeats the definition found there:

\begin{verbatim}
typedef struct _typeobject {
    PyObject_VAR_HEAD
    char *tp_name; /* For printing, in format "<module>.<name>" */
    int tp_basicsize, tp_itemsize; /* For allocation */
    /* Methods to implement standard operations */
    destructor tp_dealloc;
    printfunc tp_print;
    getattrofunc tp_getattr;
    setattrofunc tp_setattr;
} PyTypeObject;
\end{verbatim}
cmpfunc tp_compare;
reprfunc tp_repr;

/* Method suites for standard classes */
PyNumberMethods *tp_as_number;
PySequenceMethods *tp_as_sequence;
PyMappingMethods *tp_as_mapping;

/* More standard operations (here for binary compatibility) */
hashfunc tp_hash;
ternaryfunc tp_call;
reprfunc tp_str;
getattrofunc tp_getattro;
setattrofunc tp_setattro;

/* Functions to access object as input/output buffer */
PyBufferProcs *tp_as_buffer;

/* Flags to define presence of optional/expanded features */
long tp_flags;

char *tp_doc; /* Documentation string */

/* Assigned meaning in release 2.0 */
/* call function for all accessible objects */
traverseproc tp_traverse;

/* delete references to contained objects */
inquiry tp_clear;

/* Assigned meaning in release 2.1 */
/* rich comparisons */
richcmpfunc tp_richcompare;

/* weak reference enabler */
long tp_weaklistoffset;

/* Added in release 2.2 */
/* Iterators */
getiterfunc tp_iter;
iternextfunc tp_iternext;

/* Attribute descriptor and subclassing stuff */
struct PyMethodDef *tp_methods;
struct PyMemberDef *tp_members;
struct PyGetSetDef *tp_getset;
struct _typeobject *tp_base;
PyObject *tp_dict;
The type object structure extends the `PyVarObject` structure. The `ob_size` field is used for dynamic types (created by `type_new()`), usually called from a class statement). Note that `PyType_Type` (the metatype) initializes `tp_itemsize`, which means that its instances (i.e. type objects) must have the `ob_size` field.

`PyObject* PyObject._ob_next`  
`PyObject* PyObject._ob_prev`  
These fields are only present when the macro `PY_TRACE_REFS` is defined. Their initialization to `NULL` is taken care of by the `PyObject_HEAD_INIT` macro. For statically allocated objects, these fields always remain `NULL`. For dynamically allocated objects, these two fields are used to link the object into a doubly-linked list of all live objects on the heap. This could be used for various debugging purposes; currently the only use is to print the objects that are still alive at the end of a run when the environment variable `PYTHONDUMPREFS` is set.

These fields are not inherited by subtypes.

`Py_ssize_t PyObject.ob_refcnt`  
This is the type object’s reference count, initialized to 1 by the
PyObject_HEAD_INIT macro. Note that for statically allocated type objects, the type's instances (objects whose ob_type points back to the type) do not count as references. But for dynamically allocated type objects, the instances do count as references.

This field is not inherited by subtypes.

PyTypeObject* PyObject.ob_type
This is the type's type, in other words its metatype. It is initialized by the argument to the PyObject_HEAD_INIT macro, and its value should normally be &PyType_Type. However, for dynamically loadable extension modules that must be usable on Windows (at least), the compiler complains that this is not a valid initializer. Therefore, the convention is to pass NULL to the PyObject_HEAD_INIT macro and to initialize this field explicitly at the start of the module's initialization function, before doing anything else. This is typically done like this:

```
Foo_Type.ob_type = &PyType_Type;
```

This should be done before any instances of the type are created. PyType_Ready checks if ob_type is NULL, and if so, initializes it: in Python 2.2, it is set to &PyType_Type; in Python 2.2.1 and later it is initialized to the ob_type field of the base class. PyType_Ready will not change this field if it is non-zero.

In Python 2.2, this field is not inherited by subtypes. In 2.2.1, and in 2.3 and beyond, it is inherited by subtypes.

Py_ssize_t PyVarObject.ob_size
For statically allocated type objects, this should be initialized to zero. For dynamically allocated type objects, this field has a special internal meaning.
This field is not inherited by subtypes.

char* PyTypeObject.tp_name

Pointer to a NUL-terminated string containing the name of the type. For types that are accessible as module globals, the string should be the full module name, followed by a dot, followed by the type name; for built-in types, it should be just the type name. If the module is a submodule of a package, the full package name is part of the full module name. For example, a type named \( T \) defined in module \( M \) in subpackage \( Q \) in package \( P \) should have the \( \text{tp}_\text{name} \) initializer "P.Q.M.T".

For dynamically allocated type objects, this should just be the type name, and the module name explicitly stored in the type dict as the value for key '_module_'.

For statically allocated type objects, the \( \text{tp}_\text{name} \) field should contain a dot. Everything before the last dot is made accessible as the \( \text{__module__} \) attribute, and everything after the last dot is made accessible as the \( \text{__name__} \) attribute.

If no dot is present, the entire \( \text{tp}_\text{name} \) field is made accessible as the \( \text{__name__} \) attribute, and the \( \text{__module__} \) attribute is undefined (unless explicitly set in the dictionary, as explained above). This means your type will be impossible to pickle.

This field is not inherited by subtypes.

Py_ssize_t PyTypeObject.tp_basicsize
Py_ssize_t PyTypeObject.tp_itemsize

These fields allow calculating the size in bytes of instances of the type.

There are two kinds of types: types with fixed-length instances have a zero \( \text{tp}_\text{itemsize} \) field, types with variable-length
instances have a non-zero \texttt{tp\_itemsize} field. For a type with fixed-length instances, all instances have the same size, given in \texttt{tp\_basicsize}.

For a type with variable-length instances, the instances must have an \texttt{ob\_size} field, and the instance size is \texttt{tp\_basicsize} plus \(N\) times \texttt{tp\_itemsize}, where \(N\) is the “length” of the object. The value of \(N\) is typically stored in the instance’s \texttt{ob\_size} field. There are exceptions: for example, long ints use a negative \texttt{ob\_size} to indicate a negative number, and \(N\) is \(\text{abs}(ob\_size)\) there. Also, the presence of an \texttt{ob\_size} field in the instance layout doesn’t mean that the instance structure is variable-length (for example, the structure for the list type has fixed-length instances, yet those instances have a meaningful \texttt{ob\_size} field).

The basic size includes the fields in the instance declared by the macro \texttt{PyObject\_HEAD} or \texttt{PyObject\_VAR\_HEAD} (whichever is used to declare the instance struct) and this in turn includes the \_ob\_prev and \_ob\_next fields if they are present. This means that the only correct way to get an initializer for the \texttt{tp\_basicsize} is to use the \texttt{sizeof} operator on the struct used to declare the instance layout. The basic size does not include the GC header size (this is new in Python 2.2; in 2.1 and 2.0, the GC header size was included in \texttt{tp\_basicsize}).

These fields are inherited separately by subtypes. If the base type has a non-zero \texttt{tp\_itemsize}, it is generally not safe to set \texttt{tp\_itemsize} to a different non-zero value in a subtype (though this depends on the implementation of the base type).

A note about alignment: if the variable items require a particular alignment, this should be taken care of by the value of \texttt{tp\_basicsize}. Example: suppose a type implements an array of
double. **tp_itemsize** is `sizeof(double)`. It is the programmer’s responsibility that **tp_basicsize** is a multiple of `sizeof(double)` (assuming this is the alignment requirement for double).

destructor **PyTypeObject.tp_dealloc**

A pointer to the instance destructor function. This function must be defined unless the type guarantees that its instances will never be deallocated (as is the case for the singletons **None** and **Ellipsis**).

The destructor function is called by the **Py_DECREF** and **Py_XDECREF** macros when the new reference count is zero. At this point, the instance is still in existence, but there are no references to it. The destructor function should free all references which the instance owns, free all memory buffers owned by the instance (using the freeing function corresponding to the allocation function used to allocate the buffer), and finally (as its last action) call the type’s **tp_free** function. If the type is not subtypable (doesn’t have the **Py_TPFLAGS_BASETYPE** flag bit set), it is permissible to call the object deallocator directly instead of via **tp_free**. The object deallocator should be the one used to allocate the instance; this is normally **PyObject_Del** if the instance was allocated using **PyObject_New** or **PyObject_VarNew**, or **PyObject_GC_Del** if the instance was allocated using **PyObject_GC_New** or **PyObject_GC_VarNew**.

This field is inherited by subtypes.

printfunc **PyTypeObject.tp_print**

An optional pointer to the instance print function.

The print function is only called when the instance is printed to a *real* file; when it is printed to a pseudo-file (like a **StringIO**
instance), the instance’s `tp_repr` or `tp_str` function is called to convert it to a string. These are also called when the type’s `tp_print` field is `NULL`. A type should never implement `tp_print` in a way that produces different output than `tp_repr` or `tp_str` would.

The print function is called with the same signature as `PyObject_Print`: `int tp_print(PyObject *self, FILE *file, int flags)`. The `self` argument is the instance to be printed. The `file` argument is the stdio file to which it is to be printed. The `flags` argument is composed of flag bits. The only flag bit currently defined is `Py_PRINT_RAW`. When the `Py_PRINT_RAW` flag bit is set, the instance should be printed the same way as `tp_str` would format it; when the `Py_PRINT_RAW` flag bit is clear, the instance should be printed the same way as `tp_repr` would format it. It should return `-1` and set an exception condition when an error occurred during the comparison.

It is possible that the `tp_print` field will be deprecated. In any case, it is recommended not to define `tp_print`, but instead to rely on `tp_repr` and `tp_str` for printing.

This field is inherited by subtypes.

`getattrfunc` **PyTypeObject.tp_getattr**

An optional pointer to the get-attribute-string function.

This field is deprecated. When it is defined, it should point to a function that acts the same as the `tp_getattro` function, but taking a C string instead of a Python string object to give the attribute name. The signature is the same as for `PyObject_GetAttrString`.

This field is inherited by subtypes together with `tp_getattro`: a
subtype inherits both `tp_getattr` and `tp_getattro` from its base type when the subtype's `tp_getattr` and `tp_getattro` are both `NULL`.

**setattrfunc PyTypeObject.tp_setattr**

An optional pointer to the set-attribute-string function.

This field is deprecated. When it is defined, it should point to a function that acts the same as the `tp_setattro` function, but taking a C string instead of a Python string object to give the attribute name. The signature is the same as for `PyObject_SetAttrString`.

This field is inherited by subtypes together with `tp_setattro`: a subtype inherits both `tp_setattr` and `tp_setattro` from its base type when the subtype's `tp_setattr` and `tp_setattro` are both `NULL`.

**cmpfunc PyTypeObject.tp_compare**

An optional pointer to the three-way comparison function.

The signature is the same as for `PyObject_Compare`. The function should return `1` if `self` greater than `other`, `0` if `self` is equal to `other`, and `-1` if `self` less than `other`. It should return `-1` and set an exception condition when an error occurred during the comparison.

This field is inherited by subtypes together with `tp_richcompare` and `tp_hash`: a subtypes inherits all three of `tp_compare`, `tp_richcompare`, and `tp_hash` when the subtype's `tp_compare`, `tp_richcompare`, and `tp_hash` are all `NULL`.

**reprfunc PyTypeObject.tp_repr**

An optional pointer to a function that implements the built-in
function `repr()`.

The signature is the same as for `PyObject_Repr`; it must return a string or a Unicode object. Ideally, this function should return a string that, when passed to `eval()`, given a suitable environment, returns an object with the same value. If this is not feasible, it should return a string starting with `'<' and ending with '>';` from which both the type and the value of the object can be deduced.

When this field is not set, a string of the form `<%s object at %p>` is returned, where `%s` is replaced by the type name, and `%p` by the object’s memory address.

This field is inherited by subtypes.

**PyNumberMethods** `*tp_as_number`

Pointer to an additional structure that contains fields relevant only to objects which implement the number protocol. These fields are documented in *Number Object Structures*.

The `tp_as_number` field is not inherited, but the contained fields are inherited individually.

**PySequenceMethods** `*tp_as_sequence`

Pointer to an additional structure that contains fields relevant only to objects which implement the sequence protocol. These fields are documented in *Sequence Object Structures*.

The `tp_as_sequence` field is not inherited, but the contained fields are inherited individually.

**PyMappingMethods** `*tp_as_mapping`

Pointer to an additional structure that contains fields relevant only to objects which implement the mapping protocol. These fields are documented in *Mapping Object Structures*. 
The **tp_as_mapping** field is not inherited, but the contained fields are inherited individually.

**hashfunc PyTypeObject.tp_hash**

An optional pointer to a function that implements the built-in function `hash()`.

The signature is the same as for `PyObject_Hash`; it must return a C long. The value `-1` should not be returned as a normal return value; when an error occurs during the computation of the hash value, the function should set an exception and return `-1`.

This field can be set explicitly to `PyObject_HashNotImplemented` to block inheritance of the hash method from a parent type. This is interpreted as the equivalent of `__hash__ = None` at the Python level, causing `isinstance(o, collections.Hashable)` to correctly return `False`. Note that the converse is also true - setting `__hash__ = None` on a class at the Python level will result in the `tp_hash` slot being set to `PyObject_HashNotImplemented`.

When this field is not set, two possibilities exist: if the `tp_compare` and `tp_richcompare` fields are both `NULL`, a default hash value based on the object's address is returned; otherwise, a `TypeError` is raised.

This field is inherited by subtypes together with `tp_richcompare` and `tp_compare`: a subtypes inherits all three of `tp_compare`, `tp_richcompare`, and `tp_hash`, when the subtype's `tp_compare`, `tp_richcompare` and `tp_hash` are all `NULL`.

**ternaryfunc PyTypeObject.tp_call**

An optional pointer to a function that implements calling the object. This should be `NULL` if the object is not callable. The
signature is the same as for `PyObject_Call`.

This field is inherited by subtypes.

**reprfunc** `PyTypeObject.tp_str`
An optional pointer to a function that implements the built-in operation `str()`. (Note that `str` is a type now, and `str()` calls the constructor for that type. This constructor calls `PyObject_Str` to do the actual work, and `PyObject_Str` will call this handler.)

The signature is the same as for `PyObject_Str`, it must return a string or a Unicode object. This function should return a “friendly” string representation of the object, as this is the representation that will be used by the print statement.

When this field is not set, `PyObject_Repr` is called to return a string representation.

This field is inherited by subtypes.

**getattrofunc** `PyTypeObject.tp_getattro`
An optional pointer to the get-attribute function.

The signature is the same as for `PyObject_GetAttr`. It is usually convenient to set this field to `PyObject_GenericGetAttr`, which implements the normal way of looking for object attributes.

This field is inherited by subtypes together with `tp_getattr`: a subtype inherits both `tp_getattr` and `tp_getattro` from its base type when the subtype’s `tp_getattr` and `tp_getattro` are both `NULL`.

**setattrofunc** `PyTypeObject.tp_setattro`
An optional pointer to the set-attribute function.
The signature is the same as for `PyObject_SetAttr`. It is usually convenient to set this field to `PyObject_GenericSetAttr`, which implements the normal way of setting object attributes.

This field is inherited by subtypes together with `tp_setattr`: a subtype inherits both `tp_setattr` and `tp_setattro` from its base type when the subtype's `tp_setattr` and `tp_setattro` are both `NULL`.

**PyBufferProcs** `PyTypeObject.tp_as_buffer`  
Pointer to an additional structure that contains fields relevant only to objects which implement the buffer interface. These fields are documented in *Buffer Object Structures*.

The `tp_as_buffer` field is not inherited, but the contained fields are inherited individually.

**long PyTypeObject.tp_flags**  
This field is a bit mask of various flags. Some flags indicate variant semantics for certain situations; others are used to indicate that certain fields in the type object (or in the extension structures referenced via `tp_as_number`, `tp_as_sequence`, `tp_as_mapping`, and `tp_as_buffer`) that were historically not always present are valid; if such a flag bit is clear, the type fields it guards must not be accessed and must be considered to have a zero or `NULL` value instead.

Inheritance of this field is complicated. Most flag bits are inherited individually, i.e. if the base type has a flag bit set, the subtype inherits this flag bit. The flag bits that pertain to extension structures are strictly inherited if the extension structure is inherited, i.e. the base type’s value of the flag bit is copied into the subtype together with a pointer to the extension structure. The `Py_TPFLAGS_HAVE_GC` flag bit is inherited together with the
tp_traverse and tp_clear fields, i.e. if the Py_TPFLAGS_HAVE_GC flag bit is clear in the subtype and the tp_traverse and tp_clear fields in the subtype exist (as indicated by the Py_TPFLAGS_HAVE_RICHCOMPARE flag bit) and have NULL values.

The following bit masks are currently defined; these can be ORed together using the | operator to form the value of the tp_flags field. The macro PyType_HasFeature takes a type and a flags value, tp and f, and checks whether tp->tp_flags & f is non-zero.

Py_TPFLAGS_HAVE_GETCHARBUFFER
If this bit is set, the PyBufferProcs struct referenced by tp_as_buffer has the bf_getcharbuffer field.

Py_TPFLAGS_HAVE_SEQUENCE_IN
If this bit is set, the PySequenceMethods struct referenced by tp_as_sequence has the sq_contains field.

Py_TPFLAGS_GC
This bit is obsolete. The bit it used to name is no longer in use. The symbol is now defined as zero.

Py_TPFLAGS_HAVE_INPLACEOPS
If this bit is set, the PySequenceMethods struct referenced by tp_as_sequence and the PyNumberMethods structure referenced by tp_as_number contain the fields for in-place operators. In particular, this means that the PyNumberMethods structure has the fields nb_inplace_add, nb_inplace_subtract, nb_inplace_multiply, nb_inplace_divide, nb_inplace_remainder, nb_inplace_power, nb_inplace_lshift, nb_inplace_rshift, nb_inplace_and, nb_inplace_xor, and nb_inplace_or; and the PySequenceMethods struct has the fields sq_inplace_concat and sq_inplace_repeat.
Py_TPFLAGS_CHECKTYPES
If this bit is set, the binary and ternary operations in the PyNumberMethods structure referenced by tp_as_number accept arguments of arbitrary object types, and do their own type conversions if needed. If this bit is clear, those operations require that all arguments have the current type as their type, and the caller is supposed to perform a coercion operation first. This applies to nb_add, nb_subtract, nb_multiply, nb_divide, nb_remainder, nb_divmod, nb_power, nb_lshift, nb_rshift, nb_and, nb_xor, and nb_or.

Py_TPFLAGS_HAVE_RICHCOMPARE
If this bit is set, the type object has the tp_richcompare field, as well as the tp_traverse and the tp_clear fields.

Py_TPFLAGS_HAVE_WEAKREFS
If this bit is set, the tp_weaklistoffset field is defined. Instances of a type are weakly referenceable if the type’s tp_weaklistoffset field has a value greater than zero.

Py_TPFLAGS_HAVE_ITER
If this bit is set, the type object has the tp_iter and tp_iternext fields.

Py_TPFLAGS_HAVE_CLASS
If this bit is set, the type object has several new fields defined starting in Python 2.2: tp_methods, tp_members, tp_getset, tp_base, tp_dict, tp_descr_get, tp_descr_set, tp_dictoffset, tp_init, tp_alloc, tp_new, tp_free, tp_is_gc, tp_bases, tp_mro, tp_cache, tp_subclasses, and tp_weaklist.

Py_TPFLAGS_HEAPTYPE
This bit is set when the type object itself is allocated on the heap. In this case, the ob_type field of its instances is considered a reference to the type, and the type object is
INCREF'ed when a new instance is created, and DECREF’ed when an instance is destroyed (this does not apply to instances of subtypes; only the type referenced by the instance’s ob_type gets INCREF’ed or DECREF’ed).

**Py_TPFLAGS_BASETYPE**

This bit is set when the type can be used as the base type of another type. If this bit is clear, the type cannot be subtyped (similar to a “final” class in Java).

**Py_TPFLAGS_READY**

This bit is set when the type object has been fully initialized by `PyType_Ready`.

**Py_TPFLAGS_READYING**

This bit is set while `PyType_Ready` is in the process of initializing the type object.

**Py_TPFLAGS_HAVE_GC**

This bit is set when the object supports garbage collection. If this bit is set, instances must be created using `PyObject_GC_New` and destroyed using `PyObject_GC_Del`. More information in section *Supporting Cyclic Garbage Collection*. This bit also implies that the GC-related fields `tp_traverse` and `tp_clear` are present in the type object; but those fields also exist when `Py_TPFLAGS_HAVE_GC` is clear but `Py_TPFLAGS_HAVE_RICHCOMPARE` is set.

**Py_TPFLAGS_DEFAULT**

This is a bitmask of all the bits that pertain to the existence of certain fields in the type object and its extension structures. Currently, it includes the following bits: `Py_TPFLAGS_HAVE_GETCHARBUFFER`, `Py_TPFLAGS_HAVE_SEQUENCE_IN`, `Py_TPFLAGS_HAVE_INPLACEOPS`, `Py_TPFLAGS_HAVE_RICHCOMPARE`, `Py_TPFLAGS_HAVE_WEAKREFS`, ...
Py_TPFLAGS_HAVE_ITER, and Py_TPFLAGS_HAVE_CLASS.

char* PyTypeObject.tp_doc
An optional pointer to a NUL-terminated C string giving the
docstring for this type object. This is exposed as the __doc__
attribute on the type and instances of the type.

This field is not inherited by subtypes.

The following three fields only exist if the
Py_TPFLAGS_HAVE_RICHCOMPARE flag bit is set.

traverseproc PyTypeObject.tp_traverse
An optional pointer to a traversal function for the garbage
collector. This is only used if the Py_TPFLAGS_HAVE_GC flag bit is
set. More information about Python's garbage collection scheme
can be found in section Supporting Cyclic Garbage Collection.

The tp_traverse pointer is used by the garbage collector to
detect reference cycles. A typical implementation of a
tp_traverse function simply calls Py_VISIT on each of the
instance's members that are Python objects. For example, this is
function local_traverse from the thread extension module:

```c
static int
local_traverse(localobject *self, visitproc visit, void *arg
{
    Py_VISIT(self->args);
    Py_VISIT(self->kw);
    Py_VISIT(self->dict);
    return 0;
}
```

Note that Py_VISIT is called only on those members that can
participate in reference cycles. Although there is also a `self->key` member, it can only be `NULL` or a Python string and therefore cannot be part of a reference cycle.

On the other hand, even if you know a member can never be part of a cycle, as a debugging aid you may want to visit it anyway just so the `gc` module’s `get_referents()` function will include it.

Note that `Py_VISIT` requires the `visit` and `arg` parameters to `local_traverse` to have these specific names; don’t name them just anything.

This field is inherited by subtypes together with `tp_clear` and the `Py_TPFLAGS_HAVE_GC` flag bit: the flag bit, `tp_traverse`, and `tp_clear` are all inherited from the base type if they are all zero in the subtype and the subtype has the `Py_TPFLAGS_HAVE_RICHCOMPARE` flag bit set.

**inquiry** `PyTypeObject.tp_clear`

An optional pointer to a clear function for the garbage collector. This is only used if the `Py_TPFLAGS_HAVE_GC` flag bit is set.

The `tp_clear` member function is used to break reference cycles in cyclic garbage detected by the garbage collector. Taken together, all `tp_clear` functions in the system must combine to break all reference cycles. This is subtle, and if in any doubt supply a `tp_clear` function. For example, the tuple type does not implement a `tp_clear` function, because it’s possible to prove that no reference cycle can be composed entirely of tuples. Therefore the `tp_clear` functions of other types must be sufficient to break any cycle containing a tuple. This isn’t immediately obvious, and there’s rarely a good reason to avoid implementing `tp_clear`. 
Implementations of `tp_clear` should drop the instance’s references to those of its members that may be Python objects, and set its pointers to those members to `NULL`, as in the following example:

```c
static int local_clear(localobject *self)
{
    Py_CLEAR(self->key);
    Py_CLEAR(self->args);
    Py_CLEAR(self->kw);
    Py_CLEAR(self->dict);
    return 0;
}
```

The `Py_CLEAR` macro should be used, because clearing references is delicate: the reference to the contained object must not be decremented until after the pointer to the contained object is set to `NULL`. This is because decrementing the reference count may cause the contained object to become trash, triggering a chain of reclamation activity that may include invoking arbitrary Python code (due to finalizers, or weakref callbacks, associated with the contained object). If it’s possible for such code to reference `self` again, it’s important that the pointer to the contained object be `NULL` at that time, so that `self` knows the contained object can no longer be used. The `Py_CLEAR` macro performs the operations in a safe order.

Because the goal of `tp_clear` functions is to break reference cycles, it’s not necessary to clear contained objects like Python strings or Python integers, which can’t participate in reference cycles. On the other hand, it may be convenient to clear all contained Python objects, and write the type’s `tp_dealloc` function to invoke `tp_clear`. 
More information about Python's garbage collection scheme can be found in section *Supporting Cyclic Garbage Collection*.

This field is inherited by subtypes together with `tp_traverse` and the `Py_TPFLAGS_HAVE_GC` flag bit: the flag bit, `tp_traverse`, and `tp_clear` are all inherited from the base type if they are all zero in the subtype and the subtype has the `Py_TPFLAGS_HAVE_RICHCOMPARE` flag bit set.

**richcmpfunc** `PyTypeObject.tp_richcompare`  
An optional pointer to the rich comparison function, whose signature is `PyObject *tp_richcompare(PyObject *a, PyObject *b, int op)`.

The function should return the result of the comparison (usually `Py_True` or `Py_False`). If the comparison is undefined, it must return `Py_NotImplemented`, if another error occurred it must return `NULL` and set an exception condition.

**Note:** If you want to implement a type for which only a limited set of comparisons makes sense (e.g. `==` and `!=`, but not `<` and friends), directly raise `TypeError` in the rich comparison function.

This field is inherited by subtypes together with `tp_compare` and `tp_hash`: a subtype inherits all three of `tp_compare`, `tp_richcompare`, and `tp_hash`, when the subtype's `tp_compare`, `tp_richcompare`, and `tp_hash` are all `NULL`.

The following constants are defined to be used as the third argument for `tp_richcompare` and for `PyObject_RichCompare`:

<table>
<thead>
<tr>
<th>Constant</th>
<th>Comparison</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>Py_LT</code></td>
<td><code>&lt;</code></td>
</tr>
</tbody>
</table>
The next field only exists if the `Py_TPFLAGS_HAVE_WEAKREFS` flag bit is set.

**long **PyTypeObject.tp_weaklistoffset**

If the instances of this type are weakly referenceable, this field is greater than zero and contains the offset in the instance structure of the weak reference list head (ignoring the GC header, if present); this offset is used by `PyObject_ClearWeakRefs` and the `PyWeakref_*` functions. The instance structure needs to include a field of type `PyObject*` which is initialized to `NULL`.

Do not confuse this field with `tp_weaklist`; that is the list head for weak references to the type object itself.

This field is inherited by subtypes, but see the rules listed below. A subtype may override this offset; this means that the subtype uses a different weak reference list head than the base type. Since the list head is always found via `tp_weaklistoffset`, this should not be a problem.

When a type defined by a class statement has no `__slots__` declaration, and none of its base types are weakly referenceable, the type is made weakly referenceable by adding a weak reference list head slot to the instance layout and setting the `tp_weaklistoffset` of that slot's offset.

When a type’s `__slots__` declaration contains a slot named `__weakref__`, that slot becomes the weak reference list head for instances of the type, and the slot's offset is stored in the type's
tp_weaklistoffset.

When a type's __slots__ declaration does not contain a slot named __weakref__, the type inherits its tp_weaklistoffset from its base type.

The next two fields only exist if the Py_TPFLAGS_HAVE_CLASS flag bit is set.

getiterfunc PyTypeObject.tp_iter

An optional pointer to a function that returns an iterator for the object. Its presence normally signals that the instances of this type are iterable (although sequences may be iterable without this function, and classic instances always have this function, even if they don't define an __iter__() method).

This function has the same signature as PyObject_GetIter.

This field is inherited by subtypes.

iternextfunc PyTypeObject.tp_iternext

An optional pointer to a function that returns the next item in an iterator. When the iterator is exhausted, it must return NULL; a StopIteration exception may or may not be set. When another error occurs, it must return NULL too. Its presence normally signals that the instances of this type are iterators (although classic instances always have this function, even if they don’t define a next() method).

Iterator types should also define the tp_iter function, and that function should return the iterator instance itself (not a new iterator instance).

This function has the same signature as PyIter_Next.
This field is inherited by subtypes.

The next fields, up to and including `tp_weaklist`, only exist if the `Py_TPFLAGS_HAVE_CLASS` flag bit is set.

```c
struct PyMethodDef* PyTypeObject.tp_methods
```

An optional pointer to a static `NULL`-terminated array of `PyMethodDef` structures, declaring regular methods of this type.

For each entry in the array, an entry is added to the type's dictionary (see `tp_dict` below) containing a method descriptor.

This field is not inherited by subtypes (methods are inherited through a different mechanism).

```c
struct PyMemberDef* PyTypeObject.tp_members
```

An optional pointer to a static `NULL`-terminated array of `PyMemberDef` structures, declaring regular data members (fields or slots) of instances of this type.

For each entry in the array, an entry is added to the type's dictionary (see `tp_dict` below) containing a member descriptor.

This field is not inherited by subtypes (members are inherited through a different mechanism).

```c
struct PyGetSetDef* PyTypeObject.tp_getset
```

An optional pointer to a static `NULL`-terminated array of `PyGetSetDef` structures, declaring computed attributes of instances of this type.

For each entry in the array, an entry is added to the type's dictionary (see `tp_dict` below) containing a getset descriptor.

This field is not inherited by subtypes (computed attributes are
inherited through a different mechanism).

Docs for PyGetSetDef (XXX belong elsewhere):

```c
typedef PyObject *(getter)(PyObject *, void *
);
typedef int (*setter)(PyObject *, PyObject *, void *
);

typedef struct PyGetSetDef {
    char *name;     /* attribute name */
    getter get;     /* C function to get the attribute */
    setter set;     /* C function to set the attribute */
    char *doc;      /* optional doc string */
    void *closure;  /* optional additional data for getter and */
} PyGetSetDef;
```

**PyTypeObject* `PyTypeObject.tp_base`**

An optional pointer to a base type from which type properties are inherited. At this level, only single inheritance is supported; multiple inheritance require dynamically creating a type object by calling the metatype.

This field is not inherited by subtypes (obviously), but it defaults to `&PyBaseObject_Type` (which to Python programmers is known as the type `object`).

**PyObject* `PyTypeObject.tp_dict`**

The type's dictionary is stored here by `PyType_Ready`.

This field should normally be initialized to `NULL` before `PyType_Ready` is called; it may also be initialized to a dictionary containing initial attributes for the type. Once `PyType_Ready` has initialized the type, extra attributes for the type may be added to this dictionary only if they don't correspond to overloaded operations (like `__add__(())`).
This field is not inherited by subtypes (though the attributes defined in here are inherited through a different mechanism).

**descrgetfunc** `PyTypeObject.tp_descr_get`

An optional pointer to a “descriptor get” function.

The function signature is

```c
PyObject * tp_descr_get(PyObject *self, PyObject *obj, PyObject *value)
```

This field is inherited by subtypes.

**descrsetfunc** `PyTypeObject.tp_descr_set`

An optional pointer to a “descriptor set” function.

The function signature is

```c
int tp_descr_set(PyObject *self, PyObject *obj, PyObject *value)
```

This field is inherited by subtypes.

XXX explain.

**long** `PyTypeObject.tp_dictoffset`

If the instances of this type have a dictionary containing instance variables, this field is non-zero and contains the offset in the instances of the type of the instance variable dictionary; this offset is used by `PyObject_GenericGetAttr`.

Do not confuse this field with `tp_dict`; that is the dictionary for attributes of the type object itself.

If the value of this field is greater than zero, it specifies the offset
from the start of the instance structure. If the value is less than zero, it specifies the offset from the end of the instance structure. A negative offset is more expensive to use, and should only be used when the instance structure contains a variable-length part. This is used for example to add an instance variable dictionary to subtypes of `str` or `tuple`. Note that the `tp_basicsize` field should account for the dictionary added to the end in that case, even though the dictionary is not included in the basic object layout. On a system with a pointer size of 4 bytes, `tp_dictoffset` should be set to `-4` to indicate that the dictionary is at the very end of the structure.

The real dictionary offset in an instance can be computed from a negative `tp_dictoffset` as follows:

```
dictoffset = tp_basicsize + abs(ob_size)*tp_itemsize + tp_dictoffset
if dictoffset is not aligned on sizeof(void*):
    round up to sizeof(void*)
```

where `tp_basicsize`, `tp_itemsize` and `tp_dictoffset` are taken from the type object, and `ob_size` is taken from the instance. The absolute value is taken because long ints use the sign of `ob_size` to store the sign of the number. (There's never a need to do this calculation yourself; it is done for you by `_PyObject_GetDictPtr_`.)

This field is inherited by subtypes, but see the rules listed below. A subtype may override this offset; this means that the subtype instances store the dictionary at a difference offset than the base type. Since the dictionary is always found via `tp_dictoffset`, this should not be a problem.

When a type defined by a class statement has no `__slots__` declaration, and none of its base types has an instance variable
dictionary, a dictionary slot is added to the instance layout and the \texttt{tp\_dictoffset} is set to that slot’s offset.

When a type defined by a class statement has a \texttt{\_\_slots\_} declaration, the type inherits its \texttt{tp\_dictoffset} from its base type.

(Adding a slot named \texttt{\_\_dict\_} to the \texttt{\_\_slots\_} declaration does not have the expected effect, it just causes confusion. Maybe this should be added as a feature just like \texttt{\_\_weakref\_} though.)

\texttt{initproc PyTypeObject\_\_tp\_init\_}

An optional pointer to an instance initialization function.

This function corresponds to the \texttt{\_\_init\_()} method of classes. Like \texttt{\_\_init\_()}, it is possible to create an instance without calling \texttt{\_\_init\_()}, and it is possible to reinitialize an instance by calling its \texttt{\_\_init\_()} method again.

The function signature is

\begin{verbatim}
int tp_init(PyObject *self, PyObject *args, PyObject *kwds)
\end{verbatim}

The self argument is the instance to be initialized; the \texttt{args} and \texttt{kwds} arguments represent positional and keyword arguments of the call to \texttt{\_\_init\_().}

The \texttt{tp\_init} function, if not \texttt{NULL}, is called when an instance is created normally by calling its type, after the type’s \texttt{tp\_new} function has returned an instance of the type. If the \texttt{tp\_new} function returns an instance of some other type that is not a subtype of the original type, no \texttt{tp\_init} function is called; if \texttt{tp\_new} returns an instance of a subtype of the original type, the subtype’s \texttt{tp\_init} is called. (VERSION NOTE: described here is what is implemented in Python 2.2.1 and later. In Python 2.2, the
tp_init of the type of the object returned by tp_new was always called, if not NULL.)

This field is inherited by subtypes.

allocfunc PyTypeObject.tp_alloc
An optional pointer to an instance allocation function.

The function signature is

```
PyObject *tp_alloc(PyTypeObject *self, Py_ssize_t nitems)
```

The purpose of this function is to separate memory allocation from memory initialization. It should return a pointer to a block of memory of adequate length for the instance, suitably aligned, and initialized to zeros, but with ob_refcnt set to 1 and ob_type set to the type argument. If the type's tp_itemsize is non-zero, the object's ob_size field should be initialized to nitems and the length of the allocated memory block should be tp_basicsize + nitems*tp_itemsize, rounded up to a multiple of sizeof(void*); otherwise, nitems is not used and the length of the block should be tp_basicsize.

Do not use this function to do any other instance initialization, not even to allocate additional memory; that should be done by tp_new.

This field is inherited by static subtypes, but not by dynamic subtypes (subtypes created by a class statement); in the latter, this field is always set to PyType_GenericAlloc, to force a standard heap allocation strategy. That is also the recommended value for statically defined types.

newfunc PyTypeObject.tp_new
An optional pointer to an instance creation function.
If this function is *NULL* for a particular type, that type cannot be called to create new instances; presumably there is some other way to create instances, like a factory function.

The function signature is

```c
PyObject *tp_new(PyTypeObject *subtype, PyObject *args, PyObject *kwds)
```

The subtype argument is the type of the object being created; the `args` and `kwds` arguments represent positional and keyword arguments of the call to the type. Note that subtype doesn’t have to equal the type whose `tp_new` function is called; it may be a subtype of that type (but not an unrelated type).

The `tp_new` function should call `subtype->tp_alloc(subtype, nitems)` to allocate space for the object, and then do only as much further initialization as is absolutely necessary. Initialization that can safely be ignored or repeated should be placed in the `tp_init` handler. A good rule of thumb is that for immutable types, all initialization should take place in `tp_new`, while for mutable types, most initialization should be deferred to `tp_init`.

This field is inherited by subtypes, except it is not inherited by static types whose `tp_base` is *NULL* or `&PyBaseObject_Type`. The latter exception is a precaution so that old extension types don’t become callable simply by being linked with Python 2.2.

**destructor** `PyTypeObject.tp_free`  
An optional pointer to an instance deallocation function.

The signature of this function has changed slightly: in Python 2.2 and 2.2.1, its signature is `destructor`:

```c
void tp_free(PyObject *)
```
In Python 2.3 and beyond, its signature is `freefunc`:

```c
void tp_free(void *)
```

The only initializer that is compatible with both versions is `_PyObject_Del`, whose definition has suitably adapted in Python 2.3.

This field is inherited by static subtypes, but not by dynamic subtypes (subtypes created by a class statement); in the latter, this field is set to a deallocator suitable to match `PyType_GenericAlloc` and the value of the `Py_TPFLAGS_HAVE_GC` flag bit.

**inquiry** `PyTypeObject.tp_is_gc`  
An optional pointer to a function called by the garbage collector.

The garbage collector needs to know whether a particular object is collectible or not. Normally, it is sufficient to look at the object's type's `tp_flags` field, and check the `Py_TPFLAGS_HAVE_GC` flag bit. But some types have a mixture of statically and dynamically allocated instances, and the statically allocated instances are not collectible. Such types should define this function; it should return 1 for a collectible instance, and 0 for a non-collectible instance. The signature is

```c
int tp_is_gc(PyObject *self)
```

(The only example of this are types themselves. The metatype, `PyType_Type`, defines this function to distinguish between statically and dynamically allocated types.)

This field is inherited by subtypes. (VERSION NOTE: in Python 2.2, it was not inherited. It is inherited in 2.2.1 and later versions.)
PyObject* PyTypeObject.\texttt{tp\_bases}
Tuple of base types.

This is set for types created by a class statement. It should be \texttt{NULL} for statically defined types.

This field is not inherited.

PyObject* PyTypeObject.\texttt{tp\_mro}
Tuple containing the expanded set of base types, starting with the type itself and ending with \texttt{object}, in Method Resolution Order.

This field is not inherited; it is calculated fresh by \texttt{PyType\_Ready}.

PyObject* PyTypeObject.\texttt{tp\_cache}
Unused. Not inherited. Internal use only.

PyObject* PyTypeObject.\texttt{tp\_subclasses}
List of weak references to subclasses. Not inherited. Internal use only.

PyObject* PyTypeObject.\texttt{tp\_weaklist}
Weak reference list head, for weak references to this type object. Not inherited. Internal use only.

The remaining fields are only defined if the feature test macro \texttt{COUNT\_ALLOC\_S} is defined, and are for internal use only. They are documented here for completeness. None of these fields are inherited by subtypes.

Py\_ssize\_t PyTypeObject.\texttt{tp\_allocs}
Number of allocations.

Py\_ssize\_t PyTypeObject.\texttt{tp\_frees}
Number of frees.
Py_ssize_t PyTypeObject.tp_maxalloc
  Maximum simultaneously allocated objects.

PyTypeObject* PyTypeObject.tp_next
  Pointer to the next type object with a non-zero tp_allocs field.

Also, note that, in a garbage collected Python, tp_dealloc may be called from any Python thread, not just the thread which created the object (if the object becomes part of a refcount cycle, that cycle might be collected by a garbage collection on any thread). This is not a problem for Python API calls, since the thread on which tp_dealloc is called will own the Global Interpreter Lock (GIL). However, if the object being destroyed in turn destroys objects from some other C or C++ library, care should be taken to ensure that destroying those objects on the thread which called tp_dealloc will not violate any assumptions of the library.
**Number Object Structures**

**PyNumberMethods**

This structure holds pointers to the functions which an object uses to implement the number protocol. Almost every function below is used by the function of similar name documented in the *Number Protocol* section.

Here is the structure definition:

```c
typedef struct {
    binaryfunc nb_add;
    binaryfunc nb_subtract;
    binaryfunc nb_multiply;
    binaryfunc nb_remainder;
    binaryfunc nb_divmod;
    ternaryfunc nb_power;
    unaryfunc nb_negative;
    unaryfunc nb_positive;
    unaryfunc nb_absolute;
    inquiry nb_nonzero; /* Used by PyObject_IsTrue */
    unaryfunc nb_invert;
    binaryfunc nb_lshift;
    binaryfunc nb_rshift;
    binaryfunc nb_and;
    binaryfunc nb_xor;
    binaryfunc nb_or;
    coercion nb_coerce; /* Used by the coerce() function */
    unaryfunc nb_int;
    unaryfunc nb_long;
    unaryfunc nb_float;
    unaryfunc nb_oct;
    unaryfunc nb_hex;
} PyNumberMethods;
```
Binary and ternary functions may receive different kinds of arguments, depending on the flag bit `Py_TPFLAGS_CHECKTYPES`:

- If `Py_TPFLAGS_CHECKTYPES` is not set, the function arguments are guaranteed to be of the object's type; the caller is responsible for calling the coercion method specified by the `nb_coerce` member to convert the arguments:

  coercion `PyNumberMethods.nb_coerce`

  This function is used by `PyNumber_CoerceEx` and has the same signature. The first argument is always a pointer to an
object of the defined type. If the conversion to a common “larger” type is possible, the function replaces the pointers with new references to the converted objects and returns 0. If the conversion is not possible, the function returns 1. If an error condition is set, it will return -1.

- If the Py_TPFLAGS_CHECKTYPES flag is set, binary and ternary functions must check the type of all their operands, and implement the necessary conversions (at least one of the operands is an instance of the defined type). This is the recommended way; with Python 3.0 coercion will disappear completely.

If the operation is not defined for the given operands, binary and ternary functions must return Py_NotImplemented, if another error occurred they must return NULL and set an exception.
Mapping Object Structures

**PyMappingMethods**
This structure holds pointers to the functions which an object uses to implement the mapping protocol. It has three members:

*lenfunc* `PyMappingMethods.mp_length`
This function is used by `PyMapping_Length` and `PyObject_Size`, and has the same signature. This slot may be set to `NULL` if the object has no defined length.

*binaryfunc* `PyMappingMethods.mp_subscript`
This function is used by `PyObject_GetItem` and has the same signature. This slot must be filled for the `PyMapping_Check` function to return 1, it can be `NULL` otherwise.

*objobjargproc* `PyMappingMethods.mp_ass_subscript`
This function is used by `PyObject_SetItem` and has the same signature. If this slot is `NULL`, the object does not support item assignment.
Sequence Object Structures

**PySequenceMethods**
This structure holds pointers to the functions which an object uses to implement the sequence protocol.

lenfunc *PySequenceMethods.sq_length*
This function is used by *PySequence_Size* and *PyObject_Size*, and has the same signature.

binaryfunc *PySequenceMethods.sq_concat*
This function is used by *PySequence_Concat* and has the same signature. It is also used by the + operator, after trying the numeric addition via the *tp_as_number.nb_add* slot.

ssizeargfunc *PySequenceMethods.sq_repeat*
This function is used by *PySequence_Repeat* and has the same signature. It is also used by the * operator, after trying numeric multiplication via the *tp_as_number.nb_mul* slot.

ssizeargfunc *PySequenceMethods.sq_item*
This function is used by *PySequence_GetItem* and has the same signature. This slot must be filled for the *PySequence_Check* function to return 1, it can be *NULL* otherwise.

Negative indexes are handled as follows: if the *sq_length* slot is filled, it is called and the sequence length is used to compute a positive index which is passed to *sq_item*. If *sq_length* is *NULL*, the index is passed as is to the function.

ssizeobjargproc *PySequenceMethods.sq_ass_item*
This function is used by *PySequence_SetItem* and has the same signature. This slot may be left to *NULL* if the object does not
support item assignment.

**objobjproc** PySequenceMethods.sq_contains

This function may be used by **PySequence_Contains** and has the same signature. This slot may be left to **NULL**, in this case **PySequence_Contains** simply traverses the sequence until it finds a match.

**binaryfunc** PySequenceMethods.sq_inplace_concat

This function is used by **PySequence_InPlaceConcat** and has the same signature. It should modify its first operand, and return it.

**ssizeargfunc** PySequenceMethods.sq_inplace_repeat

This function is used by **PySequence_InPlaceRepeat** and has the same signature. It should modify its first operand, and return it.
Buffer Object Structures

The buffer interface exports a model where an object can expose its internal data as a set of chunks of data, where each chunk is specified as a pointer/length pair. These chunks are called segments and are presumed to be non-contiguous in memory.

If an object does not export the buffer interface, then its `tp_as_buffer` member in the `PyTypeObject` structure should be `NULL`. Otherwise, the `tp_as_buffer` will point to a `PyBufferProcs` structure.

**Note:** It is very important that your `PyTypeObject` structure uses `Py_TPFLAGS_DEFAULT` for the value of the `tp_flags` member rather than `0`. This tells the Python runtime that your `PyBufferProcs` structure contains the `bf_getcharbuffer` slot. Older versions of Python did not have this member, so a new Python interpreter using an old extension needs to be able to test for its presence before using it.

**PyBufferProcs**

Structure used to hold the function pointers which define an implementation of the buffer protocol.

The first slot is `bf_getreadbuffer`, of type `getreadbufferproc`. If this slot is `NULL`, then the object does not support reading from the internal data. This is non-sensical, so implementors should fill this in, but callers should test that the slot contains a non-`NULL` value.

The next slot is `bf_getwritebuffer` having type `getwritebufferproc`. This slot may be `NULL` if the object does not allow writing into its returned buffers.
The third slot is `bf_getsegcount`, with type `getsegcountproc`. This slot must not be `NULL` and is used to inform the caller how many segments the object contains. Simple objects such as `PyString_Type` and `PyBuffer_Type` objects contain a single segment.

The last slot is `bf_getcharbuffer`, of type `getcharbufferproc`. This slot will only be present if the `Py_TPFLAGS_HAVE_GETCHARBUFFER` flag is present in the `tp_flags` field of the object’s `PyTypeObject`. Before using this slot, the caller should test whether it is present by using the `PyType_HasFeature` function. If the flag is present, `bf_getcharbuffer` may be `NULL`, indicating that the object’s contents cannot be used as 8-bit characters. The slot function may also raise an error if the object’s contents cannot be interpreted as 8-bit characters. For example, if the object is an array which is configured to hold floating point values, an exception may be raised if a caller attempts to use `bf_getcharbuffer` to fetch a sequence of 8-bit characters. This notion of exporting the internal buffers as “text” is used to distinguish between objects that are binary in nature, and those which have character-based content.

**Note:** The current policy seems to state that these characters may be multi-byte characters. This implies that a buffer size of \( N \) does not mean there are \( N \) characters present.

**Py_TPFLAGS_HAVE_GETCHARBUFFER**

Flag bit set in the type structure to indicate that the `bf_getcharbuffer` slot is known. This being set does not indicate that the object supports the buffer interface or that the `bf_getcharbuffer` slot is non-`NULL`.

```c
Py_ssize_t (*readbufferproc)(PyObject *self, Py_ssize_t
```
*segment, void **ptrptr*)

Return a pointer to a readable segment of the buffer in *ptrptr. This function is allowed to raise an exception, in which case it must return -1. The *segment which is specified must be zero or positive, and strictly less than the number of segments returned by the *bf_getsegcount slot function. On success, it returns the length of the segment, and sets *ptrptr to a pointer to that memory.

Py_ssize_t (*writebufferproc)(PyObject *self, Py_ssize_t *segment, void **ptrptr)

Return a pointer to a writable memory buffer in *ptrptr, and the length of that segment as the function return value. The memory buffer must correspond to buffer segment *segment. Must return -1 and set an exception on error. *TypeError should be raised if the object only supports read-only buffers, and *SystemError should be raised when *segment specifies a segment that doesn’t exist.

Py_ssize_t (*segcountproc)(PyObject *self, Py_ssize_t *lenp)

Return the number of memory segments which comprise the buffer. If *lenp is not NULL, the implementation must report the sum of the sizes (in bytes) of all segments in *lenp. The function cannot fail.

Py_ssize_t (*charbufferproc)(PyObject *self, Py_ssize_t *segment, const char **ptrptr)

Return the size of the segment *segment that ptrptr is set to. *ptrptr is set to the memory buffer. Returns -1 on error.
Supporting Cyclic Garbage Collection

Python's support for detecting and collecting garbage which involves circular references requires support from object types which are "containers" for other objects which may also be containers. Types which do not store references to other objects, or which only store references to atomic types (such as numbers or strings), do not need to provide any explicit support for garbage collection.

To create a container type, the tp_flags field of the type object must include the Py_TPFLAGS_HAVE_GC and provide an implementation of the tp_traverse handler. If instances of the type are mutable, a tp_clear implementation must also be provided.

Py_TPFLAGS_HAVE_GC

Objects with a type with this flag set must conform with the rules documented here. For convenience these objects will be referred to as container objects.

Constructors for container types must conform to two rules:

1. The memory for the object must be allocated using PyObject_GC_New or PyObject_GC_VarNew.
2. Once all the fields which may contain references to other containers are initialized, it must call PyObject_GC_Track.

TYPE* PyObject_GC_New(TYPE, PyTypeObject *type)

Analogous to PyObject_New but for container objects with the Py_TPFLAGS_HAVE_GC flag set.

TYPE* PyObject_GC_NewVar(TYPE, PyTypeObject *type, Py_ssize_t size)
Analogous to `PyObject_NewVar` but for container objects with the `Py_TPFLAGS_HAVE_GC` flag set.

```c
PyVarObject * PyObject_GC_Resize(PyVarObject *op, Py_ssize_t) // Resize an object allocated by PyObject_NewVar. Returns the resized object or NULL on failure.
```

```c
void PyObject_GC_Track(PyObject *op) // Adds the object op to the set of container objects tracked by the collector. The collector can run at unexpected times so objects must be valid while being tracked. This should be called once all the fields followed by the tp_traverse handler become valid, usually near the end of the constructor.
```

```c
void _PyObject_GC_TRACK(PyObject *op) // A macro version of PyObject_GC_Track. It should not be used for extension modules.
```

Similarly, the deallocator for the object must conform to a similar pair of rules:

1. Before fields which refer to other containers are invalidated, `PyObject_GC_UnTrack` must be called.
2. The object’s memory must be deallocated using `PyObject_GC_Del`.

```c
void PyObject_GC_Del(void *op) // Releases memory allocated to an object using PyObject_GC_New or PyObject_GC_NewVar.
```

```c
void PyObject_GC_UnTrack(void *op) // Remove the object op from the set of container objects tracked by the collector. Note that PyObject_GC_Track can be called again on this object to add it back to the set of tracked objects. The
```
deallocator (*tp_dealloc* handler) should call this for the object before any of the fields used by the *tp_traverse* handler become invalid.

```c
void _PyObject_GC_UNTRACK(PyObject *op)
```

A macro version of *PyObject_GC_UnTrack*. It should not be used for extension modules.

The *tp_traverse* handler accepts a function parameter of this type:

```c
int (*visitproc)(PyObject *object, void *arg)
```

Type of the visitor function passed to the *tp_traverse* handler. The function should be called with an object to traverse as *object* and the third parameter to the *tp_traverse* handler as *arg*. The Python core uses several visitor functions to implement cyclic garbage detection; it’s not expected that users will need to write their own visitor functions.

The *tp_traverse* handler must have the following type:

```c
int (*traverseproc)(PyObject *self, visitproc visit, void *arg)
```

Traversal function for a container object. Implementations must call the *visit* function for each object directly contained by *self*, with the parameters to *visit* being the contained object and the *arg* value passed to the handler. The *visit* function must not be called with a *NULL* object argument. If *visit* returns a non-zero value that value should be returned immediately.

To simplify writing *tp_traverse* handlers, a *Py_VISIT* macro is provided. In order to use this macro, the *tp_traverse* implementation must name its arguments exactly *visit* and *arg*:

```c
void Py_VISIT(PyObject *o)
```

Call the *visit* callback, with arguments *o* and *arg*. If *visit* returns a
non-zero value, then return it. Using this macro, `tp_traverse` handlers look like:

```c
static int
my_traverse(Noddy *self, visitproc visit, void *arg)
{
    Py_VISIT(self->foo);
    Py_VISIT(self->bar);
    return 0;
}
```

New in version 2.4.

The `tp_clear` handler must be of the `inquiry` type, or `NULL` if the object is immutable.

```c
int (*inquiry)(PyObject *self)
```

Drop references that may have created reference cycles. Immutable objects do not have to define this method since they can never directly create reference cycles. Note that the object must still be valid after calling this method (don’t just call `Py_DECREF` on a reference). The collector will call this method if it detects that this object is involved in a reference cycle.
An Introduction to Distutils

This document covers using the Distutils to distribute your Python modules, concentrating on the role of developer/distributor: if you're looking for information on installing Python modules, you should refer to the *Installing Python Modules* chapter.
Using the Distutils is quite simple, both for module developers and for users/administrators installing third-party modules. As a developer, your responsibilities (apart from writing solid, well-documented and well-tested code, of course!) are:

- write a setup script (`setup.py` by convention)
- (optional) write a setup configuration file
- create a source distribution
- (optional) create one or more built (binary) distributions

Each of these tasks is covered in this document.

Not all module developers have access to a multitude of platforms, so it's not always feasible to expect them to create a multitude of built distributions. It is hoped that a class of intermediaries, called *packagers*, will arise to address this need. Packagers will take source distributions released by module developers, build them on one or more platforms, and release the resulting built distributions. Thus, users on the most popular platforms will be able to install most popular Python module distributions in the most natural way for their platform, without having to run a single setup script or compile a line of code.
A Simple Example

The setup script is usually quite simple, although since it's written in Python, there are no arbitrary limits to what you can do with it, though you should be careful about putting arbitrarily expensive operations in your setup script. Unlike, say, Autoconf-style configure scripts, the setup script may be run multiple times in the course of building and installing your module distribution.

If all you want to do is distribute a module called foo, contained in a file foo.py, then your setup script can be as simple as this:

```python
from distutils.core import setup
setup(name='foo',
      version='1.0',
      py_modules=['foo'],
)
```

Some observations:

- most information that you supply to the Distutils is supplied as keyword arguments to the `setup()` function
- those keyword arguments fall into two categories: package metadata (name, version number) and information about what's in the package (a list of pure Python modules, in this case)
- modules are specified by module name, not filename (the same will hold true for packages and extensions)
- it's recommended that you supply a little more metadata, in particular your name, email address and a URL for the project (see section *Writing the Setup Script* for an example)

To create a source distribution for this module, you would create a setup script, `setup.py`, containing the above code, and run:

```
python setup.py sdist
```
which will create an archive file (e.g., tarball on Unix, ZIP file on Windows) containing your setup script `setup.py`, and your module `foo.py`. The archive file will be named `foo-1.0.tar.gz` (or `.zip`), and will unpack into a directory `foo-1.0`.

If an end-user wishes to install your `foo` module, all she has to do is download `foo-1.0.tar.gz` (or `.zip`), unpack it, and—from the `foo-1.0` directory—run

```
python setup.py install
```

which will ultimately copy `foo.py` to the appropriate directory for third-party modules in their Python installation.

This simple example demonstrates some fundamental concepts of the Distutils. First, both developers and installers have the same basic user interface, i.e. the setup script. The difference is which Distutils *commands* they use: the `sdist` command is almost exclusively for module developers, while `install` is more often for installers (although most developers will want to install their own code occasionally).

If you want to make things really easy for your users, you can create one or more built distributions for them. For instance, if you are running on a Windows machine, and want to make things easy for other Windows users, you can create an executable installer (the most appropriate type of built distribution for this platform) with the `bdist_wininst` command. For example:

```
python setup.py bdist_wininst
```

will create an executable installer, `foo-1.0.win32.exe`, in the current directory.

Other useful built distribution formats are RPM, implemented by the
**bdist_rpm** command, Solaris **pkgtool** (**bdist_pkgtool**), and HP-UX **swinstall** (**bdist_sdux**). For example, the following command will create an RPM file called `foo-1.0.noarch.rpm`:

```
python setup.py bdist_rpm
```

(The **bdist_rpm** command uses the **rpm** executable, therefore this has to be run on an RPM-based system such as Red Hat Linux, SuSE Linux, or Mandrake Linux.)

You can find out what distribution formats are available at any time by running

```
python setup.py bdist --help-formats
```
If you’re reading this document, you probably have a good idea of what modules, extensions, and so forth are. Nevertheless, just to be sure that everyone is operating from a common starting point, we offer the following glossary of common Python terms:

module
the basic unit of code reusability in Python: a block of code imported by some other code. Three types of modules concern us here: pure Python modules, extension modules, and packages.

pure Python module
a module written in Python and contained in a single .py file (and possibly associated .pyc and/or .pyo files). Sometimes referred to as a “pure module.”

extension module
a module written in the low-level language of the Python implementation: C/C++ for Python, Java for Jython. Typically contained in a single dynamically loadable pre-compiled file, e.g. a shared object (.so) file for Python extensions on Unix, a DLL (given the .pyd extension) for Python extensions on Windows, or a Java class file for Jython extensions. (Note that currently, the Distutils only handles C/C++ extensions for Python.)

package
a module that contains other modules; typically contained in a directory in the filesystem and distinguished from other directories by the presence of a file __init__.py.

root package
the root of the hierarchy of packages. (This isn’t really a package, since it doesn’t have an __init__.py file. But we have to call it
The vast majority of the standard library is in the root package, as are many small, standalone third-party modules that don’t belong to a larger module collection. Unlike regular packages, modules in the root package can be found in many directories: in fact, every directory listed in `sys.path` contributes modules to the root package.
Distutils-specific terminology

The following terms apply more specifically to the domain of distributing Python modules using the Distutils:

module distribution
a collection of Python modules distributed together as a single downloadable resource and meant to be installed en masse. Examples of some well-known module distributions are Numeric Python, PyXML, PIL (the Python Imaging Library), or mxBase. (This would be called a package, except that term is already taken in the Python context: a single module distribution may contain zero, one, or many Python packages.)

pure module distribution
a module distribution that contains only pure Python modules and packages. Sometimes referred to as a “pure distribution."

non-pure module distribution
a module distribution that contains at least one extension module. Sometimes referred to as a “non-pure distribution."

distribution root
the top-level directory of your source tree (or source distribution); the directory where setup.py exists. Generally setup.py will be run from this directory.
Writing the Setup Script

The setup script is the centre of all activity in building, distributing, and installing modules using the Distutils. The main purpose of the setup script is to describe your module distribution to the Distutils, so that the various commands that operate on your modules do the right thing. As we saw in section *A Simple Example* above, the setup script consists mainly of a call to `setup()`, and most information supplied to the Distutils by the module developer is supplied as keyword arguments to `setup()`.

Here's a slightly more involved example, which we'll follow for the next couple of sections: the Distutils' own setup script. (Keep in mind that although the Distutils are included with Python 1.6 and later, they also have an independent existence so that Python 1.5.2 users can use them to install other module distributions. The Distutils' own setup script, shown here, is used to install the package into Python 1.5.2.)

```python
#!/usr/bin/env python

from distutils.core import setup

setup(name='Distutils',
      version='1.0',
      description='Python Distribution Utilities',
      author='Greg Ward',
      author_email='gward@python.net',
      url='http://www.python.org/sigs/distutils-sig/',
      packages=['distutils', 'distutils.command'],
)
```

There are only two differences between this and the trivial one-file distribution presented in section *A Simple Example*: more metadata, and the specification of pure Python modules by package, rather than by module. This is important since the Distutils consist of a couple of dozen modules split into (so far) two packages; an explicit
list of every module would be tedious to generate and difficult to maintain. For more information on the additional meta-data, see section *Additional meta-data*.

Note that any pathnames (files or directories) supplied in the setup script should be written using the Unix convention, i.e. slash-separated. The Distutils will take care of converting this platform-neutral representation into whatever is appropriate on your current platform before actually using the pathname. This makes your setup script portable across operating systems, which of course is one of the major goals of the Distutils. In this spirit, all pathnames in this document are slash-separated.

This, of course, only applies to pathnames given to Distutils functions. If you, for example, use standard Python functions such as `glob.glob()` or `os.listdir()` to specify files, you should be careful to write portable code instead of hardcoding path separators:

```python
glob.glob(os.path.join('mydir', 'subdir', '*.html'))
os.listdir(os.path.join('mydir', 'subdir'))
```
The `packages` option tells the Distutils to process (build, distribute, install, etc.) all pure Python modules found in each package mentioned in the `packages` list. In order to do this, of course, there has to be a correspondence between package names and directories in the filesystem. The default correspondence is the most obvious one, i.e. package `distutils` is found in the directory `distutils` relative to the distribution root. Thus, when you say `packages = ['foo']` in your setup script, you are promising that the Distutils will find a file `foo/__init__.py` (which might be spelled differently on your system, but you get the idea) relative to the directory where your setup script lives. If you break this promise, the Distutils will issue a warning but still process the broken package anyways.

If you use a different convention to lay out your source directory, that's no problem: you just have to supply the `package_dir` option to tell the Distutils about your convention. For example, say you keep all Python source under `lib`, so that modules in the “root package” (i.e., not in any package at all) are in `lib`, modules in the `foo` package are in `lib/foo`, and so forth. Then you would put

```python
package_dir = {'' : 'lib'}
```

in your setup script. The keys to this dictionary are package names, and an empty package name stands for the root package. The values are directory names relative to your distribution root. In this case, when you say `packages = ['foo']`, you are promising that the file `lib/foo/__init__.py` exists.

Another possible convention is to put the `foo` package right in `lib`,
the foo.bar package in lib/bar, etc. This would be written in the setup script as

```python
package_dir = {'foo': 'lib'}
```

A package: dir entry in the package_dir dictionary implicitly applies to all packages below package, so the foo.bar case is automatically handled here. In this example, having `packages = ['foo', 'foo.bar']` tells the Distutils to look for `lib/__init__.py` and `lib/bar/__init__.py`. (Keep in mind that although package_dir applies recursively, you must explicitly list all packages in packages: the Distutils will not recursively scan your source tree looking for any directory with an __init__.py file.)
Listing individual modules

For a small module distribution, you might prefer to list all modules rather than listing packages—especially the case of a single module that goes in the “root package” (i.e., no package at all). This simplest case was shown in section *A Simple Example*; here is a slightly more involved example:

```python
py_modules = ['mod1', 'pkg.mod2']
```

This describes two modules, one of them in the “root” package, the other in the `pkg` package. Again, the default package/directory layout implies that these two modules can be found in `mod1.py` and `pkg/mod2.py`, and that `pkg/__init__.py` exists as well. And again, you can override the package/directory correspondence using the `package_dir` option.
Describing extension modules

Just as writing Python extension modules is a bit more complicated than writing pure Python modules, describing them to the Distutils is a bit more complicated. Unlike pure modules, it’s not enough just to list modules or packages and expect the Distutils to go out and find the right files; you have to specify the extension name, source file(s), and any compile/link requirements (include directories, libraries to link with, etc.).

All of this is done through another keyword argument to setup(), the ext_modules option. ext_modules is just a list of Extension instances, each of which describes a single extension module. Suppose your distribution includes a single extension, called foo and implemented by foo.c. If no additional instructions to the compiler/linker are needed, describing this extension is quite simple:

```python
Extension('foo', ['foo.c'])
```

The Extension class can be imported from distutils.core along with setup(). Thus, the setup script for a module distribution that contains only this one extension and nothing else might be:

```python
from distutils.core import setup, Extension
setup(name='foo',
      version='1.0',
      ext_modules=[Extension('foo', ['foo.c'])],
)
```

The Extension class (actually, the underlying extension-building machinery implemented by the build_ext command) supports a great deal of flexibility in describing Python extensions, which is explained in the following sections.
Extension names and packages

The first argument to the `Extension` constructor is always the name of the extension, including any package names. For example,

```python
Extension('foo', ['src/foo1.c', 'src/foo2.c'])
```

describes an extension that lives in the root package, while

```python
Extension('pkg.foo', ['src/foo1.c', 'src/foo2.c'])
```

describes the same extension in the `pkg` package. The source files and resulting object code are identical in both cases; the only difference is where in the filesystem (and therefore where in Python's namespace hierarchy) the resulting extension lives.

If you have a number of extensions all in the same package (or all under the same base package), use the `ext_package` keyword argument to `setup()`. For example,

```python
setup(...,
    ext_package='pkg',
    ext_modules=[Extension('foo', ['foo.c']),
                 Extension('subpkg.bar', ['bar.c'])],
)
```

will compile `foo.c` to the extension `pkg.foo`, and `bar.c` to `pkg.subpkg.bar`.

Extension source files

The second argument to the `Extension` constructor is a list of source files. Since the Distutils currently only support C, C++, and Objective-C extensions, these are normally C/C++/Objective-C source files. (Be sure to use appropriate extensions to distinguish
C++ source files: `.cc` and `.cpp` seem to be recognized by both Unix and Windows compilers.)

However, you can also include SWIG interface (.i) files in the list; the `build_ext` command knows how to deal with SWIG extensions: it will run SWIG on the interface file and compile the resulting C/C++ file into your extension.

**SWIG support is rough around the edges and largely untested!**

This warning notwithstanding, options to SWIG can be currently passed like this:

```python
setup(...,
    ext_modules=[Extension('_foo', ['foo.i'],
                              swig_opts=['-modern', '-I../include'],
                              py_modules=['foo'],
                          )],
    py_modules=['foo'],
)
```

Or on the commandline like this:

```bash
> python setup.py build_ext --swig-opts="-modern -I../include"
```

On some platforms, you can include non-source files that are processed by the compiler and included in your extension. Currently, this just means Windows message text (.mc) files and resource definition (.rc) files for Visual C++. These will be compiled to binary resource (.res) files and linked into the executable.

**Preprocessor options**

Three optional arguments to `Extension` will help if you need to specify include directories to search or preprocessor macros to define/undefine: `include_dirs`, `define_macros`, and `undef_macros`. 
For example, if your extension requires header files in the `include` directory under your distribution root, use the `include_dirs` option:

```python
Extension('foo', ['foo.c'], include_dirs=['include'])
```

You can specify absolute directories there; if you know that your extension will only be built on Unix systems with X11R6 installed to `/usr`, you can get away with

```python
Extension('foo', ['foo.c'], include_dirs=['/usr/include/X11'])
```

You should avoid this sort of non-portable usage if you plan to distribute your code: it's probably better to write C code like

```c
#include <X11/Xlib.h>
```

If you need to include header files from some other Python extension, you can take advantage of the fact that header files are installed in a consistent way by the Distutils `install_header` command. For example, the Numerical Python header files are installed (on a standard Unix installation) to `/usr/local/include/python1.5/Numerical`. (The exact location will differ according to your platform and Python installation.) Since the Python include directory—`/usr/local/include/python1.5` in this case—is always included in the search path when building Python extensions, the best approach is to write C code like

```c
#include <Numerical/arrayobject.h>
```

If you must put the `Numerical` include directory right into your header search path, though, you can find that directory using the Distutils `distutils.sysconfig` module:

```python
from distutils.sysconfig import get_python_inc
ingcdir = os.path.join(get_python_inc(plat_specific=1), 'Numeric
```
setup(...,
    Extension(..., include_dirs=[incdir]),
)

Even though this is quite portable—it will work on any Python installation, regardless of platform—it’s probably easier to just write your C code in the sensible way.

You can define and undefine pre-processor macros with the define_macros and undef_macros options. define_macros takes a list of (name, value) tuples, where name is the name of the macro to define (a string) and value is its value: either a string or None. (Defining a macro FOO to None is the equivalent of a bare #define FOO in your C source: with most compilers, this sets FOO to the string 1.) undef_macros is just a list of macros to undefine.

For example:

```python
Extension(...,
    define_macros=[[('NDEBUG', '1'),
                   ('HAVE_STRFTIME', None)],
    undef_macros=['HAVE_FOO', 'HAVE_BAR'])
```

is the equivalent of having this at the top of every C source file:

```c
#define NDEBUG 1
#define HAVE_STRFTIME
#undef HAVE_FOO
#undef HAVE_BAR
```

Library options

You can also specify the libraries to link against when building your extension, and the directories to search for those libraries. The libraries option is a list of libraries to link against, library_dirs is a list of directories to search for libraries at link-time, and
**runtime_library_dirs** is a list of directories to search for shared (dynamically loaded) libraries at run-time.

For example, if you need to link against libraries known to be in the standard library search path on target systems

```
Extension(...,
    libraries=['gdbm', 'readline'])
```

If you need to link with libraries in a non-standard location, you'll have to include the location in **library_dirs**:

```
Extension(...,
    library_dirs=['/usr/X11R6/lib'],
    libraries=['X11', 'Xt'])
```

(Again, this sort of non-portable construct should be avoided if you intend to distribute your code.)

** Should mention clib libraries here or somewhere else! **

### Other options

There are still some other options which can be used to handle special cases.

The **extra_objects** option is a list of object files to be passed to the linker. These files must not have extensions, as the default extension for the compiler is used.

**extra_compile_args** and **extra_link_args** can be used to specify additional command line options for the respective compiler and linker command lines.

**export_symbols** is only useful on Windows. It can contain a list of symbols (functions or variables) to be exported. This option is not needed when building compiled extensions: Distutils will
automatically add `initmodule` to the list of exported symbols.
Relationships between Distributions and Packages

A distribution may relate to packages in three specific ways:

1. It can require packages or modules.
2. It can provide packages or modules.
3. It can obsolete packages or modules.

These relationships can be specified using keyword arguments to the `distutils.core.setup()` function.

Dependencies on other Python modules and packages can be specified by supplying the `requires` keyword argument to `setup()`. The value must be a list of strings. Each string specifies a package that is required, and optionally what versions are sufficient.

To specify that any version of a module or package is required, the string should consist entirely of the module or package name. Examples include `mymodule` and `xml.parsers.expat`.

If specific versions are required, a sequence of qualifiers can be supplied in parentheses. Each qualifier may consist of a comparison operator and a version number. The accepted comparison operators are:

```
<  >  ==
<=  >=  !=
```

These can be combined by using multiple qualifiers separated by commas (and optional whitespace). In this case, all of the qualifiers must be matched; a logical AND is used to combine the evaluations.

Let's look at a bunch of examples:
Now that we can specify dependencies, we also need to be able to specify what we provide that other distributions can require. This is done using the **provides** keyword argument to `setup()`. The value for this keyword is a list of strings, each of which names a Python module or package, and optionally identifies the version. If the version is not specified, it is assumed to match that of the distribution.

Some examples:

<table>
<thead>
<tr>
<th>Provides Expression</th>
<th>Explanation</th>
</tr>
</thead>
<tbody>
<tr>
<td>mypkg</td>
<td>Provide <code>mypkg</code>, using the distribution version</td>
</tr>
<tr>
<td>mypkg (1.1)</td>
<td>Provide <code>mypkg</code> version 1.1, regardless of the distribution version</td>
</tr>
</tbody>
</table>

A package can declare that it obsoletes other packages using the **obsoletes** keyword argument. The value for this is similar to that of the **requires** keyword: a list of strings giving module or package specifiers. Each specifier consists of a module or package name optionally followed by one or more version qualifiers. Version qualifiers are given in parentheses after the module or package name.

The versions identified by the qualifiers are those that are obsoleted by the distribution being described. If no qualifiers are given, all versions of the named module or package are understood to be obsoleted.
Installing Scripts

So far we have been dealing with pure and non-pure Python modules, which are usually not run by themselves but imported by scripts.

Scripts are files containing Python source code, intended to be started from the command line. Scripts don't require Distutils to do anything very complicated. The only clever feature is that if the first line of the script starts with `#!` and contains the word “python”, the Distutils will adjust the first line to refer to the current interpreter location. By default, it is replaced with the current interpreter location. The `--executable` (or `-e`) option will allow the interpreter path to be explicitly overridden.

The `scripts` option simply is a list of files to be handled in this way. From the PyXML setup script:

```python
setup(...,
    scripts=['scripts/xmlproc_parse', 'scripts/xmlproc_val']
)```
Installing Package Data

Often, additional files need to be installed into a package. These files are often data that’s closely related to the package’s implementation, or text files containing documentation that might be of interest to programmers using the package. These files are called *package data*.

Package data can be added to packages using the `package_data` keyword argument to the `setup()` function. The value must be a mapping from package name to a list of relative path names that should be copied into the package. The paths are interpreted as relative to the directory containing the package (information from the `package_dir` mapping is used if appropriate); that is, the files are expected to be part of the package in the source directories. They may contain glob patterns as well.

The path names may contain directory portions; any necessary directories will be created in the installation.

For example, if a package should contain a subdirectory with several data files, the files can be arranged like this in the source tree:

```bash
setup.py
src/
    mypkg/
        __init__.py
        module.py
        data/
            tables.dat
            spoons.dat
            forks.dat
```

The corresponding call to `setup()` might be:

```python
setup(..., 
```
New in version 2.4.
Installing Additional Files

The `data_files` option can be used to specify additional files needed by the module distribution: configuration files, message catalogs, data files, anything which doesn’t fit in the previous categories.

`data_files` specifies a sequence of `(directory, files)` pairs in the following way:

```python
setup(...,
    data_files=[('bitmaps', ['bm/b1.gif', 'bm/b2.gif']),
                ('config', ['cfg/data.cfg']),
                ('/etc/init.d', ['init-script'])]
)
```

Note that you can specify the directory names where the data files will be installed, but you cannot rename the data files themselves.

Each `(directory, files)` pair in the sequence specifies the installation directory and the files to install there. If `directory` is a relative path, it is interpreted relative to the installation prefix (Python's `sys.prefix` for pure-Python packages, `sys.exec_prefix` for packages that contain extension modules). Each file name in `files` is interpreted relative to the `setup.py` script at the top of the package source distribution. No directory information from `files` is used to determine the final location of the installed file; only the name of the file is used.

You can specify the `data_files` options as a simple sequence of files without specifying a target directory, but this is not recommended, and the `install` command will print a warning in this case. To install data files directly in the target directory, an empty string should be given as the directory.
The setup script may include additional meta-data beyond the name and version. This information includes:

<table>
<thead>
<tr>
<th>Meta-Data</th>
<th>Description</th>
<th>Value</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>name</td>
<td>name of the package</td>
<td>short string</td>
<td>(1)</td>
</tr>
<tr>
<td>version</td>
<td>version of this release</td>
<td>short string</td>
<td>(1)(2)</td>
</tr>
<tr>
<td>author</td>
<td>package author’s name</td>
<td>short string</td>
<td>(3)</td>
</tr>
<tr>
<td>author_email</td>
<td>email address of the package author</td>
<td>email address</td>
<td>(3)</td>
</tr>
<tr>
<td>maintainer</td>
<td>package maintainer’s name</td>
<td>short string</td>
<td>(3)</td>
</tr>
<tr>
<td>maintainer_email</td>
<td>email address of the package maintainer</td>
<td>email address</td>
<td>(3)</td>
</tr>
<tr>
<td>url</td>
<td>home page for the package</td>
<td>URL</td>
<td>(1)</td>
</tr>
<tr>
<td>description</td>
<td>short, summary description of the package</td>
<td>short string</td>
<td></td>
</tr>
<tr>
<td>long_description</td>
<td>longer description of the package</td>
<td>long string</td>
<td></td>
</tr>
<tr>
<td>download_url</td>
<td>location where the package may be</td>
<td>URL</td>
<td>(4)</td>
</tr>
<tr>
<td>classifiers</td>
<td>a list of classifiers</td>
<td>list of strings</td>
<td>(4)</td>
</tr>
</tbody>
</table>

Notes:

1. These fields are required.
2. It is recommended that versions take the form `major.minor[.patch[.sub]]`.
3. Either the author or the maintainer must be identified.
4. These fields should not be used if your package is to be compatible with Python versions prior to 2.2.3 or 2.3. The list is available from the PyPI website.

'short string'
A single line of text, not more than 200 characters.

'long string'
Multiple lines of plain text in reStructuredText format (see http://docutils.sf.net/).

'list of strings'
See below.

None of the string values may be Unicode.

Encoding the version information is an art in itself. Python packages generally adhere to the version format `major.minor[.patch][sub]`. The major number is 0 for initial, experimental releases of software. It is incremented for releases that represent major milestones in a package. The minor number is incremented when important new features are added to the package. The patch number increments when bug-fix releases are made. Additional trailing version information is sometimes used to indicate sub-releases. These are “a1,a2,...,aN” (for alpha releases, where functionality and API may change), “b1,b2,...,bN” (for beta releases, which only fix bugs) and “pr1,pr2,...,prN” (for final pre-release release testing). Some examples:

0.1.0
the first, experimental release of a package

1.0.1a2
the second alpha release of the first patch version of 1.0

classifiers are specified in a python list:
If you wish to include classifiers in your `setup.py` file and also wish to remain backwards-compatible with Python releases prior to 2.2.3, then you can include the following code fragment in your `setup.py` before the `setup()` call.

```python
# patch distutils if it can't cope with the "classifiers" or
# "download_url" keywords
from sys import version
if version < '2.2.3':
    from distutils.dist import DistributionMetadata
    DistributionMetadata.classifiers = None
    DistributionMetadata.download_url = None
```
Debugging the setup script

Sometimes things go wrong, and the setup script doesn't do what the developer wants.

Distutils catches any exceptions when running the setup script, and print a simple error message before the script is terminated. The motivation for this behaviour is to not confuse administrators who don't know much about Python and are trying to install a package. If they get a big long traceback from deep inside the guts of Distutils, they may think the package or the Python installation is broken because they don't read all the way down to the bottom and see that it's a permission problem.

On the other hand, this doesn't help the developer to find the cause of the failure. For this purpose, the DISTUTILS_DEBUG environment variable can be set to anything except an empty string, and distutils will now print detailed information what it is doing, and prints the full traceback in case an exception occurs.
Writing the Setup Configuration File

Often, it’s not possible to write down everything needed to build a distribution *a priori*: you may need to get some information from the user, or from the user’s system, in order to proceed. As long as that information is fairly simple—a list of directories to search for C header files or libraries, for example—then providing a configuration file, `setup.cfg`, for users to edit is a cheap and easy way to solicit it. Configuration files also let you provide default values for any command option, which the installer can then override either on the command-line or by editing the config file.

The setup configuration file is a useful middle-ground between the setup script—which, ideally, would be opaque to installers [1]—and the command-line to the setup script, which is outside of your control and entirely up to the installer. In fact, `setup.cfg` (and any other Distutils configuration files present on the target system) are processed after the contents of the setup script, but before the command-line. This has several useful consequences:

- installers can override some of what you put in `setup.py` by editing `setup.cfg`
- you can provide non-standard defaults for options that are not easily set in `setup.py`
- installers can override anything in `setup.cfg` using the command-line options to `setup.py`

The basic syntax of the configuration file is simple:

```plaintext
[command]
option=value
...
```

where `command` is one of the Distutils commands (e.g. `build_py`,

[1]: Footnote reference
install), and option is one of the options that command supports. Any number of options can be supplied for each command, and any number of command sections can be included in the file. Blank lines are ignored, as are comments, which run from a '#' character until the end of the line. Long option values can be split across multiple lines simply by indenting the continuation lines.

You can find out the list of options supported by a particular command with the universal --help option, e.g.

```bash
> python setup.py --help build_ext
[...]
Options for 'build_ext' command:
  --build-lib (-b) directory for compiled extension modules
  --build-temp (-t) directory for temporary files (build by-
  --inplace (-i) ignore build-lib and put compiled extens
  --include-dirs (-I) list of directories to search for header
  --define (-D) C preprocessor macros to define
  --undef (-U) C preprocessor macros to undefine
  --swig-opts list of SWIG command line options
[...]
```

Note that an option spelled --foo-bar on the command-line is spelled foo_bar in configuration files.

For example, say you want your extensions to be built “in-place”—that is, you have an extension pkg.ext, and you want the compiled extension file (ext.so on Unix, say) to be put in the same source directory as your pure Python modules pkg.mod1 and pkg.mod2. You can always use the --inplace option on the command-line to ensure this:

```bash
python setup.py build_ext --inplace
```

But this requires that you always specify the build_ext command explicitly, and remember to provide --inplace. An easier way is to “set
and forget" this option, by encoding it in `setup.cfg`, the configuration file for this distribution:

```
[build_ext]
inplace=1
```

This will affect all builds of this module distribution, whether or not you explicitly specify `build_ext`. If you include `setup.cfg` in your source distribution, it will also affect end-user builds—which is probably a bad idea for this option, since always building extensions in-place would break installation of the module distribution. In certain peculiar cases, though, modules are built right in their installation directory, so this is conceivably a useful ability. (Distributing extensions that expect to be built in their installation directory is almost always a bad idea, though.)

Another example: certain commands take a lot of options that don’t change from run to run; for example, `bdist_rpm` needs to know everything required to generate a “spec” file for creating an RPM distribution. Some of this information comes from the setup script, and some is automatically generated by the Distutils (such as the list of files installed). But some of it has to be supplied as options to `bdist_rpm`, which would be very tedious to do on the command-line for every run. Hence, here is a snippet from the Distutils' own `setup.cfg`:

```
[bdist_rpm]
release = 1
packager = Greg Ward <gward@python.net>
doc_files = CHANGES.txt
        README.txt
        USAGE.txt
        doc/
        examples/
```

Note that the `doc_files` option is simply a whitespace-separated string split across multiple lines for readability.
See also:

Syntax of config files in “Installing Python Modules”

More information on the configuration files is available in the manual for system administrators.

Footnotes

[1] This ideal probably won’t be achieved until auto-configuration is fully supported by the Distutils.
Creating a Source Distribution

As shown in section *A Simple Example*, you use the *sdist* command to create a source distribution. In the simplest case,

```
python setup.py sdist
```

(assuming you haven’t specified any *sdist* options in the setup script or config file), *sdist* creates the archive of the default format for the current platform. The default format is a gzip’ed tar file (*.tar.gz*) on Unix, and ZIP file on Windows.

You can specify as many formats as you like using the `--formats` option, for example:

```
python setup.py sdist --formats=gztar,zip
```

to create a gzipped tarball and a zip file. The available formats are:

<table>
<thead>
<tr>
<th>Format</th>
<th>Description</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>zip</td>
<td>zip file (<em>.zip</em>)</td>
<td>(1),(3)</td>
</tr>
<tr>
<td>gztar</td>
<td>gzip’ed tar file (<em>.tar.gz</em>)</td>
<td>(2),(4)</td>
</tr>
<tr>
<td>bztar</td>
<td>bzip2’ed tar file (<em>.tar.bz2</em>)</td>
<td>(4)</td>
</tr>
<tr>
<td>ztar</td>
<td>compressed tar file (<em>.tar.z</em>)</td>
<td>(4)</td>
</tr>
<tr>
<td>tar</td>
<td>tar file (<em>.tar</em>)</td>
<td>(4)</td>
</tr>
</tbody>
</table>

Notes:

1. default on Windows
2. default on Unix
3. requires either external *zip* utility or *zipfile* module (part of the standard Python library since Python 1.6)
4. requires external utilities: *tar* and possibly one of *gzip*, *bzip2*, or *compress*
Specifying the files to distribute

If you don't supply an explicit list of files (or instructions on how to generate one), the **sdist** command puts a minimal default set into the source distribution:

- all Python source files implied by the *py_modules* and *packages* options
- all C source files mentioned in the *ext_modules* or *libraries* options (``
  ** getting C library sources currently broken—no get_source_files() method in build_clib.py!**``)
- scripts identified by the *scripts* option
- anything that looks like a test script: *test/test*.py (currently, the Distutils don't do anything with test scripts except include them in source distributions, but in the future there will be a standard for testing Python module distributions)
- *README.txt* (or *README*), *setup.py* (or whatever you called your setup script), and *setup.cfg*

Sometimes this is enough, but usually you will want to specify additional files to distribute. The typical way to do this is to write a *manifest template*, called *MANIFEST.in* by default. The manifest template is just a list of instructions for how to generate your manifest file, *MANIFEST*, which is the exact list of files to include in your source distribution. The **sdist** command processes this template and generates a manifest based on its instructions and what it finds in the filesystem.
If you prefer to roll your own manifest file, the format is simple: one filename per line, regular files (or symlinks to them) only. If you do supply your own MANIFEST, you must specify everything: the default set of files described above does not apply in this case.

The manifest template has one command per line, where each command specifies a set of files to include or exclude from the source distribution. For an example, again we turn to the Distutils' own manifest template:

```
include *.txt
recursive-includes examples *.txt *.py
prune examples/sample?/build
```

The meanings should be fairly clear: include all files in the distribution root matching *.txt, all files anywhere under the examples directory matching *.txt or *.py, and exclude all directories matching examples/sample?/build. All of this is done after the standard include set, so you can exclude files from the standard set with explicit instructions in the manifest template. (Or, you can use the --no-defaults option to disable the standard set entirely.) There are several other commands available in the manifest template mini-language; see section *Creating a source distribution: the sdist command.*

The order of commands in the manifest template matters: initially, we have the list of default files as described above, and each command in the template adds to or removes from that list of files. Once we have fully processed the manifest template, we remove files that should not be included in the source distribution:

- all files in the Distutils "build" tree (default build/)
- all files in directories named RCS, CVS, .svn, .hg, .git, .bzr or ._darcs
Now we have our complete list of files, which is written to the manifest for future reference, and then used to build the source distribution archive(s).

You can disable the default set of included files with the --no-defaults option, and you can disable the standard exclude set with --no-prune.

Following the Distutils' own manifest template, let's trace how the sdist command builds the list of files to include in the Distutils source distribution:

1. include all Python source files in the distutils and distutils/command subdirectories (because packages corresponding to those two directories were mentioned in the packages option in the setup script—see section Writing the Setup Script)
2. include README.txt, setup.py, and setup.cfg (standard files)
3. include test/test*.py (standard files)
4. include *.txt in the distribution root (this will find README.txt a second time, but such redundancies are weeded out later)
5. include anything matching *.txt or *.py in the sub-tree under examples,
6. exclude all files in the sub-trees starting at directories matching examples/sample?/build—this may exclude files included by the previous two steps, so it's important that the prune command in the manifest template comes after the recursive-include command
7. exclude the entire build tree, and any RCS, CVS, .svn, .hg, .git, .bzr and _darcs directories

Just like in the setup script, file and directory names in the manifest template should always be slash-separated; the Distutils will take care of converting them to the standard representation on your
platform. That way, the manifest template is portable across operating systems.
Manifest-related options

The normal course of operations for the `sdist` command is as follows:

- If the manifest file, `MANIFEST` doesn’t exist, read `MANIFEST.in` and create the manifest.
- If neither `MANIFEST` nor `MANIFEST.in` exist, create a manifest with just the default file set.
- If either `MANIFEST.in` or the setup script (`setup.py`) are more recent than `MANIFEST`, recreate `MANIFEST` by reading `MANIFEST.in`.
- Use the list of files now in `MANIFEST` (either just generated or read in) to create the source distribution archive(s).

There are a couple of options that modify this behaviour. First, use the `--no-defaults` and `--no-prune` to disable the standard “include” and “exclude” sets.

Second, you might want to force the manifest to be regenerated—for example, if you have added or removed files or directories that match an existing pattern in the manifest template, you should regenerate the manifest:

```python
python setup.py sdist --force-manifest
```

Or, you might just want to (re)generate the manifest, but not create a source distribution:

```python
python setup.py sdist --manifest-only
```

`--manifest-only` implies `--force-manifest`. `-o` is a shortcut for `--manifest-only`, and `-f` for `--force-manifest`.
Creating Built Distributions

A “built distribution” is what you’re probably used to thinking of either as a “binary package” or an “installer” (depending on your background). It’s not necessarily binary, though, because it might contain only Python source code and/or byte-code; and we don’t call it a package, because that word is already spoken for in Python. (And “installer” is a term specific to the world of mainstream desktop systems.)

A built distribution is how you make life as easy as possible for installers of your module distribution: for users of RPM-based Linux systems, it’s a binary RPM; for Windows users, it’s an executable installer; for Debian-based Linux users, it’s a Debian package; and so forth. Obviously, no one person will be able to create built distributions for every platform under the sun, so the Distutils are designed to enable module developers to concentrate on their specialty—writing code and creating source distributions—while an intermediary species called packagers springs up to turn source distributions into built distributions for as many platforms as there are packagers.

Of course, the module developer could be his own packager; or the packager could be a volunteer “out there” somewhere who has access to a platform which the original developer does not; or it could be software periodically grabbing new source distributions and turning them into built distributions for as many platforms as the software has access to. Regardless of who they are, a packager uses the setup script and the **bdist** command family to generate built distributions.

As a simple example, if I run the following command in the Distutils source tree:
then the Distutils builds my module distribution (the Distutils itself in this case), does a “fake” installation (also in the build directory), and creates the default type of built distribution for my platform. The default format for built distributions is a “dumb” tar file on Unix, and a simple executable installer on Windows. (That tar file is considered “dumb” because it has to be unpacked in a specific location to work.)

Thus, the above command on a Unix system creates Distutils-1.0.plat.tar.gz; unpacking this tarball from the right place installs the Distutils just as though you had downloaded the source distribution and run python setup.py install. (The “right place” is either the root of the filesystem or Python’s prefix directory, depending on the options given to the bdist_dumb command; the default is to make dumb distributions relative to prefix.)

Obviously, for pure Python distributions, this isn’t any simpler than just running python setup.py install—but for non-pure distributions, which include extensions that would need to be compiled, it can mean the difference between someone being able to use your extensions or not. And creating “smart” built distributions, such as an RPM package or an executable installer for Windows, is far more convenient for users even if your distribution doesn’t include any extensions.

The bdist command has a --formats option, similar to the sdist command, which you can use to select the types of built distribution to generate: for example,

```
python setup.py bdist --format=zip
```

would, when run on a Unix system, create Distutils-1.0.plat.zip—again, this archive would be unpacked from the root directory to
install the Distutils.

The available formats for built distributions are:

<table>
<thead>
<tr>
<th>Format</th>
<th>Description</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>gztar</td>
<td>gzipped tar file (.tar.gz)</td>
<td>(1),(3)</td>
</tr>
<tr>
<td>ztar</td>
<td>compressed tar file (.tar.z)</td>
<td>(3)</td>
</tr>
<tr>
<td>tar</td>
<td>tar file (.tar)</td>
<td>(3)</td>
</tr>
<tr>
<td>zip</td>
<td>zip file (.zip)</td>
<td>(4)</td>
</tr>
<tr>
<td>rpm</td>
<td>RPM</td>
<td>(5)</td>
</tr>
<tr>
<td>pkgtool</td>
<td>Solaris pkgtool</td>
<td></td>
</tr>
<tr>
<td>sdux</td>
<td>HP-UX swinstall</td>
<td></td>
</tr>
<tr>
<td>rpm</td>
<td>RPM</td>
<td>(5)</td>
</tr>
<tr>
<td>wininst</td>
<td>self-extracting ZIP file for Windows</td>
<td>(2),(4)</td>
</tr>
</tbody>
</table>

Notes:

1. default on Unix

2. default on Windows

** to-do! **

3. requires external utilities: tar and possibly one of gzip, bzip2, or compress

4. requires either external zip utility or zipfile module (part of the standard Python library since Python 1.6)

5. requires external rpm utility, version 3.0.4 or better (use rpm --version to find out which version you have)

You don’t have to use the bdist command with the --formats option; you can also use the command that directly implements the format
you’re interested in. Some of these `bdist` “sub-commands” actually generate several similar formats; for instance, the `bdist_dumb` command generates all the “dumb” archive formats (`tar`, `ztar`, `gztar`, and `zip`), and `bdist_rpm` generates both binary and source RPMs. The `bdist` sub-commands, and the formats generated by each, are:

<table>
<thead>
<tr>
<th>Command</th>
<th>Formats</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>bdist_dumb</code></td>
<td><code>tar</code>, <code>ztar</code>, <code>gztar</code>, <code>zip</code></td>
</tr>
<tr>
<td><code>bdist_rpm</code></td>
<td><code>rpm</code>, <code>srpm</code></td>
</tr>
<tr>
<td><code>bdist_wininst</code></td>
<td><code>wininst</code></td>
</tr>
</tbody>
</table>

The following sections give details on the individual `bdist_*` commands.
Creating dumb built distributions

** Need to document absolute vs. prefix-relative packages here, but first I have to implement it! **
Creating RPM packages

The RPM format is used by many popular Linux distributions, including Red Hat, SuSE, and Mandrake. If one of these (or any of the other RPM-based Linux distributions) is your usual environment, creating RPM packages for other users of that same distribution is trivial. Depending on the complexity of your module distribution and differences between Linux distributions, you may also be able to create RPMs that work on different RPM-based distributions.

The usual way to create an RPM of your module distribution is to run the `bdist_rpm` command:

```
python setup.py bdist_rpm
```

or the `bdist` command with the `--format` option:

```
python setup.py bdist --formats=rpm
```

The former allows you to specify RPM-specific options; the latter allows you to easily specify multiple formats in one run. If you need to do both, you can explicitly specify multiple `bdist_*` commands and their options:

```
python setup.py bdist_rpm --packager="John Doe <jdoe@example.org>
bdist_wininst --target_version="2.0"
```

Creating RPM packages is driven by a `.spec` file, much as using the Distutils is driven by the setup script. To make your life easier, the `bdist_rpm` command normally creates a `.spec` file based on the information you supply in the setup script, on the command line, and in any Distutils configuration files. Various options and sections in the `.spec` file are derived from options in the setup script as follows:
<table>
<thead>
<tr>
<th>RPM .spec file option or section</th>
<th>Distutils setup script option</th>
</tr>
</thead>
<tbody>
<tr>
<td>Name</td>
<td>name</td>
</tr>
<tr>
<td>Summary (in preamble)</td>
<td>description</td>
</tr>
<tr>
<td>Version</td>
<td>version</td>
</tr>
<tr>
<td>Vendor</td>
<td>author and author_email, or — &amp; maintainer and maintainer_email</td>
</tr>
<tr>
<td>Copyright</td>
<td>license</td>
</tr>
<tr>
<td>Url</td>
<td>url</td>
</tr>
<tr>
<td>%description (section)</td>
<td>long_description</td>
</tr>
</tbody>
</table>

Additionally, there are many options in .spec files that don’t have corresponding options in the setup script. Most of these are handled through options to the bdist_rpm command as follows:

<table>
<thead>
<tr>
<th>RPM .spec file option or section</th>
<th>bdist_rpm option</th>
<th>default value</th>
</tr>
</thead>
<tbody>
<tr>
<td>Release</td>
<td>release</td>
<td>“1”</td>
</tr>
<tr>
<td>Group</td>
<td>group</td>
<td>“Development/Libraries”</td>
</tr>
<tr>
<td>Vendor</td>
<td>vendor</td>
<td>(see above)</td>
</tr>
<tr>
<td>Packager</td>
<td>packager</td>
<td>(none)</td>
</tr>
<tr>
<td>Provides</td>
<td>provides</td>
<td>(none)</td>
</tr>
<tr>
<td>Requires</td>
<td>requires</td>
<td>(none)</td>
</tr>
<tr>
<td>Conflicts</td>
<td>conflicts</td>
<td>(none)</td>
</tr>
<tr>
<td>Obsoletes</td>
<td>obsoletes</td>
<td>(none)</td>
</tr>
<tr>
<td>Distribution</td>
<td>distribution_name</td>
<td>(none)</td>
</tr>
<tr>
<td>BuildRequires</td>
<td>build_requires</td>
<td>(none)</td>
</tr>
<tr>
<td>Icon</td>
<td>icon</td>
<td>(none)</td>
</tr>
</tbody>
</table>

Obviously, supplying even a few of these options on the command-line would be tedious and error-prone, so it’s usually best to put them in the setup configuration file, setup.cfg—see section Writing the Setup Configuration File. If you distribute or package many Python
module distributions, you might want to put options that apply to all of them in your personal Distutils configuration file (~/.pydistutils.cfg).

There are three steps to building a binary RPM package, all of which are handled automatically by the Distutils:

1. create a .spec file, which describes the package (analogous to the Distutils setup script; in fact, much of the information in the setup script winds up in the .spec file)
2. create the source RPM
3. create the “binary” RPM (which may or may not contain binary code, depending on whether your module distribution contains Python extensions)

Normally, RPM bundles the last two steps together; when you use the Distutils, all three steps are typically bundled together.

If you wish, you can separate these three steps. You can use the --spec-only option to make bdist_rpm just create the .spec file and exit; in this case, the .spec file will be written to the “distribution directory”—normally dist/, but customizable with the --dist-dir option. (Normally, the .spec file winds up deep in the “build tree,” in a temporary directory created by bdist_rpm.)
Creating Windows Installers

Executable installers are the natural format for binary distributions on Windows. They display a nice graphical user interface, display some information about the module distribution to be installed taken from the metadata in the setup script, let the user select a few options, and start or cancel the installation.

Since the metadata is taken from the setup script, creating Windows installers is usually as easy as running:

```
python setup.py bdist_wininst
```

or the `bdist` command with the `--formats` option:

```
python setup.py bdist --formats=wininst
```

If you have a pure module distribution (only containing pure Python modules and packages), the resulting installer will be version independent and have a name like `foo-1.0.win32.exe`. These installers can even be created on Unix platforms or Mac OS X.

If you have a non-pure distribution, the extensions can only be created on a Windows platform, and will be Python version dependent. The installer filename will reflect this and now has the form `foo-1.0.win32-py2.0.exe`. You have to create a separate installer for every Python version you want to support.

The installer will try to compile pure modules into bytecode after installation on the target system in normal and optimizing mode. If you don’t want this to happen for some reason, you can run the `bdist_wininst` command with the `--no-target-compile` and/or the `--no-target-optimize` option.
By default the installer will display the cool “Python Powered” logo when it is run, but you can also supply your own bitmap which must be a Windows .bmp file with the --bitmap option.

The installer will also display a large title on the desktop background window when it is run, which is constructed from the name of your distribution and the version number. This can be changed to another text by using the --title option.

The installer file will be written to the “distribution directory” — normally dist/, but customizable with the --dist-dir option.
Cross-compiling on Windows

Starting with Python 2.6, distutils is capable of cross-compiling between Windows platforms. In practice, this means that with the correct tools installed, you can use a 32bit version of Windows to create 64bit extensions and vice-versa.

To build for an alternate platform, specify the --plat-name option to the build command. Valid values are currently ‘win32’, ‘win-amd64’ and ‘win-ia64’. For example, on a 32bit version of Windows, you could execute:

```
python setup.py build --plat-name=win-amd64
```

to build a 64bit version of your extension. The Windows Installers also support this option, so the command:

```
python setup.py build --plat-name=win-amd64 bdist_wininst
```

would create a 64bit installation executable on your 32bit version of Windows.

To cross-compile, you must download the Python source code and cross-compile Python itself for the platform you are targetting - it is not possible from a binary installtion of Python (as the .lib etc file for other platforms are not included.) In practice, this means the user of a 32 bit operating system will need to use Visual Studio 2008 to open the PCBuild/PCbuild.sln solution in the Python source tree and build the “x64” configuration of the ‘pythoncore’ project before cross-compiling extensions is possible.

Note that by default, Visual Studio 2008 does not install 64bit compilers or tools. You may need to reexecute the Visual Studio setup process and select these tools (using Control Panel->
The Postinstallation script

Starting with Python 2.3, a postinstallation script can be specified which the `--install-script` option. The basename of the script must be specified, and the script filename must also be listed in the scripts argument to the setup function.

This script will be run at installation time on the target system after all the files have been copied, with `argv[1]` set to `-install`, and again at uninstallation time before the files are removed with `argv[1]` set to `-remove`.

The installation script runs embedded in the windows installer, every output (`sys.stdout`, `sys.stderr`) is redirected into a buffer and will be displayed in the GUI after the script has finished.

Some functions especially useful in this context are available as additional built-in functions in the installation script.

`directory_created(path)`
`file_created(path)`

These functions should be called when a directory or file is created by the postinstall script at installation time. It will register `path` with the uninstaller, so that it will be removed when the distribution is uninstalled. To be safe, directories are only removed if they are empty.

`get_special_folder_path(csidl_string)`

This function can be used to retrieve special folder locations on Windows like the Start Menu or the Desktop. It returns the full path to the folder. `csidl_string` must be one of the following strings:
If the folder cannot be retrieved, OSError is raised.

Which folders are available depends on the exact Windows version, and probably also the configuration. For details refer to Microsoft’s documentation of the SHGetSpecialFolderPath function.
Vista User Access Control (UAC)

Starting with Python 2.6, bdist_wininst supports a --user-access-control option. The default is 'none' (meaning no UAC handling is done), and other valid values are 'auto' (meaning prompt for UAC elevation if Python was installed for all users) and 'force' (meaning always prompt for elevation)

```python
create_shortcut(target, description, filename[, arguments[, workdir[, iconpath[, iconindex]]]])
```

This function creates a shortcut. `target` is the path to the program to be started by the shortcut. `description` is the description of the shortcut. `filename` is the title of the shortcut that the user will see. `arguments` specifies the command line arguments, if any. `workdir` is the working directory for the program. `iconpath` is the file containing the icon for the shortcut, and `iconindex` is the index of the icon in the file `iconpath`. Again, for details consult the Microsoft documentation for the IShellLink interface.
Registering with the Package Index

The Python Package Index (PyPI) holds meta-data describing distributions packaged with distutils. The distutils command `register` is used to submit your distribution’s meta-data to the index. It is invoked as follows:

```
python setup.py register
```

Distutils will respond with the following prompt:

```
running register
We need to know who you are, so please choose either:
1. use your existing login,
2. register as a new user,
3. have the server generate a new password for you (and email it to you), or
4. quit
Your selection [default 1]:
```

Note: if your username and password are saved locally, you will not see this menu.

If you have not registered with PyPI, then you will need to do so now. You should choose option 2, and enter your details as required. Soon after submitting your details, you will receive an email which will be used to confirm your registration.

Once you are registered, you may choose option 1 from the menu. You will be prompted for your PyPI username and password, and `register` will then submit your meta-data to the index.

You may submit any number of versions of your distribution to the index. If you alter the meta-data for a particular version, you may submit it again and the index will be updated.

PyPI holds a record for each (name, version) combination submitted.
The first user to submit information for a given name is designated the Owner of that name. They may submit changes through the register command or through the web interface. They may also designate other users as Owners or Maintainers. Maintainers may edit the package information, but not designate other Owners or Maintainers.

By default PyPI will list all versions of a given package. To hide certain versions, the Hidden property should be set to yes. This must be edited through the web interface.
The .pypirc file

The format of the .pypirc file is as follows:

```
[distutils]
index-servers =
    pypi

[pypi]
repository: <repository-url>
username: <username>
password: <password>
```

repository can be omitted and defaults to http://www.python.org/pypi.

If you want to define another server a new section can be created:

```
[distutils]
index-servers =
    pypi
    other

[pypi]
repository: <repository-url>
username: <username>
password: <password>

[other]
repository: http://example.com/pypi
username: <username>
password: <password>
```

The command can then be called with the -r option:

```
python setup.py register -r http://example.com/pypi
```

Or even with the section name:

```
python setup.py register -r other
```
Uploading Packages to the Package Index

New in version 2.5.

The Python Package Index (PyPI) not only stores the package info, but also the package data if the author of the package wishes to. The distutils command upload pushes the distribution files to PyPI.

The command is invoked immediately after building one or more distribution files. For example, the command

```python
python setup.py sdist bdist_wininst upload
```

will cause the source distribution and the Windows installer to be uploaded to PyPI. Note that these will be uploaded even if they are built using an earlier invocation of `setup.py`, but that only distributions named on the command line for the invocation including the `upload` command are uploaded.

The `upload` command uses the username, password, and repository URL from the `$HOME/.pypirc` file (see section The `.pypirc` file for more on this file).

You can specify another PyPI server with the `--repository=*url*` option:

```python
python setup.py sdist bdist_wininst upload -r http://example.com/pypi
```

See section The `.pypirc` file for more on defining several servers.

You can use the `--sign` option to tell upload to sign each uploaded file using GPG (GNU Privacy Guard). The `gpg` program must be
available for execution on the system PATH. You can also specify which key to use for signing using the \texttt{--identity=*name*} option.

Other \texttt{upload} options include \texttt{--repository=*url*} or \texttt{--repository=*section*} where \texttt{url} is the url of the server and \texttt{section} the name of the section in $\texttt{HOME/.pypirc}$, and \texttt{--show-response} (which displays the full response text from the PyPI server for help in debugging upload problems).
Examples

This chapter provides a number of basic examples to help get started with distutils. Additional information about using distutils can be found in the Distutils Cookbook.

See also:

Distutils Cookbook
Collection of recipes showing how to achieve more control over distutils.
Pure Python distribution (by module)

If you're just distributing a couple of modules, especially if they don't live in a particular package, you can specify them individually using the `py_modules` option in the setup script.

In the simplest case, you'll have two files to worry about: a setup script and the single module you're distributing, `foo.py` in this example:

```
<root>/
    setup.py
    foo.py
```

(In all diagrams in this section, `<root>` will refer to the distribution root directory.) A minimal setup script to describe this situation would be:

```python
from distutils.core import setup
def setup(name='foo',
           version='1.0',
           py_modules=['foo'],
           )
```

Note that the name of the distribution is specified independently with the `name` option, and there's no rule that says it has to be the same as the name of the sole module in the distribution (although that's probably a good convention to follow). However, the distribution name is used to generate filenames, so you should stick to letters, digits, underscores, and hyphens.

Since `py_modules` is a list, you can of course specify multiple modules, eg. if you're distributing modules `foo` and `bar`, your setup might look like this:

```
<root>/
    setup.py
```
and the setup script might be

```python
from distutils.core import setup
go=
setup(name='foobar',
    version='1.0',
    py_modules=['foo', 'bar'],
)
```

You can put module source files into another directory, but if you have enough modules to do that, it’s probably easier to specify modules by package rather than listing them individually.
Pure Python distribution (by package)

If you have more than a couple of modules to distribute, especially if they are in multiple packages, it's probably easier to specify whole packages rather than individual modules. This works even if your modules are not in a package; you can just tell the Distutils to process modules from the root package, and that works the same as any other package (except that you don't have to have an __init__.py file).

The setup script from the last example could also be written as

```python
from distutils.core import setup
setup(name='foobar',
      version='1.0',
      packages=[''],
)
```

(The empty string stands for the root package.)

If those two files are moved into a subdirectory, but remain in the root package, e.g.:

```
<root>/
  setup.py
  src/
      foo.py
      bar.py
```

then you would still specify the root package, but you have to tell the Distutils where source files in the root package live:

```python
from distutils.core import setup
setup(name='foobar',
      version='1.0',
      package_dir={'': 'src'},
      packages=[''],
)``
More typically, though, you will want to distribute multiple modules in the same package (or in sub-packages). For example, if the foo and bar modules belong in package foobar, one way to layout your source tree is

```
<root>/
  setup.py
  foobar/
    __init__.py
    foo.py
    bar.py
```

This is in fact the default layout expected by the Distutils, and the one that requires the least work to describe in your setup script:

```
from distutils.core import setup
setup(name='foobar',
      version='1.0',
      packages=['foobar'],
      )
```

If you want to put modules in directories not named for their package, then you need to use the `package_dir` option again. For example, if the src directory holds modules in the foobar package:

```
<root>/
  setup.py
  src/
    __init__.py
    foo.py
    bar.py
```

an appropriate setup script would be

```
from distutils.core import setup
setup(name='foobar',
      version='1.0',
      package_dir={'foobar': 'src'},
      packages=['foobar'],
      )
```
Or, you might put modules from your main package right in the distribution root:

```
<root>/
    setup.py
    __init__.py
    foo.py
    bar.py
```

in which case your setup script would be

```python
from distutils.core import setup
setup(name='foobar',
      version='1.0',
      package_dir={'foobar': ''},
      packages=['foobar'],
)
```

(The empty string also stands for the current directory.)

If you have sub-packages, they must be explicitly listed in `packages`, but any entries in `package_dir` automatically extend to sub-packages. (In other words, the Distutils does not scan your source tree, trying to figure out which directories correspond to Python packages by looking for `__init__.py` files.) Thus, if the default layout grows a sub-package:

```
<root>/
    setup.py
    foobar/
        __init__.py
        foo.py
        bar.py
        subfoo/
            __init__.py
            blah.py
```

then the corresponding setup script would be

```python
from distutils.core import setup
setup(name='foobar',
      version='1.0',
      package_dir={'foobar': ''},
      packages=['foobar'],
)
```
version='1.0',
packages=['foobar', 'foobar.subfoo'],
)

(Again, the empty string in package_dir stands for the current
directory.)
Extension modules are specified using the `ext_modules` option. `package_dir` has no effect on where extension source files are found; it only affects the source for pure Python modules. The simplest case, a single extension module in a single C source file, is:

```
<root>/
    setup.py
    foo.c
```

If the `foo` extension belongs in the root package, the setup script for this could be:

```python
from distutils.core import setup
from distutils.extension import Extension
setup(name='foobar',
      version='1.0',
      ext_modules=[Extension('foo', ['foo.c'])],
)
```

If the extension actually belongs in a package, say `foopkg`, then

With exactly the same source tree layout, this extension can be put in the `foopkg` package simply by changing the name of the extension:

```python
from distutils.core import setup
from distutils.extension import Extension
setup(name='foobar',
      version='1.0',
      ext_modules=[Extension('foopkg.foo', ['foo.c'])],
)
```
Extending Distutils

Distutils can be extended in various ways. Most extensions take the form of new commands or replacements for existing commands. New commands may be written to support new types of platform-specific packaging, for example, while replacements for existing commands may be made to modify details of how the command operates on a package.

Most extensions of the distutils are made within `setup.py` scripts that want to modify existing commands; many simply add a few file extensions that should be copied into packages in addition to `.py` files as a convenience.

Most distutils command implementations are subclasses of the `Command` class from `distutils.cmd`. New commands may directly inherit from `Command`, while replacements often derive from `Command` indirectly, directly subclassing the command they are replacing. Commands are required to derive from `Command`. 
Integrating new commands

There are different ways to integrate new command implementations into distutils. The most difficult is to lobby for the inclusion of the new features in distutils itself, and wait for (and require) a version of Python that provides that support. This is really hard for many reasons.

The most common, and possibly the most reasonable for most needs, is to include the new implementations with your `setup.py` script, and cause the `distutils.core.setup()` function use them:

```python
from distutils.command.build_py import build_py as _build_py
from distutils.core import setup

class build_py(_build_py):
    """Specialized Python source builder."""

        # implement whatever needs to be different...

setup(cmdclass={'build_py': build_py},
      ...
```

This approach is most valuable if the new implementations must be used to use a particular package, as everyone interested in the package will need to have the new command implementation.

Beginning with Python 2.4, a third option is available, intended to allow new commands to be added which can support existing `setup.py` scripts without requiring modifications to the Python installation. This is expected to allow third-party extensions to provide support for additional packaging systems, but the commands can be used for anything distutils commands can be used for. A new configuration option, `command_packages` (command-line option `--command-packages`), can be used to specify additional packages to be searched for modules implementing commands. Like all distutils
options, this can be specified on the command line or in a configuration file. This option can only be set in the `[global]` section of a configuration file, or before any commands on the command line. If set in a configuration file, it can be overridden from the command line; setting it to an empty string on the command line causes the default to be used. This should never be set in a configuration file provided with a package.

This new option can be used to add any number of packages to the list of packages searched for command implementations; multiple package names should be separated by commas. When not specified, the search is only performed in the `distutils.command` package. When `setup.py` is run with the option `--command-packages distcmds,buildcmds`, however, the packages `distutils.command`, `distcmds`, and `buildcmds` will be searched in that order. New commands are expected to be implemented in modules of the same name as the command by classes sharing the same name. Given the example command line option above, the command `bdist_openpkg` could be implemented by the class `distcmds.bdist_openpkg.bdist_openpkg` or `buildcmds.bdist_openpkg.bdist_openpkg`. 
Adding new distribution types

Commands that create distributions (files in the dist/ directory) need to add (command, filename) pairs to self.distribution.dist_files so that upload can upload it to PyPI. The filename in the pair contains no path information, only the name of the file itself. In dry-run mode, pairs should still be added to represent what would have been created.
Command Reference
Installing modules: the **install** command family

The install command ensures that the build commands have been run and then runs the subcommands **install_lib**, **install_data** and **install_scripts**.

**install_data**

This command installs all data files provided with the distribution.

**install_scripts**

This command installs all (Python) scripts in the distribution.
** Creating a source distribution: the `sdist` command **

The manifest template commands are:

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>include pat1 pat2 ...</code></td>
<td>include all files matching any of the listed patterns</td>
</tr>
<tr>
<td><code>exclude pat1 pat2 ...</code></td>
<td>exclude all files matching any of the listed patterns</td>
</tr>
<tr>
<td><code>recursive-include dir pat1 pat2 ...</code></td>
<td>include all files under <code>dir</code> matching any of the listed patterns</td>
</tr>
<tr>
<td><code>recursive-exclude dir pat1 pat2 ...</code></td>
<td>exclude all files under <code>dir</code> matching any of the listed patterns</td>
</tr>
<tr>
<td><code>global-include pat1 pat2 ...</code></td>
<td>include all files anywhere in the source tree matching — &amp; any of the listed patterns</td>
</tr>
<tr>
<td><code>global-exclude pat1 pat2 ...</code></td>
<td>exclude all files anywhere in the source tree matching — &amp; any of the listed patterns</td>
</tr>
<tr>
<td><code>prune dir</code></td>
<td>exclude all files under <code>dir</code></td>
</tr>
<tr>
<td><code>graft dir</code></td>
<td>include all files under <code>dir</code></td>
</tr>
</tbody>
</table>

The patterns here are Unix-style “glob” patterns: `*` matches any sequence of regular filename characters, `?` matches any single regular filename character, and `[range]` matches any of the characters in `range` (e.g., `a-z`, `a-zA-Z`, `a-f0-9`). The definition of “regular filename character” is platform-specific: on Unix it is anything except slash; on Windows anything except backslash or colon.
** Windows support not there yet **
API Reference
distutils.core — Core Distutils functionality

The distutils.core module is the only module that needs to be installed to use the Distutils. It provides the setup() (which is called from the setup script). Indirectly provides the distutils.dist.Distribution and distutils.cmd.Command class.

distutils.core. setup( arguments )

The basic do-everything function that does most everything you could ever ask for from a Distutils method. See XXXXX

The setup function takes a large number of arguments. These are laid out in the following table.

<table>
<thead>
<tr>
<th>argument name</th>
<th>value</th>
<th>type</th>
</tr>
</thead>
<tbody>
<tr>
<td>name</td>
<td>The name of the package</td>
<td>a string</td>
</tr>
<tr>
<td>version</td>
<td>The version number of the package</td>
<td>See distutils.version</td>
</tr>
<tr>
<td>description</td>
<td>A single line describing the package</td>
<td>a string</td>
</tr>
<tr>
<td>long_description</td>
<td>Longer description of the package</td>
<td>a string</td>
</tr>
<tr>
<td>author</td>
<td>The name of the package author</td>
<td>a string</td>
</tr>
<tr>
<td>author_email</td>
<td>The email address of the package author</td>
<td>a string</td>
</tr>
<tr>
<td><strong>maintainer</strong></td>
<td>The name of the current maintainer, if different from the author</td>
<td>a string</td>
</tr>
<tr>
<td><strong>maintainer_email</strong></td>
<td>The email address of the current maintainer, if different from the author</td>
<td></td>
</tr>
<tr>
<td><strong>url</strong></td>
<td>A URL for the package (homepage)</td>
<td>a URL</td>
</tr>
<tr>
<td><strong>download_url</strong></td>
<td>A URL to download the package</td>
<td>a URL</td>
</tr>
<tr>
<td><strong>packages</strong></td>
<td>A list of Python packages that distutils will manipulate</td>
<td>a list of strings</td>
</tr>
<tr>
<td><strong>py_modules</strong></td>
<td>A list of Python modules that distutils will manipulate</td>
<td>a list of strings</td>
</tr>
<tr>
<td><strong>scripts</strong></td>
<td>A list of standalone script files to be built and installed</td>
<td>a list of strings</td>
</tr>
<tr>
<td><strong>ext_modules</strong></td>
<td>A list of Python extensions to be built</td>
<td>A list of instances of <code>distutils.core.Extension</code></td>
</tr>
<tr>
<td><strong>classifiers</strong></td>
<td>A list of categories for the package</td>
<td>The list of available categorizations <a href="http://pypi.python.org/pypi">http://pypi.python.org/pypi</a>?:action=</td>
</tr>
<tr>
<td>-----------------</td>
<td>-------------------------------------</td>
<td>-------------------------------------------------------------------------------------------------</td>
</tr>
<tr>
<td><strong>distclass</strong></td>
<td>the Distribution class to use</td>
<td>A subclass of distutils.core.Dist</td>
</tr>
<tr>
<td><strong>script_name</strong></td>
<td>The name of the setup.py script - defaults to sys.argv[0]</td>
<td>a string</td>
</tr>
<tr>
<td><strong>script_args</strong></td>
<td>Arguments to supply to the setup script</td>
<td>a list of strings</td>
</tr>
<tr>
<td><strong>options</strong></td>
<td>default options for the setup script</td>
<td>a string</td>
</tr>
<tr>
<td><strong>license</strong></td>
<td>The license for the package</td>
<td></td>
</tr>
<tr>
<td><strong>keywords</strong></td>

<td></td>
<td></td>
</tr>
<tr>
<td><strong>cmdclass</strong></td>
<td>A mapping of command names to Command subclasses</td>
<td>a dictionary</td>
</tr>
</tbody>
</table>

distutils.core.run_setup(script_name[, script_args=None, stop_after='run'])
Run a setup script in a somewhat controlled environment, and return the `distutils.dist.Distribution` instance that drives things. This is useful if you need to find out the distribution metadata (passed as keyword args from `script` to `setup()`), or the contents of the config files or command-line.

`script_name` is a file that will be run with `execfile()` `sys.argv[0]` will be replaced with `script` for the duration of the call. `script_args` is a list of strings; if supplied, `sys.argv[1:]` will be replaced by `script_args` for the duration of the call.

`stop_after` tells `setup()` when to stop processing; possible values:

<table>
<thead>
<tr>
<th>value</th>
<th>description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>init</code></td>
<td>Stop after the <code>Distribution</code> instance has been created and populated with the keyword arguments to <code>setup()</code></td>
</tr>
<tr>
<td><code>config</code></td>
<td>Stop after config files have been parsed (and their data stored in the <code>Distribution</code> instance)</td>
</tr>
<tr>
<td><code>commandline</code></td>
<td>Stop after the command-line (<code>sys.argv[1:]</code> or <code>script_args</code>) have been parsed (and the data stored in the <code>Distribution</code> instance.)</td>
</tr>
<tr>
<td><code>run</code></td>
<td>Stop after all commands have been run (the same as if <code>setup()</code> had been called in the usual way). This is the default value.</td>
</tr>
</tbody>
</table>

In addition, the `distutils.core` module exposed a number of classes that live elsewhere.

- `Extension` from `distutils.extension`
- `Command` from `distutils.cmd`
- `Distribution` from `distutils.dist`

A short description of each of these follows, but see the relevant module for the full reference.
**class distutils.core.Extension**

The Extension class describes a single C or C++ extension module in a setup script. It accepts the following keyword arguments in its constructor:

<table>
<thead>
<tr>
<th>argument name</th>
<th>value</th>
<th>type</th>
</tr>
</thead>
<tbody>
<tr>
<td>name</td>
<td>the full name of the extension, including any packages — ie. <em>not</em> a filename or pathname, but Python dotted name</td>
<td>string</td>
</tr>
<tr>
<td>sources</td>
<td>list of source filenames, relative to the distribution root (where the setup script lives), in Unix form (slash-separated) for portability. Source files may be C, C++, SWIG (.i), platform-specific resource files, or whatever else is recognized by the build_ext command as source for a Python extension.</td>
<td>string</td>
</tr>
<tr>
<td>include_dirs</td>
<td>list of directories to search for C/C++ header files (in Unix form for portability)</td>
<td>string</td>
</tr>
<tr>
<td>macros</td>
<td>list of macros to define; each macro is defined using a 2-tuple, where 'value' is either the string to define it to or None to define it</td>
<td>(string,string) tuple or None</td>
</tr>
<tr>
<td><strong>define_macros</strong></td>
<td>without a particular value (equivalent of <code>#define FOO</code> in source or <code>-DFOO</code> on Unix C compiler command line)</td>
<td>(name,<code>None</code>)</td>
</tr>
<tr>
<td>---</td>
<td>---</td>
<td>---</td>
</tr>
<tr>
<td><strong>undef_macros</strong></td>
<td>list of macros to undefine explicitly</td>
<td>string</td>
</tr>
<tr>
<td><strong>library_dirs</strong></td>
<td>list of directories to search for C/C++ libraries at link time</td>
<td>string</td>
</tr>
<tr>
<td><strong>libraries</strong></td>
<td>list of library names (not filenames or paths) to link against</td>
<td>string</td>
</tr>
<tr>
<td><strong>runtime_library_dirs</strong></td>
<td>list of directories to search for C/C++ libraries at run time (for shared extensions, this is when the extension is loaded)</td>
<td>string</td>
</tr>
<tr>
<td><strong>extra_objects</strong></td>
<td>list of extra files to link with (eg. object files not implied by 'sources', static library that must be explicitly specified, binary resource files, etc.)</td>
<td>string</td>
</tr>
<tr>
<td><strong>extra_compile_args</strong></td>
<td>any extra platform- and compiler-specific information to use when compiling the source files in 'sources'. For platforms and compilers where a command line makes sense, this is typically</td>
<td>string</td>
</tr>
</tbody>
</table>
a list of command-line arguments, but for other platforms it could be anything.

<table>
<thead>
<tr>
<th>Name</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>extra_link_args</code></td>
<td>any extra platform- and compiler-specific information to use when linking object files together to create the extension (or to create a new static Python interpreter). Similar interpretation as for ‘extra_compile_args’.</td>
</tr>
<tr>
<td><code>export_symbols</code></td>
<td>list of symbols to be exported from a shared extension. Not used on all platforms, and not generally necessary for Python extensions, which typically export exactly one symbol: <code>init + extension_name</code>.</td>
</tr>
<tr>
<td><code>depends</code></td>
<td>list of files that the extension depends on</td>
</tr>
<tr>
<td><code>language</code></td>
<td>extension language (i.e. 'c', 'c++', 'objc'). Will be detected from the source extensions if not provided.</td>
</tr>
</tbody>
</table>

class `distutils.core.Distribution`  
A `Distribution` describes how to build, install and package up a Python software package.
See the `setup()` function for a list of keyword arguments accepted by the Distribution constructor. `setup()` creates a Distribution instance.

class distutils.core.Command

A `Command` class (or rather, an instance of one of its subclasses) implement a single distutils command.
distutils.ccompiler — CCompiler base class

This module provides the abstract base class for the CCompiler classes. A CCompiler instance can be used for all the compile and link steps needed to build a single project. Methods are provided to set options for the compiler — macro definitions, include directories, link path, libraries and the like.

This module provides the following functions.

distutils.ccompiler.\texttt{gen\_lib\_options}(\texttt{compiler}, \texttt{library\_dirs}, \texttt{runtime\_library\_dirs}, \texttt{libraries})

Generate linker options for searching library directories and linking with specific libraries. \texttt{libraries} and \texttt{library\_dirs} are, respectively, lists of library names (not filenames!) and search directories. Returns a list of command-line options suitable for use with some compiler (depending on the two format strings passed in).

distutils.ccompiler.\texttt{gen\_preprocess\_options}(\texttt{macros}, \texttt{include\_dirs})

Generate C pre-processor options \texttt{(-D, -U, -I)} as used by at least two types of compilers: the typical Unix compiler and Visual C++. \texttt{macros} is the usual thing, a list of 1- or 2-tuples, where \texttt{(name,)} means undefine \texttt{(-U)} macro \texttt{name}, and \texttt{(name, value)} means define \texttt{(-D)} macro \texttt{name} to \texttt{value}. \texttt{include\_dirs} is just a list of directory names to be added to the header file search path \texttt{(-I)}. Returns a list of command-line options suitable for either Unix compilers or Visual C++.

distutils.ccompiler.\texttt{get\_default\_compiler}(\texttt{osname}, \texttt{platform})

Determine the default compiler to use for the given platform.
osname should be one of the standard Python OS names (i.e. the ones returned by os.name) and platform the common value returned by sys.platform for the platform in question.

The default values are os.name and sys.platform in case the parameters are not given.

distutils.ccompiler.new_compiler(plat=None, compiler=None, verbose=0, dry_run=0, force=0)

Factory function to generate an instance of some CCompiler subclass for the supplied platform/compiler combination. plat defaults to os.name (eg. 'posix', 'nt'), and compiler defaults to the default compiler for that platform. Currently only 'posix' and 'nt' are supported, and the default compilers are “traditional Unix interface” (UnixCCompiler class) and Visual C++ (MSVCCompiler class). Note that it's perfectly possible to ask for a Unix compiler object under Windows, and a Microsoft compiler object under Unix—if you supply a value for compiler, plat is ignored.

distutils.ccompiler.show_compilers()

Print list of available compilers (used by the --help-compiler options to build, build_ext, build_clib).

class distutils.ccompiler.CCompiler([verbose=0, dry_run=0, force=0])

The abstract base class CCompiler defines the interface that must be implemented by real compiler classes. The class also has some utility methods used by several compiler classes.

The basic idea behind a compiler abstraction class is that each instance can be used for all the compile/link steps in building a single project. Thus, attributes common to all of those compile
and link steps — include directories, macros to define, libraries to link against, etc. — are attributes of the compiler instance. To allow for variability in how individual files are treated, most of those attributes may be varied on a per-compilation or per-link basis.

The constructor for each subclass creates an instance of the Compiler object. Flags are *verbose* (show verbose output), *dry_run* (don’t actually execute the steps) and *force* (rebuild everything, regardless of dependencies). All of these flags default to 0 (off). Note that you probably don’t want to instantiate `CCompiler` or one of its subclasses directly - use the `distutils.CCompiler.new_compiler()` factory function instead.

The following methods allow you to manually alter compiler options for the instance of the Compiler class.

**add_include_dir(dir)**
Add `dir` to the list of directories that will be searched for header files. The compiler is instructed to search directories in the order in which they are supplied by successive calls to `add_include_dir()`.

**set_include_dirs(dirs)**
Set the list of directories that will be searched to `dirs` (a list of strings). Overrides any preceding calls to `add_include_dir()`; subsequent calls to `add_include_dir()` add to the list passed to `set_include_dirs()`. This does not affect any list of standard include directories that the compiler may search by default.

**add_library(libname)**
Add `libname` to the list of libraries that will be included in all links driven by this compiler object. Note that `libname` should
*not* be the name of a file containing a library, but the name of the library itself: the actual filename will be inferred by the linker, the compiler, or the compiler class (depending on the platform).

The linker will be instructed to link against libraries in the order they were supplied to `add_library()` and/or `set_libraries()`. It is perfectly valid to duplicate library names; the linker will be instructed to link against libraries as many times as they are mentioned.

**set_libraries(libnames)**
Set the list of libraries to be included in all links driven by this compiler object to `libnames` (a list of strings). This does not affect any standard system libraries that the linker may include by default.

**add_library_dir(dir)**
Add `dir` to the list of directories that will be searched for libraries specified to `add_library()` and `set_libraries()`. The linker will be instructed to search for libraries in the order they are supplied to `add_library_dir()` and/or `set_library_dirs()`.

**set_library_dirs(dirs)**
Set the list of library search directories to `dirs` (a list of strings). This does not affect any standard library search path that the linker may search by default.

**add_runtime_library_dir(dir)**
Add `dir` to the list of directories that will be searched for shared libraries at runtime.

**set_runtime_library_dirs(dirs)**
Set the list of directories to search for shared libraries at runtime to `dirs` (a list of strings). This does not affect any
standard search path that the runtime linker may search by default.

**define_macro**(name[, value=None])
Define a preprocessor macro for all compilations driven by this compiler object. The optional parameter value should be a string; if it is not supplied, then the macro will be defined without an explicit value and the exact outcome depends on the compiler used (XXX true? does ANSI say anything about this?)

**undefine_macro**(name)
Undefine a preprocessor macro for all compilations driven by this compiler object. If the same macro is defined by **define_macro()** and undefined by **undefine_macro()** the last call takes precedence (including multiple redefinitions or undefinitions). If the macro is redefined/undefined on a per-compilation basis (ie. in the call to **compile()**), then that takes precedence.

**add_link_object**(object)
Add object to the list of object files (or analogues, such as explicitly named library files or the output of “resource compilers”) to be included in every link driven by this compiler object.

**set_link_objects**(objects)
Set the list of object files (or analogues) to be included in every link to objects. This does not affect any standard object files that the linker may include by default (such as system libraries).

The following methods implement methods for autodetection of compiler options, providing some functionality similar to GNU **autoconf**.
detect_language(sources)
Detect the language of a given file, or list of files. Uses the instance attributes language_map (a dictionary), and language_order (a list) to do the job.

find_library_file(dirs, lib[, debug=0])
Search the specified list of directories for a static or shared library file lib and return the full path to that file. If debug is true, look for a debugging version (if that makes sense on the current platform). Return None if lib wasn’t found in any of the specified directories.

has_function(funcname[, includes=None, include_dirs=None, libraries=None, library_dirs=None])
Return a boolean indicating whether funcname is supported on the current platform. The optional arguments can be used to augment the compilation environment by providing additional include files and paths and libraries and paths.

library_dir_option(dir)
Return the compiler option to add dir to the list of directories searched for libraries.

library_option(lib)
Return the compiler option to add dir to the list of libraries linked into the shared library or executable.

runtime_library_dir_option(dir)
Return the compiler option to add dir to the list of directories searched for runtime libraries.

set_executables(**args)
Define the executables (and options for them) that will be run to perform the various stages of compilation. The exact set of executables that may be specified here depends on the
compiler class (via the ‘executables’ class attribute), but most will have:

<table>
<thead>
<tr>
<th>attribute</th>
<th>description</th>
</tr>
</thead>
<tbody>
<tr>
<td>compiler</td>
<td>the C/C++ compiler</td>
</tr>
<tr>
<td>linker_so</td>
<td>linker used to create shared objects and libraries</td>
</tr>
<tr>
<td>linker_exe</td>
<td>linker used to create binary executables</td>
</tr>
<tr>
<td>archiver</td>
<td>static library creator</td>
</tr>
</tbody>
</table>

On platforms with a command-line (Unix, DOS/Windows), each of these is a string that will be split into executable name and (optional) list of arguments. (Splitting the string is done similarly to how Unix shells operate: words are delimited by spaces, but quotes and backslashes can override this. See `distutils.util.split_quoted()`.)

The following methods invoke stages in the build process.

```python
compile(sources[,     output_dir=None,     macros=None,
         include_dirs=None,     debug=0,     extra_preargs=None,
         extra_postargs=None,   depends=None])
```

Compile one or more source files. Generates object files (e.g. transforms a `.c` file to a `.o` file.)

`sources` must be a list of filenames, most likely C/C++ files, but in reality anything that can be handled by a particular compiler and compiler class (eg. `MSVCCCompiler` can handle resource files in `sources`). Return a list of object filenames, one per source filename in `sources`. Depending on the implementation, not all source files will necessarily be compiled, but all corresponding object filenames will be returned.
If `output_dir` is given, object files will be put under it, while retaining their original path component. That is, `foo/bar.c` normally compiles to `foo/bar.o` (for a Unix implementation); if `output_dir` is `build`, then it would compile to `build/foo/bar.o`.

`macros`, if given, must be a list of macro definitions. A macro definition is either a `(name, value)` 2-tuple or a `(name,)` 1-tuple. The former defines a macro; if the value is `None`, the macro is defined without an explicit value. The 1-tuple case undefines a macro. Later definitions/redefinitions/undefinitions take precedence.

`include_dirs`, if given, must be a list of strings, the directories to add to the default include file search path for this compilation only.

`debug` is a boolean; if true, the compiler will be instructed to output debug symbols in (or alongside) the object file(s).

`extra_preargs` and `extra_postargs` are implementation-dependent. On platforms that have the notion of a command-line (e.g. Unix, DOS/Windows), they are most likely lists of strings: extra command-line arguments to prepend/append to the compiler command line. On other platforms, consult the implementation class documentation. In any event, they are intended as an escape hatch for those occasions when the abstract compiler framework doesn't cut the mustard.

`depends`, if given, is a list of filenames that all targets depend on. If a source file is older than any file in depends, then the source file will be recompiled. This supports dependency tracking, but only at a coarse granularity.

Raises `CompileError` on failure.
create_static_lib(objects, output_libname[, output_dir=None, debug=0, target_lang=None])

Link a bunch of stuff together to create a static library file. The “bunch of stuff” consists of the list of object files supplied as objects, the extra object files supplied to add_link_object() and/or set_link_objects(), the libraries supplied to add_library() and/or set_libraries(), and the libraries supplied as libraries (if any).

output_libname should be a library name, not a filename; the filename will be inferred from the library name. output_dir is the directory where the library file will be put. XXX defaults to what?

dependent is a boolean; if true, debugging information will be included in the object file (note that on most platforms, it is the compile step where this matters: the dependent flag is included here just for consistency).

target_lang is the target language for which the given objects are being compiled. This allows specific linkage time treatment of certain languages.

Raises LibError on failure.

link(target_desc, objects, output_filename[, output_dir=None, libraries=None, library_dirs=None, runtime_library_dirs=None, export_symbols=None, debug=0, extra_preargs=None, extra_postargs=None, build_temp=None, target_lang=None])

Link a bunch of stuff together to create an executable or shared library file.

The “bunch of stuff” consists of the list of object files supplied as objects. output_filename should be a filename. If output_dir
is supplied, \textit{output\_filename} is relative to it (i.e. \textit{output\_filename} can provide directory components if needed).

\textit{libraries} is a list of libraries to link against. These are library names, not filenames, since they're translated into filenames in a platform-specific way (eg. \textit{foo} becomes \texttt{libfoo.a} on Unix and \texttt{foo.lib} on DOS/Windows). However, they can include a directory component, which means the linker will look in that specific directory rather than searching all the normal locations.

\textit{library\_dirs}, if supplied, should be a list of directories to search for libraries that were specified as bare library names (ie. no directory component). These are on top of the system default and those supplied to \texttt{add\_library\_dir()} and/or \texttt{set\_library\_dirs()}. \textit{runtime\_library\_dirs} is a list of directories that will be embedded into the shared library and used to search for other shared libraries that *it* depends on at runtime. (This may only be relevant on Unix.)

\textit{export\_symbols} is a list of symbols that the shared library will export. (This appears to be relevant only on Windows.)

\textit{debug} is as for \texttt{compile()} and \texttt{create\_static\_lib()}, with the slight distinction that it actually matters on most platforms (as opposed to \texttt{create\_static\_lib()}, which includes a \texttt{debug} flag mostly for form's sake).

\textit{extra\_preargs} and \textit{extra\_postargs} are as for \texttt{compile()} (except of course that they supply command-line arguments for the particular linker being used).

\textit{target\_lang} is the target language for which the given objects are being compiled. This allows specific linkage time treatment of certain languages.
Raises `LinkError` on failure.

```
link_executable(objects, output_progname[, output_dir=None, libraries=None, library_dirs=None, runtime_library_dirs=None, debug=0, extra_preargs=None, extra_postargs=None, target_lang=None])
```

Link an executable. `output_progname` is the name of the file executable, while `objects` are a list of object filenames to link in. Other arguments are as for the `link()` method.

```
link_shared_lib(objects, output_libname[, output_dir=None, libraries=None, library_dirs=None, runtime_library_dirs=None, export_symbols=None, debug=0, extra_preargs=None, extra_postargs=None, build_temp=None, target_lang=None])
```

Link a shared library. `output_libname` is the name of the output library, while `objects` is a list of object filenames to link in. Other arguments are as for the `link()` method.

```
link_shared_object(objects, output_filename[, output_dir=None, libraries=None, library_dirs=None, runtime_library_dirs=None, export_symbols=None, debug=0, extra_preargs=None, extra_postargs=None, build_temp=None, target_lang=None])
```

Link a shared object. `output_filename` is the name of the shared object that will be created, while `objects` is a list of object filenames to link in. Other arguments are as for the `link()` method.

```
preprocess(source[, output_file=None, macros=None, include_dirs=None, extra_preargs=None, extra_postargs=None])
```

Preprocess a single C/C++ source file, named in `source`. Output will be written to file named `output_file`, or `stdout` if `output_file` not supplied. `macros` is a list of macro definitions.
as for compile(), which will augment the macros set with define_macro() and undefine_macro(). include_dirs is a list of directory names that will be added to the default list, in the same way as add_include_dir().

 Raises PreprocessError on failure.

 The following utility methods are defined by the CCompiler class, for use by the various concrete subclasses.

 executable_filename(basename[, strip_dir=0, output_dir=""])  
 Returns the filename of the executable for the given basename. Typically for non-Windows platforms this is the same as the basename, while Windows will get a .exe added.

 library_filename(libname[, lib_type='static', strip_dir=0, output_dir=""])  
 Returns the filename for the given library name on the current platform. On Unix a library with lib_type of 'static' will typically be of the form liblibname.a, while a lib_type of 'dynamic' will be of the form liblibname.so.

 object_filenames(source_filenames[, strip_dir=0, output_dir=""])  
 Returns the name of the object files for the given source files. source_filenames should be a list of filenames.

 shared_object_filename(basename[, strip_dir=0, output_dir=""])  
 Returns the name of a shared object file for the given file name basename.

 execute(func, args[, msg=None, level=1])
Invokes `distutils.util.execute()` This method invokes a Python function `func` with the given arguments `args`, after logging and taking into account the `dry_run` flag. XXX see also.

**spawn(cmd)**
Invokes `distutils.util.spawn()`. This invokes an external process to run the given command. XXX see also.

**mkpath(name[, mode=511])**
Invokes `distutils.dir_util.mkpath()`. This creates a directory and any missing ancestor directories. XXX see also.

**move_file(src, dst)**
Invokes `distutils.file_util.move_file()`. Renames `src` to `dst`. XXX see also.

**announce(msg[, level=1])**
Write a message using `distutils.log.debug()`. XXX see also.

**warn(msg)**
Write a warning message `msg` to standard error.

**debug_print(msg)**
If the `debug` flag is set on this `CCompiler` instance, print `msg` to standard output, otherwise do nothing.
distutils.unixccompiler — Unix C Compiler

This module provides the UnixCCompiler class, a subclass of CCompiler that handles the typical Unix-style command-line C compiler:

- macros defined with `-Dname[=value]`
- macros undefined with `-Uname`
- include search directories specified with `-Idir`
- libraries specified with `-llib`
- library search directories specified with `-Ldir`
- compile handled by `cc` (or similar) executable with `-c` option:
  - compiles `.c` to `.o`
- link static library handled by `ar` command (possibly with `ranlib`)
- link shared library handled by `cc -shared`
This module provides `MSVCCompiler`, an implementation of the abstract `CCompiler` class for Microsoft Visual Studio. Typically, extension modules need to be compiled with the same compiler that was used to compile Python. For Python 2.3 and earlier, the compiler was Visual Studio 6. For Python 2.4 and 2.5, the compiler is Visual Studio .NET 2003. The AMD64 and Itanium binaries are created using the Platform SDK.

`MSVCCompiler` will normally choose the right compiler, linker etc. on its own. To override this choice, the environment variables `DISTUTILS_USE_SDK` and `MSSdk` must be both set. `MSSdk` indicates that the current environment has been setup by the SDK's `SetEnv.Cmd` script, or that the environment variables had been registered when the SDK was installed; `DISTUTILS_USE_SDK` indicates that the distutils user has made an explicit choice to override the compiler selection by `MSVCCompiler`.
This module provides `BorlandCCompiler`, an subclass of the abstract `CCompiler` class for the Borland C++ compiler.
This module provides the `CygwinCCompiler` class, a subclass of `UnixCCompiler` that handles the Cygwin port of the GNU C compiler to Windows. It also contains the Mingw32CCompiler class which handles the mingw32 port of GCC (same as cygwin in no-cygwin mode).
This module provides the EMXCompiler class, a subclass of UnixCCompiler that handles the EMX port of the GNU C compiler to OS/2.
Contains `MWerksCompiler`, an implementation of the abstract `CCompiler` class for MetroWerks CodeWarrior on the pre-Mac OS X Macintosh. Needs work to support CW on Windows or Mac OS X.
This module provides a few functions for creating archive files, such as tarballs or zipfiles.

```
distutils.archive_util.make_archive(base_name, format[, root_dir=None, base_dir=None, verbose=0, dry_run=0])
```

Create an archive file (eg. zip or tar). `base_name` is the name of the file to create, minus any format-specific extension; `format` is the archive format: one of `zip`, `tar`, `ztar`, or `gzip`. `root_dir` is a directory that will be the root directory of the archive; i.e. we typically `chdir` into `root_dir` before creating the archive. `base_dir` is the directory where we start archiving from; i.e. `base_dir` will be the common prefix of all files and directories in the archive. `root_dir` and `base_dir` both default to the current directory. Returns the name of the archive file.

**Warning:** This should be changed to support bz2 files

```
distutils.archive_util.make_tarball(base_name, base_dir[, compress='gzip', verbose=0, dry_run=0])
```

Create an (optional compressed) archive as a tar file from all files in and under `base_dir`. `compress` must be `'gzip'` (the default), `'compress'`, `'bzip2'`, or `None`. Both `tar` and the compression utility named by `compress` must be on the default program search path, so this is probably Unix-specific. The output tar file will be named `base_dir.tar`, possibly plus the appropriate compression extension (`.gz`, `.bz2` or `.Z`). Return the output filename.

**Warning:** This should be replaced with calls to the `tarfile`
distutils.archive_util.

**make_zipfile**(*base_name*, *base_dir*, *

*verbose=0*, *dry_run=0*)

Create a zip file from all files in and under *base_dir*. The output zip file will be named *base_dir* + *.zip*. Uses either the zipfile Python module (if available) or the InfoZIP zip utility (if installed and found on the default search path). If neither tool is available, raises DistutilsExecError. Returns the name of the output zip file.
distutils.dep_util — Dependency checking

This module provides functions for performing simple, timestamp-based dependency of files and groups of files; also, functions based entirely on such timestamp dependency analysis.

distutils.dep_util.\texttt{newer}(\texttt{source}, \texttt{target})

Return true if \texttt{source} exists and is more recently modified than \texttt{target}, or if \texttt{source} exists and \texttt{target} doesn't. Return false if both exist and \texttt{target} is the same age or newer than \texttt{source}. Raise \texttt{DistutilsFileError} if \texttt{source} does not exist.

distutils.dep_util.\texttt{newer\_pairwise}(\texttt{sources}, \texttt{targets})

Walk two filename lists in parallel, testing if each source is newer than its corresponding target. Return a pair of lists (\texttt{sources}, \texttt{targets}) where source is newer than target, according to the semantics of \texttt{newer()}

distutils.dep_util.\texttt{newer\_group}(\texttt{sources}, \texttt{target}[, \texttt{missing}='error'])

Return true if \texttt{target} is out-of-date with respect to any file listed in \texttt{sources} In other words, if \texttt{target} exists and is newer than every file in \texttt{sources}, return false; otherwise return true. \texttt{missing} controls what we do when a source file is missing; the default ('error') is to blow up with an \texttt{OSError} from inside \texttt{os.stat()}; if it is 'ignore', we silently drop any missing source files; if it is 'newer', any missing source files make us assume that \texttt{target} is out-of-date (this is handy in “dry-run” mode: it'll make you pretend to carry out commands that wouldn't work because inputs are missing, but that doesn't matter because you're not actually going to run the commands).
This module provides functions for operating on directories and trees of directories.

**distutils.dir_util.mkpath(name[, mode=0777, verbose=0, dry_run=0])**

Create a directory and any missing ancestor directories. If the directory already exists (or if name is the empty string, which means the current directory, which of course exists), then do nothing. Raise DistutilsFileError if unable to create some directory along the way (eg. some sub-path exists, but is a file rather than a directory). If verbose is true, print a one-line summary of each mkdir to stdout. Return the list of directories actually created.

**distutils.dir_util.create_tree(base_dir, files[, mode=0777, verbose=0, dry_run=0])**

Create all the empty directories under base_dir needed to put files there. base_dir is just the a name of a directory which doesn't necessarily exist yet; files is a list of filenames to be interpreted relative to base_dir. base_dir + the directory portion of every file in files will be created if it doesn't already exist. mode, verbose and dry_run flags are as for mkpath().

**distutils.dir_util.copy_tree(src, dst[, preserve_mode=1, preserve_times=1, preserve_symlinks=0, update=0, verbose=0, dry_run=0])**

Copy an entire directory tree src to a new location dst. Both src and dst must be directory names. If src is not a directory, raise
**DistutilsFileError.** If \( dst \) does not exist, it is created with \( \texttt{mkpath()} \). The end result of the copy is that every file in \( src \) is copied to \( dst \), and directories under \( src \) are recursively copied to \( dst \). Return the list of files that were copied or might have been copied, using their output name. The return value is unaffected by \( \texttt{update} \) or \( \texttt{dry\_run} \): it is simply the list of all files under \( src \), with the names changed to be under \( dst \).

\( \texttt{preserve\_mode} \) and \( \texttt{preserve\_times} \) are the same as for \( \texttt{copy\_file()} \) in \( \texttt{distutils.file\_util} \); note that they only apply to regular files, not to directories. If \( \texttt{preserve\_symlinks} \) is true, symlinks will be copied as symlinks (on platforms that support them!); otherwise (the default), the destination of the symlink will be copied. \( \texttt{update} \) and \( \texttt{verbose} \) are the same as for \( \texttt{copy\_file()} \).

\begin{verbatim}
\texttt{distutils.dir\_util.remove\_tree(}directory[, \texttt{verbose=0,}\n\texttt{dry\_run=0}]\texttt{)}
\end{verbatim}

Recursively remove \( directory \) and all files and directories underneath it. Any errors are ignored (apart from being reported to \texttt{sys.stdout} if \( \texttt{verbose} \) is true).

** Some of this could be replaced with the \texttt{shutil} module? **
This module contains some utility functions for operating on individual files.

```
distutils.file_util.copy_file(src, dst[, preserve_mode=1,
    preserve_times=1, update=0, link=None, verbose=0, dry_run=0])
```

Copy file `src` to `dst`. If `dst` is a directory, then `src` is copied there with the same name; otherwise, it must be a filename. (If the file exists, it will be ruthlessly clobbered.) If `preserve_mode` is true (the default), the file’s mode (type and permission bits, or whatever is analogous on the current platform) is copied. If `preserve_times` is true (the default), the last-modified and last-access times are copied as well. If `update` is true, `src` will only be copied if `dst` does not exist, or if `dst` does exist but is older than `src`.

`link` allows you to make hard links (using `os.link()`) or symbolic links (using `os.symlink()`) instead of copying: set it to `'hard'` or `'sym'`; if it is `None` (the default), files are copied. Don’t set `link` on systems that don’t support it: `copy_file()` doesn’t check if hard or symbolic linking is available. It uses `_copy_file_contents()` to copy file contents.

Return a tuple `(dest_name, copied)`: `dest_name` is the actual name of the output file, and `copied` is true if the file was copied (or would have been copied, if `dry_run` true).

```
distutils.file_util.move_file(src, dst[, verbose, dry_run])
```

Move file `src` to `dst`. If `dst` is a directory, the file will be moved into it with the same name; otherwise, `src` is just renamed to `dst`. Returns the new full name of the file.
Warning: Handles cross-device moves on Unix using `copy_file()`. What about other systems???

distutils.file_util.write_file(filename, contents)

Create a file called `filename` and write `contents` (a sequence of strings without line terminators) to it.
This module contains other assorted bits and pieces that don't fit into any other utility module.

**distutils.util.get_platform()**

Return a string that identifies the current platform. This is used mainly to distinguish platform-specific build directories and platform-specific built distributions. Typically includes the OS name and version and the architecture (as supplied by `os.uname()`), although the exact information included depends on the OS; eg. for IRIX the architecture isn’t particularly important (IRIX only runs on SGI hardware), but for Linux the kernel version isn’t particularly important.

Examples of returned values:

- `linux-i586`
- `linux-alpha`
- `solaris-2.6-sun4u`
- `irix-5.3`
- `irix64-6.2`

For non-POSIX platforms, currently just returns `sys.platform`.

**distutils.util.convert_path(pathname)**

Return ‘pathname’ as a name that will work on the native filesystem, i.e. split it on ‘/’ and put it back together again using the current directory separator. Needed because filenames in the setup script are always supplied in Unix style, and have to be converted to the local convention before we can actually use them in the filesystem. Raises `ValueError` on non-Unix-ish
systems if *pathname* either starts or ends with a slash.

**distutils.util.change_root(new_root, pathname)**

Return *pathname* with *new_root* prepended. If *pathname* is relative, this is equivalent to `os.path.join(new_root, pathname)`
Otherwise, it requires making *pathname* relative and then joining the two, which is tricky on DOS/Windows.

**distutils.util.check_environ()**

Ensure that ‘os.environ’ has all the environment variables we guarantee that users can use in config files, command-line options, etc. Currently this includes:

- **HOME** - user’s home directory (Unix only)
- **PLAT** - description of the current platform, including hardware and OS (see `get_platform()`)  

**distutils.utilsubst_vars(s, local_vars)**

Perform shell/Perl-style variable substitution on *s*. Every occurrence of $ followed by a name is considered a variable, and variable is substituted by the value found in the *local_vars* dictionary, or in `os.environ` if it’s not in *local_vars*. `os.environ` is first checked/augmented to guarantee that it contains certain values: see `check_environ()`. Raise `ValueError` for any variables not found in either *local_vars* or `os.environ`.

Note that this is not a fully-fledged string interpolation function. A valid $variable can consist only of upper and lower case letters, numbers and an underscore. No { } or ( ) style quoting is available.

**distutils.util.grok_environment_error(exc[, prefix='error: '])**

Generate a useful error message from an `EnvironmentError` (`IOError` or `OSError`) exception object. Handles Python 1.5.1 and
later styles, and does what it can to deal with exception objects that don't have a filename (which happens when the error is due to a two-file operation, such as `rename()` or `link()`). Returns the error message as a string prefixed with `prefix`.

**distutils.util.split_quoted(s)**

Split a string up according to Unix shell-like rules for quotes and backslashes. In short: words are delimited by spaces, as long as those spaces are not escaped by a backslash, or inside a quoted string. Single and double quotes are equivalent, and the quote characters can be backslash-escaped. The backslash is stripped from any two-character escape sequence, leaving only the escaped character. The quote characters are stripped from any quoted string. Returns a list of words.

**distutils.util.execute(func, args[, msg=None, verbose=0, dry_run=0])**

Perform some action that affects the outside world (for instance, writing to the filesystem). Such actions are special because they are disabled by the `dry_run` flag. This method takes care of all that bureaucracy for you; all you have to do is supply the function to call and an argument tuple for it (to embody the “external action” being performed), and an optional message to print.

**distutils.util.strtobool(val)**

Convert a string representation of truth to true (1) or false (0).

True values are `y`, `yes`, `t`, `true`, `on` and `1`; false values are `n`, `no`, `f`, `false`, `off` and `0`. Raises `ValueError` if `val` is anything else.

**distutils.util.byte_compile(py_files[, optimize=0, force=0, prefix=None, base_dir=None, verbose=1, dry_run=0, direct=None])**

Byte-compile a collection of Python source files to either `.pyc` or
.pyo files in the same directory. py_files is a list of files to compile; any files that don't end in .py are silently skipped. optimize must be one of the following:

- 0 - don’t optimize (generate .pyc)
- 1 - normal optimization (like python -O)
- 2 - extra optimization (like python -OO)

If force is true, all files are recompiled regardless of timestamps.

The source filename encoded in each bytecode file defaults to the filenames listed in py_files; you can modify these with prefix and basedir. prefix is a string that will be stripped off of each source filename, and base_dir is a directory name that will be prepended (after prefix is stripped). You can supply either or both (or neither) of prefix and base_dir, as you wish.

If dry_run is true, doesn’t actually do anything that would affect the filesystem.

Byte-compile is either done directly in this interpreter process with the standard py_compile module, or indirectly by writing a temporary script and executing it. Normally, you should let byte_compile() figure out to use direct compilation or not (see the source for details). The direct flag is used by the script generated in indirect mode; unless you know what you’re doing, leave it set to None.

distutils.util.rfc822_escape(header)

Return a version of header escaped for inclusion in an RFC 822 header, by ensuring there are 8 spaces space after each newline. Note that it does no other modification of the string.
This module provides the `Distribution` class, which represents the module distribution being built/installed/distributed.
distutils.extension — The Extension class

This module provides the Extension class, used to describe C/C++
extension modules in setup scripts.
This module provides the DEBUG flag.
Provides exceptions used by the Distutils modules. Note that Distutils modules may raise standard exceptions; in particular, SystemExit is usually raised for errors that are obviously the end-user’s fault (eg. bad command-line arguments).

This module is safe to use in `from ... import *` mode; it only exports symbols whose names start with `Distutils` and end with `Error`. 
This module provides a wrapper around the standard `getopt` module that provides the following additional features:

- short and long options are tied together
- options have help strings, so `fancy_getopt()` could potentially create a complete usage summary
- options set attributes of a passed-in object
- boolean options can have “negative aliases” — eg. if `--quiet` is the “negative alias” of `--verbose`, then `--quiet` on the command line sets `verbose` to false.

** Should be replaced with `optik` (which is also now known as `optparse` in Python 2.3 and later). **

```python
distutils.fancy_getopt.fancy_getopt(options, negative_opt, object, args)

Wrapper function. `options` is a list of `(long_option, short_option, help_string)` 3-tuples as described in the constructor for `FancyGetopt`. `negative_opt` should be a dictionary mapping option names to option names, both the key and value should be in the `options` list. `object` is an object which will be used to store values (see the `getopt()` method of the `FancyGetopt` class). `args` is the argument list. Will use `sys.argv[1:]` if you pass `None` as `args`.

```

```python
distutils.fancy_getopt.wrap_text(text, width)

Wraps `text` to less than `width` wide.

**Warning:** Should be replaced with `textwrap` (which is
The option_table is a list of 3-tuples: (long_option, short_option, help_string)

If an option takes an argument, its long_option should have '=' appended; short_option should just be a single character, no ':' in any case. short_option should be None if a long_option doesn't have a corresponding short_option. All option tuples must have long options.

The FancyGetopt class provides the following methods:

FancyGetopt.getopt([args=None, object=None])
 Parse command-line options in args. Store as attributes on object.

If args is None or not supplied, uses sys.argv[1:]. If object is None or not supplied, creates a new OptionDummy instance, stores option values there, and returns a tuple (args, object). If object is supplied, it is modified in place and getopt() just returns args; in both cases, the returned args is a modified copy of the passed-in args list, which is left untouched.

FancyGetopt.get_option_order()
 Returns the list of (option, value) tuples processed by the previous run of getopt() Raises RuntimeError if getopt() hasn’t been called yet.

FancyGetopt.generate_help([header=None])
 Generate help text (a list of strings, one per suggested line of output) from the option table for this FancyGetopt object.
If supplied, prints the supplied *header* at the top of the help.
This module provides the `FileList` class, used for poking about the filesystem and building lists of files.
**Warning:** Should be replaced with standard `logging` module.
This module provides the `spawn()` function, a front-end to various platform-specific functions for launching another program in a sub-process. Also provides `find_executable()` to search the path for a given executable name.
distutils.sysconfig — System configuration information

The `distutils.sysconfig` module provides access to Python’s low-level configuration information. The specific configuration variables available depend heavily on the platform and configuration. The specific variables depend on the build process for the specific version of Python being run; the variables are those found in the `Makefile` and configuration header that are installed with Python on Unix systems. The configuration header is called `pyconfig.h` for Python versions starting with 2.2, and `config.h` for earlier versions of Python.

Some additional functions are provided which perform some useful manipulations for other parts of the `distutils` package.

`distutils.sysconfig.PREFIX`

The result of `os.path.normpath(sys.prefix)`.

`distutils.sysconfig.EXEC_PREFIX`

The result of `os.path.normpath(sys.exec_prefix)`.

`distutils.sysconfig.get_config_var(name)`

Return the value of a single variable. This is equivalent to `get_config_vars().get(name)`.

`distutils.sysconfig.get_config_vars(...)`

Return a set of variable definitions. If there are no arguments, this returns a dictionary mapping names of configuration variables to values. If arguments are provided, they should be strings, and the return value will be a sequence giving the associated values. If a given name does not have a corresponding value, `None` will be
included for that variable.

distutils.sysconfig.get_config_h_filename()
    Return the full path name of the configuration header. For Unix, this will be the
    header generated by the configure script; for other platforms the header will have
    been supplied directly by the Python source distribution. The file is a
    platform-specific text file.

distutils.sysconfig.get_makefile_filename()
    Return the full path name of the Makefile used to build Python. For Unix, this will
    be a file generated by the configure script; the meaning for other platforms will
    vary. The file is a platform-specific text file, if it exists. This function is only
    useful on POSIX platforms.

distutils.sysconfig.get_python_inc([plat_specific[, prefix]])
    Return the directory for either the general or platform-dependent C include files. If
    plat_specific is true, the platform-dependent include directory is returned; if false
    or omitted, the platform-independent directory is returned. If prefix is given, it is
    used as either the prefix instead of PREFIX, or as the exec-prefix instead of
    EXEC_PREFIX if plat_specific is true.

distutils.sysconfig.get_python_lib([plat_specific[, standard_lib[, prefix]]])
    Return the directory for either the general or platform-dependent library installation.
    If plat_specific is true, the platform-dependent include directory is returned; if false
    or omitted, the platform-independent directory is returned. If prefix is given, it is
    used as either the prefix instead of PREFIX, or as the exec-prefix instead of
    EXEC_PREFIX if plat_specific is true. If standard_lib is true, the directory for
    the standard library is returned rather than the directory for the installation of
    third-party extensions.
The following function is only intended for use within the `distutils` package.

```python
distutils.sysconfig.customize_compiler(compiler)
```

Do any platform-specific customization of a `distutils.ccompiler.CCompiler` instance.

This function is only needed on Unix at this time, but should be called consistently to support forward-compatibility. It inserts the information that varies across Unix flavors and is stored in Python's `Makefile`. This information includes the selected compiler, compiler and linker options, and the extension used by the linker for shared objects.

This function is even more special-purpose, and should only be used from Python's own build procedures.

```python
distutils.sysconfig.set_python_build()
```

Inform the `distutils.sysconfig` module that it is being used as part of the build process for Python. This changes a lot of relative locations for files, allowing them to be located in the build area rather than in an installed Python.
distutils.text_file — The TextFile class

This module provides the **TextFile** class, which gives an interface to
text files that (optionally) takes care of stripping comments, ignoring
blank lines, and joining lines with backslashes.

class distutils.text_file.TextFile([filename=None, file=None, **options])

This class provides a file-like object that takes care of all the
things you commonly want to do when processing a text file that
has some line-by-line syntax: strip comments (as long as # is
your comment character), skip blank lines, join adjacent lines by
escaping the newline (ie. backslash at end of line), strip leading
and/or trailing whitespace. All of these are optional and
independently controllable.

The class provides a **warn()** method so you can generate
warning messages that report physical line number, even if the
logical line in question spans multiple physical lines. Also
provides **unreadline()** for implementing line-at-a-time lookahead.

**TextFile** instances are create with either **filename**, **file**, or both.
**RuntimeError** is raised if both are **None**. **filename** should be a
string, and **file** a file object (or something that provides
**readline()** and **close()** methods). It is recommended that you
supply at least **filename**, so that **TextFile** can include it in
warning messages. If **file** is not supplied, **TextFile** creates its
own using the **open()** built-in function.

The options are all boolean, and affect the values returned by
**readline()**
<table>
<thead>
<tr>
<th>option name</th>
<th>description</th>
<th>default</th>
</tr>
</thead>
<tbody>
<tr>
<td>strip_comments</td>
<td>strip from '#' to end-of-line, as well as any whitespace leading up to the '#'—unless it is escaped by a backslash</td>
<td>true</td>
</tr>
<tr>
<td>lstrip_ws</td>
<td>strip leading whitespace from each line before returning it</td>
<td>false</td>
</tr>
<tr>
<td>rstrip_ws</td>
<td>strip trailing whitespace (including line terminator!) from each line before returning it.</td>
<td>true</td>
</tr>
<tr>
<td>skip_blanks</td>
<td>skip lines that are empty <em>after</em> stripping comments and whitespace. (If both lstrip_ws and rstrip_ws are false, then some lines may consist of solely whitespace: these will <em>not</em> be skipped, even if skip_blanks is true.)</td>
<td>true</td>
</tr>
<tr>
<td>join_lines</td>
<td>if a backslash is the last non-newline character on a line after stripping comments and whitespace, join the following line to it to form one logical line; if N consecutive lines end with a backslash, then N+1 physical lines will be joined to form one logical line.</td>
<td>false</td>
</tr>
<tr>
<td>collapse_join</td>
<td>strip leading whitespace from lines that are joined to their predecessor; only matters if (join_lines and not lstrip_ws)</td>
<td>false</td>
</tr>
</tbody>
</table>

Note that since rstrip_ws can strip the trailing newline, the semantics of readline() must differ from those of the builtin file object's readline() method! In particular, readline() returns None for end-of-file: an empty string might just be a blank line (or an all-whitespace line), if rstrip_ws is true but skip_blanks is not.
open(filename)
Open a new file filename. This overrides any file or filename constructor arguments.

close()
Close the current file and forget everything we know about it (including the filename and the current line number).

warn(msg[, line=None])
Print (to stderr) a warning message tied to the current logical line in the current file. If the current logical line in the file spans multiple physical lines, the warning refers to the whole range, such as "lines 3-5". If line is supplied, it overrides the current line number; it may be a list or tuple to indicate a range of physical lines, or an integer for a single physical line.

readline()
Read and return a single logical line from the current file (or from an internal buffer if lines have previously been “unread” with unreadline()). If the join_lines option is true, this may involve reading multiple physical lines concatenated into a single string. Updates the current line number, so calling warn() after readline() emits a warning about the physical line(s) just read. Returns None on end-of-file, since the empty string can occur if rstrip_ws is true but strip_blanks is not.

readlines()
Read and return the list of all logical lines remaining in the current file. This updates the current line number to the last line of the file.

unreadline(line)
Push line (a string) onto an internal buffer that will be checked by future readline() calls. Handy for implementing a parser with line-at-a-time lookahead. Note that lines that are “unread”
with unreadline() are not subsequently re-cleansed (whitespace stripped, or whatever) when read with readline(). If multiple calls are made to unreadline() before a call to readline(), the lines will be returned most in most recent first order.
This module supplies the abstract base class `Command`.

class distutils.cmd.Command(dist)

Abstract base class for defining command classes, the “worker bees” of the Distutils. A useful analogy for command classes is to think of them as subroutines with local variables called `options`. The options are declared in `initialize_options()` and defined (given their final values) in `finalize_options()`, both of which must be defined by every command class. The distinction between the two is necessary because option values might come from the outside world (command line, config file, ...), and any options dependent on other options must be computed after these outside influences have been processed — hence `finalize_options()`. The body of the subroutine, where it does all its work based on the values of its options, is the `run()` method, which must also be implemented by every command class.

The class constructor takes a single argument `dist`, a `Distribution` instance.
distutils.command — Individual Distutils commands
distutils.command.bdist — Build a binary installer
distutils.command.bdist_packager — Abstract base class for packagers
distutils.command.bdist_dumb — Build a “dumb” installer
distutils.command.bdist_msi — Build a Microsoft Installer binary package
distutils.command.bdist_rpm — Build a binary distribution as a Redhat RPM and SRPM
distutils.command.bdist_wininst — Build a Windows installer
distutils.command.sdist — Build a source distribution
distutils.command.build — Build all files of a package
distutils.command.build_clib — Build any C libraries in a package
distutils.command.build_ext — Build any extensions in a package
distutils.command.build_py — Build the .py/.pyc files of a package
distutils.command.build_scripts — Build the scripts of a package
distutils.command.clean — Clean a package build area
distutils.command.config — Perform package configuration
distutils.command.install — Install a package
distutils.command.install_data — Install data files from a package
distutils.command.install_headers — Install C/C++ header files from a package
distutils.command.install_lib — Install library files from a package
distutils.command.install_scripts — Install script files from a package
distutils.command.register — Register a module with the Python Package Index

The `register` command registers the package with the Python Package Index. This is described in more detail in PEP 301.
Creating a new Distutils command

This section outlines the steps to create a new Distutils command.

A new command lives in a module in the `distutils.command` package. There is a sample template in that directory called `command_template`. Copy this file to a new module with the same name as the new command you’re implementing. This module should implement a class with the same name as the module (and the command). So, for instance, to create the command `peel_banana` (so that users can run `setup.py peel_banana`), you’d copy `command_template` to `distutils/command/peel_banana.py`, then edit it so that it’s implementing the class `peel_banana`, a subclass of `distutils.cmd.Command`.

Subclasses of `Command` must define the following methods.

**Command`.initialize_options()`**

Set default values for all the options that this command supports. Note that these defaults may be overridden by other commands, by the setup script, by config files, or by the command-line. Thus, this is not the place to code dependencies between options; generally, `initialize_options()` implementations are just a bunch of `self.foo = None` assignments.

**Command`.finalize_options()`**

Set final values for all the options that this command supports. This is always called as late as possible, i.e. after any option assignments from the command-line or from other commands have been done. Thus, this is the place to to code option dependencies: if `foo` depends on `bar`, then it is safe to set `foo` from `bar` as long as `foo` still has the same value it was assigned
in `initialize_options()`.

Command `run()`

A command's raison d'être: carry out the action it exists to perform, controlled by the options initialized in `initialize_options()`, customized by other commands, the setup script, the command-line, and config files, and finalized in `finalize_options()`. All terminal output and filesystem interaction should be done by `run()`.

`sub_commands` formalizes the notion of a “family” of commands, eg. `install` as the parent with sub-commands `install_lib`, `install_headers`, etc. The parent of a family of commands defines `sub_commands` as a class attribute; it's a list of 2-tuples `(command_name, predicate)`, with `command_name` a string and `predicate` an unbound method, a string or None. `predicate` is a method of the parent command that determines whether the corresponding command is applicable in the current situation. (Eg. we `install_headers` is only applicable if we have any C header files to install.) If `predicate` is None, that command is always applicable.

`sub_commands` is usually defined at the *end* of a class, because predicates can be unbound methods, so they must already have been defined. The canonical example is the `install` command.
Introduction

Python’s documentation has long been considered to be good for a free programming language. There are a number of reasons for this, the most important being the early commitment of Python’s creator, Guido van Rossum, to providing documentation on the language and its libraries, and the continuing involvement of the user community in providing assistance for creating and maintaining documentation.

The involvement of the community takes many forms, from authoring to bug reports to just plain complaining when the documentation could be more complete or easier to use.

This document is aimed at authors and potential authors of documentation for Python. More specifically, it is for people contributing to the standard documentation and developing additional documents using the same tools as the standard documents. This guide will be less useful for authors using the Python documentation tools for topics other than Python, and less useful still for authors not using the tools at all.

If your interest is in contributing to the Python documentation, but you don’t have the time or inclination to learn reStructuredText and the markup structures documented here, there’s a welcoming place for you among the Python contributors as well. Any time you feel that you can clarify existing documentation or provide documentation that’s missing, the existing documentation team will gladly work with you to integrate your text, dealing with the markup for you. Please don’t let the material in this document stand between the documentation and your desire to help out!
The Python documentation should follow the Apple Publications Style Guide wherever possible. This particular style guide was selected mostly because it seems reasonable and is easy to get online.

Topics which are not covered in the Apple's style guide will be discussed in this document.

All reST files use an indentation of 3 spaces. The maximum line length is 80 characters for normal text, but tables, deeply indented code samples and long links may extend beyond that.

Make generous use of blank lines where applicable; they help grouping things together.

A sentence-ending period may be followed by one or two spaces; while reST ignores the second space, it is customarily put in by some users, for example to aid Emacs’ auto-fill mode.

Footnotes are generally discouraged, though they may be used when they are the best way to present specific information. When a footnote reference is added at the end of the sentence, it should follow the sentence-ending punctuation. The reST markup should appear something like this:

This sentence has a footnote reference. [#]_ This is the next s

Footnotes should be gathered at the end of a file, or if the file is very long, at the end of a section. The docutils will automatically create backlinks to the footnote reference.

Footnotes may appear in the middle of sentences where appropriate.
Many special names are used in the Python documentation, including the names of operating systems, programming languages, standards bodies, and the like. Most of these entities are not assigned any special markup, but the preferred spellings are given here to aid authors in maintaining the consistency of presentation in the Python documentation.

Other terms and words deserve special mention as well; these conventions should be used to ensure consistency throughout the documentation:

**CPU**
For “central processing unit.” Many style guides say this should be spelled out on the first use (and if you must use it, do so!). For the Python documentation, this abbreviation should be avoided since there’s no reasonable way to predict which occurrence will be the first seen by the reader. It is better to use the word “processor” instead.

**POSIX**
The name assigned to a particular group of standards. This is always uppercase.

**Python**
The name of our favorite programming language is always capitalized.

**Unicode**
The name of a character set and matching encoding. This is always written capitalized.

**Unix**
The name of the operating system developed at AT&T Bell Labs in the early 1970s.
This section is a brief introduction to reStructuredText (reST) concepts and syntax, intended to provide authors with enough information to author documents productively. Since reST was designed to be a simple, unobtrusive markup language, this will not take too long.

See also: The authoritative reStructuredText User Documentation.
The paragraph is the most basic block in a reST document. Paragraphs are simply chunks of text separated by one or more blank lines. As in Python, indentation is significant in reST, so all lines of the same paragraph must be left-aligned to the same level of indentation.
Inline markup

The standard reST inline markup is quite simple: use

- one asterisk: *text* for emphasis (italics),
- two asterisks: **text** for strong emphasis (boldface), and
- backquotes: ```text``` for code samples.

If asterisks or backquotes appear in running text and could be confused with inline markup delimiters, they have to be escaped with a backslash.

Be aware of some restrictions of this markup:

- it may not be nested,
- content may not start or end with whitespace: * text* is wrong,
- it must be separated from surrounding text by non-word characters. Use a backslash escaped space to work around that: this is\ *one*\ word.

These restrictions may be lifted in future versions of the docutils.

reST also allows for custom “interpreted text roles”, which signify that the enclosed text should be interpreted in a specific way. Sphinx uses this to provide semantic markup and cross-referencing of identifiers, as described in the appropriate section. The general syntax is :rolename:`content`.
Lists and Quotes

List markup is natural: just place an asterisk at the start of a paragraph and indent properly. The same goes for numbered lists; they can also be autonumbered using a # sign:

* This is a bulleted list.
* It has two items, the second item uses two lines.

1. This is a numbered list.
2. It has two items too.

#. This is a numbered list.
#. It has two items too.

Note that Sphinx disables the use of enumerated lists introduced by alphabetic or roman numerals, such as

A. First item
B. Second item

Nested lists are possible, but be aware that they must be separated from the parent list items by blank lines:

* this is
* a list
  * with a nested list
  * and some subitems
* and here the parent list continues

Definition lists are created as follows:

term (up to a line of text)
  Definition of the term, which must be indented
  and can even consist of multiple paragraphs
Paragraphs are quoted by just indenting them more than the surrounding paragraphs.
Literal code blocks are introduced by ending a paragraph with the special marker `::`. The literal block must be indented, to be able to include blank lines:

```
This is a normal text paragraph. The next paragraph is a code sample:

   It is not processed in any way, except that the indentation is removed.

   It can span multiple lines.
```

This is a normal text paragraph again.

The handling of the `::` marker is smart:

- If it occurs as a paragraph of its own, that paragraph is completely left out of the document.
- If it is preceded by whitespace, the marker is removed.
- If it is preceded by non-whitespace, the marker is replaced by a single colon.

That way, the second sentence in the above example's first paragraph would be rendered as “The next paragraph is a code sample.”.
Hyperlinks

External links

Use `Link text <http://target>` for inline web links. If the link text should be the web address, you don't need special markup at all, the parser finds links and mail addresses in ordinary text.

Internal links

Internal linking is done via a special reST role, see the section on specific markup, *Cross-linking markup*. 
Section headers are created by underlining (and optionally overlining) the section title with a punctuation character, at least as long as the text:

```
=================
This is a heading
=================
```

Normally, there are no heading levels assigned to certain characters as the structure is determined from the succession of headings. However, for the Python documentation, we use this convention:

- `#` with overline, for parts
- `*` with overline, for chapters
- `=` for sections
- `-` for subsections
- `^` for subsubsections
- `''` for paragraphs
“Explicit markup” is used in reST for most constructs that need special handling, such as footnotes, specially-highlighted paragraphs, comments, and generic directives.

An explicit markup block begins with a line starting with `..` followed by whitespace and is terminated by the next paragraph at the same level of indentation. (There needs to be a blank line between explicit markup and normal paragraphs. This may all sound a bit complicated, but it is intuitive enough when you write it.)
Directives

A directive is a generic block of explicit markup. Besides roles, it is one of the extension mechanisms of reST, and Sphinx makes heavy use of it.

Basically, a directive consists of a name, arguments, options and content. (Keep this terminology in mind, it is used in the next chapter describing custom directives.) Looking at this example,

```plaintext
.. function:: foo(x)
   foo(y, z)
   :bar: no

   Return a line of text input from the user.
```

`function` is the directive name. It is given two arguments here, the remainder of the first line and the second line, as well as one option `bar` (as you can see, options are given in the lines immediately following the arguments and indicated by the colons).

The directive content follows after a blank line and is indented relative to the directive start.
Footnotes

For footnotes, use [#]_ to mark the footnote location, and add the footnote body at the bottom of the document after a “Footnotes” rubric heading, like so:

Lorem ipsum [#]_ dolor sit amet ... [#]_

.. rubric:: Footnotes

.. [#] Text of the first footnote.
.. [#] Text of the second footnote.

You can also explicitly number the footnotes for better context.
Comments

Every explicit markup block which isn’t a valid markup construct (like the footnotes above) is regarded as a comment.
Source encoding

Since the easiest way to include special characters like em dashes or copyright signs in reST is to directly write them as Unicode characters, one has to specify an encoding:

All Python documentation source files must be in UTF-8 encoding, and the HTML documents written from them will be in that encoding as well.
Gotchas

There are some problems one commonly runs into while authoring reST documents:

- **Separation of inline markup:** As said above, inline markup spans must be separated from the surrounding text by non-word characters, you have to use an escaped space to get around that.
Additional Markup Constructs

Sphinx adds a lot of new directives and interpreted text roles to standard reST markup. This section contains the reference material for these facilities. Documentation for “standard” reST constructs is not included here, though they are used in the Python documentation.
File-wide metadata

reST has the concept of “field lists”; these are a sequence of fields marked up like this:

:Field name: Field content

A field list at the very top of a file is parsed as the “docinfo”, which in normal documents can be used to record the author, date of publication and other metadata. In Sphinx, the docinfo is used as metadata, too, but not displayed in the output.

At the moment, only one metadata field is recognized:

nocomments

If set, the web application won't display a comment form for a page generated from this source file.
Meta-information markup

sectionauthor

Identifies the author of the current section. The argument should include the author's name such that it can be used for presentation (though it isn't) and email address. The domain name portion of the address should be lower case. Example:

.. sectionauthor:: Guido van Rossum <guido@python.org>

Currently, this markup isn't reflected in the output in any way, but it helps keep track of contributions.
Module-specific markup

The markup described in this section is used to provide information about a module being documented. Each module should be documented in its own file. Normally this markup appears after the title heading of that file; a typical file might start like this:

```
:mod:`parrot` -- Dead parrot access

.. module:: parrot
   :platform: Unix, Windows
   :synopsis: Analyze and reanimate dead parrots.
   .. moduleauthor:: Eric Cleese <eric@python.invalid>
   .. moduleauthor:: John Idle <john@python.invalid>
```

As you can see, the module-specific markup consists of two directives, the `module` directive and the `moduleauthor` directive.

**module**

This directive marks the beginning of the description of a module (or package submodule, in which case the name should be fully qualified, including the package name).

The `platform` option, if present, is a comma-separated list of the platforms on which the module is available (if it is available on all platforms, the option should be omitted). The keys are short identifiers; examples that are in use include “IRIX”, “Mac”, “Windows”, and “Unix”. It is important to use a key which has already been used when applicable.

The `synopsis` option should consist of one sentence describing the module’s purpose – it is currently only used in the Global Module Index.

The `deprecated` option can be given (with no value) to mark a
module as deprecated; it will be designated as such in various locations then.

moduleauthor

The moduleauthor directive, which can appear multiple times, names the authors of the module code, just like sectionauthor names the author(s) of a piece of documentation. It too does not result in any output currently.

Note: It is important to make the section title of a module-describing file meaningful since that value will be inserted in the table-of-contents trees in overview files.
Information units

There are a number of directives used to describe specific features provided by modules. Each directive requires one or more signatures to provide basic information about what is being described, and the content should be the description. The basic version makes entries in the general index; if no index entry is desired, you can give the directive option flag `:noindex:`. The following example shows all of the features of this directive type:

```
.. function:: spam(eggs)
    ham(eggs)
    :noindex:

    Spam or ham the foo.
```

The signatures of object methods or data attributes should always include the type name (`.. method:: FileInput.input(...) `), even if it is obvious from the context which type they belong to; this is to enable consistent cross-references. If you describe methods belonging to an abstract protocol, such as “context managers”, include a (pseudo-)type name too to make the index entries more informative.

The directives are:

cfunction

Describes a C function. The signature should be given as in C, e.g.:

```
.. cfunction:: PyObject* PyType_GenericAlloc(PyTypeObject *type,
    Py_ssize_t nitems)
```

This is also used to describe function-like preprocessor macros. The names of the arguments should be given so they may be
used in the description.

Note that you don’t have to backslash-escape asterisks in the signature, as it is not parsed by the reST inliner.

**cmember**

Describes a C struct member. Example signature:

```
.. cmember:: PyObject* PyTypeObject.tp_bases
```

The text of the description should include the range of values allowed, how the value should be interpreted, and whether the value can be changed. References to structure members in text should use the `member` role.

**cmacro**

Describes a “simple” C macro. Simple macros are macros which are used for code expansion, but which do not take arguments so cannot be described as functions. This is not to be used for simple constant definitions. Examples of its use in the Python documentation include `PyObject_HEAD` and `Py_BEGIN_ALLOW_THREADS`.

**ctype**

Describes a C type. The signature should just be the type name.

**cvar**

Describes a global C variable. The signature should include the type, such as:

```
.. cvar:: PyObject* PyClass_Type
```

**data**

Describes global data in a module, including both variables and values used as “defined constants.” Class and object attributes
are not documented using this environment.

**exception**

Describes an exception class. The signature can, but need not include parentheses with constructor arguments.

**function**

Describes a module-level function. The signature should include the parameters, enclosing optional parameters in brackets. Default values can be given if it enhances clarity. For example:

```
.. function:: Timer.repeat([repeat=3[, number=1000000]])
```

Object methods are not documented using this directive. Bound object methods placed in the module namespace as part of the public interface of the module are documented using this, as they are equivalent to normal functions for most purposes.

The description should include information about the parameters required and how they are used (especially whether mutable objects passed as parameters are modified), side effects, and possible exceptions. A small example may be provided.

**class**

Describes a class. The signature can include parentheses with parameters which will be shown as the constructor arguments.

**attribute**

Describes an object data attribute. The description should include information about the type of the data to be expected and whether it may be changed directly.

**method**

Describes an object method. The parameters should not include the \texttt{self} parameter. The description should include similar information to that described for \texttt{function}. 
**opcode**

Describes a Python *bytecode* instruction.

**cmdoption**

Describes a command line option or switch. Option argument names should be enclosed in angle brackets. Example:

```
.. cmdoption:: -m <module>

Run a module as a script.
```

**envvar**

Describes an environment variable that Python uses or defines.

There is also a generic version of these directives:

**describe**

This directive produces the same formatting as the specific ones explained above but does not create index entries or cross-referencing targets. It is used, for example, to describe the directives in this document. Example:

```
.. describe:: opcode

Describes a Python bytecode instruction.
```
Examples of Python source code or interactive sessions are represented using standard reST literal blocks. They are started by a `::` at the end of the preceding paragraph and delimited by indentation.

Representing an interactive session requires including the prompts and output along with the Python code. No special markup is required for interactive sessions. After the last line of input or output presented, there should not be an “unused” primary prompt; this is an example of what not to do:

```python
>>> 1 + 1
2
>>>```

Syntax highlighting is handled in a smart way:

- There is a “highlighting language” for each source file. Per default, this is `python` as the majority of files will have to highlight Python snippets.

- Within Python highlighting mode, interactive sessions are recognized automatically and highlighted appropriately.

- The highlighting language can be changed using the `highlightlang` directive, used as follows:

  ```highlightlang:: c```

  This language is used until the next `highlightlang` directive is encountered.
The valid values for the highlighting language are:

- python (the default)
- c
- rest
- none (no highlighting)

If highlighting with the current language fails, the block is not highlighted in any way.

Longer displays of verbatim text may be included by storing the example text in an external file containing only plain text. The file may be included using the `literalinclude` directive. [1] For example, to include the Python source file `example.py`, use:

```
.. literalinclude:: example.py
```

The file name is relative to the current file's path. Documentation-specific include files should be placed in the `Doc/includes` subdirectory.
As said before, Sphinx uses interpreted text roles to insert semantic markup in documents.

Variable names are an exception, they should be marked simply with *var*.

For all other roles, you have to write `:rolename:``content`:

**Note:** For all cross-referencing roles, if you prefix the content with `!`, no reference/hyperlink will be created.

The following roles refer to objects in modules and are possibly hyperlinked if a matching identifier is found:

**mod**

The name of a module; a dotted name may be used. This should also be used for package names.

**func**

The name of a Python function; dotted names may be used. The role text should not include trailing parentheses to enhance readability. The parentheses are stripped when searching for identifiers.

**data**

The name of a module-level variable.

**const**

The name of a “defined” constant. This may be a C-language `#define` or a Python variable that is not intended to be changed.

**class**
A class name; a dotted name may be used.

**meth**
The name of a method of an object. The role text should include the type name and the method name. A dotted name may be used.

**attr**
The name of a data attribute of an object.

**exc**
The name of an exception. A dotted name may be used.

The name enclosed in this markup can include a module name and/or a class name. For example, `:func:`filter` could refer to a function named filter in the current module, or the built-in function of that name. In contrast, `:func:`foo.filter` clearly refers to the filter function in the foo module.

Normally, names in these roles are searched first without any further qualification, then with the current module name prepended, then with the current module and class name (if any) prepended. If you prefix the name with a dot, this order is reversed. For example, in the documentation of the codecs module, `:func:`open` always refers to the built-in function, while `:func:`.open` refers to codecs.open().

A similar heuristic is used to determine whether the name is an attribute of the currently documented class.

The following roles create cross-references to C-language constructs if they are defined in the API documentation:

**cdata**
The name of a C-language variable.

**cfunc**
The name of a C-language function. Should include trailing parentheses.

cmacro
The name of a “simple” C macro, as defined above.

cctype
The name of a C-language type.

The following role does possibly create a cross-reference, but does not refer to objects:

token
The name of a grammar token (used in the reference manual to create links between production displays).

The following role creates a cross-reference to the term in the glossary:

term
Reference to a term in the glossary. The glossary is created using the glossary directive containing a definition list with terms and definitions. It does not have to be in the same file as the term markup, in fact, by default the Python docs have one global glossary in the glossary.rst file.

If you use a term that’s not explained in a glossary, you’ll get a warning during build.

The following roles don’t do anything special except formatting the text in a different style:

command
The name of an OS-level command, such as rm.

dfn
Mark the defining instance of a term in the text. (No index entries are generated.)

envvar
An environment variable. Index entries are generated.

file
The name of a file or directory. Within the contents, you can use curly braces to indicate a “variable” part, for example:

```
... is installed in :file:`/usr/lib/python2.{x}/site-packages`
```

In the built documentation, the `{x}` will be displayed differently to indicate that it is to be replaced by the Python minor version.

guilabel
Labels presented as part of an interactive user interface should be marked using `guilabel`. This includes labels from text-based interfaces such as those created using `curses` or other text-based libraries. Any label used in the interface should be marked with this role, including button labels, window titles, field names, menu and menu selection names, and even values in selection lists.

kbd
Mark a sequence of keystrokes. What form the key sequence takes may depend on platform- or application-specific conventions. When there are no relevant conventions, the names of modifier keys should be spelled out, to improve accessibility for new users and non-native speakers. For example, an `xemacs` key sequence may be marked like `:kbd:`C-x C-f`, but without reference to a specific application or platform, the same sequence should be marked as `:kbd:`Control-x Control-f`.

keyword
The name of a keyword in Python.
**mailheader**

The name of an RFC 822-style mail header. This markup does not imply that the header is being used in an email message, but can be used to refer to any header of the same “style.” This is also used for headers defined by the various MIME specifications. The header name should be entered in the same way it would normally be found in practice, with the camel-casing conventions being preferred where there is more than one common usage. For example: `:mailheader: `Content-Type` `.

**makevar**

The name of a **make** variable.

**manpage**

A reference to a Unix manual page including the section, e.g. `:manpage:`ls(1)`.

**menuselection**

Menu selections should be marked using the **menuselection** role. This is used to mark a complete sequence of menu selections, including selecting submenus and choosing a specific operation, or any subsequence of such a sequence. The names of individual selections should be separated by `-->`.

For example, to mark the selection “Start > Programs”, use this markup:

```
:menuselection:`Start --> Programs`
```

When including a selection that includes some trailing indicator, such as the ellipsis some operating systems use to indicate that the command opens a dialog, the indicator should be omitted from the selection name.

**mimetype**
The name of a MIME type, or a component of a MIME type (the major or minor portion, taken alone).

**newsgroup**
The name of a Usenet newsgroup.

**option**
A command-line option to an executable program. The leading hyphen(s) must be included.

**program**
The name of an executable program. This may differ from the file name for the executable for some platforms. In particular, the `.exe` (or other) extension should be omitted for Windows programs.

**regexp**
A regular expression. Quotes should not be included.

**samp**
A piece of literal text, such as code. Within the contents, you can use curly braces to indicate a “variable” part, as in `:file:`.

If you don’t need the “variable part” indication, use the standard ```code``` instead.

**var**
A Python or C variable or parameter name.

The following roles generate external links:

**pep**
A reference to a Python Enhancement Proposal. This generates appropriate index entries. The text “PEP *number*” is generated; in the HTML output, this text is a hyperlink to an online copy of the specified PEP.
rfc

A reference to an Internet Request for Comments. This generates appropriate index entries. The text “RFC number” is generated; in the HTML output, this text is a hyperlink to an online copy of the specified RFC.

Note that there are no special roles for including hyperlinks as you can use the standard reST markup for that purpose.
Cross-linking markup

To support cross-referencing to arbitrary sections in the documentation, the standard reST labels are “abused” a bit: Every label must precede a section title; and every label name must be unique throughout the entire documentation source.

You can then reference to these sections using the `:ref:` role.

Example:

```_.my-reference-label:

Section to cross-reference
--------------------------

This is the text of the section.

It refers to the section itself, see `:ref:`.
```

The `:ref:` invocation is replaced with the section title.
These directives create short paragraphs and can be used inside information units as well as normal text:

**note**

An especially important bit of information about an API that a user should be aware of when using whatever bit of API the note pertains to. The content of the directive should be written in complete sentences and include all appropriate punctuation.

Example:

```
.. note::

    This function is not suitable for sending spam e-mails.
```

**warning**

An important bit of information about an API that a user should be very aware of when using whatever bit of API the warning pertains to. The content of the directive should be written in complete sentences and include all appropriate punctuation. This differs from `note` in that it is recommended over `note` for information regarding security.

**versionadded**

This directive documents the version of Python which added the described feature to the library or C API. When this applies to an entire module, it should be placed at the top of the module section before any prose.

The first argument must be given and is the version in question; you can add a second argument consisting of a *brief* explanation of the change.
Example:

```
.. versionadded:: 2.5
   The `spam` parameter.
```

Note that there must be no blank line between the directive head and the explanation; this is to make these blocks visually continuous in the markup.

**versionchanged**

Similar to `versionadded`, but describes when and what changed in the named feature in some way (new parameters, changed side effects, etc.).

**seealso**

Many sections include a list of references to module documentation or external documents. These lists are created using the `seealso` directive.

The `seealso` directive is typically placed in a section just before any sub-sections. For the HTML output, it is shown boxed off from the main flow of the text.

The content of the `seealso` directive should be a reST definition list. Example:

```
.. seealso::

   Module :mod:`zipfile`
       Documentation of the :mod:`zipfile` standard module.

   `GNU tar manual, Basic Tar Format <http://link>`_
       Documentation for tar archive files, including GNU tar
```
rubric
This directive creates a paragraph heading that is not used to create a table of contents node. It is currently used for the “Footnotes” caption.

centered
This directive creates a centered boldfaced paragraph. Use it as follows:

```
.. centered::

   Paragraph contents.
```
Since reST does not have facilities to interconnect several documents, or split documents into multiple output files, Sphinx uses a custom directive to add relations between the single files the documentation is made of, as well as tables of contents. The `toctree` directive is the central element.

**toctree**

This directive inserts a “TOC tree” at the current location, using the individual TOCs (including “sub-TOC trees”) of the files given in the directive body. A numeric `maxdepth` option may be given to indicate the depth of the tree; by default, all levels are included.

Consider this example (taken from the library reference index):

```plaintext
.. toctree::
   :maxdepth: 2

   intro.rst
   strings.rst
   datatypes.rst
   numeric.rst
   (many more files listed here)
```

This accomplishes two things:

- Tables of contents from all those files are inserted, with a maximum depth of two, that means one nested heading. `toctree` directives in those files are also taken into account.
- Sphinx knows that the relative order of the files `intro.rst`, `strings.rst` and so forth, and it knows that they are children of the shown file, the library index. From this information it
generates “next chapter”, “previous chapter” and “parent chapter” links.

In the end, all files included in the build process must occur in one \toctree directive; Sphinx will emit a warning if it finds a file that is not included, because that means that this file will not be reachable through standard navigation.

The special file \contents.rst at the root of the source directory is the “root” of the TOC tree hierarchy; from it the “Contents” page is generated.
Index-generating markup

Sphinx automatically creates index entries from all information units (like functions, classes or attributes) like discussed before.

However, there is also an explicit directive available, to make the index more comprehensive and enable index entries in documents where information is not mainly contained in information units, such as the language reference.

The directive is `index` and contains one or more index entries. Each entry consists of a type and a value, separated by a colon.

For example:

```plaintext
.. index::
   single: execution; context
   module: __main__
   module: sys
   triple: module; search; path
```

This directive contains five entries, which will be converted to entries in the generated index which link to the exact location of the index statement (or, in case of offline media, the corresponding page number).

The possible entry types are:

- **single**
  Creates a single index entry. Can be made a subentry by separating the subentry text with a semicolon (this notation is also used below to describe what entries are created).

- **pair**
  `pair: loop; statement` is a shortcut that creates two index entries, namely `loop; statement` and `statement; loop`. 
Likewise, `triple: module; search; path` is a shortcut that creates three index entries, which are `module; search path`, `search; path, module` and `path; module search`.

module, keyword, operator, object, exception, statement, builtin
These all create two index entries. For example, `module: hashlib` creates the entries `module; hashlib` and `hashlib; module`.

For index directives containing only “single” entries, there is a shorthand notation:

```
.. index:: BNF, grammar, syntax, notation
```

This creates four index entries.
Grammar production displays

Special markup is available for displaying the productions of a formal grammar. The markup is simple and does not attempt to model all aspects of BNF (or any derived forms), but provides enough to allow context-free grammars to be displayed in a way that causes uses of a symbol to be rendered as hyperlinks to the definition of the symbol. There is this directive:

**productionlist**

This directive is used to enclose a group of productions. Each production is given on a single line and consists of a name, separated by a colon from the following definition. If the definition spans multiple lines, each continuation line must begin with a colon placed at the same column as in the first line.

Blank lines are not allowed within `productionlist` directive arguments.

The definition can contain token names which are marked as interpreted text (e.g. `sum ::= `integer` "+" `integer`) – this generates cross-references to the productions of these tokens.

Note that no further reST parsing is done in the production, so that you don’t have to escape * or | characters.

The following is an example taken from the Python Reference Manual:

```
.. productionlist::
    try_stmt: try1_stmt | try2_stmt
    try1_stmt: "try" "::=" `suite`
               : ("except" [`expression` [""," `target`] ] "::=" `suite`
               : ["else" "::=" `suite`]
               : ["finally" "::=" `suite`]
    try2_stmt: "try" "::=" `suite`
```
: "finally" ":: suite"
Substitutions

The documentation system provides three substitutions that are defined by default. They are set in the build configuration file, see *The build configuration file*.

|release|
---
Replaced by the Python release the documentation refers to. This is the full version string including alpha/beta/release candidate tags, e.g. 2.5.2b3.

|version|
---
Replaced by the Python version the documentation refers to. This consists only of the major and minor version parts, e.g. 2.5, even for version 2.5.1.

|today|
---
Replaced by either today's date, or the date set in the build configuration file. Normally has the format April 14, 2007.

Footnotes

[1] There is a standard .. include directive, but it raises errors if the file is not found. This one only emits a warning.
Differences to the LaTeX markup

Though the markup language is different, most of the concepts and markup types of the old LaTeX docs have been kept – environments as reST directives, inline commands as reST roles and so forth.

However, there are some differences in the way these work, partly due to the differences in the markup languages, partly due to improvements in Sphinx. This section lists these differences, in order to give those familiar with the old format a quick overview of what they might run into.
Inline markup

These changes have been made to inline markup:

- **Cross-reference roles**

  Most of the following semantic roles existed previously as inline commands, but didn’t do anything except formatting the content as code. Now, they cross-reference to known targets (some names have also been shortened):

  - `mod` (previously `refmodule` or `module`)
  - `func` (previously `function`)
  - `data` (new)
  - `const`
  - `class`
  - `meth` (previously `method`)
  - `attr` (previously `member`)
  - `exc` (previously `exception`)
  - `cdata`
  - `cfunc` (previously `cfunction`)
  - `cmacro` (previously `csimplemacro`)
  - `ctype`

  Also different is the handling of `func` and `meth`: while previously parentheses were added to the callable name (like `\func{str()}`), they are now appended by the build system – appending them in the source will result in double parentheses. This also means that `:func:`\str(object)` will not work as expected – use `\``str(object)` instead!

- **Inline commands implemented as directives**

  These were inline commands in LaTeX, but are now directives in
reST:

deprecated
versionadded
versionchanged

These are used like so:

```reST
.. deprecated:: 2.5
    Reason of deprecation.
```

Also, no period is appended to the text for `versionadded` and `versionchanged`.

`note`

`warning`

These are used like so:

```reST
.. note::
    Content of note.
```

- **Otherwise changed commands**

  The `samp` command previously formatted code and added quotation marks around it. The `samp` role, however, features a new highlighting system just like `file` does:

  ```reST
  :samp:`open({filename}, {mode})`
  results in
  open(filename, mode)
  ```

- **Dropped commands**

  These were commands in LaTeX, but are not available as roles:
bfcode
character (use `c'

citetitle (use `Title <URL>`_)
code (use `code`

email (just write the address in body text)
filenq
filevar (use the {...} highlighting feature of file)
programopt, longprogramopt (use option)
ulink (use `Title <URL>`_)
url (just write the URL in body text)
var (use *var*

infinity, plusminus (use the Unicode character)
shortversion, version (use the |version| and |release| substitutions)
emph, strong (use the reST markup)

• Backslash escaping

In reST, a backslash must be escaped in normal text, and in the content of roles. However, in code literals and literal blocks, it must not be escaped. Example: :file:`C:\Temp\my.tmp` VS. `open("C:\Temp\my.tmp")`.
Information units

Information units (...desc environments) have been made reST directives. These changes to information units should be noted:

- **New names**

  “desc” has been removed from every name. Additionally, these directives have new names:

  - `cfunction` (previously `cfuncdesc`)
  - `cmacro` (previously `csimplemacrodesc`)
  - `exception` (previously `excdesc`)
  - `function` (previously `funcdesc`)
  - `attribute` (previously `memberdesc`)

  The `classdesc*` and `excclassdesc` environments have been dropped, the `class` and `exception` directives support classes documented with and without constructor arguments.

- **Multiple objects**

  The equivalent of the `...line` commands is:

  ```
  .. function:: do_foo(bar)
      do_bar(baz)

  Description of the functions.
  ```

  IOW, just give one signatures per line, at the same indentation level.

- **Arguments**

  There is no `optional` command. Just give function signatures like
they should appear in the output:

```plaintext
.. function:: open(filename[, mode[, buffering]])

    Description.
```

Note: markup in the signature is not supported.

- **Indexing**

  The ...descni environments have been dropped. To mark an information unit as unsuitable for index entry generation, use the noindex option like so:

```plaintext
.. function:: foo_*
    :noindex:

    Description.
```

- **New information units**

  There are new generic information units: One is called “describe” and can be used to document things that are not covered by the other units:

```plaintext
.. describe:: a == b

    The equals operator.
```

The others are:

```plaintext
.. cmdoption:: -O

    Describes a command-line option.
```
.. envvar:: PYTHONINSPECT

    Describes an environment variable.
Structure

The LaTeX docs were split in several toplevel manuals. Now, all files are part of the same documentation tree, as indicated by the `toctree` directives in the sources (though individual output formats may choose to split them up into parts again). Every `toctree` directive embeds other files as subdocuments of the current file (this structure is not necessarily mirrored in the filesystem layout). The toplevel file is `contents.rst`.

However, most of the old directory structure has been kept, with the directories renamed as follows:

- `api` -> `c-api`
- `dist` -> `distutils`, with the single TeX file split up
- `doc` -> `documenting`
- `ext` -> `extending`
- `inst` -> `installing`
- `lib` -> `library`
- `mac` -> merged into `library`, with `mac/using.tex` moved to `using/mac.rst`
- `ref` -> `reference`
- `tut` -> `tutorial`, with the single TeX file split up
The Sphinx build system
The build configuration file

The documentation root, that is the doc subdirectory of the source distribution, contains a file named conf.py. This file is called the “build configuration file”, and it contains several variables that are read and used during a build run.

These variables are:

version : string
A string that is used as a replacement for the |version| reST substitution. It should be the Python version the documentation refers to. This consists only of the major and minor version parts, e.g. 2.5, even for version 2.5.1.

release : string
A string that is used as a replacement for the |release| reST substitution. It should be the full version string including alpha/beta/release candidate tags, e.g. 2.5.2b3.

Both release and version can be 'auto', which means that they are determined at runtime from the Include/patchlevel.h file, if a complete Python source distribution can be found, or else from the interpreter running Sphinx.

today_fmt : string
A strftime format that is used to format a replacement for the |today| reST substitution.

today : string
A string that can contain a date that should be written to the documentation output literally. If this is nonzero, it is used instead of strftime(today_fmt).
unused_files : list of strings
A list of reST filenames that are to be disregarded during building. This could be docs for temporarily disabled modules or documentation that's not yet ready for public consumption.

add_function_parentheses : bool
If true, () will be appended to the content of :func:, :meth: and :cfunc: cross-references.

add_module_names : bool
If true, the current module name will be prepended to all description unit titles (such as . function:).

**Builder-specific variables**

html_download_base_url : string
The base URL for download links on the download page.

html_last_updated_fmt : string
If this is not an empty string, it will be given to \texttt{time.strftime()} and written to each generated output file after “last updated on:”.

html_use_smartypants : bool
If true, use SmartyPants to convert quotes and dashes to the typographically correct entities.

latex_paper_size : “letter” or “a4”
The paper size option for the LaTeX document class.

latex_font_size : “10pt”, “11pt” or “12pt”
The font size option for the LaTeX document class.
Abstract

It's usually difficult to get your management to accept open source software, and Python is no exception to this rule. This document discusses reasons to use Python, strategies for winning acceptance, facts and arguments you can use, and cases where you shouldn't try to use Python.
Reasons to Use Python

There are several reasons to incorporate a scripting language into your development process, and this section will discuss them, and why Python has some properties that make it a particularly good choice.

Programmability

Programs are often organized in a modular fashion. Lower-level operations are grouped together, and called by higher-level functions, which may in turn be used as basic operations by still further upper levels.

For example, the lowest level might define a very low-level set of functions for accessing a hash table. The next level might use hash tables to store the headers of a mail message, mapping a header name like Date to a value such as Tue, 13 May 1997 20:00:54 -0400. A yet higher level may operate on message objects, without knowing or caring that message headers are stored in a hash table, and so forth.

Often, the lowest levels do very simple things; they implement a data structure such as a binary tree or hash table, or they perform some simple computation, such as converting a date string to a number. The higher levels then contain logic connecting these primitive operations. Using the approach, the primitives can be seen as basic building blocks which are then glued together to produce the complete product.

Why is this design approach relevant to Python? Because Python is well suited to functioning as such a glue language. A common approach is to write a Python module that implements the lower level
operations; for the sake of speed, the implementation might be in C, Java, or even Fortran. Once the primitives are available to Python programs, the logic underlying higher level operations is written in the form of Python code. The high-level logic is then more understandable, and easier to modify.

John Ousterhout wrote a paper that explains this idea at greater length, entitled “Scripting: Higher Level Programming for the 21st Century”. I recommend that you read this paper; see the references for the URL. Ousterhout is the inventor of the TCL language, and therefore argues that TCL should be used for this purpose; he only briefly refers to other languages such as Python, Perl, and Lisp/Scheme, but in reality, Ousterhout's argument applies to scripting languages in general, since you could equally write extensions for any of the languages mentioned above.

### Prototyping

In *The Mythical Man-Month*, Fredrick Brooks suggests the following rule when planning software projects: “Plan to throw one away; you will anyway.” Brooks is saying that the first attempt at a software design often turns out to be wrong; unless the problem is very simple or you’re an extremely good designer, you’ll find that new requirements and features become apparent once development has actually started. If these new requirements can’t be cleanly incorporated into the program’s structure, you're presented with two unpleasant choices: hammer the new features into the program somehow, or scrap everything and write a new version of the program, taking the new features into account from the beginning.

Python provides you with a good environment for quickly developing an initial prototype. That lets you get the overall program structure and logic right, and you can fine-tune small details in the fast development cycle that Python provides. Once you’re satisfied with the GUI interface or program output, you can translate the Python
code into C++, Fortran, Java, or some other compiled language.

Prototyping means you have to be careful not to use too many Python features that are hard to implement in your other language. Using `eval()`, or regular expressions, or the `pickle` module, means that you're going to need C or Java libraries for formula evaluation, regular expressions, and serialization, for example. But it's not hard to avoid such tricky code, and in the end the translation usually isn't very difficult. The resulting code can be rapidly debugged, because any serious logical errors will have been removed from the prototype, leaving only more minor slip-ups in the translation to track down.

This strategy builds on the earlier discussion of programmability. Using Python as glue to connect lower-level components has obvious relevance for constructing prototype systems. In this way Python can help you with development, even if end users never come in contact with Python code at all. If the performance of the Python version is adequate and corporate politics allow it, you may not need to do a translation into C or Java, but it can still be faster to develop a prototype and then translate it, instead of attempting to produce the final version immediately.

One example of this development strategy is Microsoft Merchant Server. Version 1.0 was written in pure Python, by a company that subsequently was purchased by Microsoft. Version 2.0 began to translate the code into C++, shipping with some C++code and some Python code. Version 3.0 didn't contain any Python at all; all the code had been translated into C++. Even though the product doesn't contain a Python interpreter, the Python language has still served a useful purpose by speeding up development.

This is a very common use for Python. Past conference papers have also described this approach for developing high-level numerical algorithms; see David M. Beazley and Peter S. Lomdahl's paper
“Feeding a Large-scale Physics Application to Python” in the references for a good example. If an algorithm’s basic operations are things like “Take the inverse of this 4000x4000 matrix”, and are implemented in some lower-level language, then Python has almost no additional performance cost; the extra time required for Python to evaluate an expression like `m.invert()` is dwarfed by the cost of the actual computation. It’s particularly good for applications where seemingly endless tweaking is required to get things right. GUI interfaces and Web sites are prime examples.

The Python code is also shorter and faster to write (once you’re familiar with Python), so it’s easier to throw it away if you decide your approach was wrong; if you’d spent two weeks working on it instead of just two hours, you might waste time trying to patch up what you’ve got out of a natural reluctance to admit that those two weeks were wasted. Truthfully, those two weeks haven’t been wasted, since you’ve learnt something about the problem and the technology you’re using to solve it, but it’s human nature to view this as a failure of some sort.

### Simplicity and Ease of Understanding

Python is definitely *not* a toy language that’s only usable for small tasks. The language features are general and powerful enough to enable it to be used for many different purposes. It’s useful at the small end, for 10- or 20-line scripts, but it also scales up to larger systems that contain thousands of lines of code.

However, this expressiveness doesn’t come at the cost of an obscure or tricky syntax. While Python has some dark corners that can lead to obscure code, there are relatively few such corners, and proper design can isolate their use to only a few classes or modules. It’s certainly possible to write confusing code by using too many features with too little concern for clarity, but most Python code can
look a lot like a slightly-formalized version of human-understandable pseudocode.

In *The New Hacker’s Dictionary*, Eric S. Raymond gives the following definition for “compact”:

Compact *adj.* Of a design, describes the valuable property that it can all be apprehended at once in one’s head. This generally means the thing created from the design can be used with greater facility and fewer errors than an equivalent tool that is not compact. Compactness does not imply triviality or lack of power; for example, C is compact and FORTRAN is not, but C is more powerful than FORTRAN. Designs become non-compact through accreting features and cruft that don’t merge cleanly into the overall design scheme (thus, some fans of Classic C maintain that ANSI C is no longer compact).

(From http://www.catb.org/~esr/jargon/html/C/compact.html)

In this sense of the word, Python is quite compact, because the language has just a few ideas, which are used in lots of places. Take namespaces, for example. Import a module with `import math`, and you create a new namespace called `math`. Classes are also namespaces that share many of the properties of modules, and have a few of their own; for example, you can create instances of a class. Instances? They’re yet another namespace. Namespaces are currently implemented as Python dictionaries, so they have the same methods as the standard dictionary data type: `.keys()` returns all the keys, and so forth.

This simplicity arises from Python’s development history. The language syntax derives from different sources; ABC, a relatively obscure teaching language, is one primary influence, and Modula-3 is another. (For more information about ABC and Modula-3, consult their respective Web sites at http://www.cwi.nl/~steven/abc/ and
http://www.m3.org.) Other features have come from C, Icon, Algol-68, and even Perl. Python hasn’t really innovated very much, but instead has tried to keep the language small and easy to learn, building on ideas that have been tried in other languages and found useful.

Simplicity is a virtue that should not be underestimated. It lets you learn the language more quickly, and then rapidly write code – code that often works the first time you run it.

Java Integration

If you’re working with Java, Jython (http://www.jython.org/) is definitely worth your attention. Jython is a re-implementation of Python in Java that compiles Python code into Java bytecodes. The resulting environment has very tight, almost seamless, integration with Java. It’s trivial to access Java classes from Python, and you can write Python classes that subclass Java classes. Jython can be used for prototyping Java applications in much the same way CPython is used, and it can also be used for test suites for Java code, or embedded in a Java application to add scripting capabilities.
Let's say that you've decided upon Python as the best choice for your application. How can you convince your management, or your fellow developers, to use Python? This section lists some common arguments against using Python, and provides some possible rebuttals.

**Python is freely available software that doesn’t cost anything. How good can it be?**

Very good, indeed. These days Linux and Apache, two other pieces of open source software, are becoming more respected as alternatives to commercial software, but Python hasn't had all the publicity.

Python has been around for several years, with many users and developers. Accordingly, the interpreter has been used by many people, and has gotten most of the bugs shaken out of it. While bugs are still discovered at intervals, they're usually either quite obscure (they'd have to be, for no one to have run into them before) or they involve interfaces to external libraries. The internals of the language itself are quite stable.

Having the source code should be viewed as making the software available for peer review; people can examine the code, suggest (and implement) improvements, and track down bugs. To find out more about the idea of open source code, along with arguments and case studies supporting it, go to [http://www.opensource.org](http://www.opensource.org).

**Who's going to support it?**

Python has a sizable community of developers, and the number is still growing. The Internet community surrounding the language is an
active one, and is worth being considered another one of Python’s advantages. Most questions posted to the comp.lang.python newsgroup are quickly answered by someone.

Should you need to dig into the source code, you’ll find it’s clear and well-organized, so it’s not very difficult to write extensions and track down bugs yourself. If you’d prefer to pay for support, there are companies and individuals who offer commercial support for Python.

**Who uses Python for serious work?**

Lots of people; one interesting thing about Python is the surprising diversity of applications that it’s been used for. People are using Python to:

- Run Web sites
- Write GUI interfaces
- Control number-crunching code on supercomputers
- Make a commercial application scriptable by embedding the Python interpreter inside it
- Process large XML data sets
- Build test suites for C or Java code

Whatever your application domain is, there’s probably someone who’s used Python for something similar. Yet, despite being useable for such high-end applications, Python’s still simple enough to use for little jobs.

See [http://wiki.python.org/moin/OrganizationsUsingPython](http://wiki.python.org/moin/OrganizationsUsingPython) for a list of some of the organizations that use Python.

**What are the restrictions on Python’s use?**

They’re practically nonexistent. Consult the `Misc/COPYRIGHT` file in the source distribution, or the section *History and License* for the full language, but it boils down to three conditions:
You have to leave the copyright notice on the software; if you don't include the source code in a product, you have to put the copyright notice in the supporting documentation.

Don't claim that the institutions that have developed Python endorse your product in any way.

If something goes wrong, you can't sue for damages. Practically all software licenses contain this condition.

Notice that you don't have to provide source code for anything that contains Python or is built with it. Also, the Python interpreter and accompanying documentation can be modified and redistributed in any way you like, and you don't have to pay anyone any licensing fees at all.

Why should we use an obscure language like Python instead of well-known language X?

I hope this HOWTO, and the documents listed in the final section, will help convince you that Python isn't obscure, and has a healthily growing user base. One word of advice: always present Python's positive advantages, instead of concentrating on language X's failings. People want to know why a solution is good, rather than why all the other solutions are bad. So instead of attacking a competing solution on various grounds, simply show how Python's virtues can help.
http://www.pythonology.com/success

The Python Success Stories are a collection of stories from successful users of Python, with the emphasis on business and corporate users.

http://home.pacbell.net/ouster/scripting.html

John Ousterhout's white paper on scripting is a good argument for the utility of scripting languages, though naturally enough, he emphasizes Tcl, the language he developed. Most of the arguments would apply to any scripting language.

http://www.python.org/workshops/1997-10/proceedings/beazley.html

The authors, David M. Beazley and Peter S. Lomdahl, describe their use of Python at Los Alamos National Laboratory. It's another good example of how Python can help get real work done. This quotation from the paper has been echoed by many people:

Originally developed as a large monolithic application for massively parallel processing systems, we have used Python to transform our application into a flexible, highly modular, and extremely powerful system for performing simulation, data analysis, and visualization. In addition, we describe how Python has solved a number of important problems related to the development, debugging, deployment, and maintenance of scientific software.

This interview with Andy Feit, discussing Infoseek's use of Python, can be used to show that choosing Python didn't introduce any difficulties into a company's development process,
and provided some substantial benefits.

http://www.python.org/workshops/1997-10/proceedings/stein.ps

For the 6th Python conference, Greg Stein presented a paper that traced Python’s adoption and usage at a startup called eShop, and later at Microsoft.

http://www.opensource.org

Management may be doubtful of the reliability and usefulness of software that wasn’t written commercially. This site presents arguments that show how open source software can have considerable advantages over closed-source software.

http://www.faqs.org/docs/Linux-mini/Advocacy.html

The Linux Advocacy mini-HOWTO was the inspiration for this document, and is also well worth reading for general suggestions on winning acceptance for a new technology, such as Linux or Python. In general, you won’t make much progress by simply attacking existing systems and complaining about their inadequacies; this often ends up looking like unfocused whining. It’s much better to point out some of the many areas where Python is an improvement over other systems.
Porting Extension Modules to 3.0

**author:** Benjamin Peterson

**Abstract**

Although changing the C-API was not one of Python 3.0's objectives, the many Python level changes made leaving 2.x's API intact impossible. In fact, some changes such as `int()` and `long()` unification are more obvious on the C level. This document endeavors to document incompatibilities and how they can be worked around.
Conditional compilation

The easiest way to compile only some code for 3.0 is to check if `PY_MAJOR_VERSION` is greater than or equal to 3.

```c
#if PY_MAJOR_VERSION >= 3
#define IS_PY3K
#endif
```

API functions that are not present can be aliased to their equivalents within conditional blocks.
Changes to Object APIs

Python 3.0 merged together some types with similar functions while cleanly separating others.

str/unicode Unification

Python 3.0’s `str()` (PyString_* functions in C) type is equivalent to 2.x’s `unicode()` (PyUnicode_*). The old 8-bit string type has become `bytes()`. Python 2.6 and later provide a compatibility header, `bytesobject.h`, mapping `PyBytes` names to `PyString` ones. For best compatibility with 3.0, `PyUnicode` should be used for textual data and `PyBytes` for binary data. It’s also important to remember that `PyBytes` and `PyUnicode` in 3.0 are not interchangeable like `PyString` and `PyUnicode` in 2.x. The following example shows best practices with regards to `PyUnicode`, `PyString`, and `PyBytes`.

```c
#include "stdlib.h"
#include "Python.h"
#include "bytesobject.h"

/* text example */
static PyObject *
say_hello(PyObject *self, PyObject *args) {
    PyObject *name, *result;

    if (!PyArg_ParseTuple(args, "U:say_hello", &name))
        return NULL;

    result = PyUnicode_FromFormat("Hello, %S!", name);
    return result;
}

/* just a forward */
static char * do_encode(PyObject *);

/* bytes example */
static PyObject *
```
long/int Unification

In Python 3.0, there is only one integer type. It is called `int()` on the Python level, but actually corresponds to 2.x's `long()` type. In the C-API, `PyInt_*` functions are replaced by their `PyLong_*` neighbors. The best course of action here is using the `PyInt_*` functions aliased to `PyLong_*` found in `intobject.h`. The abstract `PyNumber_*` APIs can also be used in some cases.
Module initialization and state

Python 3.0 has a revamped extension module initialization system. (See PEP PEP 3121.) Instead of storing module state in globals, they should be stored in an interpreter specific structure. Creating modules that act correctly in both 2.x and 3.0 is tricky. The following simple example demonstrates how.

```c
#include "Python.h"

struct module_state {
    PyObject *error;
};

#if PY_MAJOR_VERSION >= 3
#define GETSTATE(m) ((struct module_state*)PyModule_GetState(m))
#else
#define GETSTATE(m) (&_state)
#endif

static struct module_state _state;

static PyObject *
error_out(PyObject *m) {
    struct module_state *st = GETSTATE(m);
    PyErr_SetString(st->error, "something bad happened");
    return NULL;
}

static PyMethodDef myextension_methods[] = {
    {"error_out", (PyCFunction)error_out, METH_NOARGS, NULL},
    {NULL, NULL}
};

#if PY_MAJOR_VERSION >= 3
static int myextension_traverse(PyObject *m, visitproc visit, void *v) {
    Py_VISIT(GETSTATE(m)->error);
    return 0;
}

static int myextension_clear(PyObject *m) {
    Py_CLEAR(GETSTATE(m)->error);
    return 0;
}
```
static struct PyModuleDef moduledef = {
    PyModuleDef_HEAD_INIT,
    "myextension",
    NULL,
    sizeof(struct module_state),
    myextension_methods,
    NULL,
    myextension_traverse,
    myextension_clear,
    NULL
};

#define INITERROR return NULL

PyObject * PyInit_myextension(void)

#else
#define INITERROR return void
#endif

{ #if PY_MAJOR_VERSION >= 3
    PyObject *module = PyModule_Create(&moduledef);
#else
    PyObject *module = Py_InitModule("myextension", myextension_methods);
#endif

if (module == NULL)
    INITERROR;
struct module_state *st = GETSTATE(module);

st->error = PyErr_NewException("myextension.Error", NULL, NULL);
if (st->error == NULL) {
    Py_DECREF(module);
    INITERROR;
}

#if PY_MAJOR_VERSION >= 3
    return module;
#endif
}
Other options

If you are writing a new extension module, you might consider Cython. It translates a Python-like language to C. The extension modules it creates are compatible with Python 3.x and 2.x.
Curses Programming with Python

Author: A.M. Kuchling, Eric S. Raymond
Release: 2.03

Abstract

This document describes how to write text-mode programs with Python 2.x, using the `curses` extension module to control the display.
What is curses?

The curses library supplies a terminal-independent screen-painting and keyboard-handling facility for text-based terminals; such terminals include VT100s, the Linux console, and the simulated terminal provided by X11 programs such as xterm and rxvt. Display terminals support various control codes to perform common operations such as moving the cursor, scrolling the screen, and erasing areas. Different terminals use widely differing codes, and often have their own minor quirks.

In a world of X displays, one might ask “why bother”? It’s true that character-cell display terminals are an obsolete technology, but there are niches in which being able to do fancy things with them are still valuable. One is on small-footprint or embedded Unixes that don’t carry an X server. Another is for tools like OS installers and kernel configurators that may have to run before X is available.

The curses library hides all the details of different terminals, and provides the programmer with an abstraction of a display, containing multiple non-overlapping windows. The contents of a window can be changed in various ways—adding text, erasing it, changing its appearance—and the curses library will automagically figure out what control codes need to be sent to the terminal to produce the right output.

The curses library was originally written for BSD Unix; the later System V versions of Unix from AT&T added many enhancements and new functions. BSD curses is no longer maintained, having been replaced by ncurses, which is an open-source implementation of the AT&T interface. If you're using an open-source Unix such as Linux or FreeBSD, your system almost certainly uses ncurses. Since most current commercial Unix versions are based on System V code, all the functions described here will probably be available. The older
versions of curses carried by some proprietary Unixes may not support everything, though.

No one has made a Windows port of the curses module. On a Windows platform, try the Console module written by Fredrik Lundh. The Console module provides cursor-addressable text output, plus full support for mouse and keyboard input, and is available from http://effbot.org/zone/console-index.htm.

The Python curses module

 Thy Python module is a fairly simple wrapper over the C functions provided by curses; if you're already familiar with curses programming in C, it's really easy to transfer that knowledge to Python. The biggest difference is that the Python interface makes things simpler, by merging different C functions such as `addstr()`, `mvaddstr()`, `mvwaddstr()`, into a single `addstr()` method. You'll see this covered in more detail later.

This HOWTO is simply an introduction to writing text-mode programs with curses and Python. It doesn't attempt to be a complete guide to the curses API; for that, see the Python library guide's section on `ncurses`, and the C manual pages for `ncurses`. It will, however, give you the basic ideas.
Starting and ending a curses application

Before doing anything, curses must be initialized. This is done by calling the `initscr()` function, which will determine the terminal type, send any required setup codes to the terminal, and create various internal data structures. If successful, `initscr()` returns a window object representing the entire screen; this is usually called `stdscr`, after the name of the corresponding C variable.

```python
import curses
stdscr = curses.initscr()
```

Usually curses applications turn off automatic echoing of keys to the screen, in order to be able to read keys and only display them under certain circumstances. This requires calling the `noecho()` function.

```python
curses.noecho()
```

Applications will also commonly need to react to keys instantly, without requiring the Enter key to be pressed; this is called cbreak mode, as opposed to the usual buffered input mode.

```python
curses.cbreak()
```

Terminals usually return special keys, such as the cursor keys or navigation keys such as Page Up and Home, as a multibyte escape sequence. While you could write your application to expect such sequences and process them accordingly, curses can do it for you, returning a special value such as `curses.KEY_LEFT`. To get curses to do the job, you'll have to enable keypad mode.

```python
stdscr.keypad(1)
```

Terminating a curses application is much easier than starting one.
You'll need to call

curses.nocbreak(); stdscr.kepad(0); curses.echo()

to reverse the curses-friendly terminal settings. Then call the `endwin()` function to restore the terminal to its original operating mode.

curses.endwin()

A common problem when debugging a curses application is to get your terminal messed up when the application dies without restoring the terminal to its previous state. In Python this commonly happens when your code is buggy and raises an uncaught exception. Keys are no longer be echoed to the screen when you type them, for example, which makes using the shell difficult.

In Python you can avoid these complications and make debugging much easier by importing the module `curses.wrapper`. It supplies a `wrapper()` function that takes a callable. It does the initializations described above, and also initializes colors if color support is present. It then runs your provided callable and finally deinitializes appropriately. The callable is called inside a try-catch clause which catches exceptions, performs curses deinitialization, and then passes the exception upwards. Thus, your terminal won’t be left in a funny state on exception.
Windows and Pads

Windows are the basic abstraction in curses. A window object represents a rectangular area of the screen, and supports various methods to display text, erase it, allow the user to input strings, and so forth.

The `stdscr` object returned by the `initscr()` function is a window object that covers the entire screen. Many programs may need only this single window, but you might wish to divide the screen into smaller windows, in order to redraw or clear them separately. The `newwin()` function creates a new window of a given size, returning the new window object.

```
begin_x = 20 ; begin_y = 7
height = 5 ; width = 40
win = curses.newwin(height, width, begin_y, begin_x)
```

A word about the coordinate system used in curses: coordinates are always passed in the order \( y,x \), and the top-left corner of a window is coordinate \((0,0)\). This breaks a common convention for handling coordinates, where the \( x \) coordinate usually comes first. This is an unfortunate difference from most other computer applications, but it's been part of curses since it was first written, and it's too late to change things now.

When you call a method to display or erase text, the effect doesn't immediately show up on the display. This is because curses was originally written with slow 300-baud terminal connections in mind; with these terminals, minimizing the time required to redraw the screen is very important. This lets curses accumulate changes to the screen, and display them in the most efficient manner. For example, if your program displays some characters in a window, and then clears the window, there's no need to send the original characters
because they'd never be visible.

Accordingly, curses requires that you explicitly tell it to redraw windows, using the `refresh()` method of window objects. In practice, this doesn't really complicate programming with curses much. Most programs go into a flurry of activity, and then pause waiting for a keypress or some other action on the part of the user. All you have to do is to be sure that the screen has been redrawn before pausing to wait for user input, by simply calling `stdscr.refresh()` or the `refresh()` method of some other relevant window.

A pad is a special case of a window; it can be larger than the actual display screen, and only a portion of it displayed at a time. Creating a pad simply requires the pad's height and width, while refreshing a pad requires giving the coordinates of the on-screen area where a subsection of the pad will be displayed.

```python
pad = curses.newpad(100, 100)
# These loops fill the pad with letters; this is explained in the next section
for y in range(0, 100):
    for x in range(0, 100):
        try: pad.addch(y, x, ord('a') + (x*x+y*y) % 26 )
        except curses.error: pass

# Displays a section of the pad in the middle of the screen
pad.refresh( 0,0, 5,5, 20,75)
```

The `refresh()` call displays a section of the pad in the rectangle extending from coordinate (5,5) to coordinate (20,75) on the screen; the upper left corner of the displayed section is coordinate (0,0) on the pad. Beyond that difference, pads are exactly like ordinary windows and support the same methods.

If you have multiple windows and pads on screen there is a more efficient way to go, which will prevent annoying screen flicker at refresh time. Use the `noutrefresh()` method of each window to
update the data structure representing the desired state of the screen; then change the physical screen to match the desired state in one go with the function `doupdate()`. The normal `refresh()` method calls `doupdate()` as its last act.
Displaying Text

From a C programmer’s point of view, curses may sometimes look like a twisty maze of functions, all subtly different. For example, `addstr()` displays a string at the current cursor location in the `stdscr` window, while `mvaddstr()` moves to a given y,x coordinate first before displaying the string. `waddstr()` is just like `addstr()`, but allows specifying a window to use, instead of using `stdscr` by default. `mvwaddstr()` follows similarly.

Fortunately the Python interface hides all these details; `stdscr` is a window object like any other, and methods like `addstr()` accept multiple argument forms. Usually there are four different forms.

<table>
<thead>
<tr>
<th>Form</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>str</code> or <code>ch</code></td>
<td>Display the string <code>str</code> or character <code>ch</code> at the current position</td>
</tr>
<tr>
<td><code>str</code> or <code>ch</code>, <code>attr</code></td>
<td>Display the string <code>str</code> or character <code>ch</code>, using attribute <code>attr</code> at the current position</td>
</tr>
<tr>
<td><code>y, x, str or ch</code></td>
<td>Move to position <code>y,x</code> within the window, and display <code>str</code> or <code>ch</code></td>
</tr>
<tr>
<td><code>y, x, str or ch</code>, <code>attr</code></td>
<td>Move to position <code>y,x</code> within the window, and display <code>str</code> or <code>ch</code>, using attribute <code>attr</code></td>
</tr>
</tbody>
</table>

Attributes allow displaying text in highlighted forms, such as in boldface, underline, reverse code, or in color. They’ll be explained in more detail in the next subsection.

The `addstr()` function takes a Python string as the value to be displayed, while the `addch()` functions take a character, which can be either a Python string of length 1 or an integer. If it's a string, you're
limited to displaying characters between 0 and 255. SVr4 curses provides constants for extension characters; these constants are integers greater than 255. For example, **ACS_PLMINUS** is a +/- symbol, and **ACS_ULCORNER** is the upper left corner of a box (handy for drawing borders).

Windows remember where the cursor was left after the last operation, so if you leave out the \( y,x \) coordinates, the string or character will be displayed wherever the last operation left off. You can also move the cursor with the `move(y,x)` method. Because some terminals always display a flashing cursor, you may want to ensure that the cursor is positioned in some location where it won’t be distracting; it can be confusing to have the cursor blinking at some apparently random location.

If your application doesn’t need a blinking cursor at all, you can call `curs_set(0)` to make it invisible. Equivalently, and for compatibility with older curses versions, there’s a `leaveok(bool)` function. When `bool` is true, the curses library will attempt to suppress the flashing cursor, and you won’t need to worry about leaving it in odd locations.

### Attributes and Color

Characters can be displayed in different ways. Status lines in a text-based application are commonly shown in reverse video; a text viewer may need to highlight certain words. curses supports this by allowing you to specify an attribute for each cell on the screen.

An attribute is a integer, each bit representing a different attribute. You can try to display text with multiple attribute bits set, but curses doesn’t guarantee that all the possible combinations are available, or that they’re all visually distinct. That depends on the ability of the terminal being used, so it’s safest to stick to the most commonly available attributes, listed here.
<table>
<thead>
<tr>
<th>Attribute</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>A_BLINK</td>
<td>Blinking text</td>
</tr>
<tr>
<td>A_BOLD</td>
<td>Extra bright or bold text</td>
</tr>
<tr>
<td>A_DIM</td>
<td>Half bright text</td>
</tr>
<tr>
<td>A_REVERSE</td>
<td>Reverse-video text</td>
</tr>
<tr>
<td>A_STANDOUT</td>
<td>The best highlighting mode available</td>
</tr>
<tr>
<td>A_UNDERLINE</td>
<td>Underlined text</td>
</tr>
</tbody>
</table>

So, to display a reverse-video status line on the top line of the screen, you could code:

```python
stdscr.addstr(0, 0, "Current mode: Typing mode", curses.A_REVERSE)
stdscr.refresh()
```

The curses library also supports color on those terminals that provide it. The most common such terminal is probably the Linux console, followed by color xterms.

To use color, you must call the `start_color()` function soon after calling `initscr()`, to initialize the default color set (the `curses.wrapper.wrapper()` function does this automatically). Once that's done, the `has_colors()` function returns TRUE if the terminal in use can actually display color. (Note: curses uses the American spelling ‘color’, instead of the Canadian/British spelling ‘colour’. If you’re used to the British spelling, you’ll have to resign yourself to misspelling it for the sake of these functions.)

The curses library maintains a finite number of color pairs, containing a foreground (or text) color and a background color. You can get the attribute value corresponding to a color pair with the `color_pair()` function; this can be bitwise-OR’ed with other attributes such as `A_REVERSE`, but again, such combinations are not guaranteed to work
on all terminals.

An example, which displays a line of text using color pair 1:

```python
stdscr.addstr( "Pretty text", curses.color_pair(1) )
stdscr.refresh()
```

As I said before, a color pair consists of a foreground and background color. `start_color()` initializes 8 basic colors when it activates color mode. They are: 0:black, 1:red, 2:green, 3:yellow, 4:blue, 5:magenta, 6:cyan, and 7:white. The curses module defines named constants for each of these colors: `curses.COLOR_BLACK`, `curses.COLOR_RED`, and so forth.

The `init_pair(n, f, b)` function changes the definition of color pair `n`, to foreground color `f` and background color `b`. Color pair 0 is hard-wired to white on black, and cannot be changed.

Let’s put all this together. To change color 1 to red text on a white background, you would call:

```python
curses.init_pair(1, curses.COLOR_RED, curses.COLOR_WHITE)
```

When you change a color pair, any text already displayed using that color pair will change to the new colors. You can also display new text in this color with:

```python
stdscr.addstr(0,0, "RED ALERT!", curses.color_pair(1) )
```

Very fancy terminals can change the definitions of the actual colors to a given RGB value. This lets you change color 1, which is usually red, to purple or blue or any other color you like. Unfortunately, the Linux console doesn’t support this, so I’m unable to try it out, and can’t provide any examples. You can check if your terminal can do this by calling `can_change_color()`, which returns `TRUE` if the
capability is there. If you're lucky enough to have such a talented terminal, consult your system's man pages for more information.
The curses library itself offers only very simple input mechanisms. Python's support adds a text-input widget that makes up some of the lack.

The most common way to get input to a window is to use its `getch()` method. `getch()` pauses and waits for the user to hit a key, displaying it if `echo()` has been called earlier. You can optionally specify a coordinate to which the cursor should be moved before pausing.

It's possible to change this behavior with the method `nodelay()`. After `nodelay(1)`, `getch()` for the window becomes non-blocking and returns `curses.ERR` (a value of -1) when no input is ready. There's also a `halfdelay()` function, which can be used to (in effect) set a timer on each `getch()`; if no input becomes available within a specified delay (measured in tenths of a second), curses raises an exception.

The `getch()` method returns an integer; if it's between 0 and 255, it represents the ASCII code of the key pressed. Values greater than 255 are special keys such as Page Up, Home, or the cursor keys. You can compare the value returned to constants such as `curses.KEY_PPAGE`, `curses.KEY_HOME`, or `curses.KEY_LEFT`. Usually the main loop of your program will look something like this:

```python
while 1:
    c = stdscr.getch()
    if c == ord('p'): PrintDocument()
    elif c == ord('q'): break  # Exit the while()
    elif c == curses.KEY_HOME: x = y = 0
```

The `curses.ascii` module supplies ASCII class membership
functions that take either integer or 1-character-string arguments; these may be useful in writing more readable tests for your command interpreters. It also supplies conversion functions that take either integer or 1-character-string arguments and return the same type. For example, `curses.ascii.ctrl()` returns the control character corresponding to its argument.

There's also a method to retrieve an entire string, `getstr()`. It isn't used very often, because its functionality is quite limited; the only editing keys available are the backspace key and the Enter key, which terminates the string. It can optionally be limited to a fixed number of characters.

```python
curses.echo()  # Enable echoing of characters

# Get a 15-character string, with the cursor on the top line
s = stdscr.getstr(0,0, 15)
```

The Python `curses.textpad` module supplies something better. With it, you can turn a window into a text box that supports an Emacs-like set of keybindings. Various methods of `Textbox` class support editing with input validation and gathering the edit results either with or without trailing spaces. See the library documentation on `curses.textpad` for the details.
For More Information

This HOWTO didn’t cover some advanced topics, such as screen-scraping or capturing mouse events from an xterm instance. But the Python library page for the curses modules is now pretty complete. You should browse it next.

If you’re in doubt about the detailed behavior of any of the ncurses entry points, consult the manual pages for your curses implementation, whether it’s ncurses or a proprietary Unix vendor’s. The manual pages will document any quirks, and provide complete lists of all the functions, attributes, and \texttt{ACS_*} characters available to you.

Because the curses API is so large, some functions aren’t supported in the Python interface, not because they’re difficult to implement, but because no one has needed them yet. Feel free to add them and then submit a patch. Also, we don’t yet have support for the menus or panels libraries associated with ncurses; feel free to add that.

If you write an interesting little program, feel free to contribute it as another demo. We can always use more of them!

Idioms and Anti-Idioms in Python

Author: Moshe Zadka

This document is placed in the public domain.

Abstract

This document can be considered a companion to the tutorial. It shows how to use Python, and even more importantly, how not to use Python.
Language Constructs You Should Not Use

While Python has relatively few gotchas compared to other languages, it still has some constructs which are only useful in corner cases, or are plain dangerous.

from module import *

Inside Function Definitions

`from module import *` is *invalid* inside function definitions. While many versions of Python do not check for the invalidity, it does not make it more valid, no more then having a smart lawyer makes a man innocent. Do not use it like that ever. Even in versions where it was accepted, it made the function execution slower, because the compiler could not be certain which names are local and which are global. In Python 2.1 this construct causes warnings, and sometimes even errors.

At Module Level

While it is valid to use `from module import *` at module level it is usually a bad idea. For one, this loses an important property Python otherwise has — you can know where each toplevel name is defined by a simple “search” function in your favourite editor. You also open yourself to trouble in the future, if some module grows additional functions or classes.

One of the most awful question asked on the newsgroup is why this code:

```
f = open("www")
f.read()
```
does not work. Of course, it works just fine (assuming you have a file called “www”). But it does not work if somewhere in the module, the statement `from os import *` is present. The `os` module has a function called `open()` which returns an integer. While it is very useful, shadowing builtins is one of its least useful properties.

Remember, you can never know for sure what names a module exports, so either take what you need — `from module import name1, name2`, or keep them in the module and access on a per-need basis — `import module; print module.name`.

**When It Is Just Fine**

There are situations in which `from module import *` is just fine:

- The interactive prompt. For example, `from math import *` makes Python an amazing scientific calculator.
- When extending a module in C with a module in Python.
- When the module advertises itself as `from import *` safe.

**Unadorned exec, execfile() and friends**

The word “unadorned” refers to the use without an explicit dictionary, in which case those constructs evaluate code in the `current` environment. This is dangerous for the same reasons `from import *` is dangerous — it might step over variables you are counting on and mess up things for the rest of your code. Simply do not do that.

Bad examples:

```python
>>> for name in sys.argv[1]:
    exec "%s=1" % name
>>> def func(s, **kw):
    for var, val in kw.items():
        exec "%s.%s=val" % var  # invalid!
>>> execfile("handler.py")
```
from module import name1, name2

This is a “don’t” which is much weaker than the previous “don’t”s but is still something you should not do if you don’t have good reasons to do that. The reason it is usually bad idea is because you suddenly have an object which lives in two separate namespaces. When the binding in one namespace changes, the binding in the other will not, so there will be a discrepancy between them. This happens when, for example, one module is reloaded, or changes the definition of a function at runtime.

Bad example:

```python
# foo.py
a = 1

# bar.py
from foo import a
if something():
    a = 2 # danger: foo.a != a
```

Good example:

```python
# foo.py
a = 1
```
Python has the `except:` clause, which catches all exceptions. Since every error in Python raises an exception, this makes many programming errors look like runtime problems, and hinders the debugging process.

The following code shows a great example:

```python
try:
    foo = open("file")  # misspelled "open"
except:
    sys.exit("could not open file!")
```

The second line triggers a `NameError` which is caught by the `except` clause. The program will exit, and you will have no idea that this has nothing to do with the readability of "file".

The example above is better written

```python
try:
    foo = open("file")  # will be changed to "open" as soon as we run it
except IOError:
    sys.exit("could not open file")
```

There are some situations in which the `except:` clause is useful: for example, in a framework when running callbacks, it is good not to let any callback disturb the framework.
Exceptions

Exceptions are a useful feature of Python. You should learn to raise them whenever something unexpected occurs, and catch them only where you can do something about them.

The following is a very popular anti-idiom

```python
def get_status(file):
    if not os.path.exists(file):
        print "file not found"
        sys.exit(1)
    return open(file).readline()
```

Consider the case the file gets deleted between the time the call to `os.path.exists()` is made and the time `open()` is called. That means the last line will throw an `IOError`. The same would happen if `file` exists but has no read permission. Since testing this on a normal machine on existing and non-existing files make it seem bugless, that means in testing the results will seem fine, and the code will get shipped. Then an unhandled `IOError` escapes to the user, who has to watch the ugly traceback.

Here is a better way to do it.

```python
def get_status(file):
    try:
        return open(file).readline()
    except (IOError, OSError):
        print "file not found"
        sys.exit(1)
```

In this version, *either* the file gets opened and the line is read (so it works even on flaky NFS or SMB connections), or the message is printed and the application aborted.
Still, `get_status()` makes too many assumptions — that it will only be used in a short running script, and not, say, in a long running server. Sure, the caller could do something like

```python
try:
    status = get_status(log)
except SystemExit:
    status = None
```

So, try to make as few `except` clauses in your code — those will usually be a catch-all in the `main()`, or inside calls which should always succeed.

So, the best version is probably

```python
def get_status(file):
    return open(file).readline()
```

The caller can deal with the exception if it wants (for example, if it tries several files in a loop), or just let the exception filter upwards to its caller.

The last version is not very good either — due to implementation details, the file would not be closed when an exception is raised until the handler finishes, and perhaps not at all in non-C implementations (e.g., Jython).

```python
def get_status(file):
    fp = open(file)
    try:
        return fp.readline()
    finally:
        fp.close()
```
Using the Batteries

Every so often, people seem to be writing stuff in the Python library again, usually poorly. While the occasional module has a poor interface, it is usually much better to use the rich standard library and data types that come with Python then inventing your own.

A useful module very few people know about is `os.path`. It always has the correct path arithmetic for your operating system, and will usually be much better then whatever you come up with yourself.

Compare:

```python
# ugh!
return dir+"/"+file
# better
return os.path.join(dir, file)
```

More useful functions in `os.path`: `basename()`, `dirname()` and `splitext()`.

There are also many useful builtin functions people seem not to be aware of for some reason: `min()` and `max()` can find the minimum/maximum of any sequence with comparable semantics, for example, yet many people write their own `max()/min()`. Another highly useful function is `reduce()`. A classical use of `reduce()` is something like

```python
import sys, operator
nums = map(float, sys.argv[1:])
print reduce(operator.add, nums)/len(nums)
```

This cute little script prints the average of all numbers given on the command line. The `reduce()` adds up all the numbers, and the rest is just some pre- and postprocessing.
On the same note, note that `float()`, `int()` and `long()` all accept arguments of type string, and so are suited to parsing — assuming you are ready to deal with the `ValueError` they raise.
Using Backslash to Continue Statements

Since Python treats a newline as a statement terminator, and since statements are often more than is comfortable to put in one line, many people do:

```python
if foo.bar()]['first'][0] == baz.quux(1, 2)[5:9] and \
calculate_number(10, 20) != forbulate(500, 360):
    pass
```

You should realize that this is dangerous: a stray space after the `\` would make this line wrong, and stray spaces are notoriously hard to see in editors. In this case, at least it would be a syntax error, but if the code was:

```python
value = foo.bar()]['first'][0]*baz.quux(1, 2)[5:9] \n    + calculate_number(10, 20)*forbulate(500, 360)
```

then it would just be subtly wrong.

It is usually much better to use the implicit continuation inside parenthesis:

This version is bulletproof:

```python
value = (foo.bar()]['first'][0]*baz.quux(1, 2)[5:9] 
    + calculate_number(10, 20)*forbulate(500, 360)
```
Functional Programming HOWTO

**Author:** A. M. Kuchling  
**Release:** 0.31

(This is a first draft. Please send comments/error reports/suggestions to amk@amk.ca.)

In this document, we'll take a tour of Python's features suitable for implementing programs in a functional style. After an introduction to the concepts of functional programming, we'll look at language features such as *iterators* and *generators* and relevant library modules such as *itertools* and *functools*. 

Introduction

This section explains the basic concept of functional programming; if you’re just interested in learning about Python language features, skip to the next section.

Programming languages support decomposing problems in several different ways:

- Most programming languages are **procedural**: programs are lists of instructions that tell the computer what to do with the program’s input. C, Pascal, and even Unix shells are procedural languages.
- In **declarative** languages, you write a specification that describes the problem to be solved, and the language implementation figures out how to perform the computation efficiently. SQL is the declarative language you’re most likely to be familiar with; a SQL query describes the data set you want to retrieve, and the SQL engine decides whether to scan tables or use indexes, which subclauses should be performed first, etc.
- **Object-oriented** programs manipulate collections of objects. Objects have internal state and support methods that query or modify this internal state in some way. Smalltalk and Java are object-oriented languages. C++ and Python are languages that support object-oriented programming, but don’t force the use of object-oriented features.
- **Functional** programming decomposes a problem into a set of functions. Ideally, functions only take inputs and produce outputs, and don’t have any internal state that affects the output produced for a given input. Well-known functional languages include the ML family (Standard ML, OCaml, and other variants) and Haskell.

The designers of some computer languages choose to emphasize
one particular approach to programming. This often makes it difficult to write programs that use a different approach. Other languages are multi-paradigm languages that support several different approaches. Lisp, C++, and Python are multi-paradigm; you can write programs or libraries that are largely procedural, object-oriented, or functional in all of these languages. In a large program, different sections might be written using different approaches; the GUI might be object-oriented while the processing logic is procedural or functional, for example.

In a functional program, input flows through a set of functions. Each function operates on its input and produces some output. Functional style discourages functions with side effects that modify internal state or make other changes that aren’t visible in the function’s return value. Functions that have no side effects at all are called purely functional. Avoiding side effects means not using data structures that get updated as a program runs; every function’s output must only depend on its input.

Some languages are very strict about purity and don’t even have assignment statements such as `a=3` or `c = a + b`, but it’s difficult to avoid all side effects. Printing to the screen or writing to a disk file are side effects, for example. For example, in Python a `print` statement or a `time.sleep(1)` both return no useful value; they’re only called for their side effects of sending some text to the screen or pausing execution for a second.

Python programs written in functional style usually won’t go to the extreme of avoiding all I/O or all assignments; instead, they’ll provide a functional-appearing interface but will use non-functional features internally. For example, the implementation of a function will still use assignments to local variables, but won’t modify global variables or have other side effects.

Functional programming can be considered the opposite of object-
oriented programming. Objects are little capsules containing some internal state along with a collection of method calls that let you modify this state, and programs consist of making the right set of state changes. Functional programming wants to avoid state changes as much as possible and works with data flowing between functions. In Python you might combine the two approaches by writing functions that take and return instances representing objects in your application (e-mail messages, transactions, etc.).

Functional design may seem like an odd constraint to work under. Why should you avoid objects and side effects? There are theoretical and practical advantages to the functional style:

- Formal provability.
- Modularity.
- Composability.
- Ease of debugging and testing.

**Formal provability**

A theoretical benefit is that it's easier to construct a mathematical proof that a functional program is correct.

For a long time researchers have been interested in finding ways to mathematically prove programs correct. This is different from testing a program on numerous inputs and concluding that its output is usually correct, or reading a program's source code and concluding that the code looks right; the goal is instead a rigorous proof that a program produces the right result for all possible inputs.

The technique used to prove programs correct is to write down **invariants**, properties of the input data and of the program's variables that are always true. For each line of code, you then show that if invariants \( X \) and \( Y \) are true **before** the line is executed, the slightly different invariants \( X' \) and \( Y' \) are true **after** the line is
executed. This continues until you reach the end of the program, at which point the invariants should match the desired conditions on the program's output.

Functional programming's avoidance of assignments arose because assignments are difficult to handle with this technique; assignments can break invariants that were true before the assignment without producing any new invariants that can be propagated onward.

Unfortunately, proving programs correct is largely impractical and not relevant to Python software. Even trivial programs require proofs that are several pages long; the proof of correctness for a moderately complicated program would be enormous, and few or none of the programs you use daily (the Python interpreter, your XML parser, your web browser) could be proven correct. Even if you wrote down or generated a proof, there would then be the question of verifying the proof; maybe there's an error in it, and you wrongly believe you've proved the program correct.

**Modularity**

A more practical benefit of functional programming is that it forces you to break apart your problem into small pieces. Programs are more modular as a result. It's easier to specify and write a small function that does one thing than a large function that performs a complicated transformation. Small functions are also easier to read and to check for errors.

**Ease of debugging and testing**

Testing and debugging a functional-style program is easier.

Debugging is simplified because functions are generally small and clearly specified. When a program doesn't work, each function is an interface point where you can check that the data are correct. You
can look at the intermediate inputs and outputs to quickly isolate the function that's responsible for a bug.

Testing is easier because each function is a potential subject for a unit test. Functions don’t depend on system state that needs to be replicated before running a test; instead you only have to synthesize the right input and then check that the output matches expectations.

### Composability

As you work on a functional-style program, you’ll write a number of functions with varying inputs and outputs. Some of these functions will be unavoidably specialized to a particular application, but others will be useful in a wide variety of programs. For example, a function that takes a directory path and returns all the XML files in the directory, or a function that takes a filename and returns its contents, can be applied to many different situations.

Over time you'll form a personal library of utilities. Often you’ll assemble new programs by arranging existing functions in a new configuration and writing a few functions specialized for the current task.
Iterators

I’ll start by looking at a Python language feature that’s an important foundation for writing functional-style programs: iterators.

An iterator is an object representing a stream of data; this object returns the data one element at a time. A Python iterator must support a method called `next()` that takes no arguments and always returns the next element of the stream. If there are no more elements in the stream, `next()` must raise the `StopIteration` exception. Iterators don’t have to be finite, though; it’s perfectly reasonable to write an iterator that produces an infinite stream of data.

The built-in `iter()` function takes an arbitrary object and tries to return an iterator that will return the object’s contents or elements, raising `TypeError` if the object doesn’t support iteration. Several of Python’s built-in data types support iteration, the most common being lists and dictionaries. An object is called an `iterable` object if you can get an iterator for it.

You can experiment with the iteration interface manually:

```python
>>> L = [1,2,3]
>>> it = iter(L)
>>> print(it)
<...iterator object at ...>
>>> it.next()
1
>>> it.next()
2
>>> it.next()
3
>>> it.next()
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
StopIteration
>>>```
Python expects iterable objects in several different contexts, the most important being the `for` statement. In the statement `for X in Y`, Y must be an iterator or some object for which `iter()` can create an iterator. These two statements are equivalent:

```python
for i in iter(obj):
    print i

for i in obj:
    print i
```

Iterators can be materialized as lists or tuples by using the `list()` or `tuple()` constructor functions:

```python
>>> L = [1,2,3]
>>> iterator = iter(L)
>>> t = tuple(iterator)
>>> t
(1, 2, 3)
```

Sequence unpacking also supports iterators: if you know an iterator will return N elements, you can unpack them into an N-tuple:

```python
>>> L = [1,2,3]
>>> iterator = iter(L)
>>> a,b,c = iterator
>>> a,b,c
(1, 2, 3)
```

Built-in functions such as `max()` and `min()` can take a single iterator argument and will return the largest or smallest element. The "in" and "not in" operators also support iterators: `X in iterator` is true if X is found in the stream returned by the iterator. You'll run into obvious problems if the iterator is infinite; `max()`, `min()`, and "not in" will never return, and if the element X never appears in the stream, the "in" operator won't return either.
Note that you can only go forward in an iterator; there's no way to get the previous element, reset the iterator, or make a copy of it. Iterator objects can optionally provide these additional capabilities, but the iterator protocol only specifies the `next()` method. Functions may therefore consume all of the iterator's output, and if you need to do something different with the same stream, you'll have to create a new iterator.

### Data Types That Support Iterators

We've already seen how lists and tuples support iterators. In fact, any Python sequence type, such as strings, will automatically support creation of an iterator.

Calling `iter()` on a dictionary returns an iterator that will loop over the dictionary's keys:

```python
>>> m = {'Jan': 1, 'Feb': 2, 'Mar': 3, 'Apr': 4, 'May': 5, 'Jun ...
...     'Jul': 7, 'Aug': 8, 'Sep': 9, 'Oct': 10, 'Nov': 11, 'D

>>> for key in m:
...     print key, m[key]
Mar 3
Feb 2
Aug 8
Sep 9
Apr 4
Jun 6
Jul 7
Jan 1
May 5
Nov 11
Dec 12
Oct 10
```

Note that the order is essentially random, because it's based on the hash ordering of the objects in the dictionary.

Applying `iter()` to a dictionary always loops over the keys, but
dictionaries have methods that return other iterators. If you want to iterate over keys, values, or key/value pairs, you can explicitly call the `iterkeys()`, `itervalues()`, or `iteritems()` methods to get an appropriate iterator.

The `dict()` constructor can accept an iterator that returns a finite stream of `(key, value)` tuples:

```python
>>> L = [('Italy', 'Rome'), ('France', 'Paris'), ('US', 'Washington DC')
>>> dict(iter(L))
{'Italy': 'Rome', 'US': 'Washington DC', 'France': 'Paris'}
```

Files also support iteration by calling the `readline()` method until there are no more lines in the file. This means you can read each line of a file like this:

```python
for line in file:
    # do something for each line
...
```

Sets can take their contents from an iterable and let you iterate over the set's elements:

```python
S = set((2, 3, 5, 7, 11, 13))
for i in S:
    print i
```
Generator expressions and list comprehensions

Two common operations on an iterator’s output are 1) performing some operation for every element, 2) selecting a subset of elements that meet some condition. For example, given a list of strings, you might want to strip off trailing whitespace from each line or extract all the strings containing a given substring.

List comprehensions and generator expressions (short form: “listcomps” and “genexps”) are a concise notation for such operations, borrowed from the functional programming language Haskell (http://www.haskell.org). You can strip all the whitespace from a stream of strings with the following code:

```python
line_list = [' line 1
', 'line 2
', ...]

# Generator expression -- returns iterator
stripped_iter = (line.strip() for line in line_list)

# List comprehension -- returns list
stripped_list = [line.strip() for line in line_list]
```

You can select only certain elements by adding an "if" condition:

```python
stripped_list = [line.strip() for line in line_list
if line != '']
```

With a list comprehension, you get back a Python list; `stripped_list` is a list containing the resulting lines, not an iterator. Generator expressions return an iterator that computes the values as necessary, not needing to materialize all the values at once. This means that list comprehensions aren’t useful if you’re working with iterators that return an infinite stream or a very large amount of data. Generator expressions are preferable in these situations.
Generator expressions are surrounded by parentheses (“()”) and list comprehensions are surrounded by square brackets (“[]”). Generator expressions have the form:

```python
(expression for expr in sequence1
  if condition1
  for expr2 in sequence2
    if condition2
    for expr3 in sequence3 ...
      if condition3
      for exprN in sequenceN
        if conditionN)
```

Again, for a list comprehension only the outside brackets are different (square brackets instead of parentheses).

The elements of the generated output will be the successive values of `expression`. The `if` clauses are all optional; if present, `expression` is only evaluated and added to the result when `condition` is true.

Generator expressions always have to be written inside parentheses, but the parentheses signalling a function call also count. If you want to create an iterator that will be immediately passed to a function you can write:

```python
obj_total = sum(obj.count for obj in list_all_objects())
```

The `for...in` clauses contain the sequences to be iterated over. The sequences do not have to be the same length, because they are iterated over from left to right, **not** in parallel. For each element in `sequence1`, `sequence2` is looped over from the beginning. `sequence3` is then looped over for each resulting pair of elements from `sequence1` and `sequence2`.

To put it another way, a list comprehension or generator expression is equivalent to the following Python code:
for expr1 in sequence1:
    if not (condition1):
        continue  # Skip this element
for expr2 in sequence2:
    if not (condition2):
        continue  # Skip this element
...
for exprN in sequenceN:
    if not (conditionN):
        continue  # Skip this element

# Output the value of
# the expression.

This means that when there are multiple for...in clauses but no if clauses, the length of the resulting output will be equal to the product of the lengths of all the sequences. If you have two lists of length 3, the output list is 9 elements long:

```python
globals()['seq1'] = 'abc'
globals()['seq2'] = (1,2,3)
globals()['[(x,y) for x in seq1 for y in seq2]']
[['a', 1], ['a', 2], ['a', 3],
 ['b', 1], ['b', 2], ['b', 3],
 ['c', 1], ['c', 2], ['c', 3]]
```

To avoid introducing an ambiguity into Python's grammar, if expression is creating a tuple, it must be surrounded with parentheses. The first list comprehension below is a syntax error, while the second one is correct:

```python
# Syntax error
[ x,y for x in seq1 for y in seq2]
# Correct
[ (x,y) for x in seq1 for y in seq2]
```
Generators

Generators are a special class of functions that simplify the task of writing iterators. Regular functions compute a value and return it, but generators return an iterator that returns a stream of values.

You’re doubtless familiar with how regular function calls work in Python or C. When you call a function, it gets a private namespace where its local variables are created. When the function reaches a `return` statement, the local variables are destroyed and the value is returned to the caller. A later call to the same function creates a new private namespace and a fresh set of local variables. But, what if the local variables weren’t thrown away on exiting a function? What if you could later resume the function where it left off? This is what generators provide; they can be thought of as resumable functions.

Here’s the simplest example of a generator function:

```python
def generate_ints(N):
    for i in range(N):
        yield i
```

Any function containing a `yield` keyword is a generator function; this is detected by Python’s `bytecode` compiler which compiles the function specially as a result.

When you call a generator function, it doesn’t return a single value; instead it returns a generator object that supports the iterator protocol. On executing the `yield` expression, the generator outputs the value of `i`, similar to a `return` statement. The big difference between `yield` and a `return` statement is that on reaching a `yield` the generator’s state of execution is suspended and local variables are preserved. On the next call to the generator’s `.next()` method, the function will resume executing.
Here's a sample usage of the `generate_ints()` generator:

```python
>>> gen = generate_ints(3)
>>> gen
<generator object at ...>
>>> gen.next()
0
>>> gen.next()
1
>>> gen.next()
2
>>> gen.next()
Traceback (most recent call last):
  File "stdin", line 1, in ?
  File "stdin", line 2, in generate_ints
StopIteration
```

You could equally write `for i in generate_ints(5)`, or `a,b,c = generate_ints(3)`.

Inside a generator function, the `return` statement can only be used without a value, and signals the end of the procession of values; after executing a `return` the generator cannot return any further values. `return` with a value, such as `return 5`, is a syntax error inside a generator function. The end of the generator's results can also be indicated by raising `StopIteration` manually, or by just letting the flow of execution fall off the bottom of the function.

You could achieve the effect of generators manually by writing your own class and storing all the local variables of the generator as instance variables. For example, returning a list of integers could be done by setting `self.count` to 0, and having the `next()` method increment `self.count` and return it. However, for a moderately complicated generator, writing a corresponding class can be much messier.

The test suite included with Python's library, `test_generators.py`, contains a number of more interesting examples. Here's one
generator that implements an in-order traversal of a tree using
generators recursively.

```python
# A recursive generator that generates Tree leaves in in-order.
def inorder(t):
    if t:
        for x in inorder(t.left):
            yield x
        yield t.label
        for x in inorder(t.right):
            yield x
```

Two other examples in `test_generators.py` produce solutions for the
N-Queens problem (placing N queens on an NxN chess board so
that no queen threatens another) and the Knight's Tour (finding a
route that takes a knight to every square of an NxN chessboard
without visiting any square twice).

### Passing values into a generator

In Python 2.4 and earlier, generators only produced output. Once a
generator's code was invoked to create an iterator, there was no way
to pass any new information into the function when its execution is
resumed. You could hack together this ability by making the
generator look at a global variable or by passing in some mutable
object that callers then modify, but these approaches are messy.

In Python 2.5 there's a simple way to pass values into a generator.  
`yield` became an expression, returning a value that can be assigned
to a variable or otherwise operated on:

```python
val = (yield i)
```

I recommend that you **always** put parentheses around a `yield`
expression when you're doing something with the returned value, as
in the above example. The parentheses aren't always necessary, but it's easier to always add them instead of having to remember when they're needed.

(PEP 342 explains the exact rules, which are that a `yield`-expression must always be parenthesized except when it occurs at the top-level expression on the right-hand side of an assignment. This means you can write `val = yield i` but have to use parentheses when there's an operation, as in `val = (yield i) + 12`.)

Values are sent into a generator by calling its `send(value)` method. This method resumes the generator's code and the `yield` expression returns the specified value. If the regular `next()` method is called, the `yield` returns `None`.

Here's a simple counter that increments by 1 and allows changing the value of the internal counter.

```python
def counter(maximum):
    i = 0
    while i < maximum:
        val = (yield i)
        # If value provided, change counter
        if val is not None:
            i = val
        else:
            i += 1
```

And here's an example of changing the counter:

```python
generate = counter(10)
generate.send(2)
generate.send(3)
generate.send(4)
```
Because `yield` will often be returning `None`, you should always check for this case. Don’t just use its value in expressions unless you’re sure that the `send()` method will be the only method used to resume your generator function.

In addition to `send()`, there are two other new methods on generators:

- `throw(type, value=None, traceback=None)` is used to raise an exception inside the generator; the exception is raised by the `yield` expression where the generator’s execution is paused.

- `close()` raises a `GeneratorExit` exception inside the generator to terminate the iteration. On receiving this exception, the generator’s code must either raise `GeneratorExit` or `StopIteration`; catching the exception and doing anything else is illegal and will trigger a `RuntimeError`. `close()` will also be called by Python’s garbage collector when the generator is garbage-collected.

If you need to run cleanup code when a `GeneratorExit` occurs, I suggest using a `try: ... finally:` suite instead of catching `GeneratorExit`.

The cumulative effect of these changes is to turn generators from one-way producers of information into both producers and consumers.

Generators also become **coroutines**, a more generalized form of subroutines. Subroutines are entered at one point and exited at
another point (the top of the function, and a return statement), but coroutines can be entered, exited, and resumed at many different points (the yield statements).
Let’s look in more detail at built-in functions often used with iterators.

Two of Python’s built-in functions, `map()` and `filter()`, are somewhat obsolete; they duplicate the features of list comprehensions but return actual lists instead of iterators.

```
map(f, iterA, iterB, ...) returns a list containing f(iterA[0], iterB[0]), f(iterA[1], iterB[1]), f(iterA[2], iterB[2]), ...
```

```
>>> def upper(s):
...    return s.upper()
```

```
>>> map(upper, ['sentence', 'fragment'])
['SENTENCE', 'FRAGMENT']
```

```
>>> [upper(s) for s in ['sentence', 'fragment']]
['SENTENCE', 'FRAGMENT']
```

As shown above, you can achieve the same effect with a list comprehension. The `itertools.imap()` function does the same thing but can handle infinite iterators; it’ll be discussed later, in the section on the `itertools` module.

```
filter(predicate, iter) returns a list that contains all the sequence elements that meet a certain condition, and is similarly duplicated by list comprehensions. A predicate is a function that returns the truth value of some condition; for use with `filter()`, the predicate must take a single value.
```

```
>>> def is_even(x):
...    return (x % 2) == 0
```

```
>>> filter(is_even, range(10))
[0, 2, 4, 6, 8]
```
This can also be written as a list comprehension:

```python
>>> [x for x in range(10) if is_even(x)]
[0, 2, 4, 6, 8]
```

`filter()` also has a counterpart in the `itertools` module, `itertools.ifilter()`, that returns an iterator and can therefore handle infinite sequences just as `itertools.imap()` can.

`reduce(func, iter, [initial_value])` doesn't have a counterpart in the `itertools` module because it cumulatively performs an operation on all the iterable’s elements and therefore can’t be applied to infinite iterables. `func` must be a function that takes two elements and returns a single value. `reduce()` takes the first two elements A and B returned by the iterator and calculates `func(A, B)`. It then requests the third element, C, calculates `func(func(A, B), C)`, combines this result with the fourth element returned, and continues until the iterable is exhausted. If the iterable returns no values at all, a `TypeError` exception is raised. If the initial value is supplied, it’s used as a starting point and `func(initial_value, A)` is the first calculation.

```python
>>> import operator
>>> reduce(operator.concat, ['A', 'BB', 'C'])
'ABBC'
>>> reduce(operator.concat, [])
Traceback (most recent call last):
  ...  
TypeError: reduce() of empty sequence with no initial value
>>> reduce(operator.mul, [1,2,3], 1)
6
>>> reduce(operator.mul, [], 1)
1
```

If you use `operator.add()` with `reduce()`, you’ll add up all the elements of the iterable. This case is so common that there’s a
special built-in called `sum()` to compute it:

```python
>>> reduce(operator.add, [1,2,3,4], 0)
10
>>> sum([1,2,3,4])
10
>>> sum([])
0
```

For many uses of `reduce()`, though, it can be clearer to just write the obvious `for` loop:

```python
# Instead of:
product = reduce(operator.mul, [1,2,3], 1)

# You can write:
product = 1
for i in [1,2,3]:
    product *= i
```

`enumerate(iter)` counts off the elements in the iterable, returning 2-tuples containing the count and each element.

```python
>>> for item in enumerate(['subject', 'verb', 'object']):
...     print item
(0, 'subject')
(1, 'verb')
(2, 'object')
```

`enumerate()` is often used when looping through a list and recording the indexes at which certain conditions are met:

```python
f = open('data.txt', 'r')
for i, line in enumerate(f):
    if line.strip() == '':
        print 'Blank line at line #%i' % i
```

`sorted(iterable, cmp=None, key=None, reverse=False)` collects all the elements of the iterable into a list, sorts the list, and returns the sorted result. The `cmp`, `key`, and `reverse` arguments are
passed through to the constructed list's `.sort()` method.

```python
>>> import random
>>> # Generate 8 random numbers between [0, 10000)
>>> rand_list = random.sample(range(10000), 8)
>>> rand_list
[769, 7953, 9828, 6431, 8442, 9878, 6213, 2207]
>>> sorted(rand_list)
[769, 2207, 6213, 6431, 7953, 8442, 9828, 9878]
>>> sorted(rand_list, reverse=True)
[9878, 9828, 8442, 7953, 6431, 6213, 2207, 769]
```

(For a more detailed discussion of sorting, see the Sorting mini-
HOWTO in the Python wiki at http://wiki.python.org/moin/HowTo/Sorting.)

The `any(iter)` and `all(iter)` built-ins look at the truth values of an iterable's contents. `any()` returns True if any element in the iterable is a true value, and `all()` returns True if all of the elements are true values:

```python
>>> any([0,1,0])
True
>>> any([0,0,0])
False
>>> any([1,1,1])
True
>>> all([0,1,0])
False
>>> all([0,0,0])
False
>>> all([1,1,1])
True
```
Small functions and the lambda expression

When writing functional-style programs, you’ll often need little functions that act as predicates or that combine elements in some way.

If there’s a Python built-in or a module function that’s suitable, you don’t need to define a new function at all:

```python
stripped_lines = [line.strip() for line in lines]
existing_files = filter(os.path.exists, file_list)
```

If the function you need doesn’t exist, you need to write it. One way to write small functions is to use the `lambda` statement. `lambda` takes a number of parameters and an expression combining these parameters, and creates a small function that returns the value of the expression:

```python
lowercase = lambda x: x.lower()
print_assign = lambda name, value: name + '==' + str(value)
adder = lambda x, y: x+y
```

An alternative is to just use the `def` statement and define a function in the usual way:

```python
def lowercase(x):
    return x.lower()

def print_assign(name, value):
    return name + '==' + str(value)

def adder(x,y):
    return x + y
```

Which alternative is preferable? That’s a style question; my usual
course is to avoid using `lambda`.

One reason for my preference is that `lambda` is quite limited in the functions it can define. The result has to be computable as a single expression, which means you can’t have multiway `if... elif... else` comparisons or `try... except` statements. If you try to do too much in a `lambda` statement, you’ll end up with an overly complicated expression that’s hard to read. Quick, what’s the following code doing?

```python
total = reduce(lambda a, b: (0, a[1] + b[1]), items)[1]
```

You can figure it out, but it takes time to disentangle the expression to figure out what’s going on. Using a short nested `def` statements makes things a little bit better:

```python
def combine (a, b):
    return 0, a[1] + b[1]

total = reduce(combine, items)[1]
```

But it would be best of all if I had simply used a `for` loop:

```python
total = 0
for a, b in items:
    total += b
```

Or the `sum()` built-in and a generator expression:

```python
total = sum(b for a, b in items)
```

Many uses of `reduce()` are clearer when written as `for` loops.

Fredrik Lundh once suggested the following set of rules for refactoring uses of `lambda`:
1. Write a lambda function.
2. Write a comment explaining what the heck that lambda does.
3. Study the comment for a while, and think of a name that captures the essence of the comment.
4. Convert the lambda to a def statement, using that name.
5. Remove the comment.

I really like these rules, but you’re free to disagree about whether this lambda-free style is better.
The *itertools* module

The *itertools* module contains a number of commonly-used iterators as well as functions for combining several iterators. This section will introduce the module’s contents by showing small examples.

The module’s functions fall into a few broad classes:

- Functions that create a new iterator based on an existing iterator.
- Functions for treating an iterator’s elements as function arguments.
- Functions for selecting portions of an iterator’s output.
- A function for grouping an iterator’s output.

Creating new iterators

*itertools.count(n)* returns an infinite stream of integers, increasing by 1 each time. You can optionally supply the starting number, which defaults to 0:

```python
itertools.count() =>
0, 1, 2, 3, 4, 5, 6, 7, 8, 9, ...
itertools.count(10) =>
10, 11, 12, 13, 14, 15, 16, 17, 18, 19, ...
```

*itertools.cycle(iter)* saves a copy of the contents of a provided iterable and returns a new iterator that returns its elements from first to last. The new iterator will repeat these elements infinitely.

```python
itertools.cycle([1,2,3,4,5]) =>
1, 2, 3, 4, 5, 1, 2, 3, 4, 5, ...
```

*itertools.repeat(elem, [n])* returns the provided element n times,
or returns the element endlessly if \( n \) is not provided.

\[
\text{itertools.repeat('abc')} => \\
\text{abc, abc, abc, abc, abc, abc, abc, abc, abc, ...} \\
\text{itertools.repeat('abc', 5)} => \\
\text{abc, abc, abc, abc, abc}
\]

\text{itertools.chain(iterA, iterB, ...)} takes an arbitrary number of iterables as input, and returns all the elements of the first iterator, then all the elements of the second, and so on, until all of the iterables have been exhausted.

\[
\text{itertools.chain([}'a', 'b', 'c'], (1, 2, 3)) => \\
a, b, c, 1, 2, 3
\]

\text{itertools.izip(iterA, iterB, ...)} takes one element from each iterable and returns them in a tuple:

\[
\text{itertools.izip([}'a', 'b', 'c'], (1, 2, 3)) => \\
('a', 1), ('b', 2), ('c', 3)
\]

It's similar to the built-in \texttt{zip()} function, but doesn't construct an in-memory list and exhaust all the input iterators before returning; instead tuples are constructed and returned only if they're requested. (The technical term for this behaviour is lazy evaluation.)

This iterator is intended to be used with iterables that are all of the same length. If the iterables are of different lengths, the resulting stream will be the same length as the shortest iterable.

\[
\text{itertools.izip([}'a', 'b'], (1, 2, 3)) => \\
('a', 1), ('b', 2)
\]

You should avoid doing this, though, because an element may be taken from the longer iterators and discarded. This means you can't go on to use the iterators further because you risk skipping a discarded element.
itertools.islice(iter, [start], stop, [step]) returns a stream that’s a slice of the iterator. With a single stop argument, it will return the first stop elements. If you supply a starting index, you’ll get stop-start elements, and if you supply a value for step, elements will be skipped accordingly. Unlike Python’s string and list slicing, you can’t use negative values for start, stop, or step.

```
itertools.islice(range(10), 8) =>
    0, 1, 2, 3, 4, 5, 6, 7
itertools.islice(range(10), 2, 8) =>
    2, 3, 4, 5, 6, 7
itertools.islice(range(10), 2, 8, 2) =>
    2, 4, 6
```

itertools.tee(iter, [n]) replicates an iterator; it returns n independent iterators that will all return the contents of the source iterator. If you don’t supply a value for n, the default is 2. Replicating iterators requires saving some of the contents of the source iterator, so this can consume significant memory if the iterator is large and one of the new iterators is consumed more than the others.

```
itertools.tee( itertools.count() ) =>
    iterA, iterB

where iterA ->
    0, 1, 2, 3, 4, 5, 6, 7, 8, 9, ...

and iterB ->
    0, 1, 2, 3, 4, 5, 6, 7, 8, 9, ...
```

### Calling functions on elements

Two functions are used for calling other functions on the contents of an iterable.

itertools.imap(f, iterA, iterB, ...) returns a stream containing 
f(iterA[0], iterB[0]), f(iterA[1], iterB[1]), f(iterA[2],
iterB[2]), ...

```python
itertools.imap(operator.add, [5, 6, 5], [1, 2, 3]) =>
6, 8, 8
```

The `operator` module contains a set of functions corresponding to Python's operators. Some examples are `operator.add(a, b)` (adds two values), `operator.ne(a, b)` (same as `a!=b`), and `operator.attrgetter('id')` (returns a callable that fetches the "id" attribute).

```python
itertools.starmap(func, iter) assumes that the iterable will return a stream of tuples, and calls `f()` using these tuples as the arguments:

```python
itertools.starmap(os.path.join,
     [('/usr', 'bin', 'java'), ('/bin', 'python'), ('/usr', 'bin', 'perl'), ('/usr', 'bin', 'ruby')])
=>
/usr/bin/java, /bin/python, /usr/bin/perl, /usr/bin/ruby
```

### Selecting elements

Another group of functions chooses a subset of an iterator’s elements based on a predicate.

```python
itertools.ifilter(predicate, iter) returns all the elements for which the predicate returns true:

```python
def is_even(x):
    return (x % 2) == 0

itertools.ifilter(is_even, itertools.count()) =>
0, 2, 4, 6, 8, 10, 12, 14, ...
```

`itertools.ifilterfalse(predicate, iter)` is the opposite, returning
all elements for which the predicate returns false:

```python
itertools.ifilterfalse(is_even, itertools.count()) =>
  1, 3, 5, 7, 9, 11, 13, 15, ...
```

`itertools.takewhile(predicate, iter)` returns elements for as long as the predicate returns true. Once the predicate returns false, the iterator will signal the end of its results.

```python
def less_than_10(x):
    return (x < 10)

itertools.takewhile(less_than_10, itertools.count()) =>
  0, 1, 2, 3, 4, 5, 6, 7, 8, 9

itertools.takewhile(is_even, itertools.count()) =>
  0
```

`itertools.dropwhile(predicate, iter)` discards elements while the predicate returns true, and then returns the rest of the iterable’s results.

```python
itertools.dropwhile(less_than_10, itertools.count()) =>
  10, 11, 12, 13, 14, 15, 16, 17, 18, 19, ...

itertools.dropwhile(is_even, itertools.count()) =>
  1, 2, 3, 4, 5, 6, 7, 8, 9, 10, ...
```

**Grouping elements**

The last function I’ll discuss, `itertools.groupby(iter, key_func=None)`, is the most complicated. `key_func(elem)` is a function that can compute a key value for each element returned by the iterable. If you don’t supply a key function, the key is simply each element itself.

`groupby()` collects all the consecutive elements from the underlying iterable that have the same key value, and returns a stream of 2-
tuples containing a key value and an iterator for the elements with that key.

city_list = [('Decatur', 'AL'), ('Huntsville', 'AL'), ('Selma', 'AL'),
             ('Anchorage', 'AK'), ('Nome', 'AK'),
             ('Flagstaff', 'AZ'), ('Phoenix', 'AZ'), ('Tucson', 'AZ'), ...]

def get_state((city, state)):
    return state

itertools.groupby(city_list, get_state) =>
    ('AL', iterator-1),
    ('AK', iterator-2),
    ('AZ', iterator-3), ...

where

iterator-1 =>
    ('Decatur', 'AL'), ('Huntsville', 'AL'), ('Selma', 'AL')
iterator-2 =>
    ('Anchorage', 'AK'), ('Nome', 'AK')
iterator-3 =>
    ('Flagstaff', 'AZ'), ('Phoenix', 'AZ'), ('Tucson', 'AZ')

`groupby()` assumes that the underlying iterable’s contents will already be sorted based on the key. Note that the returned iterators also use the underlying iterable, so you have to consume the results of iterator-1 before requesting iterator-2 and its corresponding key.
The **functools** module

The **functools** module in Python 2.5 contains some higher-order functions. A **higher-order function** takes one or more functions as input and returns a new function. The most useful tool in this module is the **functools.partial()** function.

For programs written in a functional style, you'll sometimes want to construct variants of existing functions that have some of the parameters filled in. Consider a Python function \(f(a, b, c)\); you may wish to create a new function \(g(b, c)\) that's equivalent to \(f(1, b, c)\); you're filling in a value for one of \(f()\)'s parameters. This is called "partial function application".

The constructor for **partial** takes the arguments \((function, \text{arg1}, \text{arg2}, \ldots, \text{kwarg1}=	ext{value1}, \text{kwarg2}=	ext{value2})\). The resulting object is callable, so you can just call it to invoke `function` with the filled-in arguments.

Here's a small but realistic example:

```python
import functools

def log(message, subsystem):
    """Write the contents of 'message' to the specified subsystem"
    print '%s: %s' % (subsystem, message)
...

server_log = functools.partial(log, subsystem='server')
server_log('Unable to open socket')
```

The **operator** module

The **operator** module was mentioned earlier. It contains a set of
functions corresponding to Python’s operators. These functions are often useful in functional-style code because they save you from writing trivial functions that perform a single operation.

Some of the functions in this module are:

- **Math operations**: `add()`, `sub()`, `mul()`, `div()`, `floordiv()`, `abs()`, ...
- **Logical operations**: `not_()`, `truth()`.
- **Bitwise operations**: `and_()`, `or_()`, `invert()`.
- **Comparisons**: `eq()`, `ne()`, `lt()`, `le()`, `gt()`, and `ge()`.
- **Object identity**: `is_()`, `is_not()`.

Consult the operator module’s documentation for a complete list.

**The functional module**

Collin Winter’s *functional module* provides a number of more advanced tools for functional programming. It also reimplements several Python built-ins, trying to make them more intuitive to those used to functional programming in other languages.

This section contains an introduction to some of the most important functions in *functional*; full documentation can be found at the project’s website.

```python
compose(outer, inner, unpack=False)
```

The `compose()` function implements function composition. In other words, it returns a wrapper around the `outer` and `inner` callables, such that the return value from `inner` is fed directly to `outer`. That is,

```python
>>> def add(a, b):
...     return a + b
... >>>
>>> def double(a):
...     return 2 * a
... >>>
```
... return 2 * a
...
>>> compose(double, add)(5, 6)
22

is equivalent to

>>> double(add(5, 6))
22

The **unpack** keyword is provided to work around the fact that Python functions are not always fully curried. By default, it is expected that the inner function will return a single object and that the outer function will take a single argument. Setting the **unpack** argument causes `compose` to expect a tuple from inner which will be expanded before being passed to outer. Put simply,

```
compose(f, g)(5, 6)
```

is equivalent to:

```
f(g(5, 6))
```

while

```
compose(f, g, unpack=True)(5, 6)
```

is equivalent to:

```
f(*g(5, 6))
```

Even though `compose()` only accepts two functions, it's trivial to build up a version that will compose any number of functions. We'll use `reduce()`, `compose()` and `partial()` (the last of which is provided by both `functional` and `functools`).

```
from functional import compose, partial
```
multi_compose = partial(reduce, compose)

We can also use map(), compose() and partial() to craft a version of "".join(...) that converts its arguments to string:

```python
from functional import compose, partial
join = compose("".join, partial(map, str))
```

flip(func)

flip() wraps the callable in func and causes it to receive its non-keyword arguments in reverse order.

```python
>>> def triple(a, b, c):
...     return (a, b, c)
... >>> triple(5, 6, 7)
(5, 6, 7)
>>> >>> flipped_triple = flip(triple)
>>> >>> flipped_triple(5, 6, 7)
(7, 6, 5)
```

foldl(func, start, iterable)

foldl() takes a binary function, a starting value (usually some kind of ‘zero’), and an iterable. The function is applied to the starting value and the first element of the list, then the result of that and the second element of the list, then the result of that and the third element of the list, and so on.

This means that a call such as:

```python
foldl(f, 0, [1, 2, 3])
```

is equivalent to:
\[
f(f(f(0, 1), 2), 3)
\]

foldl() is roughly equivalent to the following recursive function:

```python
def foldl(func, start, seq):
    if len(seq) == 0:
        return start
    return foldl(func, func(start, seq[0]), seq[1:])
```

Speaking of equivalence, the above foldl call can be expressed in terms of the built-in reduce like so:

```
reduce(f, [1, 2, 3], 0)
```

We can use foldl(), operator.concat() and partial() to write a cleaner, more aesthetically-pleasing version of Python's \".join(...) idiom:

```python
from functional import foldl, partial from operator import concat
join = partial(foldl, concat, ")""
```
Revision History and Acknowledgements

The author would like to thank the following people for offering suggestions, corrections and assistance with various drafts of this article: Ian Bicking, Nick Coghlan, Nick Efford, Raymond Hettinger, Jim Jewett, Mike Krell, Leandro Lameiro, Jussi Salmela, Collin Winter, Blake Winton.

Version 0.1: posted June 30 2006.

Version 0.11: posted July 1 2006. Typo fixes.

Version 0.2: posted July 10 2006. Merged genexp and listcomp sections into one. Typo fixes.

Version 0.21: Added more references suggested on the tutor mailing list.

Version 0.30: Adds a section on the `functional` module written by Collin Winter; adds short section on the operator module; a few other edits.
General

**Structure and Interpretation of Computer Programs**, by Harold Abelson and Gerald Jay Sussman with Julie Sussman. Full text at [http://mitpress.mit.edu/sicp/](http://mitpress.mit.edu/sicp/). In this classic textbook of computer science, chapters 2 and 3 discuss the use of sequences and streams to organize the data flow inside a program. The book uses Scheme for its examples, but many of the design approaches described in these chapters are applicable to functional-style Python code.

[http://www.defmacro.org/ramblings/fp.html](http://www.defmacro.org/ramblings/fp.html): A general introduction to functional programming that uses Java examples and has a lengthy historical introduction.

Documentation for the `itertools` module.

Documentation for the `operator` module.

**PEP 289**: “Generator Expressions”

**PEP 342**: “Coroutines via Enhanced Generators” describes the new generator features in Python 2.5.
This document is an introductory tutorial to using regular expressions in Python with the \texttt{re} module. It provides a gentler introduction than the corresponding section in the Library Reference.
The `re` module was added in Python 1.5, and provides Perl-style regular expression patterns. Earlier versions of Python came with the `regex` module, which provided Emacs-style patterns. The `regex` module was removed completely in Python 2.5.

Regular expressions (called REs, or regexes, or regex patterns) are essentially a tiny, highly specialized programming language embedded inside Python and made available through the `re` module. Using this little language, you specify the rules for the set of possible strings that you want to match; this set might contain English sentences, or e-mail addresses, or TeX commands, or anything you like. You can then ask questions such as “Does this string match the pattern?”, or “Is there a match for the pattern anywhere in this string?”. You can also use REs to modify a string or to split it apart in various ways.

Regular expression patterns are compiled into a series of bytecodes which are then executed by a matching engine written in C. For advanced use, it may be necessary to pay careful attention to how the engine will execute a given RE, and write the RE in a certain way in order to produce bytecode that runs faster. Optimization isn’t covered in this document, because it requires that you have a good understanding of the matching engine’s internals.

The regular expression language is relatively small and restricted, so not all possible string processing tasks can be done using regular expressions. There are also tasks that can be done with regular expressions, but the expressions turn out to be very complicated. In these cases, you may be better off writing Python code to do the processing; while Python code will be slower than an elaborate regular expression, it will also probably be more understandable.
Simple Patterns

We'll start by learning about the simplest possible regular expressions. Since regular expressions are used to operate on strings, we'll begin with the most common task: matching characters.

For a detailed explanation of the computer science underlying regular expressions (deterministic and non-deterministic finite automata), you can refer to almost any textbook on writing compilers.

Matching Characters

Most letters and characters will simply match themselves. For example, the regular expression `test` will match the string `test` exactly. (You can enable a case-insensitive mode that would let this RE match `Test` or `TEST` as well; more about this later.)

There are exceptions to this rule; some characters are special *metacharacters*, and don't match themselves. Instead, they signal that some out-of-the-ordinary thing should be matched, or they affect other portions of the RE by repeating them or changing their meaning. Much of this document is devoted to discussing various metacharacters and what they do.

Here's a complete list of the metacharacters; their meanings will be discussed in the rest of this HOWTO.

```
.  ^  $  *  +  ?  {  [  ]  \  |  (  )
```

The first metacharacters we'll look at are `[` and `]`. They're used for specifying a character class, which is a set of characters that you wish to match. Characters can be listed individually, or a range of
characters can be indicated by giving two characters and separating them by a '-' sign. For example, [abc] will match any of the characters a, b, or c; this is the same as [a-c], which uses a range to express the same set of characters. If you wanted to match only lowercase letters, your RE would be [a-z].

Metacharacters are not active inside classes. For example, [akm$] will match any of the characters 'a', 'k', 'm', or '$'; '$' is usually a metacharacter, but inside a character class it's stripped of its special nature.

You can match the characters not listed within the class by complementing the set. This is indicated by including a '^' as the first character of the class; '^' outside a character class will simply match the '^' character. For example, [^5] will match any character except '5'.

Perhaps the most important metacharacter is the backslash, \\. As in Python string literals, the backslash can be followed by various characters to signal various special sequences. It's also used to escape all the metacharacters so you can still match them in patterns; for example, if you need to match a [ or \, you can precede them with a backslash to remove their special meaning: \\ or \\\. Some of the special sequences beginning with '\\' represent predefined sets of characters that are often useful, such as the set of digits, the set of letters, or the set of anything that isn't whitespace. The following predefined special sequences are available:

\d

Matches any decimal digit; this is equivalent to the class [0-9].

\D

Matches any non-digit character; this is equivalent to the class
^[^0-9].
\s
Matches any whitespace character; this is equivalent to the class [ \t\n\r\f\v].
\S
Matches any non-whitespace character; this is equivalent to the class [^ \t\n\r\f\v].
\w
Matches any alphanumeric character; this is equivalent to the class [a-zA-Z0-9_].
\W
Matches any non-alphanumeric character; this is equivalent to the class [^a-zA-Z0-9_].

These sequences can be included inside a character class. For example, [\s,.] is a character class that will match any whitespace character, or ' ' or '.'.

The final metacharacter in this section is .. It matches anything except a newline character, and there’s an alternate mode (\re\DOTALL) where it will match even a newline. ' . ' is often used where you want to match “any character”.

Repeating Things

Being able to match varying sets of characters is the first thing regular expressions can do that isn’t already possible with the methods available on strings. However, if that was the only additional capability of regexes, they wouldn’t be much of an advance. Another capability is that you can specify that portions of the RE must be repeated a certain number of times.

The first metacharacter for repeating things that we’ll look at is *. *
doesn't match the literal character *; instead, it specifies that the previous character can be matched zero or more times, instead of exactly once.

For example, ca*t will match ct (0 a characters), cat (1 a), caaat (3 a characters), and so forth. The RE engine has various internal limitations stemming from the size of C's int type that will prevent it from matching over 2 billion a characters; you probably don't have enough memory to construct a string that large, so you shouldn’t run into that limit.

Repetitions such as * are greedy; when repeating a RE, the matching engine will try to repeat it as many times as possible. If later portions of the pattern don’t match, the matching engine will then back up and try again with few repetitions.

A step-by-step example will make this more obvious. Let's consider the expression a[bcd]*b. This matches the letter 'a', zero or more letters from the class [bcd], and finally ends with a 'b'. Now imagine matching this RE against the string abcbd.

<table>
<thead>
<tr>
<th>Step</th>
<th>Matched</th>
<th>Explanation</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>a</td>
<td>The a in the RE matches.</td>
</tr>
<tr>
<td>2</td>
<td>abcbd</td>
<td>The engine matches [bcd]*, going as far as it can, which is to the end of the string.</td>
</tr>
<tr>
<td>3</td>
<td>Failure</td>
<td>The engine tries to match b, but the current position is at the end of the string, so it fails.</td>
</tr>
<tr>
<td>4</td>
<td>abcb</td>
<td>Back up, so that [bcd]* matches one less character.</td>
</tr>
<tr>
<td>5</td>
<td>Failure</td>
<td>Try b again, but the current position is at the last character, which is a 'd'.</td>
</tr>
<tr>
<td>6</td>
<td>abc</td>
<td>Back up again, so that [bcd]* is only matching bc.</td>
</tr>
</tbody>
</table>

Try b again. This time the character at the
The end of the RE has now been reached, and it has matched $abcb$. This demonstrates how the matching engine goes as far as it can at first, and if no match is found it will then progressively back up and retry the rest of the RE again and again. It will back up until it has tried zero matches for $[bcd]^*$, and if that subsequently fails, the engine will conclude that the string doesn’t match the RE at all.

Another repeating metacharacter is $+$, which matches one or more times. Pay careful attention to the difference between $*$ and $+$; $*$ matches zero or more times, so whatever’s being repeated may not be present at all, while $+$ requires at least one occurrence. To use a similar example, $ca+t$ will match $cat$ (1 a), $caaat$ (3 a’s), but won’t match $ct$.

There are two more repeating qualifiers. The question mark character, $?$, matches either once or zero times; you can think of it as marking something as being optional. For example, $home-?brew$ matches either $homebrew$ or $home-brew$.

The most complicated repeated qualifier is $\{m,n\}$, where $m$ and $n$ are decimal integers. This qualifier means there must be at least $m$ repetitions, and at most $n$. For example, $a/\{1,3\}b$ will match $a/b$, $a//b$, and $a///b$. It won’t match $ab$, which has no slashes, or $a/////b$, which has four.

You can omit either $m$ or $n$; in that case, a reasonable value is assumed for the missing value. Omitting $m$ is interpreted as a lower limit of 0, while omitting $n$ results in an upper bound of infinity — actually, the upper bound is the 2-billion limit mentioned earlier, but that might as well be infinity.
Readers of a reductionist bent may notice that the three other qualifiers can all be expressed using this notation. \( \{0,\} \) is the same as \(*\), \( \{1,\} \) is equivalent to \(+\), and \( \{0,1\} \) is the same as \( ? \). It’s better to use \(*\), \(+\), or \( ? \) when you can, simply because they’re shorter and easier to read.
Using Regular Expressions

Now that we've looked at some simple regular expressions, how do we actually use them in Python? The `re` module provides an interface to the regular expression engine, allowing you to compile REs into objects and then perform matches with them.

Compiling Regular Expressions

Regular expressions are compiled into `RegexObject` instances, which have methods for various operations such as searching for pattern matches or performing string substitutions.

```python
>>> import re
>>> p = re.compile('ab*')
>>> print p
<re.RegexObject instance at 80b4150>
```

`re.compile()` also accepts an optional `flags` argument, used to enable various special features and syntax variations. We'll go over the available settings later, but for now a single example will do:

```python
>>> p = re.compile('ab*', re.IGNORECASE)
```

The RE is passed to `re.compile()` as a string. REs are handled as strings because regular expressions aren't part of the core Python language, and no special syntax was created for expressing them. (There are applications that don’t need REs at all, so there's no need to bloat the language specification by including them.) Instead, the `re` module is simply a C extension module included with Python, just like the `socket` or `zlib` modules.

Putting REs in strings keeps the Python language simpler, but has one disadvantage which is the topic of the next section.
As stated earlier, regular expressions use the backslash character (\"\") to indicate special forms or to allow special characters to be used without invoking their special meaning. This conflicts with Python’s usage of the same character for the same purpose in string literals.

Let’s say you want to write a RE that matches the string \section, which might be found in a LaTeX file. To figure out what to write in the program code, start with the desired string to be matched. Next, you must escape any backslashes and other metacharacters by preceding them with a backslash, resulting in the string \section. The resulting string that must be passed to \texttt{re.compile()} must be \section. However, to express this as a Python string literal, both backslashes must be escaped again.

<table>
<thead>
<tr>
<th>Characters</th>
<th>Stage</th>
</tr>
</thead>
<tbody>
<tr>
<td>\section</td>
<td>Text string to be matched</td>
</tr>
<tr>
<td>\section</td>
<td>Escaped backslash for \texttt{re.compile()}</td>
</tr>
<tr>
<td>&quot;\section&quot;</td>
<td>Escaped backslashes for a string literal</td>
</tr>
</tbody>
</table>

In short, to match a literal backslash, one has to write '\\' as the RE string, because the regular expression must be \, and each backslash must be expressed as \ inside a regular Python string literal. In REs that feature backslashes repeatedly, this leads to lots of repeated backslashes and makes the resulting strings difficult to understand.

The solution is to use Python’s raw string notation for regular expressions; backslashes are not handled in any special way in a string literal prefixed with '\r', so r"\n" is a two-character string
containing \'\' and 'n', while \"\n\" is a one-character string containing a newline. Regular expressions will often be written in Python code using this raw string notation.

<table>
<thead>
<tr>
<th>Regular String</th>
<th>Raw string</th>
</tr>
</thead>
<tbody>
<tr>
<td>&quot;ab*&quot;</td>
<td>r&quot;ab*&quot;</td>
</tr>
<tr>
<td>&quot;\section&quot;</td>
<td>r&quot;\section&quot;</td>
</tr>
<tr>
<td>&quot;\w+\s+\1&quot;</td>
<td>r&quot;\w+\s+\1&quot;</td>
</tr>
</tbody>
</table>

Performing Matches

Once you have an object representing a compiled regular expression, what do you do with it? RegexObject instances have several methods and attributes. Only the most significant ones will be covered here; consult the re docs for a complete listing.

<table>
<thead>
<tr>
<th>Method/Attribute</th>
<th>Purpose</th>
</tr>
</thead>
<tbody>
<tr>
<td>match()</td>
<td>Determine if the RE matches at the beginning of the string.</td>
</tr>
<tr>
<td>search()</td>
<td>Scan through a string, looking for any location where this RE matches.</td>
</tr>
<tr>
<td>findall()</td>
<td>Find all substrings where the RE matches, and returns them as a list.</td>
</tr>
<tr>
<td>finditer()</td>
<td>Find all substrings where the RE matches, and returns them as an iterator.</td>
</tr>
</tbody>
</table>

match() and search() return None if no match can be found. If they're successful, a MatchObject instance is returned, containing information about the match: where it starts and ends, the substring it matched, and more.

You can learn about this by interactively experimenting with the re module. If you have Tkinter available, you may also want to look at Tools/scripts/redemo.py, a demonstration program included with
the Python distribution. It allows you to enter REs and strings, and displays whether the RE matches or fails. `redemo.py` can be quite useful when trying to debug a complicated RE. Phil Schwartz’s Kodos is also an interactive tool for developing and testing RE patterns.

This HOWTO uses the standard Python interpreter for its examples. First, run the Python interpreter, import the `re` module, and compile a RE:

```
Python 2.2.2 (#1, Feb 10 2003, 12:57:01)
>>> import re
>>> p = re.compile('[a-z]+')
>>> p
<_sre.SRE_Pattern object at 80c3c28>
```

Now, you can try matching various strings against the RE `[a-z]+`. An empty string shouldn’t match at all, since `+` means ‘one or more repetitions’. `match()` should return `None` in this case, which will cause the interpreter to print no output. You can explicitly print the result of `match()` to make this clear.

```
>>> p.match('')
>>> print p.match('')
None
```

Now, let’s try it on a string that it should match, such as `tempo`. In this case, `match()` will return a `MatchObject`, so you should store the result in a variable for later use.

```
>>> m = p.match('tempo')
>>> print m
<_sre.SRE_Match object at 80c4f68>
```

Now you can query the `MatchObject` for information about the matching string. `MatchObject` instances also have several methods and attributes; the most important ones are:
<table>
<thead>
<tr>
<th>Method/Attribute</th>
<th>Purpose</th>
</tr>
</thead>
<tbody>
<tr>
<td>group()</td>
<td>Return the string matched by the RE</td>
</tr>
<tr>
<td>start()</td>
<td>Return the starting position of the match</td>
</tr>
<tr>
<td>end()</td>
<td>Return the ending position of the match</td>
</tr>
<tr>
<td>span()</td>
<td>Return a tuple containing the (start, end) positions of the match</td>
</tr>
</tbody>
</table>

Trying these methods will soon clarify their meaning:

```python
>>> m.group()
'tempo'
>>> m.start(), m.end()
(0, 5)
>>> m.span()
(0, 5)
```

`group()` returns the substring that was matched by the RE. `start()` and `end()` return the starting and ending index of the match. `span()` returns both start and end indexes in a single tuple. Since the `match()` method only checks if the RE matches at the start of a string, `start()` will always be zero. However, the `search()` method of `RegexObject` instances scans through the string, so the match may not start at zero in that case.

```python
>>> print p.match('::: message')
None
>>> m = p.search('::: message') ; print m
<re.MatchObject instance at 80c9650>
>>> m.group()
'message'
>>> m.span()
(4, 11)
```

In actual programs, the most common style is to store the `MatchObject` in a variable, and then check if it was `None`. This usually looks like:

```python
p = re.compile( ... )
```
```python
m = p.match( 'string goes here' )
if m:
    print 'Match found: ', m.group()
else:
    print 'No match'
```

Two `RegexObject` methods return all of the matches for a pattern. `findall()` returns a list of matching strings:

```python
>>> p = re.compile('d+')
>>> p.findall('12 drummers drumming, 11 pipers piping, 10 lords
['12', '11', '10']
```

`findall()` has to create the entire list before it can be returned as the result. The `finditer()` method returns a sequence of `MatchObject` instances as an `iterator`. [1]

```python
>>> iterator = p.finditer('12 drummers drumming, 11 ... 10 ...
<callable-iterator object at 0x401833ac>
>>> for match in iterator:
...      print match.span()
...
(0, 2)
(22, 24)
(29, 31)
```

### Module-Level Functions

You don’t have to create a `RegexObject` and call its methods; the `re` module also provides top-level functions called `match()`, `search()`, `findall()`, `sub()`, and so forth. These functions take the same arguments as the corresponding `RegexObject` method, with the RE string added as the first argument, and still return either `None` or a `MatchObject` instance.

```python
>>> print re.match(r'\s+\s+\s+', 'Fromage amk')
```
Under the hood, these functions simply produce a `RegexObject` for you and call the appropriate method on it. They also store the compiled object in a cache, so future calls using the same RE are faster.

Should you use these module-level functions, or should you get the `RegexObject` and call its methods yourself? That choice depends on how frequently the RE will be used, and on your personal coding style. If the RE is being used at only one point in the code, then the module functions are probably more convenient. If a program contains a lot of regular expressions, or re-uses the same ones in several locations, then it might be worthwhile to collect all the definitions in one place, in a section of code that compiles all the REs ahead of time. To take an example from the standard library, here's an extract from `xmlLib.py`:

```python
ref = re.compile( ... )
extityref = re.compile( ... )
charref = re.compile( ... )
starttagopen = re.compile( ... )
```

I generally prefer to work with the compiled object, even for one-time uses, but few people will be as much of a purist about this as I am.

### Compilation Flags

Compilation flags let you modify some aspects of how regular expressions work. Flags are available in the `re` module under two names, a long name such as `IGNORECASE` and a short, one-letter form such as `I`. (If you're familiar with Perl's pattern modifiers, the one-letter forms use the same letters; the short form of `re.VERBOSE` is `re.X`, for example.) Multiple flags can be specified by bitwise OR-ing
them; `re.I | re.M` sets both the I and M flags, for example.

Here’s a table of the available flags, followed by a more detailed explanation of each one.

<table>
<thead>
<tr>
<th>Flag</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>DOTALL, S</td>
<td>Make . match any character, including newlines</td>
</tr>
<tr>
<td>IGNORECASE, I</td>
<td>Do case-insensitive matches</td>
</tr>
<tr>
<td>LOCALE, L</td>
<td>Do a locale-aware match</td>
</tr>
<tr>
<td>MULTILINE, M</td>
<td>Multi-line matching, affecting ^ and $</td>
</tr>
<tr>
<td>VERBOSE, X</td>
<td>Enable verbose REs, which can be organized more cleanly and understandably.</td>
</tr>
</tbody>
</table>

**I**

**IGNORECASE**

Perform case-insensitive matching; character class and literal strings will match letters by ignoring case. For example, `[A-Z]` will match lowercase letters, too, and `Spam` will match `Spam`, `spam`, or `spAM`. This lowercasing doesn’t take the current locale into account; it will if you also set the **LOCALE** flag.

**L**

**LOCALE**

Make `\w`, `\W`, `\b`, and `\B`, dependent on the current locale.

Locales are a feature of the C library intended to help in writing programs that take account of language differences. For example, if you’re processing French text, you’d want to be able to write `\w+` to match words, but `\w` only matches the character class `[A-Za-z]`; it won’t match 'é' or 'ç'. If your system is configured properly and a French locale is selected, certain C functions will tell the program that 'é' should also be considered
a letter. Setting the **locale** flag when compiling a regular expression will cause the resulting compiled object to use these C functions for \w; this is slower, but also enables \w+ to match French words as you’d expect.

**M**

**MULTILINE**

(^ and $ haven’t been explained yet; they’ll be introduced in section **More Metacharacters**.)

Usually ^ matches only at the beginning of the string, and $ matches only at the end of the string and immediately before the newline (if any) at the end of the string. When this flag is specified, ^ matches at the beginning of the string and at the beginning of each line within the string, immediately following each newline. Similarly, the $ metacharacter matches either at the end of the string and at the end of each line (immediately preceding each newline).

**S**

**DOTALL**

Makes the . special character match any character at all, including a newline; without this flag, . will match anything except a newline.

**X**

**VERBOSE**

This flag allows you to write regular expressions that are more readable by granting you more flexibility in how you can format them. When this flag has been specified, whitespace within the RE string is ignored, except when the whitespace is in a character class or preceded by an unescaped backslash; this lets you organize and indent the RE more clearly. This flag also lets you put comments within a RE that will be ignored by the engine; comments are marked by a # that’s neither in a character class
or preceded by an unescaped backslash.

For example, here's a RE that uses `re.VERBOSE`; see how much easier it is to read?

```python
charref = re.compile(r"""
&[#]																		#	Start of a numeric entity reference
 (  		 0[0-7]+ 									#	Octal form
  | [0-9]+ 									#	Decimal form
  | x[0-9a-fA-F]+ 			#	Hexadecimal form
 )
; 																			#	Trailing semicolon
"""", re.VERBOSE)
```

Without the verbose setting, the RE would look like this:

```python
charref = re.compile("&#(0[0-7]+" 
   "|[0-9]+" 
   "|x[0-9a-fA-F]+";")
```

In the above example, Python’s automatic concatenation of string literals has been used to break up the RE into smaller pieces, but it's still more difficult to understand than the version using `re.VERBOSE`. 
More Pattern Power

So far we've only covered a part of the features of regular expressions. In this section, we'll cover some new metacharacters, and how to use groups to retrieve portions of the text that was matched.

More Metacharacters

There are some metacharacters that we haven't covered yet. Most of them will be covered in this section.

Some of the remaining metacharacters to be discussed are zero-width assertions. They don't cause the engine to advance through the string; instead, they consume no characters at all, and simply succeed or fail. For example, \b is an assertion that the current position is located at a word boundary; the position isn't changed by the \b at all. This means that zero-width assertions should never be repeated, because if they match once at a given location, they can obviously be matched an infinite number of times.

| Alternation, or the “or” operator. If A and B are regular expressions, A|B will match any string that matches either A or B. | has very low precedence in order to make it work reasonably when you're alternating multi-character strings. Crow|Servo will match either Crow or Servo, not Cro, a 'w' or an 'S', and ervo.

To match a literal '|', use \|, or enclose it inside a character class, as in [\|].

^ Matches at the beginning of lines. Unless the MULTILINE flag has
been set, this will only match at the beginning of the string. In **MULTILINE** mode, this also matches immediately after each newline within the string.

For example, if you wish to match the word *From* only at the beginning of a line, the RE to use is `^From`.

```python
>>> print re.search('^From', 'From Here to Eternity')
<re.MatchObject instance at 80c1520>
>>> print re.search('^From', 'Reciting From Memory')
None
```

Matches at the end of a line, which is defined as either the end of the string, or any location followed by a newline character.

```python
>>> print re.search('}$', '{block}')
<re.MatchObject instance at 80adfa8>
>>> print re.search('}$', '{block} ')
None
>>> print re.search('}$', '{block}\n')
<re.MatchObject instance at 80adfa8>
```

To match a literal `'$'`, use `\$` or enclose it inside a character class, as in `[\$]`.

```
\A
```

Matches only at the start of the string. When not in **MULTILINE** mode, `\A` and `^` are effectively the same. In **MULTILINE** mode, they're different: `\A` still matches only at the beginning of the string, but `^` may match at any location inside the string that follows a newline character.

```
\Z
```

Matches only at the end of the string.
Word boundary. This is a zero-width assertion that matches only at the beginning or end of a word. A word is defined as a sequence of alphanumeric characters, so the end of a word is indicated by whitespace or a non-alphanumeric character.

The following example matches `class` only when it’s a complete word; it won’t match when it’s contained inside another word.

```python
>>> p = re.compile(r'\bclass\b')
>>> print p.search('no class at all')
<re.MatchObject instance at 80c8f28>
>>> print p.search('the declassified algorithm')
None
>>> print p.search('one subclass is')
None
```

There are two subtleties you should remember when using this special sequence. First, this is the worst collision between Python’s string literals and regular expression sequences. In Python’s string literals, `\b` is the backspace character, ASCII value 8. If you’re not using raw strings, then Python will convert the `\b` to a backspace, and your RE won’t match as you expect it to. The following example looks the same as our previous RE, but omits the `r` in front of the RE string.

```python
>>> p = re.compile('\bclass\b')
>>> print p.search('no class at all')
None
>>> print p.search('\b' + 'class' + '\b')
<re.MatchObject instance at 80c3ee0>
```

Second, inside a character class, where there’s no use for this assertion, `\b` represents the backspace character, for
compatibility with Python’s string literals.

Another zero-width assertion, this is the opposite of \b, only matching when the current position is not at a word boundary.

### Grouping

Frequently you need to obtain more information than just whether the RE matched or not. Regular expressions are often used to dissect strings by writing a RE divided into several subgroups which match different components of interest. For example, an RFC-822 header line is divided into a header name and a value, separated by a ':', like this:

```
From: author@example.com
User-Agent: Thunderbird 1.5.0.9 (X11/20061227)
MIME-Version: 1.0
To: editor@example.com
```

This can be handled by writing a regular expression which matches an entire header line, and has one group which matches the header name, and another group which matches the header’s value.

Groups are marked by the '(, ')' metacharacters. '(' and ')') have much the same meaning as they do in mathematical expressions; they group together the expressions contained inside them, and you can repeat the contents of a group with a repeating qualifier, such as *, +, ?, or {m,n}. For example, (ab)* will match zero or more repetitions of ab.

```python
>>> p = re.compile('(ab)*')
>>> print p.match('ababababab').span()
(0, 10)
```

Groups indicated with '(, )' also capture the starting and ending
index of the text that they match; this can be retrieved by passing an argument to `group()`, `start()`, `end()`, and `span()`. Groups are numbered starting with 0. Group 0 is always present; it’s the whole RE, so `MatchObject` methods all have group 0 as their default argument. Later we’ll see how to express groups that don’t capture the span of text that they match.

```python
>>> p = re.compile('(a)b')
>>> m = p.match('ab')
>>> m.group()
'ab'
>>> m.group(0)
'ab'
```

Subgroups are numbered from left to right, from 1 upward. Groups can be nested; to determine the number, just count the opening parenthesis characters, going from left to right.

```python
>>> p = re.compile('(a(b)c)d')
>>> m = p.match('abcd')
>>> m.group(0)
'abcd'
>>> m.group(1)
'abc'
>>> m.group(2)
'b'
```

`group()` can be passed multiple group numbers at a time, in which case it will return a tuple containing the corresponding values for those groups.

```python
>>> m.group(2, 1, 2)
('b', 'abc', 'b')
```

The `groups()` method returns a tuple containing the strings for all the subgroups, from 1 up to however many there are.

```python
>>> m.groups()
('abc', 'b')
```
Backreferences in a pattern allow you to specify that the contents of an earlier capturing group must also be found at the current location in the string. For example, \1 will succeed if the exact contents of group 1 can be found at the current position, and fails otherwise. Remember that Python's string literals also use a backslash followed by numbers to allow including arbitrary characters in a string, so be sure to use a raw string when incorporating backreferences in a RE.

For example, the following RE detects doubled words in a string.

```python
>>> p = re.compile(r'\b\w+\s+\1')
>>> p.search('Paris in the the spring').group()
'the the'
```

Backreferences like this aren't often useful for just searching through a string — there are few text formats which repeat data in this way — but you'll soon find out that they're very useful when performing string substitutions.

### Non-capturing and Named Groups

Elaborate REs may use many groups, both to capture substrings of interest, and to group and structure the RE itself. In complex REs, it becomes difficult to keep track of the group numbers. There are two features which help with this problem. Both of them use a common syntax for regular expression extensions, so we'll look at that first.

Perl 5 added several additional features to standard regular expressions, and the Python `re` module supports most of them. It would have been difficult to choose new single-keystroke metacharacters or new special sequences beginning with `\` to represent the new features without making Perl's regular expressions confusingly different from standard REs. If you chose & as a new metacharacter, for example, old expressions would be assuming that & was a regular character and wouldn't have escaped
it by writing \& or [\&].

The solution chosen by the Perl developers was to use (?...) as the extension syntax. ? immediately after a parenthesis was a syntax error because the ? would have nothing to repeat, so this didn’t introduce any compatibility problems. The characters immediately after the ? indicate what extension is being used, so (?=foo) is one thing (a positive lookahead assertion) and (?:foo) is something else (a non-capturing group containing the subexpression foo).

Python adds an extension syntax to Perl’s extension syntax. If the first character after the question mark is a p, you know that it’s an extension that’s specific to Python. Currently there are two such extensions: (?P<name>...) defines a named group, and (?P=name) is a backreference to a named group. If future versions of Perl 5 add similar features using a different syntax, the re module will be changed to support the new syntax, while preserving the Python-specific syntax for compatibility’s sake.

Now that we’ve looked at the general extension syntax, we can return to the features that simplify working with groups in complex REs. Since groups are numbered from left to right and a complex expression may use many groups, it can become difficult to keep track of the correct numbering. Modifying such a complex RE is annoying, too: insert a new group near the beginning and you change the numbers of everything that follows it.

Sometimes you’ll want to use a group to collect a part of a regular expression, but aren’t interested in retrieving the group’s contents. You can make this fact explicit by using a non-capturing group: (?:...), where you can replace the ... with any other regular expression.

```python
>>> m = re.match("([abc])+", "abc")
```
Except for the fact that you can't retrieve the contents of what the group matched, a non-capturing group behaves exactly the same as a capturing group; you can put anything inside it, repeat it with a repetition metacharacter such as *, and nest it within other groups (capturing or non-capturing). (?:...) is particularly useful when modifying an existing pattern, since you can add new groups without changing how all the other groups are numbered. It should be mentioned that there's no performance difference in searching between capturing and non-capturing groups; neither form is any faster than the other.

A more significant feature is named groups: instead of referring to them by numbers, groups can be referenced by a name.

The syntax for a named group is one of the Python-specific extensions: (?P<name>...). name is, obviously, the name of the group. Named groups also behave exactly like capturing groups, and additionally associate a name with a group. The MatchObject methods that deal with capturing groups all accept either integers that refer to the group by number or strings that contain the desired group's name. Named groups are still given numbers, so you can retrieve information about a group in two ways:

```
>>> p = re.compile(r'(?!P<word>\b\w+\b)')
>>> m = p.search( '(((( Lots of punctuation )))')
>>> m.group('word')
'Lots'
```

Named groups are handy because they let you use easily-remembered names, instead of having to remember numbers.
Here's an example RE from the `imaplib` module:

```python
InternalDate = re.compile(r'INTERNALDATE "'
    r'(?P<day>[1-9][0-9])-(?P<mon>[A-Z][a-z][a-z])-'
    r'(?P<year>[0-9][0-9][0-9][0-9])' 
    r' (?P<hour>[0-9][0-9]):(?P<min>[0-9][0-9]):(?P<sec>[0-9][0-9])' 
    r' (?P<zonen>[-+])(?P<zoneh>[0-9][0-9])(?P<zonem>[0-9][0-9])' 
    r"')
```

It's obviously much easier to retrieve `m.group('zonem')`, instead of having to remember to retrieve group 9.

The syntax for backreferences in an expression such as `(\d+)` refers to the number of the group. There's naturally a variant that uses the group name instead of the number. This is another Python extension: `(?P=name)` indicates that the contents of the group called `name` should again be matched at the current point. The regular expression for finding doubled words, `(\b\w+)\s+(?P=word)` can also be written as `(?P<word>\b\w+)\s+(?P=word):

```python
>>> p = re.compile(r'(\b\w+)\s+(?P=word)')
>>> p.search('Paris in the the spring').group()
'the the'
```

### Lookahead Assertions

Another zero-width assertion is the lookahead assertion. Lookahead assertions are available in both positive and negative form, and look like this:

```python
(?=...)  
```

Positive lookahead assertion. This succeeds if the contained regular expression, represented here by `...`, successfully matches at the current location, and fails otherwise. But, once the contained expression has been tried, the matching engine doesn't advance at all; the rest of the pattern is tried right where
the assertion started.

(?!=...)

Negative lookahead assertion. This is the opposite of the positive assertion; it succeeds if the contained expression doesn’t match at the current position in the string.

To make this concrete, let’s look at a case where a lookahead is useful. Consider a simple pattern to match a filename and split it apart into a base name and an extension, separated by a .. For example, in `news.rc`, `news` is the base name, and `rc` is the filename’s extension.

The pattern to match this is quite simple:

`.\.*$`

Notice that the . needs to be treated specially because it’s a metacharacter; I’ve put it inside a character class. Also notice the trailing $; this is added to ensure that all the rest of the string must be included in the extension. This regular expression matches `foo.bar` and `autoexec.bat` and `sendmail.cf` and `printers.conf`.

Now, consider complicating the problem a bit; what if you want to match filenames where the extension is not bat? Some incorrect attempts:

`.\.[^b].*$` The first attempt above tries to exclude bat by requiring that the first character of the extension is not a b. This is wrong, because the pattern also doesn’t match `foo.bar`.

`.\.[^[a][^t]]$`

The expression gets messier when you try to patch up the first solution by requiring one of the following cases to match: the first character of the extension isn’t b; the second character isn’t a; or the
third character isn't t. This accepts foo.bar and rejects autoexec.bat, but it requires a three-letter extension and won't accept a filename with a two-letter extension such as sendmail.cf. We'll complicate the pattern again in an effort to fix it.

```
.*[.]([^b].?|[^a].?|..[^t]?).*$
```

In the third attempt, the second and third letters are all made optional in order to allow matching extensions shorter than three characters, such as sendmail.cf.

The pattern's getting really complicated now, which makes it hard to read and understand. Worse, if the problem changes and you want to exclude both bat and exe as extensions, the pattern would get even more complicated and confusing.

A negative lookahead cuts through all this confusion:

```
.*[.](!bat)$.*$ The negative lookahead means: if the expression bat doesn't match at this point, try the rest of the pattern; if bat$ does match, the whole pattern will fail. The trailing $ is required to ensure that something like sample.batch, where the extension only starts with bat, will be allowed.

Excluding another filename extension is now easy; simply add it as an alternative inside the assertion. The following pattern excludes filenames that end in either bat or exe:

```
.*[.](?!bat$|exe$).*$
```
Modifying Strings

Up to this point, we've simply performed searches against a static string. Regular expressions are also commonly used to modify strings in various ways, using the following `RegexObject` methods:

<table>
<thead>
<tr>
<th>Method/Attribute</th>
<th>Purpose</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>split()</code></td>
<td>Split the string into a list, splitting it wherever the RE matches</td>
</tr>
<tr>
<td><code>sub()</code></td>
<td>Find all substrings where the RE matches, and replace them with a different string</td>
</tr>
<tr>
<td><code>subn()</code></td>
<td>Does the same thing as <code>sub()</code>, but returns the new string and the number of replacements</td>
</tr>
</tbody>
</table>

Splitting Strings

The `split()` method of a `RegexObject` splits a string apart wherever the RE matches, returning a list of the pieces. It's similar to the `split()` method of strings but provides much more generality in the delimiters that you can split by; `split()` only supports splitting by whitespace or by a fixed string. As you'd expect, there's a module-level `re.split()` function, too.

```python
.split(string[, maxsplit=0])
```

Split `string` by the matches of the regular expression. If capturing parentheses are used in the RE, then their contents will also be returned as part of the resulting list. If `maxsplit` is nonzero, at most `maxsplit` splits are performed.

You can limit the number of splits made, by passing a value for `maxsplit`. When `maxsplit` is nonzero, at most `maxsplit` splits will be made, and the remainder of the string is returned as the final
element of the list. In the following example, the delimiter is any sequence of non-alphanumeric characters.

```python
>>> p = re.compile(r'\W+')
>>> p.split('This is a test, short and sweet, of split().')
['This', 'is', 'a', 'test', 'short', 'and', 'sweet', 'of', 'split()']
>>> p.split('This is a test, short and sweet, of split().', 3)
['This', 'is', 'a', 'test, short and sweet, of split().']
```

Sometimes you're not only interested in what the text between delimiters is, but also need to know what the delimiter was. If capturing parentheses are used in the RE, then their values are also returned as part of the list. Compare the following calls:

```python
>>> p = re.compile(r'\W+')
>>> p2 = re.compile(r'(\W+)')
>>> p.split('This... is a test.')
['This', 'is', 'a', 'test', '']
>>> p2.split('This... is a test.')
['This', '...', 'is', '', 'a', '', 'test', '.', '', '']
```

The module-level function `re.split()` adds the RE to be used as the first argument, but is otherwise the same.

```python
>>> re.split('\\W+', 'Words, words, words.')
['Words', 'words', 'words', '']
>>> re.split('\\([\W]+)', 'Words, words, words.')
['Words', '', '', 'words', '', '', 'words', '', '', '']
>>> re.split('\\W+', 'Words, words, words.', 1)
['Words', 'words, words.']
```

### Search and Replace

Another common task is to find all the matches for a pattern, and replace them with a different string. The `sub()` method takes a replacement value, which can be either a string or a function, and the string to be processed.
.sub(replacement, string[, count=0])

Returns the string obtained by replacing the leftmost non-overlapping occurrences of the RE in string by the replacement replacement. If the pattern isn't found, string is returned unchanged.

The optional argument count is the maximum number of pattern occurrences to be replaced; count must be a non-negative integer. The default value of 0 means to replace all occurrences.

Here's a simple example of using the sub() method. It replaces colour names with the word colour:

```python
>>> p = re.compile( '(blue|white|red)' )
>>> p.sub('colour', 'blue socks and red shoes')
'colour socks and colour shoes'
>>> p.sub('colour', 'blue socks and red shoes', count=1)
'colour socks and red shoes'
```

The subn() method does the same work, but returns a 2-tuple containing the new string value and the number of replacements that were performed:

```python
>>> p = re.compile( '(blue|white|red)' )
>>> p.subn('colour', 'blue socks and red shoes')
('colour socks and colour shoes', 2)
>>> p.subn('colour', 'no colours at all')
('no colours at all', 0)
```

Empty matches are replaced only when they're not adjacent to a previous match.

```python
>>> p = re.compile('x*')
>>> p.sub('-', 'abxd')
'-a-b-d-'
```

If replacement is a string, any backslash escapes in it are processed. That is, \n is converted to a single newline character, \r is converted
to a carriage return, and so forth. Unknown escapes such as \j are left alone. Backreferences, such as \6, are replaced with the substring matched by the corresponding group in the RE. This lets you incorporate portions of the original text in the resulting replacement string.

This example matches the word section followed by a string enclosed in {, }, and changes section to subsection:

```python
>>> p = re.compile('section{ (?P<name>[^{}]* ) }', re.VERBOSE)
>>> p.sub(r'subsection{\1}','section{First} section{second}')
'subsection{First} subsection{second}'
```

There’s also a syntax for referring to named groups as defined by the (?P<name>...) syntax. \g<name> will use the substring matched by the group named name, and \g<number> uses the corresponding group number. \g<2> is therefore equivalent to \2, but isn’t ambiguous in a replacement string such as \g<2>0. (\20 would be interpreted as a reference to group 20, not a reference to group 2 followed by the literal character '0'.) The following substitutions are all equivalent, but use all three variations of the replacement string.

```python
>>> p = re.compile('section{ (?P<name>[^{}]* ) }', re.VERBOSE)
>>> p.sub(r'subsection{\1}','section{First}')
'subsection{First}'
>>> p.sub(r'subsection{\g<1>}','section{First}')
'subsection{First}'
>>> p.sub(r'subsection{\g<name>}','section{First}')
'subsection{First}'
```

replacement can also be a function, which gives you even more control. If replacement is a function, the function is called for every non-overlapping occurrence of pattern. On each call, the function is passed a MatchObject argument for the match and can use this information to compute the desired replacement string and return it.

In the following example, the replacement function translates
decimals into hexadecimal:

```python
>>> def hexrepl( match ):
...     "Return the hex string for a decimal number"
...     value = int( match.group() )
...     return hex(value)
...
>>> p = re.compile(r'\d+')
>>> p.sub(hexrepl, 'Call 65490 for printing, 49152 for user code.
Call 0xffffd2 for printing, 0xc000 for user code.')
```

When using the module-level `re.sub()` function, the pattern is passed as the first argument. The pattern may be a string or a `RegexObject`; if you need to specify regular expression flags, you must either use a `RegexObject` as the first parameter, or use embedded modifiers in the pattern, e.g. `sub("(?i)b+", "x", "bbbb BBBB")` returns 'x x'.
Common Problems

Regular expressions are a powerful tool for some applications, but in some ways their behaviour isn’t intuitive and at times they don’t behave the way you may expect them to. This section will point out some of the most common pitfalls.

Use String Methods

Sometimes using the re module is a mistake. If you’re matching a fixed string, or a single character class, and you’re not using any re features such as the IGNORECASE flag, then the full power of regular expressions may not be required. Strings have several methods for performing operations with fixed strings and they’re usually much faster, because the implementation is a single small C loop that’s been optimized for the purpose, instead of the large, more generalized regular expression engine.

One example might be replacing a single fixed string with another one; for example, you might replace \texttt{word} with \texttt{deed}. \texttt{re.sub()} seems like the function to use for this, but consider the \texttt{replace()} method. Note that \texttt{replace()} will also replace \texttt{word} inside words, turning \texttt{swordfish} into \texttt{sdeedfish}, but the naive RE \texttt{word} would have done that, too. (To avoid performing the substitution on parts of words, the pattern would have to be \texttt{\bword\b}, in order to require that \texttt{word} have a word boundary on either side. This takes the job beyond \texttt{replace()}'s abilities.)

Another common task is deleting every occurrence of a single character from a string or replacing it with another single character. You might do this with something like \texttt{re.sub('\n', '', S)}, but \texttt{translate()} is capable of doing both tasks and will be faster than
any regular expression operation can be.

In short, before turning to the re module, consider whether your problem can be solved with a faster and simpler string method.

**match() versus search()**

The `match()` function only checks if the RE matches at the beginning of the string while `search()` will scan forward through the string for a match. It’s important to keep this distinction in mind. Remember, `match()` will only report a successful match which will start at 0; if the match wouldn’t start at zero, `match()` will *not* report it.

```python
>>> print re.match('super', 'superstition').span()
(0, 5)
>>> print re.match('super', 'insuperable')
None
```

On the other hand, `search()` will scan forward through the string, reporting the first match it finds.

```python
>>> print re.search('super', 'superstition').span()
(0, 5)
>>> print re.search('super', 'insuperable').span()
(2, 7)
```

Sometimes you’ll be tempted to keep using `re.match()`, and just add `.*` to the front of your RE. Resist this temptation and use `re.search()` instead. The regular expression compiler does some analysis of REs in order to speed up the process of looking for a match. One such analysis figures out what the first character of a match must be; for example, a pattern starting with `Crow` must match starting with a `'c'`. The analysis lets the engine quickly scan through the string looking for the starting character, only trying the full match if a `'c'` is found.
Adding .* defeats this optimization, requiring scanning to the end of the string and then backtracking to find a match for the rest of the RE. Use re.search() instead.

**Greedy versus Non-Greedy**

When repeating a regular expression, as in a*, the resulting action is to consume as much of the pattern as possible. This fact often bites you when you’re trying to match a pair of balanced delimiters, such as the angle brackets surrounding an HTML tag. The naive pattern for matching a single HTML tag doesn’t work because of the greedy nature of .*.

```python
>>> s = '<html><head><title>Title</title>'
>>> len(s)
32
>>> print re.match('<.*>', s).span()
(0, 32)
>>> print re.match('<.*>', s).group()
<html><head><title>Title</title>
```

The RE matches the '<' in <html>, and the .* consumes the rest of the string. There’s still more left in the RE, though, and the > can’t match at the end of the string, so the regular expression engine has to backtrack character by character until it finds a match for the >. The final match extends from the '<' in <html> to the '>' in </title>, which isn’t what you want.

In this case, the solution is to use the non-greedy qualifiers *, +, ?, or {m,n}, which match as *little* text as possible. In the above example, the '>' is tried immediately after the first '<' matches, and when it fails, the engine advances a character at a time, retrying the '>' at every step. This produces just the right result:

```python
>>> print re.match('<.*?>', s).group()
<html>
```
(Note that parsing HTML or XML with regular expressions is painful. Quick-and-dirty patterns will handle common cases, but HTML and XML have special cases that will break the obvious regular expression; by the time you've written a regular expression that handles all of the possible cases, the patterns will be very complicated. Use an HTML or XML parser module for such tasks.)

Not Using re.VERBOSE

By now you've probably noticed that regular expressions are a very compact notation, but they're not terribly readable. REs of moderate complexity can become lengthy collections of backslashes, parentheses, and metacharacters, making them difficult to read and understand.

For such REs, specifying the re.VERBOSE flag when compiling the regular expression can be helpful, because it allows you to format the regular expression more clearly.

The re.VERBOSE flag has several effects. Whitespace in the regular expression that isn't inside a character class is ignored. This means that an expression such as dog | cat is equivalent to the less readable dog|cat, but [a b] will still match the characters 'a', 'b', or a space. In addition, you can also put comments inside a RE; comments extend from a # character to the next newline. When used with triple-quoted strings, this enables REs to be formatted more neatly:

```python
pat = re.compile(r'''
\s*
(?P<header>[^:]+)\n\s*:\n(?P<value>.*?)\n\s*$
'''

# Skip leading whitespace
# Header name
# Whitespace, and a colon
# The header's value -- *? used to
# lose the following trailing whitespace
# Trailing whitespace to end-of-line
```
This is far more readable than:

```python
pat = re.compile(r'^\s*(?P<header>[^:]+)\s*:\s*(?P<value>,*\s*)\s*$')
```
Regular expressions are a complicated topic. Did this document help you understand them? Were there parts that were unclear, or Problems you encountered that weren’t covered here? If so, please send suggestions for improvements to the author.

The most complete book on regular expressions is almost certainly Jeffrey Friedl's Mastering Regular Expressions, published by O'Reilly. Unfortunately, it exclusively concentrates on Perl and Java's flavours of regular expressions, and doesn’t contain any Python material at all, so it won't be useful as a reference for programming in Python. (The first edition covered Python's now-removed `regex` module, which won't help you much.) Consider checking it out from your library.

**Footnotes**

[1] Introduced in Python 2.2.2.
Abstract

Sockets are used nearly everywhere, but are one of the most severely misunderstood technologies around. This is a 10,000 foot overview of sockets. It’s not really a tutorial - you'll still have work to do in getting things operational. It doesn’t cover the fine points (and there are a lot of them), but I hope it will give you enough background to begin using them decently.
Sockets

Sockets are used nearly everywhere, but are one of the most severely misunderstood technologies around. This is a 10,000 foot overview of sockets. It's not really a tutorial - you'll still have work to do in getting things working. It doesn't cover the fine points (and there are a lot of them), but I hope it will give you enough background to begin using them decently.

I'm only going to talk about INET sockets, but they account for at least 99% of the sockets in use. And I'll only talk about STREAM sockets - unless you really know what you're doing (in which case this HOWTO isn't for you!), you'll get better behavior and performance from a STREAM socket than anything else. I will try to clear up the mystery of what a socket is, as well as some hints on how to work with blocking and non-blocking sockets. But I'll start by talking about blocking sockets. You'll need to know how they work before dealing with non-blocking sockets.

Part of the trouble with understanding these things is that “socket” can mean a number of subtly different things, depending on context. So first, let's make a distinction between a “client” socket - an endpoint of a conversation, and a “server” socket, which is more like a switchboard operator. The client application (your browser, for example) uses “client” sockets exclusively; the web server it's talking to uses both “server” sockets and “client” sockets.

History

Of the various forms of IPC (Inter Process Communication), sockets are by far the most popular. On any given platform, there are likely to be other forms of IPC that are faster, but for cross-platform communication, sockets are about the only game in town.
They were invented in Berkeley as part of the BSD flavor of Unix. They spread like wildfire with the Internet. With good reason — the combination of sockets with INET makes talking to arbitrary machines around the world unbelievably easy (at least compared to other schemes).
Creating a Socket

Roughly speaking, when you clicked on the link that brought you to this page, your browser did something like the following:

```
# create an INET, STREAMing socket
s = socket.socket(  
    socket.AF_INET, socket.SOCK_STREAM)
# now connect to the web server on port 80
# - the normal http port
s.connect(('www.mcmillan-inc.com', 80))
```

When the `connect` completes, the socket `s` can now be used to send in a request for the text of this page. The same socket will read the reply, and then be destroyed. That’s right - destroyed. Client sockets are normally only used for one exchange (or a small set of sequential exchanges).

What happens in the web server is a bit more complex. First, the web server creates a “server socket”.

```
# create an INET, STREAMing socket
serversocket = socket.socket(  
    socket.AF_INET, socket.SOCK_STREAM)
# bind the socket to a public host,  
# and a well-known port
serversocket.bind((socket.gethostname(), 80))
# become a server socket
serversocket.listen(5)
```

A couple things to notice: we used `socket.gethostname()` so that the socket would be visible to the outside world. If we had used `s.bind(('', 80))` or `s.bind(('localhost', 80))` or `s.bind(('127.0.0.1', 80))` we would still have a “server” socket, but one that was only visible within the same machine.

A second thing to note: low number ports are usually reserved for
“well known” services (HTTP, SNMP etc). If you’re playing around, use a nice high number (4 digits).

Finally, the argument to `listen` tells the socket library that we want it to queue up as many as 5 connect requests (the normal max) before refusing outside connections. If the rest of the code is written properly, that should be plenty.

OK, now we have a “server” socket, listening on port 80. Now we enter the mainloop of the web server:

```python
while 1:
    # accept connections from outside
    (clientsocket, address) = serversocket.accept()
    # now do something with the clientsocket
    # in this case, we'll pretend this is a threaded server
    ct = client_thread(clientsocket)
    ct.run()
```

There's actually 3 general ways in which this loop could work - dispatching a thread to handle `clientsocket`, create a new process to handle `clientsocket`, or restructure this app to use non-blocking sockets, and multiplex between our “server” socket and any active `clientsockets` using `select`. More about that later. The important thing to understand now is this: this is all a “server” socket does. It doesn’t send any data. It doesn’t receive any data. It just produces “client” sockets. Each `clientsocket` is created in response to some other “client” socket doing a `connect()` to the host and port we’re bound to. As soon as we’ve created that `clientsocket`, we go back to listening for more connections. The two “clients” are free to chat it up - they are using some dynamically allocated port which will be recycled when the conversation ends.

**IPC**

If you need fast IPC between two processes on one machine, you
should look into whatever form of shared memory the platform offers. A simple protocol based around shared memory and locks or semaphores is by far the fastest technique.

If you do decide to use sockets, bind the “server” socket to 'localhost'. On most platforms, this will take a shortcut around a couple of layers of network code and be quite a bit faster.
Using a Socket

The first thing to note, is that the web browser’s “client” socket and the web server’s “client” socket are identical beasts. That is, this is a “peer to peer” conversation. Or to put it another way, as the designer, you will have to decide what the rules of etiquette are for a conversation. Normally, the connecting socket starts the conversation, by sending in a request, or perhaps a signon. But that’s a design decision - it’s not a rule of sockets.

Now there are two sets of verbs to use for communication. You can use send and recv, or you can transform your client socket into a file-like beast and use read and write. The latter is the way Java presents their sockets. I'm not going to talk about it here, except to warn you that you need to use flush on sockets. These are buffered “files”, and a common mistake is to write something, and then read for a reply. Without a flush in there, you may wait forever for the reply, because the request may still be in your output buffer.

Now we come the major stumbling block of sockets - send and recv operate on the network buffers. They do not necessarily handle all the bytes you hand them (or expect from them), because their major focus is handling the network buffers. In general, they return when the associated network buffers have been filled (send) or emptied (recv). They then tell you how many bytes they handled. It is your responsibility to call them again until your message has been completely dealt with.

When a recv returns 0 bytes, it means the other side has closed (or is in the process of closing) the connection. You will not receive any more data on this connection. Ever. You may be able to send data successfully; I’ll talk about that some on the next page.
A protocol like HTTP uses a socket for only one transfer. The client sends a request, the server reads a reply. That’s it. The socket is discarded. This means that a client can detect the end of the reply by receiving 0 bytes.

But if you plan to reuse your socket for further transfers, you need to realize that there is no “EOT” (End of Transfer) on a socket. I repeat: if a socket `send` or `recv` returns after handling 0 bytes, the connection has been broken. If the connection has not been broken, you may wait on a `recv` forever, because the socket will not tell you that there’s nothing more to read (for now). Now if you think about that a bit, you’ll come to realize a fundamental truth of sockets: messages must either be fixed length (yuck), or be delimited (shrug), or indicate how long they are (much better), or end by shutting down the connection. The choice is entirely yours, (but some ways are righter than others).

Assuming you don’t want to end the connection, the simplest solution is a fixed length message:

```python
class mysocket:
    '''demonstration class only
    - coded for clarity, not efficiency
    ',''
    def __init__(self, sock=None):
        if sock is None:
            self.sock = socket.socket(socket.AF_INET, socket.SOCK_STREAM)
        else:
            self.sock = sock
    def connect(self, host, port):
        self.sock.connect((host, port))
    def mysend(self, msg):
        totalsent = 0
        while totalsent < MSGLEN:
            sent = self.sock.send(msg[totalsent:])
            if sent == 0:
                raise RuntimeError,
```
"socket connection broken"
totsent = totsent + sent

def myreceive(self):
    msg = ''
    while len(msg) < MSGLEN:
        chunk = self.sock.recv(MSGLEN-len(msg))
        if chunk == '':
            raise RuntimeError,
            "socket connection broken"
        msg = msg + chunk
    return msg

The sending code here is usable for almost any messaging scheme - in Python you send strings, and you can use `len()` to determine its length (even if it has embedded `\0` characters). It’s mostly the receiving code that gets more complex. (And in C, it’s not much worse, except you can’t use `strlen` if the message has embedded `\0`s.)

The easiest enhancement is to make the first character of the message an indicator of message type, and have the type determine the length. Now you have two `recv`s - the first to get (at least) that first character so you can look up the length, and the second in a loop to get the rest. If you decide to go the delimited route, you’ll be receiving in some arbitrary chunk size, (4096 or 8192 is frequently a good match for network buffer sizes), and scanning what you’ve received for a delimiter.

One complication to be aware of: if your conversational protocol allows multiple messages to be sent back to back (without some kind of reply), and you pass `recv` an arbitrary chunk size, you may end up reading the start of a following message. You’ll need to put that aside and hold onto it, until it’s needed.

Prefixing the message with it’s length (say, as 5 numeric characters) gets more complex, because (believe it or not), you may not get all 5 characters in one `recv`. In playing around, you’ll get away with it; but
in high network loads, your code will very quickly break unless you use two `recv` loops - the first to determine the length, the second to get the data part of the message. Nasty. This is also when you'll discover that `send` does not always manage to get rid of everything in one pass. And despite having read this, you will eventually get bit by it!

In the interests of space, building your character, (and preserving my competitive position), these enhancements are left as an exercise for the reader. Lets move on to cleaning up.

**Binary Data**

It is perfectly possible to send binary data over a socket. The major problem is that not all machines use the same formats for binary data. For example, a Motorola chip will represent a 16 bit integer with the value 1 as the two hex bytes 00 01. Intel and DEC, however, are byte-reversed - that same 1 is 01 00. Socket libraries have calls for converting 16 and 32 bit integers - `ntohl`, `htonl`, `ntohs`, `htons` where “n” means *network* and “h” means *host*, “s” means *short* and “l” means *long*. Where network order is host order, these do nothing, but where the machine is byte-reversed, these swap the bytes around appropriately.

In these days of 32 bit machines, the ascii representation of binary data is frequently smaller than the binary representation. That's because a surprising amount of the time, all those longs have the value 0, or maybe 1. The string “0” would be two bytes, while binary is four. Of course, this doesn't fit well with fixed-length messages. Decisions, decisions.
Disconnecting

Strictly speaking, you're supposed to use `shutdown` on a socket before you `close` it. The `shutdown` is an advisory to the socket at the other end. Depending on the argument you pass it, it can mean “I'm not going to send anymore, but I'll still listen”, or “I'm not listening, good riddance!”. Most socket libraries, however, are so used to programmers neglecting to use this piece of etiquette that normally a `close` is the same as `shutdown(); close()`. So in most situations, an explicit `shutdown` is not needed.

One way to use `shutdown` effectively is in an HTTP-like exchange. The client sends a request and then does a `shutdown(1)`. This tells the server “This client is done sending, but can still receive.” The server can detect “EOF” by a receive of 0 bytes. It can assume it has the complete request. The server sends a reply. If the `send` completes successfully then, indeed, the client was still receiving.

Python takes the automatic shutdown a step further, and says that when a socket is garbage collected, it will automatically do a `close` if it's needed. But relying on this is a very bad habit. If your socket just disappears without doing a `close`, the socket at the other end may hang indefinitely, thinking you're just being slow. Please `close` your sockets when you're done.

When Sockets Die

Probably the worst thing about using blocking sockets is what happens when the other side comes down hard (without doing a `close`). Your socket is likely to hang. SOCKSTREAM is a reliable protocol, and it will wait a long, long time before giving up on a connection. If you're using threads, the entire thread is essentially
dead. There’s not much you can do about it. As long as you aren’t doing something dumb, like holding a lock while doing a blocking read, the thread isn’t really consuming much in the way of resources. Do not try to kill the thread - part of the reason that threads are more efficient than processes is that they avoid the overhead associated with the automatic recycling of resources. In other words, if you do manage to kill the thread, your whole process is likely to be screwed up.
Non-blocking Sockets

If you've understood the preceeding, you already know most of what you need to know about the mechanics of using sockets. You'll still use the same calls, in much the same ways. It's just that, if you do it right, your app will be almost inside-out.

In Python, you use `socket.setblocking(0)` to make it non-blocking. In C, it's more complex, (for one thing, you'll need to choose between the BSD flavor `O_NONBLOCK` and the almost indistinguishable Posix flavor `O_NDELAY`, which is completely different from `TCP_NODELAY`), but it's the exact same idea. You do this after creating the socket, but before using it. (Actually, if you're nuts, you can switch back and forth.)

The major mechanical difference is that `send`, `recv`, `connect` and `accept` can return without having done anything. You have (of course) a number of choices. You can check return code and error codes and generally drive yourself crazy. If you don't believe me, try it sometime. Your app will grow large, buggy and suck CPU. So let's skip the brain-dead solutions and do it right.

Use `select`.

In C, coding `select` is fairly complex. In Python, it's a piece of cake, but it's close enough to the C version that if you understand `select` in Python, you'll have little trouble with it in C.

```python
ready_to_read, ready_to_write, in_error = 
select.select(
    potential_readers,
    potential_writers,
    potential_errs,
    timeout)
```
You pass `select` three lists: the first contains all sockets that you might want to try reading; the second all the sockets you might want to try writing to, and the last (normally left empty) those that you want to check for errors. You should note that a socket can go into more than one list. The `select` call is blocking, but you can give it a timeout. This is generally a sensible thing to do - give it a nice long timeout (say a minute) unless you have good reason to do otherwise.

In return, you will get three lists. They have the sockets that are actually readable, writable and in error. Each of these lists is a subset (possibly empty) of the corresponding list you passed in. And if you put a socket in more than one input list, it will only be (at most) in one output list.

If a socket is in the output readable list, you can be as-close-to-certain-as-we-ever-get-in-this-business that a `recv` on that socket will return `something`. Same idea for the writable list. You’ll be able to send `something`. Maybe not all you want to, but `something` is better than nothing. (Actually, any reasonably healthy socket will return as writable - it just means outbound network buffer space is available.)

If you have a “server” socket, put it in the potential_readers list. If it comes out in the readable list, your `accept` will (almost certainly) work. If you have created a new socket to `connect` to someone else, put it in the potential_writers list. If it shows up in the writable list, you have a decent chance that it has connected.

One very nasty problem with `select`: if somewhere in those input lists of sockets is one which has died a nasty death, the `select` will fail. You then need to loop through every single damn socket in all those lists and do a `select([sock],[],[],0)` until you find the bad one. That timeout of 0 means it won’t take long, but it’s ugly.
Actually, `select` can be handy even with blocking sockets. It’s one way of determining whether you will block - the socket returns as readable when there’s something in the buffers. However, this still doesn’t help with the problem of determining whether the other end is done, or just busy with something else.

**Portability alert:** On Unix, `select` works both with the sockets and files. Don’t try this on Windows. On Windows, `select` works with sockets only. Also note that in C, many of the more advanced socket options are done differently on Windows. In fact, on Windows I usually use threads (which work very, very well) with my sockets. Face it, if you want any kind of performance, your code will look very different on Windows than on Unix.

## Performance

There’s no question that the fastest sockets code uses non-blocking sockets and `select` to multiplex them. You can put together something that will saturate a LAN connection without putting any strain on the CPU. The trouble is that an app written this way can’t do much of anything else - it needs to be ready to shuffle bytes around at all times.

Assuming that your app is actually supposed to do something more than that, threading is the optimal solution, (and using non-blocking sockets will be faster than using blocking sockets). Unfortunately, threading support in Unixes varies both in API and quality. So the normal Unix solution is to fork a subprocess to deal with each connection. The overhead for this is significant (and don’t do this on Windows - the overhead of process creation is enormous there). It also means that unless each subprocess is completely independent, you’ll need to use another form of IPC, say a pipe, or shared memory and semaphores, to communicate between the parent and child processes.
Finally, remember that even though blocking sockets are somewhat slower than non-blocking, in many cases they are the “right” solution. After all, if your app is driven by the data it receives over a socket, there’s not much sense in complicating the logic just so your app can wait on `select` instead of `recv`.
Release: 1.02

This HOWTO discusses Python’s support for Unicode, and explains various problems that people commonly encounter when trying to work with Unicode.
Introduction to Unicode

History of Character Codes

In 1968, the American Standard Code for Information Interchange, better known by its acronym ASCII, was standardized. ASCII defined numeric codes for various characters, with the numeric values running from 0 to 127. For example, the lowercase letter ‘a’ is assigned 97 as its code value.

ASCII was an American-developed standard, so it only defined unaccented characters. There was an ‘e’, but no ‘é’ or ‘Í’. This meant that languages which required accented characters couldn’t be faithfully represented in ASCII. (Actually the missing accents matter for English, too, which contains words such as ‘naïve’ and ‘cafér’, and some publications have house styles which require spellings such as ‘coöperate’.)

For a while people just wrote programs that didn’t display accents. I remember looking at Apple ][ BASIC programs, published in French-language publications in the mid-1980s, that had lines like these:

```
PRINT "FICHER EST COMPLETE."
PRINT "CARACTERE NON ACCEPTE."
```

Those messages should contain accents, and they just look wrong to someone who can read French.

In the 1980s, almost all personal computers were 8-bit, meaning that bytes could hold values ranging from 0 to 255. ASCII codes only went up to 127, so some machines assigned values between 128 and 255 to accented characters. Different machines had different codes, however, which led to problems exchanging files. Eventually various commonly used sets of values for the 128-255 range
emerged. Some were true standards, defined by the International Standards Organization, and some were \textit{de facto} conventions that were invented by one company or another and managed to catch on.

255 characters aren't very many. For example, you can’t fit both the accented characters used in Western Europe and the Cyrillic alphabet used for Russian into the 128-255 range because there are more than 127 such characters.

You could write files using different codes (all your Russian files in a coding system called KOI8, all your French files in a different coding system called Latin1), but what if you wanted to write a French document that quotes some Russian text? In the 1980s people began to want to solve this problem, and the Unicode standardization effort began.

Unicode started out using 16-bit characters instead of 8-bit characters. 16 bits means you have $2^{16} = 65,536$ distinct values available, making it possible to represent many different characters from many different alphabets; an initial goal was to have Unicode contain the alphabets for every single human language. It turns out that even 16 bits isn’t enough to meet that goal, and the modern Unicode specification uses a wider range of codes, 0-1,114,111 (0x10ffff in base-16).

There’s a related ISO standard, ISO 10646. Unicode and ISO 10646 were originally separate efforts, but the specifications were merged with the 1.1 revision of Unicode.

(This discussion of Unicode’s history is highly simplified. I don’t think the average Python programmer needs to worry about the historical details; consult the Unicode consortium site listed in the References for more information.)

\textbf{Definitions}
A **character** is the smallest possible component of a text. ‘A’, ‘B’, ‘C’, etc., are all different characters. So are ‘È’ and ‘Í’. Characters are abstractions, and vary depending on the language or context you’re talking about. For example, the symbol for ohms (Ω) is usually drawn much like the capital letter omega (Ω) in the Greek alphabet (they may even be the same in some fonts), but these are two different characters that have different meanings.

The Unicode standard describes how characters are represented by **code points**. A code point is an integer value, usually denoted in base 16. In the standard, a code point is written using the notation U+12ca to mean the character with value 0x12ca (4810 decimal). The Unicode standard contains a lot of tables listing characters and their corresponding code points:

<table>
<thead>
<tr>
<th>Code</th>
<th>Character</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>0061</td>
<td>'a';</td>
<td>LATIN SMALL LETTER 'A'</td>
</tr>
<tr>
<td>0062</td>
<td>'b';</td>
<td>LATIN SMALL LETTER 'B'</td>
</tr>
<tr>
<td>0063</td>
<td>'c';</td>
<td>LATIN SMALL LETTER 'C'</td>
</tr>
<tr>
<td>...</td>
<td></td>
<td></td>
</tr>
<tr>
<td>007B</td>
<td>'{';</td>
<td>LEFT CURLY BRACKET</td>
</tr>
</tbody>
</table>

Strictly, these definitions imply that it’s meaningless to say ‘this is character U+12ca’. U+12ca is a code point, which represents some particular character; in this case, it represents the character ‘ETHIOPIAN SYLLABLE WI’. In informal contexts, this distinction between code points and characters will sometimes be forgotten.

A character is represented on a screen or on paper by a set of graphical elements that’s called a **glyph**. The glyph for an uppercase A, for example, is two diagonal strokes and a horizontal stroke, though the exact details will depend on the font being used. Most Python code doesn’t need to worry about glyphs; figuring out the correct glyph to display is generally the job of a GUI toolkit or a terminal’s font renderer.
To summarize the previous section: a Unicode string is a sequence of code points, which are numbers from 0 to 0x10ffff. This sequence needs to be represented as a set of bytes (meaning, values from 0-255) in memory. The rules for translating a Unicode string into a sequence of bytes are called an encoding.

The first encoding you might think of is an array of 32-bit integers. In this representation, the string “Python” would look like this:

<table>
<thead>
<tr>
<th>P</th>
<th>y</th>
<th>t</th>
<th>h</th>
<th>o</th>
</tr>
</thead>
<tbody>
<tr>
<td>0x50</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>0</td>
</tr>
<tr>
<td>0</td>
<td>1</td>
<td>2</td>
<td>3</td>
<td>4</td>
</tr>
<tr>
<td>5</td>
<td>6</td>
<td>7</td>
<td>8</td>
<td>9</td>
</tr>
<tr>
<td>10</td>
<td>11</td>
<td>12</td>
<td>13</td>
<td>14</td>
</tr>
<tr>
<td>15</td>
<td>16</td>
<td>17</td>
<td>18</td>
<td>19</td>
</tr>
<tr>
<td>20</td>
<td>21</td>
<td>22</td>
<td>23</td>
<td>24</td>
</tr>
</tbody>
</table>

This representation is straightforward but using it presents a number of problems.

1. It’s not portable; different processors order the bytes differently.
2. It’s very wasteful of space. In most texts, the majority of the code points are less than 127, or less than 255, so a lot of space is occupied by zero bytes. The above string takes 24 bytes compared to the 6 bytes needed for an ASCII representation. Increased RAM usage doesn’t matter too much (desktop computers have megabytes of RAM, and strings aren’t usually that large), but expanding our usage of disk and network bandwidth by a factor of 4 is intolerable.
3. It’s not compatible with existing C functions such as strlen(), so a new family of wide string functions would need to be used.
4. Many Internet standards are defined in terms of textual data, and can’t handle content with embedded zero bytes.

Generally people don’t use this encoding, instead choosing other encodings that are more efficient and convenient.

Encodings don’t have to handle every possible Unicode character, and most encodings don’t. For example, Python’s default encoding is
the ‘ascii’ encoding. The rules for converting a Unicode string into the ASCII encoding are simple; for each code point:

1. If the code point is < 128, each byte is the same as the value of the code point.
2. If the code point is 128 or greater, the Unicode string can’t be represented in this encoding. (Python raises a `UnicodeEncodeError` exception in this case.)

Latin-1, also known as ISO-8859-1, is a similar encoding. Unicode code points 0-255 are identical to the Latin-1 values, so converting to this encoding simply requires converting code points to byte values; if a code point larger than 255 is encountered, the string can’t be encoded into Latin-1.

Encodings don’t have to be simple one-to-one mappings like Latin-1. Consider IBM’s EBCDIC, which was used on IBM mainframes. Letter values weren’t in one block: ‘a’ through ‘i’ had values from 129 to 137, but ‘j’ through ‘r’ were 145 through 153. If you wanted to use EBCDIC as an encoding, you’d probably use some sort of lookup table to perform the conversion, but this is largely an internal detail.

UTF-8 is one of the most commonly used encodings. UTF stands for “Unicode Transformation Format”, and the ‘8’ means that 8-bit numbers are used in the encoding. (There’s also a UTF-16 encoding, but it’s less frequently used than UTF-8.) UTF-8 uses the following rules:

1. If the code point is <128, it’s represented by the corresponding byte value.
2. If the code point is between 128 and 0x7ff, it’s turned into two byte values between 128 and 255.
3. Code points >0x7ff are turned into three- or four-byte sequences, where each byte of the sequence is between 128 and 255.
UTF-8 has several convenient properties:

1. It can handle any Unicode code point.
2. A Unicode string is turned into a string of bytes containing no embedded zero bytes. This avoids byte-ordering issues, and means UTF-8 strings can be processed by C functions such as `strcpy()` and sent through protocols that can’t handle zero bytes.
3. A string of ASCII text is also valid UTF-8 text.
4. UTF-8 is fairly compact; the majority of code points are turned into two bytes, and values less than 128 occupy only a single byte.
5. If bytes are corrupted or lost, it’s possible to determine the start of the next UTF-8-encoded code point and resynchronize. It’s also unlikely that random 8-bit data will look like valid UTF-8.

The Unicode Consortium site at <http://www.unicode.org> has character charts, a glossary, and PDF versions of the Unicode specification. Be prepared for some difficult reading. <http://www.unicode.org/history/> is a chronology of the origin and development of Unicode.

Two other good introductory articles were written by Joel Spolsky <http://www.joelonsoftware.com/articles/Unicode.html> and Jason Orendorff <http://www.jorendorff.com/articles/unicode/>. If this introduction didn’t make things clear to you, you should try reading one of these alternate articles before continuing.

Wikipedia entries are often helpful; see the entries for “character
Python’s Unicode Support

Now that you’ve learned the rudiments of Unicode, we can look at Python’s Unicode features.

The Unicode Type

Unicode strings are expressed as instances of the `unicode` type, one of Python’s repertoire of built-in types. It derives from an abstract type called `basestring`, which is also an ancestor of the `str` type; you can therefore check if a value is a string type with `isinstance(value, basestring)`. Under the hood, Python represents Unicode strings as either 16- or 32-bit integers, depending on how the Python interpreter was compiled.

The `unicode()` constructor has the signature `unicode(string[, encoding, errors])`. All of its arguments should be 8-bit strings. The first argument is converted to Unicode using the specified encoding; if you leave off the `encoding` argument, the ASCII encoding is used for the conversion, so characters greater than 127 will be treated as errors:

```python
>>> unicode('abcdef')
 u'abcdef'
>>> s = unicode('abcdef')
>>> type(s)
<type 'unicode'>
>>> unicode('abcdef' + chr(255))
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
UnicodeDecodeError: 'ascii' codec can't decode byte 0xff in position 6: ordinal not in range(128)
```

The `errors` argument specifies the response when the input string can’t be converted according to the encoding’s rules. Legal values
for this argument are ‘strict’ (raise a `UnicodeDecodeError` exception), ‘replace’ (add U+FFFD, ‘REPLACEMENT CHARACTER’), or ‘ignore’ (just leave the character out of the Unicode result). The following examples show the differences:

```python
global encoding_type

# Examples of different encoding behaviors

for encoding in ['strict', 'replace', 'ignore']:
    try:
        encoding_type = encoding
        data = encoding_type('\x80abc', errors=encoding)
        print(data)
    except UnicodeDecodeError as e:
        print(e)
    except Exception as e:
        print(e)
```

Encodings are specified as strings containing the encoding’s name. Python 2.4 comes with roughly 100 different encodings; see the Python Library Reference at *Standard Encodings* for a list. Some encodings have multiple names; for example, ‘latin-1’, ‘iso_8859_1’ and ‘8859’ are all synonyms for the same encoding.

One-character Unicode strings can also be created with the `unichr()` built-in function, which takes integers and returns a Unicode string of length 1 that contains the corresponding code point. The reverse operation is the built-in `ord()` function that takes a one-character Unicode string and returns the code point value:

```python
>>> unichr(40960)
u'\u0000'
```

Instances of the `unicode` type have many of the same methods as the 8-bit string type for operations such as searching and formatting:
Note that the arguments to these methods can be Unicode strings or 8-bit strings. 8-bit strings will be converted to Unicode before carrying out the operation; Python's default ASCII encoding will be used, so characters greater than 127 will cause an exception:

```
>>> s.find('Was\x9f')
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
UnicodeDecodeError: 'ascii' codec can't decode byte 0x9f in position 3
```  

Much Python code that operates on strings will therefore work with Unicode strings without requiring any changes to the code. (Input and output code needs more updating for Unicode; more on this later.)

Another important method is `.encode([encoding], [errors='strict'])`, which returns an 8-bit string version of the Unicode string, encoded in the requested encoding. The errors parameter is the same as the parameter of the `unicode()` constructor, with one additional possibility; as well as ‘strict’, ‘ignore’, and ‘replace’, you can also pass ‘xmlcharrefreplace’ which uses XML's character references. The following example shows the different results:

```
>>> u = unichr(40960) + u'abcd' + unichr(1972)
>>> u.encode('utf-8')
'\xea\x80\x80abcd\xde\xb4'
>>> u.encode('ascii')
```
Python’s 8-bit strings have a `.decode([encoding], [errors])` method that interprets the string using the given encoding:

```python
>>> u = unichr(40960) + u'abcd' + unichr(1972)
    # Assemble a string
>>> utf8_version = u.encode('utf-8')
    # Encode as UTF-8
>>> type(utf8_version), utf8_version
(<type 'str'>, '\xea\x80\x80abcd\xde\xb4')
>>> u2 = utf8_version.decode('utf-8')
    # Decode using UTF-8
>>> u == u2
True
```

The low-level routines for registering and accessing the available encodings are found in the `codecs` module. However, the encoding and decoding functions returned by this module are usually more low-level than is comfortable, so I’m not going to describe the `codecs` module here. If you need to implement a completely new encoding, you’ll need to learn about the `codecs` module interfaces, but implementing encodings is a specialized task that also won’t be covered here. Consult the Python documentation to learn more about this module.

The most commonly used part of the `codecs` module is the `codecs.open()` function which will be discussed in the section on input and output.

---

**Unicode Literals in Python Source Code**
In Python source code, Unicode literals are written as strings prefixed with the ‘u’ or ‘U’ character: u'abcdefgijk'. Specific code points can be written using the \u escape sequence, which is followed by four hex digits giving the code point. The \U escape sequence is similar, but expects 8 hex digits, not 4.

Unicode literals can also use the same escape sequences as 8-bit strings, including \x, but \x only takes two hex digits so it can’t express an arbitrary code point. Octal escapes can go up to U+01ff, which is octal 777.

```
>>> s = u"a\xac\u1234\u20ac\U00008000"
    ^^^^ two-digit hex escape
    ^^^^^^ four-digit Unicode escape
    ^^^^^^^^^ eight-digit Unicode escape
>>> for c in s:  print ord(c),
...  97 172 4660 8364 32768
```

Using escape sequences for code points greater than 127 is fine in small doses, but becomes an annoyance if you’re using many accented characters, as you would in a program with messages in French or some other accent-using language. You can also assemble strings using the unichr() built-in function, but this is even more tedious.

Ideally, you’d want to be able to write literals in your language’s natural encoding. You could then edit Python source code with your favorite editor which would display the accented characters naturally, and have the right characters used at runtime.

Python supports writing Unicode literals in any encoding, but you have to declare the encoding being used. This is done by including a special comment as either the first or second line of the source file:

```
#!/usr/bin/env python
```
The syntax is inspired by Emacs's notation for specifying variables local to a file. Emacs supports many different variables, but Python only supports 'coding'. The "-*=" symbols indicate that the comment is special; within them, you must supply the name `coding` and the name of your chosen encoding, separated by ':'.

If you don’t include such a comment, the default encoding used will be ASCII. Versions of Python before 2.4 were Euro-centric and assumed Latin-1 as a default encoding for string literals; in Python 2.4, characters greater than 127 still work but result in a warning. For example, the following program has no encoding declaration:

```python
#!/usr/bin/env python
u = u'abcdé'
print ord(u[-1])
```

When you run it with Python 2.4, it will output the following warning:

```
amk:~$ python p263.py
sys:1: DeprecationWarning: Non-ASCII character '\xe9'
in file p263.py on line 2, but no encoding declared;
see http://www.python.org/peps/pep-0263.html for details
```

### Unicode Properties

The Unicode specification includes a database of information about code points. For each code point that's defined, the information includes the character's name, its category, the numeric value if applicable (Unicode has characters representing the Roman numerals and fractions such as one-third and four-fifths). There are also properties related to the code point's use in bidirectional text and other display-related properties.
The following program displays some information about several characters, and prints the numeric value of one particular character:

```python
import unicodedata
u = unichr(233) + unichr(0x0bf2) + unichr(3972) + unichr(6000)
for i, c in enumerate(u):
    print i, '{%04x}' % ord(c), unicodedata.category(c),
    print unicodedata.name(c)

# Get numeric value of second character
print unicodedata.numeric(u[1])
```

When run, this prints:

```
0 00e9 Ll LATIN SMALL LETTER E WITH ACUTE
1 0bf2 No TAMIL NUMBER ONE THOUSAND
2 0f84 Mn TIBETAN MARK HALANTA
3 1770 Lo TAGBANWA LETTER SA
4 33af So SQUARE RAD OVER S SQUARED
1000.0
```

The category codes are abbreviations describing the nature of the character. These are grouped into categories such as “Letter”, “Number”, “Punctuation”, or “Symbol”, which in turn are broken up into subcategories. To take the codes from the above output, 'Ll' means ‘Letter, lowercase’, 'No' means “Number, other”, 'Mn' is “Mark, nonspacing”, and 'So' is “Symbol, other”. See <http://www.unicode.org/Public/UNIDATA/UCD.html#General_Category> for a list of category codes.

The Unicode and 8-bit string types are described in the Python library reference at *Sequence Types — str, unicode, list, tuple, buffer, xrange*.
The documentation for the `unicodedata` module.

The documentation for the `codecs` module.

Marc-André Lemburg gave a presentation at EuroPython 2002 titled “Python and Unicode”. A PDF version of his slides is available at `<http://downloads.egenix.com/python/Unicode-EPC2002-Talk.pdf>`, and is an excellent overview of the design of Python’s Unicode features.
Once you’ve written some code that works with Unicode data, the next problem is input/output. How do you get Unicode strings into your program, and how do you convert Unicode into a form suitable for storage or transmission?

It’s possible that you may not need to do anything depending on your input sources and output destinations; you should check whether the libraries used in your application support Unicode natively. XML parsers often return Unicode data, for example. Many relational databases also support Unicode-valued columns and can return Unicode values from an SQL query.

Unicode data is usually converted to a particular encoding before it gets written to disk or sent over a socket. It’s possible to do all the work yourself: open a file, read an 8-bit string from it, and convert the string with `unicode(str, encoding)`. However, the manual approach is not recommended.

One problem is the multi-byte nature of encodings; one Unicode character can be represented by several bytes. If you want to read the file in arbitrary-sized chunks (say, 1K or 4K), you need to write error-handling code to catch the case where only part of the bytes encoding a single Unicode character are read at the end of a chunk. One solution would be to read the entire file into memory and then perform the decoding, but that prevents you from working with files that are extremely large; if you need to read a 2Gb file, you need 2Gb of RAM. (More, really, since for at least a moment you’d need to have both the encoded string and its Unicode version in memory.)

The solution would be to use the low-level decoding interface to catch the case of partial coding sequences. The work of implementing this has already been done for you: the `codecs` module
includes a version of the open() function that returns a file-like object that assumes the file's contents are in a specified encoding and accepts Unicode parameters for methods such as .read() and .write().

The function’s parameters are open(filename, mode='rb', encoding=None, errors='strict', buffering=1). mode can be 'r', 'w', or 'a', just like the corresponding parameter to the regular built-in open() function; add a '+' to update the file. buffering is similarly parallel to the standard function’s parameter. encoding is a string giving the encoding to use; if it's left as None, a regular Python file object that accepts 8-bit strings is returned. Otherwise, a wrapper object is returned, and data written to or read from the wrapper object will be converted as needed. errors specifies the action for encoding errors and can be one of the usual values of ‘strict’, ‘ignore’, and ‘replace’.

Reading Unicode from a file is therefore simple:

```python
import codecs
f = codecs.open('unicode.rst', encoding='utf-8')
for line in f:
    print repr(line)
```

It’s also possible to open files in update mode, allowing both reading and writing:

```python
f = codecs.open('test', encoding='utf-8', mode='w+')
f.write(u'\u4500 blah blah blah\n')
f.seek(0)
print repr(f.readline()[:1])
f.close()
```

Unicode character U+FEFF is used as a byte-order mark (BOM), and is often written as the first character of a file in order to assist with autodetection of the file’s byte ordering. Some encodings, such
as UTF-16, expect a BOM to be present at the start of a file; when such an encoding is used, the BOM will be automatically written as the first character and will be silently dropped when the file is read. There are variants of these encodings, such as 'utf-16-le' and 'utf-16-be' for little-endian and big-endian encodings, that specify one particular byte ordering and don’t skip the BOM.

### Unicode filenames

Most of the operating systems in common use today support filenames that contain arbitrary Unicode characters. Usually this is implemented by converting the Unicode string into some encoding that varies depending on the system. For example, Mac OS X uses UTF-8 while Windows uses a configurable encoding; on Windows, Python uses the name “mbcs” to refer to whatever the currently configured encoding is. On Unix systems, there will only be a filesystem encoding if you’ve set the `LANG` or `LC_CTYPE` environment variables; if you haven’t, the default encoding is ASCII.

The `sys.getfilesystemencoding()` function returns the encoding to use on your current system, in case you want to do the encoding manually, but there’s not much reason to bother. When opening a file for reading or writing, you can usually just provide the Unicode string as the filename, and it will be automatically converted to the right encoding for you:

```python
filename = u'filename\u4500abc'
f = open(filename, 'w')
f.write('blah
')
f.close()
```

Functions in the `os` module such as `os.stat()` will also accept Unicode filenames.

`os.listdir()`, which returns filenames, raises an issue: should it
return the Unicode version of filenames, or should it return 8-bit strings containing the encoded versions? `os.listdir()` will do both, depending on whether you provided the directory path as an 8-bit string or a Unicode string. If you pass a Unicode string as the path, filenames will be decoded using the filesystem's encoding and a list of Unicode strings will be returned, while passing an 8-bit path will return the 8-bit versions of the filenames. For example, assuming the default filesystem encoding is UTF-8, running the following program:

```python
fn = u'filename\u4500abc'
f = open(fn, 'w')
f.close()

import os
print os.listdir('.

print os.listdir(u'.
```

will produce the following output:

```
amk:~$ python t.py
['.svn', 'filename\xe4\x94\x80abc', ...]
[u'.svn', u'filename\u4500abc', ...]
```

The first list contains UTF-8-encoded filenames, and the second list contains the Unicode versions.

**Tips for Writing Unicode-aware Programs**

This section provides some suggestions on writing software that deals with Unicode.

The most important tip is:

Software should only work with Unicode strings internally, converting to a particular encoding on output.

If you attempt to write processing functions that accept both Unicode and 8-bit strings, you will find your program vulnerable to bugs
wherever you combine the two different kinds of strings. Python’s default encoding is ASCII, so whenever a character with an ASCII value > 127 is in the input data, you’ll get a `UnicodeDecodeError` because that character can’t be handled by the ASCII encoding.

It’s easy to miss such problems if you only test your software with data that doesn’t contain any accents; everything will seem to work, but there’s actually a bug in your program waiting for the first user who attempts to use characters > 127. A second tip, therefore, is:

Include characters > 127 and, even better, characters > 255 in your test data.

When using data coming from a web browser or some other untrusted source, a common technique is to check for illegal characters in a string before using the string in a generated command line or storing it in a database. If you’re doing this, be careful to check the string once it’s in the form that will be used or stored; it’s possible for encodings to be used to disguise characters. This is especially true if the input data also specifies the encoding; many encodings leave the commonly checked-for characters alone, but Python includes some encodings such as `'base64'` that modify every single character.

For example, let’s say you have a content management system that takes a Unicode filename, and you want to disallow paths with a ‘/’ character. You might write this code:

```python
def read_file (filename, encoding):
    if '/' in filename:
        raise ValueError("'/' not allowed in filenames")
    unicode_name = filename.decode(encoding)
    f = open(unicode_name, 'r')
    # ... return contents of file ...
```

However, if an attacker could specify the `'base64'` encoding, they could pass `'L2V0Yy9wYXNzd2Q='`, which is the base-64 encoded form
of the string '\etc/passwd', to read a system file. The above code looks for '/' characters in the encoded form and misses the dangerous character in the resulting decoded form.

HOWTO Fetch Internet Resources Using urllib2

Author: Michael Foord

Note: There is an French translation of an earlier revision of this HOWTO, available at urllib2 - Le Manuel manquant.
Introduction

Related Articles

You may also find useful the following article on fetching web resources with Python:

- Basic Authentication

  A tutorial on Basic Authentication, with examples in Python.

urllib2 is a Python module for fetching URLs (Uniform Resource Locators). It offers a very simple interface, in the form of the urlopen function. This is capable of fetching URLs using a variety of different protocols. It also offers a slightly more complex interface for handling common situations - like basic authentication, cookies, proxies and so on. These are provided by objects called handlers and openers.

urllib2 supports fetching URLs for many “URL schemes” (identified by the string before the “:” in URL - for example “ftp” is the URL scheme of “ftp://python.org/“) using their associated network protocols (e.g. FTP, HTTP). This tutorial focuses on the most common case, HTTP.

For straightforward situations urlopen is very easy to use. But as soon as you encounter errors or non-trivial cases when opening HTTP URLs, you will need some understanding of the HyperText Transfer Protocol. The most comprehensive and authoritative reference to HTTP is RFC 2616. This is a technical document and not intended to be easy to read. This HOWTO aims to illustrate using urllib2, with enough detail about HTTP to help you through. It is not intended to replace the urllib2 docs, but is supplementary to them.
Fetching URLs

The simplest way to use urllib2 is as follows:

```python
import urllib2
response = urllib2.urlopen('http://python.org/)
html = response.read()
```

Many uses of urllib2 will be that simple (note that instead of an ‘http:’ URL we could have used an URL starting with ‘ftp:’, ‘file:’, etc.). However, it’s the purpose of this tutorial to explain the more complicated cases, concentrating on HTTP.

HTTP is based on requests and responses - the client makes requests and servers send responses. urllib2 mirrors this with a Request object which represents the HTTP request you are making. In its simplest form you create a Request object that specifies the URL you want to fetch. Calling `urlopen` with this Request object returns a response object for the URL requested. This response is a file-like object, which means you can for example call `.read()` on the response:

```python
import urllib2

req = urllib2.Request('http://www.voidspace.org.uk')
response = urllib2.urlopen(req)
the_page = response.read()
```

Note that urllib2 makes use of the same Request interface to handle all URL schemes. For example, you can make an FTP request like so:

```python
req = urllib2.Request('ftp://example.com/)
```

In the case of HTTP, there are two extra things that Request objects
allow you to do: First, you can pass data to be sent to the server. Second, you can pass extra information ("metadata") about the data or the about request itself, to the server - this information is sent as HTTP "headers". Let's look at each of these in turn.

Data

Sometimes you want to send data to a URL (often the URL will refer to a CGI (Common Gateway Interface) script or other web application). With HTTP, this is often done using what's known as a POST request. This is often what your browser does when you submit a HTML form that you filled in on the web. Not all POSTs have to come from forms: you can use a POST to transmit arbitrary data to your own application. In the common case of HTML forms, the data needs to be encoded in a standard way, and then passed to the Request object as the data argument. The encoding is done using a function from the urllib library not from urllib2.

```python
import urllib
import urllib2

url = 'http://www.someserver.com/cgi-bin/register.cgi'
values = {'name' : 'Michael Foord',
          'location' : 'Northampton',
          'language' : 'Python'
}

data = urllib.urlencode(values)
req = urllib2.Request(url, data)
response = urllib2.urlopen(req)
the_page = response.read()
```

Note that other encodings are sometimes required (e.g. for file upload from HTML forms - see HTML Specification, Form Submission for more details).

If you do not pass the data argument, urllib2 uses a GET request. One way in which GET and POST requests differ is that POST requests often have "side-effects": they change the state of the
system in some way (for example by placing an order with the website for a hundredweight of tinned spam to be delivered to your door). Though the HTTP standard makes it clear that POSTs are intended to always cause side-effects, and GET requests never to cause side-effects, nothing prevents a GET request from having side-effects, nor a POST requests from having no side-effects. Data can also be passed in an HTTP GET request by encoding it in the URL itself.

This is done as follows:

```python
>>> import urllib2
>>> import urllib
>>> data = {}
>>> data['name'] = 'Somebody Here'
>>> data['location'] = 'Northampton'
>>> data['language'] = 'Python'
>>> url_values = urllib.urlencode(data)
>>> print url_values
name=Somebody+Here&language=Python&location=Northampton
>>> url = 'http://www.example.com/example.cgi'
>>> full_url = url + '?' + url_values
>>> data = urllib2.open(full_url)
```

Notice that the full URL is created by adding a ? to the URL, followed by the encoded values.

**Headers**

We'll discuss here one particular HTTP header, to illustrate how to add headers to your HTTP request.

Some websites [2] dislike being browsed by programs, or send different versions to different browsers [3]. By default urllib2 identifies itself as Python-urllib/x.y (where x and y are the major and minor version numbers of the Python release, e.g. Python-urllib/2.5), which may confuse the site, or just plain not work. The way a browser identifies itself is through the User-Agent header [4].
When you create a Request object you can pass a dictionary of headers in. The following example makes the same request as above, but identifies itself as a version of Internet Explorer [5].

```python
import urllib
import urllib2

url = 'http://www.someserver.com/cgi-bin/register.cgi'
user_agent = 'Mozilla/4.0 (compatible; MSIE 5.5; Windows NT)'
values = {'name': 'Michael Foord',
          'location': 'Northampton',
          'language': 'Python'}
headers = {'User-Agent': user_agent}
data = urllib.urlencode(values)
req = urllib2.Request(url, data, headers)
response = urllib2.urlopen(req)
the_page = response.read()
```

The response also has two useful methods. See the section on info and geturl which comes after we have a look at what happens when things go wrong.
Handling Exceptions

`urlopen` raises `URLError` when it cannot handle a response (though as usual with Python APIs, builtin exceptions such as `ValueError`, `TypeError` etc. may also be raised).

`HTTPError` is the subclass of `URLError` raised in the specific case of HTTP URLs.

**URLError**

Often, `URLError` is raised because there is no network connection (no route to the specified server), or the specified server doesn’t exist. In this case, the exception raised will have a 'reason' attribute, which is a tuple containing an error code and a text error message.

e.g.

```python
>>> req = urllib2.Request('http://www.pretend_server.org')
>>> try:
...     urllib2.urlopen(req)
>>> except URLError, e:
...     print e.reason
>>>(4, 'getaddrinfo failed')
```

**HTTPError**

Every HTTP response from the server contains a numeric “status code”. Sometimes the status code indicates that the server is unable to fulfil the request. The default handlers will handle some of these responses for you (for example, if the response is a “redirection” that requests the client fetch the document from a different URL, `urllib2` will handle that for you). For those it can’t handle, `urlopen` will raise an `HTTPError`. Typical errors include ‘404’ (page not found), ‘403’
(request forbidden), and ‘401’ (authentication required).

See section 10 of RFC 2616 for a reference on all the HTTP error codes.

The `HTTPError` instance raised will have an integer ‘code’ attribute, which corresponds to the error sent by the server.

**Error Codes**

Because the default handlers handle redirects (codes in the 300 range), and codes in the 100-299 range indicate success, you will usually only see error codes in the 400-599 range.

`BaseHTTPServer.BaseHTTPRequestHandler.responses` is a useful dictionary of response codes in that shows all the response codes used by RFC 2616. The dictionary is reproduced here for convenience.

```
# Table mapping response codes to messages; entries have the
# form {code: (shortmessage, longmessage)}.
responses = {
    100: ('Continue', 'Request received, please continue'),
    101: ('Switching Protocols',
         'Switching to new protocol; obey Upgrade header'),
    200: ('OK', 'Request fulfilled, document follows'),
    201: ('Created', 'Document created, URL follows'),
    202: ('Accepted',
         'Request accepted, processing continues off-line'),
    203: ('Non-Authoritative Information', 'Request fulfilled f
    204: ('No Content', 'Request fulfilled, nothing follows'),
    205: ('Reset Content', 'Clear input form for further input.
    206: ('Partial Content', 'Partial content follows.'),
    300: ('Multiple Choices',
         'Object has several resources -- see URI list'),
    301: ('Moved Permanently', 'Object moved permanently -- see
    302: ('Found', 'Object moved temporarily -- see URI list'),
    303: ('See Other', 'Object moved -- see Method and URL list
    304: ('Not Modified',
         'Document has not changed since given time'),
```
305: ('Use Proxy',
    'You must use proxy specified in Location to access this resource.'),
307: ('Temporary Redirect',
    'Object moved temporarily -- see URI list'),
400: ('Bad Request',
    'Bad request syntax or unsupported method'),
401: ('Unauthorized',
    'No permission -- see authorization schemes'),
402: ('Payment Required',
    'No payment -- see charging schemes'),
403: ('Forbidden',
    'Request forbidden -- authorization will not help'),
404: ('Not Found',
    'Nothing matches the given URI'),
405: ('Method Not Allowed',
    'Specified method is invalid for this server.'),
406: ('Not Acceptable',
    'URI not available in preferred format'),
407: ('Proxy Authentication Required',
    'You must authenticate with this proxy before proceeding.'),
408: ('Request Timeout',
    'Request timed out; try again later'),
409: ('Conflict',
    'Request conflict.'),
410: ('Gone',
    'URI no longer exists and has been permanently removed'),
411: ('Length Required',
    'Client must specify Content-Length'),
412: ('Precondition Failed',
    'Precondition in headers is false'),
413: ('Request Entity Too Large',
    'Entity is too large.'),
414: ('Request-URI Too Long',
    'URI is too long.'),
415: ('Unsupported Media Type',
    'Entity body in unsupported format'),
416: ('Requested Range Not Satisfiable',
    'Cannot satisfy request range.'),
417: ('Expectation Failed',
    'Expect condition could not be satisfied.'),
500: ('Internal Server Error',
    'Server got itself in trouble'),
501: ('Not Implemented',
    'Server does not support this operation'),
502: ('Bad Gateway',
    'Invalid responses from another server'),
503: ('Service Unavailable',
    'The server cannot process the request due to a high load'),
504: ('Gateway Timeout',
    'The gateway server did not receive a timely response'),
505: ('HTTP Version Not Supported',
    'Cannot fulfill request'}

When an error is raised the server responds by returning an HTTP error code and an error page. You can use the HTTPError instance as
a response on the page returned. This means that as well as the
code attribute, it also has read, geturl, and info, methods.

```python
>>> req = urllib2.Request('http://www.python.org/fish.html')
>>> try:
...    urllib2.urlopen(req)
>>> except URLError, e:
...    print e.code
...    print e.read()
>>> 404
<!DOCTYPE html PUBLIC "-//W3C//DTD HTML 4.01 Transitional//EN" "http://www.w3.org/TR/html4/loose.dtd">
<?xml-stylesheet href="/css/ht2html.css" type="text/css"?>
<html><head><title>Error 404: File Not Found</title>
...... etc...
```

Wrapping it Up

So if you want to be prepared for `HTTPError` or `URLError` there are
two basic approaches. I prefer the second approach.

### Number 1

```python
from urllib2 import Request, urlopen, URLError, HTTPError
req = Request(someurl)
try:
    response = urlopen(req)
except HTTPError, e:
    print 'The server couldn\'t fulfill the request.'
    print 'Error code: ', e.code
except URLError, e:
    print 'We failed to reach a server.'
    print 'Reason: ', e.reason
else:
    # everything is fine
```

**Note:** The except `HTTPError` *must* come first, otherwise except `URLError` will *also* catch an `HTTPError`.
from urllib2 import Request, urlopen, URLError
req = Request(someurl)
try:
    response = urlopen(req)
except URLError, e:
    if hasattr(e, 'reason'):
        print 'We failed to reach a server.'
        print 'Reason: ', e.reason
    elif hasattr(e, 'code'):
        print 'The server couldn\'t fulfill the request.'
        print 'Error code: ', e.code
else:
    # everything is fine
info and geturl

The response returned by urlopen (or the HTTPError instance) has two useful methods info() and geturl().

geturl - this returns the real URL of the page fetched. This is useful because urlopen (or the opener object used) may have followed a redirect. The URL of the page fetched may not be the same as the URL requested.

info - this returns a dictionary-like object that describes the page fetched, particularly the headers sent by the server. It is currently an httpplib.HTTPMessage instance.

Typical headers include ‘Content-length’, ‘Content-type’, and so on. See the Quick Reference to HTTP Headers for a useful listing of HTTP headers with brief explanations of their meaning and use.
Openers and Handlers

When you fetch a URL you use an opener (an instance of the perhaps confusingly-named `urllib2.OpenerDirector`). Normally we have been using the default opener - via `urlopen` - but you can create custom openers. Openers use handlers. All the “heavy lifting” is done by the handlers. Each handler knows how to open URLs for a particular URL scheme (http, ftp, etc.), or how to handle an aspect of URL opening, for example HTTP redirections or HTTP cookies.

You will want to create openers if you want to fetch URLs with specific handlers installed, for example to get an opener that handles cookies, or to get an opener that does not handle redirections.

To create an opener, instantiate an `OpenerDirector`, and then call `.add_handler(some_handler_instance)` repeatedly.

Alternatively, you can use `build_opener`, which is a convenience function for creating opener objects with a single function call. `build_opener` adds several handlers by default, but provides a quick way to add more and/or override the default handlers.

Other sorts of handlers you might want to can handle proxies, authentication, and other common but slightly specialised situations.

`install_opener` can be used to make an opener object the (global) default opener. This means that calls to `urlopen` will use the opener you have installed.

Opener objects have an `open` method, which can be called directly to fetch urls in the same way as the `urlopen` function: there's no need to call `install_opener`, except as a convenience.
Basic Authentication

To illustrate creating and installing a handler we will use the HTTPBasicAuthHandler. For a more detailed discussion of this subject – including an explanation of how Basic Authentication works - see the Basic Authentication Tutorial.

When authentication is required, the server sends a header (as well as the 401 error code) requesting authentication. This specifies the authentication scheme and a ‘realm’. The header looks like: 

```
WWW-Authenticate: SCHEME realm="REALM".
```

e.g.

```
WWW-Authenticate: Basic realm="cPanel Users"
```

The client should then retry the request with the appropriate name and password for the realm included as a header in the request. This is ‘basic authentication’. In order to simplify this process we can create an instance of HTTPBasicAuthHandler and an opener to use this handler.

The HTTPBasicAuthHandler uses an object called a password manager to handle the mapping of URLs and realms to passwords and usernames. If you know what the realm is (from the authentication header sent by the server), then you can use a HTTPPasswordMgr. Frequently one doesn’t care what the realm is. In that case, it is convenient to use HTTPPasswordMgrWithDefaultRealm. This allows you to specify a default username and password for a URL. This will be supplied in the absence of you providing an alternative combination for a specific realm. We indicate this by providing None as the realm argument to the add_password method.
The top-level URL is the first URL that requires authentication. URLs “deeper” than the URL you pass to .add_password() will also match.

```python
# create a password manager
password_mgr = urllib2.HTTPPasswordMgrWithDefaultRealm()

# Add the username and password.
# If we knew the realm, we could use it instead of ```None```

top_level_url = "http://example.com/foo/
password_mgr.add_password(Nothing, top_level_url, username, passw

handler = urllib2.HTTPBasicAuthHandler(password_mgr)

# create "opener" (OpenerDirector instance)

opener = urllib2.build_opener(handler)

# use the opener to fetch a URL

opener.open(a_url)

# Install the opener.
# Now all calls to urllib2.urlopen use our opener.

urllib2.install_opener(opener)
```

**Note:** In the above example we only supplied our HTTPBasicAuthHandler to build_opener. By default openers have the handlers for normal situations – ProxyHandler, UnknownHandler, HTTPHandler, HTTPDefaultErrorHandler, HTTPRedirectHandler, FTPHandler, FileHandler, HTTPErrorProcessor.

top_level_url is in fact *either* a full URL (including the ‘http:’ scheme component and the hostname and optionally the port number) e.g. “http://example.com/” or an “authority” (i.e. the hostname, optionally including the port number) e.g. “example.com” or “example.com:8080” (the latter example includes a port number). The authority, if present, must NOT contain the “userinfo” component - for example “joe@password:example.com” is not correct.
**Proxies**

*urllib2* will auto-detect your proxy settings and use those. This is through the *ProxyHandler* which is part of the normal handler chain. Normally that’s a good thing, but there are occasions when it may not be helpful [6]. One way to do this is to setup our own *ProxyHandler*, with no proxies defined. This is done using similar steps to setting up a *Basic Authentication* handler:

```python
>>> proxy_support = urllib2.ProxyHandler({})
>>> opener = urllib2.build_opener(proxy_support)
>>> urllib2.install_opener(opener)
```

**Note:** Currently *urllib2* *does not* support fetching of https locations through a proxy. However, this can be enabled by extending urllib2 as shown in the recipe [7].
Sockets and Layers

The Python support for fetching resources from the web is layered. `urllib2` uses the `httplib` library, which in turn uses the `socket` library.

As of Python 2.3 you can specify how long a socket should wait for a response before timing out. This can be useful in applications which have to fetch web pages. By default the socket module has no timeout and can hang. Currently, the socket timeout is not exposed at the `httplib` or `urllib2` levels. However, you can set the default timeout globally for all sockets using

```python
import socket
import urllib2

# timeout in seconds
timeout = 10
socket.setdefaulttimeout(timeout)

# this call to urllib2.urlopen now uses the default timeout
# we have set in the socket module
req = urllib2.Request('http://www.voidspace.org.uk')
response = urllib2.urlopen(req)
```
This document was reviewed and revised by John Lee.

[1] For an introduction to the CGI protocol see Writing Web Applications in Python.

Like Google for example. The proper way to use google from a program is to use PyGoogle of course. See Voidspace Google for some examples of using the Google API.

Browser sniffing is a very bad practise for website design - building sites using web standards is much more sensible. Unfortunately a lot of sites still send different versions to different browsers.

[3] The user agent for MSIE 6 is ‘Mozilla/4.0 (compatible; MSIE 6.0; Windows NT 5.1; SV1; .NET CLR 1.1.4322)’

For details of more HTTP request headers, see Quick Reference to HTTP Headers.

In my case I have to use a proxy to access the internet at work. If you attempt to fetch localhost URLs through this proxy it blocks them. IE is set to use the proxy, which urllib2 picks up on. In order to test scripts with a localhost server, I have to prevent urllib2 from using the proxy.

HOWTO Use Python in the web

Author: Marek Kubica

Abstract

This document shows how Python fits into the web. It presents some ways on how to integrate Python with the web server and general practices useful for developing web sites.

Programming for the Web has become a hot topic since the raise of the “Web 2.0”, which focuses on user-generated content on web sites. It has always been possible to use Python for creating web sites, but it was a rather tedious task. Therefore, many so-called “frameworks” and helper tools were created to help developers creating sites faster and these sites being more robust. This HOWTO describes some of the methods used to combine Python with a web server to create dynamic content. It is not meant as a general introduction as this topic is far too broad to be covered in one single document. However, a short overview of the most popular libraries is provided.

See also: While this HOWTO tries to give an overview over Python in the Web, it cannot always be as up to date as desired. Web development in Python is moving forward rapidly, so the wiki page on Web Programming might be more in sync with recent development.
The low-level view

When a user enters a web site, his browser makes a connection to the site’s webserver (this is called the request). The server looks up the file in the file system and sends it back to the user’s browser, which displays it (this is the response). This is roughly how the underlying protocol, HTTP works.

Now, dynamic web sites are not files in the file system, but rather programs which are run by the web server when a request comes in. They can do all sorts of useful things, like display the postings of a bulletin board, show your mails, configure software or just display the current time. These programs can be written in about any programming language the server supports, so it is easy to use Python for creating dynamic web sites.

As most of HTTP servers are written in C or C++, they cannot execute Python code in a simple way – a bridge is needed between the server and the program. These bridges or rather interfaces define how programs interact with the server. In the past there have been numerous attempts to create the best possible interface, but there are only a few worth mentioning.

Not every web server supports every interface. Many web servers do support only old, now-obsolete interfaces. But they can often be extended using some third-party modules to support new interfaces.

Common Gateway Interface

This interface is the oldest one, supported by nearly every web server out of the box. Programs using CGI to communicate with their web server need to be started by the server for every request. So, every request starts a new Python interpreter – which takes some
time to start up – thus making the whole interface only usable for low load situations.

The upside of CGI is that it is simple – writing a program which uses CGI is a matter of about three lines of code. But this simplicity comes at a price: it does very few things to help the developer.

Writing CGI programs, while still possible, is not recommended anymore. With WSGI (more on that later) it is possible to write programs that emulate CGI, so they can be run as CGI if no better option is available.

**See also:** The Python standard library includes some modules that are helpful for creating plain CGI programs:

- `cgi` – Handling of user input in CGI scripts
- `cgitb` – Displays nice tracebacks when errors happen in of CGI applications, instead of presenting a “500 Internal Server Error” message

The Python wiki features a page on [CGI scripts](https://wiki.python.org/moin/CGIscripts) with some additional information about CGI in Python.

### Simple script for testing CGI

To test whether your web server works with CGI, you can use this short and simple CGI program:

```python
#!/usr/bin/env python
#
#
# enable debugging
import cgitb; cgitb.enable()

print "Content-Type: text/plain;charset=utf-8"
print
print "Hello World!"
```
You need to write this code into a file with a `.py` or `.cgi` extension, this depends on your web server configuration. Depending on your web server configuration, this file may also need to be in a `cgi-bin` folder, for security reasons.

You might wonder what the `cgitb` line is about. This line makes it possible to display a nice traceback instead of just crashing and displaying an “Internal Server Error” in the user’s browser. This is useful for debugging, but it might risk exposing some confidential data to the user. Don’t use it when the script is ready for production use. Still, you should *always* catch exceptions, and display proper error pages – end-users don’t like to see nondescript “Internal Server Errors” in their browsers.

**Setting up CGI on your own server**

If you don’t have your own web server, this does not apply to you. You can check whether if works as-is and if not you need to talk to the administrator of your web server anyway. If it is a big hoster, you can try filing a ticket asking for Python support.

If you’re your own administrator or want to install it for testing purposes on your own computers, you have to configure it by yourself. There is no one and single way on how to configure CGI, as there are many web servers with different configuration options. The currently most widely used free web server is Apache HTTPd, Apache for short – this is the one that most people use, it can be easily installed on nearly every system using the systems’ package management. But lighttpd has been gaining attention since some time and is said to have a better performance. On many systems this server can also be installed using the package management, so manually compiling the web server is never needed.

- On Apache you can take a look into the Dynamic Content with
CGI tutorial, where everything is described. Most of the time it is enough just to set `+ExecCGI`. The tutorial also describes the most common gotchas that might arise.

- On lighttpd you need to use the **CGI module** which can be configured in a straightforward way. It boils down to setting `cgi.assign` properly.

### Common problems with CGI scripts

Trying to use CGI sometimes leads to small annoyances that one might experience while trying to get these scripts to run. Sometimes it happens that a seemingly correct script does not work as expected, which is caused by some small hidden reason that's difficult to spot.

Some of these reasons are:

- The Python script is not marked executable. When CGI scripts are not executable most of the web servers will let the user download it, instead of running it and sending the output to the user. For CGI scripts to run properly the `+x` bit needs to be set. Using `chmod a+x your_script.py` might already solve the problem.

- The line endings must be of Unix-type. This is important because the web server checks the first line of the script (called shebang) and tries to run the program specified there. It gets easily confused by Windows line endings (Carriage Return & Line Feed, also called CRLF), so you have to convert the file to Unix line endings (only Line Feed, LF). This can be done automatically by uploading the file via FTP in text mode instead of binary mode, but the preferred way is just telling your editor to save the files with Unix line endings. Most proper editors support this.

- Your web server must be able to read the file, you need to make
sure the permissions are fine. Often the server runs as user and group www-data, so it might be worth a try to change the file ownership or making the file world readable by using `chmod a+r your_script.py`.

- The webserver must be able to know that the file you’re trying to access is a CGI script. Check the configuration of your web server, maybe there is some mistake.
- The path to the interpreter in the shebang (`#!/usr/bin/env python`) must be correct. This line calls `/usr/bin/env` to find Python, but it’ll fail if there is no `/usr/bin/env`. If you know where your Python is installed, you can also use that path. The commands `whereis python` and `type -p python` might also help to find where it is installed. Once this is known, the shebang line can be changed accordingly: `#!/usr/bin/python`.
- The file must not contain a BOM (Byte Order Mark). The BOM is meant for determining the byte order of UTF-16 encodings, but some editors write this also into UTF-8 files. The BOM interferes with the shebang line, so be sure to tell your editor not to write the BOM.
- `mod_python` might be making problems. `mod_python` is able to handle CGI scripts by itself, but it can also be a source for problems. Be sure you disable it.

### mod_python

People coming from PHP often find it hard to grasp how to use Python in the web. Their first thought is mostly `mod_python` because they think that this is the equivalent to `mod_php`. Actually it is not really. It does embed the interpreter into the Apache process, thus speeding up requests by not having to start a Python interpreter every request. On the other hand, it is by far not “Python intermixed with HTML” as PHP often does. The Python equivalent of that is a template engine. `mod_python` itself is much more powerful and gives
more access to Apache internals. It can emulate CGI, it can work an a “Python Server Pages” mode similar to JSP which is “HTML intermangled with Python” and it has a “Publisher” which designates one file to accept all requests and decide on what to do then.

But mod_python has some problems. Unlike the PHP interpreter the Python interpreter uses caching when executing files, so when changing a file the whole web server needs to be re-started to update. Another problem ist the basic concept – Apache starts some child processes to handle the requests and unfortunately every child process needs to load the whole Python interpreter even if it does not use it. This makes the whole web server slower. Another problem is that as mod_python is linked against a specific version of `libpython`, it is not possible to switch from an older version to a newer (e.g. 2.4 to 2.5) without recompiling mod_python. mod_python is also bound to the Apache web server, so programs written for mod_python cannot easily run on other web servers.

These are the reasons why mod_python should be avoided when writing new programs. In some circumstances it might be still a good idea to use mod_python for deployment, but WSGI makes it possible to run WSGI programs under mod_python as well.

**FastCGI and SCGI**

FastCGI and SCGI try to solve the performance problem of CGI in another way. Instead of embedding the interpreter into the web server, they create long-running processes which run in the background. There still is some module in the web server which makes it possible for the web server to “speak” with the background process. As the background process is independent from the server, it can be written in any language of course also in Python. The language just needs to have a library which handles the communication with the web server.
The difference between FastCGI and SCGI is very small, as SCGI is essentially just a "simpler FastCGI". But as the web server support for SCGI is limited most people use FastCGI instead, which works the same way. Almost everything that applies to SCGI also applies to FastCGI as well, so we'll only write about the latter.

These days, FastCGI is never used directly. Just like mod_python it is only used for the deployment of WSGI applications.

**See also:**

- FastCGI, SCGI, and Apache: Background and Future is a discussion on why the concept of FastCGI and SCGI is better that that of mod_python.

### Setting up FastCGI

Depending on the web server you need to have a special module.

- Apache has both mod_fastcgi and mod_fcgid. mod_fastcgi is the original one, but it has some licensing issues that's why it is sometimes considered non-free. mod_fcgid is a smaller, compatible alternative. One of these modules needs to be loaded by Apache.
- lighttpd ships its own FastCGI module as well as an SCGI module.
- nginx also supports FastCGI.

Once you have installed and configured the module, you can test it with the following WSGI-application:

```bash
#!/usr/bin/env python
# -*- coding: UTF-8 -*-

from cgi import escape
```
import sys, os
from flup.server.fcgi import WSGIServer

def app(environ, start_response):
    start_response('200 OK', [('Content-Type', 'text/html')])
    yield '<h1>FastCGI Environment</h1>
    yield '<table>
    for k, v in sorted(environ.items()):
        yield '<tr><th>%s</th><td>%s</td></tr>' % (escape(k), escape(v))
    yield '</table>'

WSGIServer(app).run()

This is a simple WSGI application, but you need to install flup first, as flup handles the low level FastCGI access.

See also: There is some documentation on setting up Django with FastCGI, most of which can be reused for other WSGI-compliant frameworks and libraries. Only the manage.py part has to be changed, the example used here can be used instead. Django does more or less the exact same thing.

mod_wsgi

mod_wsgi is an attempt to get rid of the low level gateways. As FastCGI, SCGI, mod_python are mostly used to deploy WSGI applications anyway, mod_wsgi was started to directly embed WSGI applications into the Apache web server. The benefit from this approach is that WSGI applications can be deployed much easier as it is specially designed to host WSGI applications – unlike the other low level methods which have glue code to host WSGI applications (like flup which was mentioned before). The downside is that mod_wsgi is limited to the Apache web server, other servers would need their own implementations of mod_wsgi.

It supports two modes: the embedded mode in which it integrates
with the Apache process and the daemon mode which is more FastCGI-like. Contrary to FastCGI, mod_wsgi handles the worker-processes by itself which makes administration easier.
WSGI was already mentioned several times so it has to be something important. In fact it really is, so now it’s time to explain.

The Web Server Gateway Interface, PEP 333 or WSGI for short is currently the best possible way to Python web programming. While it is great for programmers writing frameworks, the normal person does not need to get in direct contact with it. But when choosing a framework for web development it is a good idea to take one which supports WSGI.

The big profit from WSGI is the unification. When your program is compatible with WSGI – that means that your framework has support for WSGI, your program can be deployed on every web server interface for which there are WSGI wrappers. So you do not need to care about whether the user uses mod_python or FastCGI – with WSGI it just works on any gateway interface. The Python standard library contains its own WSGI server wsgiref, which is a small web server that can be used for testing.

A really great WSGI feature are the middlewares. Middlewares are layers around your program which can add various functionality to it. There is a number of middlewares already available. For example, instead of writing your own session management (to identify a user in subsequent requests, as HTTP does not maintain state, so it does now know that the requests belong to the same user) you can just take one middleware, plug it in and you can rely an already existing functionality. The same thing is compression – say you want to compress your HTML using gzip, to save your server’s bandwidth. So you only need to plug-in a middleware and you’re done. Authentication is also a problem easily solved using a middleware.

So, generally – although WSGI may seem complex, the initial phase
of learning can be very rewarding as WSGI does already have solutions to many problems that might arise while writing web sites.

## WSGI Servers

The code that is used to connect to various low level gateways like CGI or mod_python is called **WSGI server**. One of these servers is `flup` which was already mentioned and supports FastCGI, SCGI as well as AJP. Some of these servers are written in Python as `flup` is, but there also exist others which are written in C and can be used as drop-in replacements.

There are quite a lot of servers already available, so a Python web application can be deployed nearly everywhere. This is one big advantage that Python has compared with other web techniques.

**See also:** A good overview of all WSGI-related code can be found in the WSGI wiki, which contains an extensive list of WSGI servers, which can be used by every application supporting WSGI. You might be interested in some WSGI-supporting modules already contained in the standard library, namely:

- `wsgiref` – some tiny utilities and servers for WSGI

## Case study: MoinMoin

What does WSGI give the web application developer? Let's take a look on one long existing web application written in Python without using WSGI.

One of the most widely used wiki software is MoinMoin. It was created in 2000, so it predates WSGI by about three years. While it now includes support for WSGI, older versions needed separate
code to run on CGI, mod_python, FastCGI and standalone. Now, this all is possible by using WSGI and the already-written gateways. For running with on FastCGI `flup` can be used, for running a standalone server `wsgiref` is the way to go.
The term *MVC* is often heard in statements like “framework foo supports MVC”. While MVC is not really something technical but rather organisational, many web frameworks use this model to help the developer to bring structure into his program. Bigger web applications can have lots of code so it is a good idea to have structure in the program right from the beginnings. That way, even users of other frameworks (or even languages, as MVC is nothing Python-specific) can understand the existing code easier, as they are already familiar with the structure.

MVC stands for three components:

- The *model*. This is the data that is meant to modify. In Python frameworks this component is often represented by the classes used by the object-relational mapper. So, all declarations go here.
- The *view*. This component’s job is to display the data of the model to the user. Typically this component is represented by the templates.
- The *controller*. This is the layer between the user and the model. The controller reacts on user actions (like opening some specific URL) and tells the model to modify the data if neccessary.

While one might think that MVC is a complex design pattern, in fact it is not. It is used in Python because it has turned out to be useful for creating clean, maintainable web sites.

**Note:** While not all Python frameworks explicitly support MVC, it is often trivial to create a web site which uses the MVC pattern by seperating the data logic (the model) from the user interaction logic (the controller) and the templates (the view). That's why it is
important not to write unnecessary Python code in the templates – it is against MVC and creates more chaos.

See also: The english Wikipedia has an article about the Model-View-Controller pattern, which includes a long list of web frameworks for different programming languages.
Ingredients for web sites

Web sites are complex constructs, so tools were created to help the web site developer to make his work maintainable. None of these tools are in any way Python specific, they also exist for other programming languages as well. Of course, developers are not forced to use these tools and often there is no “best” tool, but it is worth informing yourself before choosing something because of the big number of helpers that the developer can use.

See also: People have written far more components that can be combined than these presented here. The Python wiki has a page about these components, called Web Components.

Templates

Mixing of HTML and Python code is possible with some libraries. While convenient at first, it leads to horribly unmaintainable code. That’s why templates exist. Templates are, in the simplest case, just HTML files with placeholders. The HTML is sent to the user’s browser after filling out the placeholders.

Python already includes such simple templates:

```python
# a simple template
template = "<html><body><h1>Hello %s!</h1></body></html>"
print template % "Reader"
```

The Python standard library also includes some more advanced templates usable through `string.Template`, but in HTML templates it is needed to use conditional and looping contracts like Python’s `for` and `if`. So, some `template engine` is needed.

Now, Python has a lot of template engines which can be used with or
without a framework. Some of these are using a plain-text programming language which is very easy to learn as it is quite limited while others use XML so the template output is always guaranteed to be valid XML. Some frameworks ship their own template engine or recommend one particular. If one is not yet sure, using these is a good idea.

**Note:** While Python has quite a lot of different template engines it usually does not make sense to use a homebrewed template system. The time needed to evaluate all templating systems is not really worth it, better invest the time in looking through the most popular ones. Some frameworks have their own template engine or have a recommendation for one. It's wise to use these. Popular template engines include:

- Mako
- Genshi
- Jinja

**See also:** Lots of different template engines divide the attention between themselves because it's easy to create them in Python. The page **Templating** in the wiki lists a big, ever-growing number of these.

---

### Data persistence

_Data persistence_, while sounding very complicated is just about storing data. This data might be the text of blog entries, the postings of a bulletin board or the text of a wiki page. As always, there are different ways to store informations on a web server.

Often relational database engines like **MySQL** or **PostgreSQL** are used due to their good performance handling very large databases
consisting of up to millions of entries. These are *queried* using a language called **SQL**. Python programmers in general do not like SQL too much, they prefer to work with objects. It is possible to save Python objects into a database using a technology called **ORM**. ORM translates all object-oriented access into SQL code under the hood, the user does not need to think about it. Most frameworks use ORMs and it works quite well.

A second possibility is using files that are saved on the hard disk (sometimes called flatfiles). This is very easy, but is not too fast. There is even a small database engine called **SQLite** which is bundled with Python in the `sqlite` module and uses only one file. This database can be used to store objects via an ORM and has no other dependencies. For smaller sites SQLite is just enough. But it is not the only way in which data can be saved into the file systems. Sometimes normal, plain text files are enough.

The third and least used possibility are so-called object oriented databases. These databases store the **actual objects** instead of the relations that OR-mapping creates between rows in a database. This has the advantage that nearly all objects can be saves in a straightforward way, unlike in relational databases where some objects are very hard to represent with ORMs.

**Frameworks** often give the users hints on which method to choose, it is usually a good idea to stick to these unless there are some special requirements which require to use the one method and not the other.

---

**See also:**

- **Persistence Tools** lists possibilities on how to save data in the file system, some of these modules are part of the standard library
- **Database Programming** helps on choosing a method on how to save the data
• SQLAlchemy, the most powerful OR-Mapper for Python and Elixir which makes it easier to use
• SQLObject, another popular OR-Mapper
• ZODB and Durus, two object oriented databases
As web sites can easily become quite large, there are so-called frameworks which were created to help the developer with making these sites. Although the most well-known framework is Ruby on Rails, Python does also have its own frameworks which are partly inspired by Rails or which were existing a long time before Rails.

Two possible approaches to web frameworks exist: the minimalistic approach and the all-inclusive approach (sometimes called full-stack). Frameworks which are all-inclusive give you everything you need to start working, like a template engine, some way to save and access data in databases and many features more. Most users are best off using these as they are widely used by lots of other users and well documented in form of books and tutorials. Other web frameworks go the minimalistic approach trying to be as flexible as possible leaving the user the freedom to choose what's best for him.

The majority of users is best off with all-inclusive frameworks. They bring everything along so a user can just jump in and start to code. While they do have some limitations they can fullfill 80% of what one will ever want to perfectly. They consist of various components which are designed to work together as good as possible.

The multitude of web frameworks written in Python demonstrates that it is really easy to write one. One of the most well-known web applications written in Python is Zope which can be regarded as some kind of big framework. But Zope was not the only framework, there were some others which are by now nearly forgotten. These do not need to be mentioned anymore, because most people that used them moved on to newer ones.

Some notable frameworks
There is an incredible number of frameworks, so there is no way to describe them all. It is not even neccessary, as most of these frameworks are nothing special and everything that can be done with these can also be done with one of the popular ones.

**Django**

*Django* is a framework consisting of several tightly coupled elements which were written from scratch and work together very well. It includes an ORM which is quite powerful while being simple to use and has a great online administration interface which makes it possible to edit the data in the database with a browser. The template engine is text-based and is designed to be usable for page designers who cannot write Python. It supports so-called template inheritance and filters (which work like Unix pipes). Django has many handy features bundled, like creation of RSS feeds or generic views which make it possible to write web sites nearly without any Python code.

It has a big, international community which has created many sites using Django. There are also quite a lot of add-on projects which extend Django’s normal functionality. This is partly due to Django’s well written online documentation and the *Django book*.

**Note:** Although Django is an MVC-style framework, it calls the components differently, which is described in the *Django FAQ*.

**TurboGears**

The other popular web framework in Python is *TurboGears*. It takes the approach of using already existing components and combining them with glue code to create a seamless experience. TurboGears gives the user more flexibility on which components to choose, the ORM can be switched between some easy to use but limited and
complex but very powerful. Same goes for the template engine. One strong point about TurboGears is that the components that it consists of can be used easily in other projects without depending on TurboGears, for example the underlying web server CherryPy.

The documentation can be found in the TurboGears wiki, where links to screencasts can be found. TurboGears has also an active user community which can respond to most related questions. There is also a TurboGears book published, which is a good starting point.

The plan for the next major version of TurboGears, version 2.0 is to switch to a more flexible base provided by another very flexible web framework called Pylons.

**Other notable frameworks**

These two are of course not the only frameworks that are available, there are also some less-popular frameworks worth mentioning.

One of these is the already mentioned Zope, which has been around for quite a long time. With Zope 2.x having been known as rather un-pythonic, the newer Zope 3.x tries to change that and therefore gets more acceptance from Python programmers. These efforts already showed results, there is a project which connects Zope with WSGI called Repoze and another project called Grok which makes it possible for “normal” Python programmers use the very mature Zope components.

Another framework that's already been mentioned is Pylons. Pylons is much like TurboGears with ab even stronger emphasis on flexibility, which is bought at the cost of being more difficult to use. Nearly every component can be exchanged, which makes it neccessary to use the documentation of every single component, because there are so many Pylons combinations possible that can satisfy every requirement. Pylons builds upon Paste, an extensive
set of tools which are handy for WSGI.

And that's still not everything. The most up-to-date information can always be found in the Python wiki.

**See also:** The Python wiki contains an extensive list of web frameworks. Most frameworks also have their own mailing lists and IRC channels, look out for these on the projects’ websites. There is also a general “Python in the Web” IRC channel on freenode called #python.web.
The default Python prompt of the interactive shell. Often seen for code examples which can be executed interactively in the interpreter.

The default Python prompt of the interactive shell when entering code for an indented code block or within a pair of matching left and right delimiters (parentheses, square brackets or curly braces).

2to3
A tool that tries to convert Python 2.x code to Python 3.x code by handling most of the incompatibilities which can be detected by parsing the source and traversing the parse tree.

2to3 is available in the standard library as `lib2to3`; a standalone entry point is provided as `Tools/scripts/2to3`. See 2to3 - Automated Python 2 to 3 code translation.

abstract base class
Abstract Base Classes (abbreviated ABCs) complement duck-typing by providing a way to define interfaces when other techniques like `hasattr()` would be clumsy. Python comes with many built-in ABCs for data structures (in the `collections` module), numbers (in the `numbers` module), and streams (in the `io` module). You can create your own ABC with the `abc` module.

argument
A value passed to a function or method, assigned to a named local variable in the function body. A function or method may have both positional arguments and keyword arguments in its definition. Positional and keyword arguments may be variable-
length: * accepts or passes (if in the function definition or call) several positional arguments in a list, while ** does the same for keyword arguments in a dictionary.

Any expression may be used within the argument list, and the evaluated value is passed to the local variable.

**attribute**
A value associated with an object which is referenced by name using dotted expressions. For example, if an object o has an attribute a it would be referenced as o.a.

**BDFL**
Benevolent Dictator For Life, a.k.a. Guido van Rossum, Python’s creator.

**bytecode**
Python source code is compiled into bytecode, the internal representation of a Python program in the interpreter. The bytecode is also cached in .pyc and .pyo files so that executing the same file is faster the second time (recompilation from source to bytecode can be avoided). This “intermediate language” is said to run on a virtual machine that executes the machine code corresponding to each bytecode.

**class**
A template for creating user-defined objects. Class definitions normally contain method definitions which operate on instances of the class.

**classic class**
Any class which does not inherit from object. See new-style class. Classic classes will be removed in Python 3.0.

**coercion**
The implicit conversion of an instance of one type to another
during an operation which involves two arguments of the same type. For example, \texttt{int(3.15)} converts the floating point number to the integer 3, but in \texttt{3+4.5}, each argument is of a different type (one int, one float), and both must be converted to the same type before they can be added or it will raise a \texttt{TypeError}. Coercion between two operands can be performed with the \texttt{coerce} built-in function; thus, \texttt{3+4.5} is equivalent to calling \texttt{operator.add(*coerce(3, 4.5))} and results in \texttt{operator.add(3.0, 4.5)}. Without coercion, all arguments of even compatible types would have to be normalized to the same value by the programmer, e.g., \texttt{float(3)+4.5} rather than just \texttt{3+4.5}.

**complex number**

An extension of the familiar real number system in which all numbers are expressed as a sum of a real part and an imaginary part. Imaginary numbers are real multiples of the imaginary unit (the square root of \(-1\)), often written \(i\) in mathematics or \(j\) in engineering. Python has built-in support for complex numbers, which are written with this latter notation; the imaginary part is written with a \(j\) suffix, e.g., \(3+1j\). To get access to complex equivalents of the \texttt{math} module, use \texttt{cmath}. Use of complex numbers is a fairly advanced mathematical feature. If you’re not aware of a need for them, it’s almost certain you can safely ignore them.

**context manager**

An object which controls the environment seen in a \texttt{with} statement by defining \texttt{__enter__()} and \texttt{__exit__()} methods. See PEP 343.

**CPython**

The canonical implementation of the Python programming language. The term “CPython” is used in contexts when necessary to distinguish this implementation from others such as
Jython or IronPython.

**decorator**
A function returning another function, usually applied as a function transformation using the `@wrapper` syntax. Common examples for decorators are `classmethod()` and `staticmethod()`.

The decorator syntax is merely syntactic sugar, the following two function definitions are semantically equivalent:

```python
def f(...):
    ...
f = staticmethod(f)
```

```python
@staticmethod
def f(...):
    ...
```

**descriptor**
Any *new-style* object which defines the methods `__get__()`, `__set__()`, or `__delete__()`. When a class attribute is a descriptor, its special binding behavior is triggered upon attribute lookup. Normally, using `a.b` to get, set or delete an attribute looks up the object named `b` in the class dictionary for `a`, but if `b` is a descriptor, the respective descriptor method gets called. Understanding descriptors is a key to a deep understanding of Python because they are the basis for many features including functions, methods, properties, class methods, static methods, and reference to super classes.

For more information about descriptors’ methods, see *Implementing Descriptors*.

**dictionary**
An associative array, where arbitrary keys are mapped to values.
The use of `dict` closely resembles that for `list`, but the keys can be any object with a `__hash__()` function, not just integers. Called a hash in Perl.

**docstring**

A string literal which appears as the first expression in a class, function or module. While ignored when the suite is executed, it is recognized by the compiler and put into the `__doc__` attribute of the enclosing class, function or module. Since it is available via introspection, it is the canonical place for documentation of the object.

**duck-typing**

A pythonic programming style which determines an object’s type by inspection of its method or attribute signature rather than by explicit relationship to some type object ("If it looks like a duck and quacks like a duck, it must be a duck.") By emphasizing interfaces rather than specific types, well-designed code improves its flexibility by allowing polymorphic substitution. Duck-typing avoids tests using `type()` or `instance()`. (Note, however, that duck-typing can be complemented with abstract base classes.) Instead, it typically employs `hasattr()` tests or **EAFP** programming.

**EAFP**

Easier to ask for forgiveness than permission. This common Python coding style assumes the existence of valid keys or attributes and catches exceptions if the assumption proves false. This clean and fast style is characterized by the presence of many `try` and `except` statements. The technique contrasts with the **LBYL** style common to many other languages such as C.

**expression**

A piece of syntax which can be evaluated to some value. In other words, an expression is an accumulation of expression elements
like literals, names, attribute access, operators or function calls which all return a value. In contrast to many other languages, not all language constructs are expressions. There are also statements which cannot be used as expressions, such as print or if. Assignments are also statements, not expressions.

extension module
A module written in C or C++, using Python’s C API to interact with the core and with user code.

function
A series of statements which returns some value to a caller. It can also be passed zero or more arguments which may be used in the execution of the body. See also argument and method.

__future__
A pseudo module which programmers can use to enable new language features which are not compatible with the current interpreter. For example, the expression 11/4 currently evaluates to 2. If the module in which it is executed had enabled true division by executing:

```python
from __future__ import division
```

the expression 11/4 would evaluate to 2.75. By importing the __future__ module and evaluating its variables, you can see when a new feature was first added to the language and when it will become the default:

```python
>>> import __future__
>>> __future__.division
_Feature((2, 2, 0, 'alpha', 2), (3, 0, 0, 'alpha', 0), 8192)
```

garbage collection
The process of freeing memory when it is not used anymore. Python performs garbage collection via reference counting and a cyclic garbage collector that is able to detect and break reference cycles.

**generator**

A function which returns an iterator. It looks like a normal function except that values are returned to the caller using a `yield` statement instead of a `return` statement. Generator functions often contain one or more `for` or `while` loops which `yield` elements back to the caller. The function execution is stopped at the `yield` keyword (returning the result) and is resumed there when the next element is requested by calling the `next()` method of the returned iterator.

**generator expression**

An expression that returns a generator. It looks like a normal expression followed by a `for` expression defining a loop variable, range, and an optional `if` expression. The combined expression generates values for an enclosing function:

```python
>>> sum(i*i for i in range(10))  # sum of squares 0, 1, 4, ..., 81
285
```

**GIL**

See *global interpreter lock*.

**global interpreter lock**

The lock used by Python threads to assure that only one thread executes in the *CPython virtual machine* at a time. This simplifies the CPython implementation by assuring that no two processes can access the same memory at the same time. Locking the entire interpreter makes it easier for the interpreter to be multi-threaded, at the expense of much of the parallelism afforded by
multi-processor machines. Efforts have been made in the past to create a “free-threaded” interpreter (one which locks shared data at a much finer granularity), but so far none have been successful because performance suffered in the common single-processor case.

**hashable**

An object is *hashable* if it has a hash value which never changes during its lifetime (it needs a `__hash__()` method), and can be compared to other objects (it needs an `__eq__()` or `__cmp__()` method). Hashable objects which compare equal must have the same hash value.

Hashability makes an object usable as a dictionary key and a set member, because these data structures use the hash value internally.

All of Python’s immutable built-in objects are hashable, while no mutable containers (such as lists or dictionaries) are. Objects which are instances of user-defined classes are hashable by default; they all compare unequal, and their hash value is their `id()`.

**IDLE**

An Integrated Development Environment for Python. IDLE is a basic editor and interpreter environment which ships with the standard distribution of Python. Good for beginners, it also serves as clear example code for those wanting to implement a moderately sophisticated, multi-platform GUI application.

**immutable**

An object with a fixed value. Immutable objects include numbers, strings and tuples. Such an object cannot be altered. A new object has to be created if a different value has to be stored. They play an important role in places where a constant hash
value is needed, for example as a key in a dictionary.

**integer division**

Mathematical division discarding any remainder. For example, the expression $11/4$ currently evaluates to 2 in contrast to the 2.75 returned by float division. Also called *floor division*. When dividing two integers the outcome will always be another integer (having the floor function applied to it). However, if one of the operands is another numeric type (such as a *float*), the result will be coerced (see *coercion*) to a common type. For example, an integer divided by a float will result in a float value, possibly with a decimal fraction. Integer division can be forced by using the // operator instead of the / operator. See also __future__.

**interactive**

Python has an interactive interpreter which means you can enter statements and expressions at the interpreter prompt, immediately execute them and see their results. Just launch python with no arguments (possibly by selecting it from your computer’s main menu). It is a very powerful way to test out new ideas or inspect modules and packages (remember help(x)).

**interpreted**

Python is an interpreted language, as opposed to a compiled one, though the distinction can be blurry because of the presence of the bytecode compiler. This means that source files can be run directly without explicitly creating an executable which is then run. Interpreted languages typically have a shorter development/debug cycle than compiled ones, though their programs generally also run more slowly. See also interactive.

**iterable**

A container object capable of returning its members one at a time. Examples of iterables include all sequence types (such as list, str, and tuple) and some non-sequence types like dict
and file and objects of any classes you define with an
__iter__() or __getitem__() method. Iterables can be used in a
for loop and in many other places where a sequence is needed
(zip(), map(), ...). When an iterable object is passed as an
argument to the builtin function iter(), it returns an iterator for
the object. This iterator is good for one pass over the set of
values. When using iterables, it is usually not necessary to call
iter() or deal with iterator objects yourself. The for statement
does that automatically for you, creating a temporary unnamed
variable to hold the iterator for the duration of the loop. See also
iterator, sequence, and generator.

iterator
An object representing a stream of data. Repeated calls to the
iterator's next() method return successive items in the stream.
When no more data are available a StopIteration exception is
raised instead. At this point, the iterator object is exhausted and
any further calls to its next() method just raise StopIteration
again. Iterators are required to have an __iter__() method that
returns the iterator object itself so every iterator is also iterable
and may be used in most places where other iterables are
accepted. One notable exception is code which attempts multiple
iteration passes. A container object (such as a list) produces a
fresh new iterator each time you pass it to the iter() function or
use it in a for loop. Attempting this with an iterator will just return
the same exhausted iterator object used in the previous iteration
pass, making it appear like an empty container.

More information can be found in Iterator Types.

keyword argument
Arguments which are preceded with a variable_name= in the call.
The variable name designates the local name in the function to
which the value is assigned. ** is used to accept or pass a
dictionary of keyword arguments. See `argument`.

**lambda**

An anonymous inline function consisting of a single `expression`
which is evaluated when the function is called. The syntax to
create a lambda function is `lambda [arguments]: expression`

**LBYL**

Look before you leap. This coding style explicitly tests for pre-
conditions before making calls or lookups. This style contrasts
with the `EAFP` approach and is characterized by the presence of
many `if` statements.

**list**

A built-in Python `sequence`. Despite its name it is more akin to an
array in other languages than to a linked list since access to
elements are O(1).

**list comprehension**

A compact way to process all or part of the elements in a
sequence and return a list with the results. `result = ["0x%02x" %
x for x in range(256) if x % 2 == 0]` generates a list of strings
containing even hex numbers (0x..) in the range from 0 to 255.
The `if` clause is optional. If omitted, all elements in `range(256)`
are processed.

**mapping**

A container object (such as `dict`) which supports arbitrary key
lookups using the special method `__getitem__()`.

**metaclass**

The class of a class. Class definitions create a class name, a
class dictionary, and a list of base classes. The metaclass is
responsible for taking those three arguments and creating the
class. Most object oriented programming languages provide a
default implementation. What makes Python special is that it is possible to create custom metaclasses. Most users never need this tool, but when the need arises, metaclasses can provide powerful, elegant solutions. They have been used for logging attribute access, adding thread-safety, tracking object creation, implementing singletons, and many other tasks.

More information can be found in *Customizing class creation*.

**method**

A function which is defined inside a class body. If called as an attribute of an instance of that class, the method will get the instance object as its first *argument* (which is usually called `self`). See function and nested scope.

**mutable**

Mutable objects can change their value but keep their `id()`. See also immutable.

**named tuple**

Any tuple subclass whose indexable elements are also accessible using named attributes (for example, `time.localtime()` returns a tuple-like object where the year is accessible either with an index such as `t[0]` or with a named attribute like `t.tm_year`).

A named tuple can be a built-in type such as `time.struct_time`, or it can be created with a regular class definition. A full featured named tuple can also be created with the factory function `collections.namedtuple()`. The latter approach automatically provides extra features such as a self-documenting representation like `Employee(name='jones', title='programmer')`.

**namespace**

The place where a variable is stored. Namespaces are
implemented as dictionaries. There are the local, global and builtin namespaces as well as nested namespaces in objects (in methods). Namespaces support modularity by preventing naming conflicts. For instance, the functions `__builtin__.open()` and `os.open()` are distinguished by their namespaces. Namespaces also aid readability and maintainability by making it clear which module implements a function. For instance, writing `random.seed()` or `itertools.izip()` makes it clear that those functions are implemented by the `random` and `itertools` modules, respectively.

**nested scope**
The ability to refer to a variable in an enclosing definition. For instance, a function defined inside another function can refer to variables in the outer function. Note that nested scopes work only for reference and not for assignment which will always write to the innermost scope. In contrast, local variables both read and write in the innermost scope. Likewise, global variables read and write to the global namespace.

**new-style class**
Any class which inherits from `object`. This includes all built-in types like `list` and `dict`. Only new-style classes can use Python’s newer, versatile features like `__slots__`, descriptors, properties, and `__getattribute__()`.

More information can be found in *New-style and classic classes*.

**object**
Any data with state (attributes or value) and defined behavior (methods). Also the ultimate base class of any *new-style class*.

**positional argument**
The arguments assigned to local names inside a function or method, determined by the order in which they were given in the
call. * is used to either accept multiple positional arguments (when in the definition), or pass several arguments as a list to a function. See argument.

Python 3000
Nickname for the next major Python version, 3.0 (coined long ago when the release of version 3 was something in the distant future.) This is also abbreviated “Py3k”.

Pythonic
An idea or piece of code which closely follows the most common idioms of the Python language, rather than implementing code using concepts common to other languages. For example, a common idiom in Python is to loop over all elements of an iterable using a for statement. Many other languages don’t have this type of construct, so people unfamiliar with Python sometimes use a numerical counter instead:

```python
for i in range(len(food)):
    print food[i]
```

As opposed to the cleaner, Pythonic method:

```python
for piece in food:
    print piece
```

reference count
The number of references to an object. When the reference count of an object drops to zero, it is deallocated. Reference counting is generally not visible to Python code, but it is a key element of the CPython implementation. The sys module defines a getrefcount() function that programmers can call to return the reference count for a particular object.

__slots__
A declaration inside a *new-style class* that saves memory by pre-declaring space for instance attributes and eliminating instance dictionaries. Though popular, the technique is somewhat tricky to get right and is best reserved for rare cases where there are large numbers of instances in a memory-critical application.

**sequence**

An *iterable* which supports efficient element access using integer indices via the `__getitem__()` special method and defines a `len()` method that returns the length of the sequence. Some built-in sequence types are `list`, `str`, `tuple`, and `unicode`. Note that `dict` also supports `__getitem__()` and `__len__()`, but is considered a mapping rather than a sequence because the lookups use arbitrary *immutable* keys rather than integers.

**slice**

An object usually containing a portion of a *sequence*. A slice is created using the subscript notation, `[]` with colons between numbers when several are given, such as in `variable_name[1:3:5]`. The bracket (subscript) notation uses `slice` objects internally (or in older versions, `__getslice__()` and `__setslice__()`).

**statement**

A statement is part of a suite (a “block” of code). A statement is either an *expression* or a one of several constructs with a keyword, such as `if`, `while` or `print`.

**triple-quoted string**

A string which is bound by three instances of either a quotation mark ("") or an apostrophe ('). While they don't provide any functionality not available with single-quoted strings, they are useful for a number of reasons. They allow you to include unescaped single and double quotes within a string and they can span multiple lines without the use of the continuation character,
making them especially useful when writing docstrings.

**type**

The type of a Python object determines what kind of object it is; every object has a type. An object’s type is accessible as its `__class__` attribute or can be retrieved with `type(obj)`.

**virtual machine**

A computer defined entirely in software. Python’s virtual machine executes the *bytecode* emitted by the bytecode compiler.

**Zen of Python**

Listing of Python design principles and philosophies that are helpful in understanding and using the language. The listing can be found by typing “import this” at the interactive prompt.
About these documents

These documents are generated from reStructuredText sources by Sphinx, a document processor specifically written for the Python documentation.

In the online version of these documents, you can submit comments and suggest changes directly on the documentation pages.

Development of the documentation and its toolchain takes place on the docs@python.org mailing list. We’re always looking for volunteers wanting to help with the docs, so feel free to send a mail there!

Many thanks go to:

- Fred L. Drake, Jr., the creator of the original Python documentation toolset and writer of much of the content;
- the Docutils project for creating reStructuredText and the Docutils suite;
- Fredrik Lundh for his Alternative Python Reference project from which Sphinx got many good ideas.

See Reporting Bugs in Python for information how to report bugs in Python itself.
Contributors to the Python Documentation

This section lists people who have contributed in some way to the Python documentation. It is probably not complete – if you feel that you or anyone else should be on this list, please let us know (send email to docs@python.org), and we'll be glad to correct the problem.

It is only with the input and contributions of the Python community that Python has such wonderful documentation – Thank You!
Reporting Bugs in Python

Python is a mature programming language which has established a reputation for stability. In order to maintain this reputation, the developers would like to know of any deficiencies you find in Python.

Bug reports should be submitted via the Python Bug Tracker (http://bugs.python.org/). The bug tracker offers a Web form which allows pertinent information to be entered and submitted to the developers.

The first step in filing a report is to determine whether the problem has already been reported. The advantage in doing so, aside from saving the developers time, is that you learn what has been done to fix it; it may be that the problem has already been fixed for the next release, or additional information is needed (in which case you are welcome to provide it if you can!). To do this, search the bug database using the search box on the top of the page.

If the problem you're reporting is not already in the bug tracker, go back to the Python Bug Tracker. If you don’t already have a tracker account, select the “Register” link in the sidebar and undergo the registration procedure. Otherwise, if you're not logged in, enter your credentials and select “Login”. It is not possible to submit a bug report anonymously.

Being now logged in, you can submit a bug. Select the “Create New” link in the sidebar to open the bug reporting form.

The submission form has a number of fields. For the “Title” field, enter a very short description of the problem; less than ten words is good. In the “Type” field, select the type of your problem; also select the “Component” and “Versions” to which the bug relates.

In the “Comment” field, describe the problem in detail, including what
you expected to happen and what did happen. Be sure to include whether any extension modules were involved, and what hardware and software platform you were using (including version information as appropriate).

Each bug report will be assigned to a developer who will determine what needs to be done to correct the problem. You will receive an update each time action is taken on the bug.

History and License
History of the software

Python was created in the early 1990s by Guido van Rossum at Stichting Mathematisch Centrum (CWI, see http://www.cwi.nl/) in the Netherlands as a successor of a language called ABC. Guido remains Python’s principal author, although it includes many contributions from others.

In 1995, Guido continued his work on Python at the Corporation for National Research Initiatives (CNRI, see http://www.cnri.reston.va.us/) in Reston, Virginia where he released several versions of the software.

In May 2000, Guido and the Python core development team moved to BeOpen.com to form the BeOpen PythonLabs team. In October of the same year, the PythonLabs team moved to Digital Creations (now Zope Corporation; see http://www.zope.com/). In 2001, the Python Software Foundation (PSF, see http://www.python.org/psf/) was formed, a non-profit organization created specifically to own Python-related Intellectual Property. Zope Corporation is a sponsoring member of the PSF.

All Python releases are Open Source (see http://www.opensource.org/ for the Open Source Definition). Historically, most, but not all, Python releases have also been GPL-compatible; the table below summarizes the various releases.

**Note:** GPL-compatible doesn’t mean that we’re distributing Python under the GPL. All Python licenses, unlike the GPL, let you distribute a modified version without making your changes open source. The GPL-compatible licenses make it possible to combine...
Python with other software that is released under the GPL; the others don't.

Thanks to the many outside volunteers who have worked under Guido's direction to make these releases possible.
1. This LICENSE AGREEMENT is between the Python Software Foundation ("PSF"), and the Individual or Organization ("Licensee") accessing and otherwise using Python 2.6 software in source or binary form and its associated documentation.

2. Subject to the terms and conditions of this License Agreement, PSF hereby grants Licensee a nonexclusive, royalty-free, worldwide license to reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use Python 2.6 alone or in any derivative version, provided, however, that PSF's License Agreement and PSF's notice of copyright, i.e., “Copyright © 2001-2008 Python Software Foundation; All Rights Reserved” are retained in Python 2.6 alone or in any derivative version prepared by Licensee.

3. In the event Licensee prepares a derivative work that is based on or incorporates Python 2.6 or any part thereof, and wants to make the derivative work available to others as provided herein, then Licensee hereby agrees to include in any such work a brief summary of the changes made to Python 2.6.

4. PSF is making Python 2.6 available to Licensee on an “AS IS” basis. PSF MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT LIMITATION, PSF MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF PYTHON 2.6 WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.

5. PSF SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER
6. This License Agreement will automatically terminate upon a material breach of its terms and conditions.

7. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between PSF and Licensee. This License Agreement does not grant permission to use PSF trademarks or trade name in a trademark sense to endorse or promote products or services of Licensee, or any third party.

8. By copying, installing or otherwise using Python 2.6, Licensee agrees to be bound by the terms and conditions of this License Agreement.

BEOPEN.COM LICENSE AGREEMENT FOR PYTHON 2.0

BEOPEN PYTHON OPEN SOURCE LICENSE AGREEMENT
VERSION 1

1. This LICENSE AGREEMENT is between BeOpen.com (“BeOpen”), having an office at 160 Saratoga Avenue, Santa Clara, CA 95051, and the Individual or Organization (“Licensee”) accessing and otherwise using this software in source or binary form and its associated documentation (“the Software”).

2. Subject to the terms and conditions of this BeOpen Python License Agreement, BeOpen hereby grants Licensee a non-exclusive, royalty-free, world-wide license to reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use the Software alone or in any derivative version, provided, however, that the BeOpen Python License is retained in the Software, alone or in any
derivative version prepared by Licensee.

3. BeOpen is making the Software available to Licensee on an “AS IS” basis. BEOPEN MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT LIMITATION, BEOPEN MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF THE SOFTWARE WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.

4. BEOPEN SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS OF THE SOFTWARE FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF USING, MODIFYING OR DISTRIBUTING THE SOFTWARE, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.

5. This License Agreement will automatically terminate upon a material breach of its terms and conditions.

6. This License Agreement shall be governed by and interpreted in all respects by the law of the State of California, excluding conflict of law provisions. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between BeOpen and Licensee. This License Agreement does not grant permission to use BeOpen trademarks or trade names in a trademark sense to endorse or promote products or services of Licensee, or any third party. As an exception, the “BeOpen Python” logos available at http://www.pythonlabs.com/logos.html may be used according to the permissions granted on that web page.

7. By copying, installing or otherwise using the software, Licensee agrees to be bound by the terms and conditions of this License Agreement.

**CNRI LICENSE AGREEMENT FOR PYTHON 1.6.1**
1. This LICENSE AGREEMENT is between the Corporation for National Research Initiatives, having an office at 1895 Preston White Drive, Reston, VA 20191 (“CNRI”), and the Individual or Organization (“Licensee”) accessing and otherwise using Python 1.6.1 software in source or binary form and its associated documentation.

2. Subject to the terms and conditions of this License Agreement, CNRI hereby grants Licensee a nonexclusive, royalty-free, world-wide license to reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use Python 1.6.1 alone or in any derivative version, provided, however, that CNRI’s License Agreement and CNRI’s notice of copyright, i.e., “Copyright © 1995-2001 Corporation for National Research Initiatives; All Rights Reserved” are retained in Python 1.6.1 alone or in any derivative version prepared by Licensee. Alternately, in lieu of CNRI’s License Agreement, Licensee may substitute the following text (omitting the quotes): “Python 1.6.1 is made available subject to the terms and conditions in CNRI’s License Agreement. This Agreement together with Python 1.6.1 may be located on the Internet using the following unique, persistent identifier (known as a handle): 1895.22/1013. This Agreement may also be obtained from a proxy server on the Internet using the following URL: http://hdl.handle.net/1895.22/1013.”

3. In the event Licensee prepares a derivative work that is based on or incorporates Python 1.6.1 or any part thereof, and wants to make the derivative work available to others as provided herein, then Licensee hereby agrees to include in any such work a brief summary of the changes made to Python 1.6.1.

4. CNRI is making Python 1.6.1 available to Licensee on an “AS IS” basis. CNRI MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT LIMITATION, CNRI MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF
MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF PYTHON 1.6.1 WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.

5. CNRI SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS OF PYTHON 1.6.1 FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF MODIFYING, DISTRIBUTING, OR OTHERWISE USING PYTHON 1.6.1, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.

6. This License Agreement will automatically terminate upon a material breach of its terms and conditions.

7. This License Agreement shall be governed by the federal intellectual property law of the United States, including without limitation the federal copyright law, and, to the extent such U.S. federal law does not apply, by the law of the Commonwealth of Virginia, excluding Virginia’s conflict of law provisions. Notwithstanding the foregoing, with regard to derivative works based on Python 1.6.1 that incorporate non-separable material that was previously distributed under the GNU General Public License (GPL), the law of the Commonwealth of Virginia shall govern this License Agreement only as to issues arising under or with respect to Paragraphs 4, 5, and 7 of this License Agreement. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between CNRI and Licensee. This License Agreement does not grant permission to use CNRI trademarks or trade name in a trademark sense to endorse or promote products or services of Licensee, or any third party.

8. By clicking on the “ACCEPT” button where indicated, or by copying, installing or otherwise using Python 1.6.1, Licensee agrees to be bound by the terms and conditions of this License Agreement.

Licenses and Acknowledgements for Incorporated Software

This section is an incomplete, but growing list of licenses and acknowledgements for third-party software incorporated in the Python distribution.

Mersenne Twister

The `_random` module includes code based on a download from http://www.math.keio.ac.jp/ matumoto/MT2002/emt19937ar.html. The following are the verbatim comments from the original code:

```
A C-program for MT19937, with initialization improved 2002/1/26.
Coded by Takuji Nishimura and Makoto Matsumoto.

Before using, initialize the state by using init_genrand(seed)
or init_by_array(init_key, key_length).

Copyright (C) 1997 - 2002, Makoto Matsumoto and Takuji Nishimura.

```
Sockets

The `socket` module uses the functions, `getaddrinfo()`, and `getnameinfo()`, which are coded in separate source files from the WIDE Project, [http://www.wide.ad.jp/](http://www.wide.ad.jp/).

CONTRIBUTORS BE LIABLE FOR ANY DIRECT, INDIRECT, INCIDENTAL, SPECIAL, EXEMPLARY, OR CONSEQUENTIAL DAMAGES (INCLUDING, BUT NOT LIMITED TO PROCUREMENT OF SUBSTITUTE GOODS OR SERVICES; LOSS OF USE, DATA, PROFITS; OR BUSINESS INTERRUPTION) HOWEVER CAUSED AND ON ANY THEORY OF LIABILITY, WHETHER IN CONTRACT, STRICT LIABILITY, OR TORT (INCLUDING NEGLIGENCE OR OTHERWISE) ARISING IN ANY WAY OUT OF THE USE OF THIS SOFTWARE, EVEN IF ADVISED OF THE POSSIBILITY OF SUCH DAMAGE.

Any feedback is very welcome.

```
The source code for the md5 module contains the following notice:

Copyright (C) 1999, 2002 Aladdin Enterprises. All rights reserved.

This software is provided 'as-is', without any express or implied warranty. In no event will the authors be held liable for any arising from the use of this software.

Permission is granted to anyone to use this software for any purpose, including commercial applications, and to alter it and redistribute it freely, subject to the following restrictions:

1. The origin of this software must not be misrepresented; you must not claim that you wrote the original software. If you use this in a product, an acknowledgment in the product documentation would be appreciated but is not required.
2. Altered source versions must be plainly marked as such, and not misrepresented as being the original software.
3. This notice may not be removed or altered from any source distribution.

L. Peter Deutsch
ghost@aladdin.com

Independent implementation of MD5 (RFC 1321).

This code implements the MD5 Algorithm defined in RFC 1321, whose text is available at
http://www.ietf.org/rfc/rfc1321.txt
The code is derived from the text of the RFC, including the test suite (section A.5) but excluding the rest of Appendix A. It does not include any code or documentation that is identified in the RFC as being copyrighted.

The original and principal author of md5.h is L. Peter Deutsch <ghost@aladdin.com>. Other authors are noted in the change history that follows (in reverse chronological order):

2002-04-13 lpd Removed support for non-ANSI compilers; removed references to Ghostscript; clarified derivation from RFC 132; now handles byte order either statically or dynamically.
1999-11-04 lpd Edited comments slightly for automatic TOC extra.
1999-10-18 lpd Fixed typo in header comment (ansi2knr rather than ansi2knl).
1999-05-03 lpd Original version.
Asynchronous socket services

The `asynchat` and `asyncore` modules contain the following notice:

Copyright 1996 by Sam Rushing

All Rights Reserved

WHATSOEVER RESULTING FROM LOSS OF USE, DATA OR PROFITS, WHETHER
ACTION OF CONTRACT, NEGLIGENCE OR OTHER TORTIOUS ACTION, ARISIN
OF OR IN CONNECTION WITH THE USE OR PERFORMANCE OF THIS SOFTWARE.
Modified by Jack Jansen, CWI, July 1995:
- Use binascii module to do the actual line-by-line conversion between ascii and binary. This results in a 1000-fold speedup version is still 5 times faster, though.
- Arguments more compliant with python standard

XML Remote Procedure Calls

The `xmlrpclib` module contains the following notice:

```
The XML-RPC client interface is

Copyright (c) 1999-2002 by Secret Labs AB

- **bisect** — Array bisection algorithm
  - Examples
- **array** — Efficient arrays of numeric values
- **sets** — Unordered collections of unique elements
- Set Objects
  - Example
  - Protocol for automatic conversion to immutable
  - Comparison to the built-in set types

- sched — Event scheduler
  - Scheduler Objects

- mutex — Mutual exclusion support
  - Mutex Objects

- queue — A synchronized queue class
  - Queue Objects

- weakref — Weak references
  - Weak Reference Objects
  - Example

- UserDict — Class wrapper for dictionary objects
- UserList — Class wrapper for list objects
- UserString — Class wrapper for string objects
- types — Names for built-in types
- new — Creation of runtime internal objects
- copy — Shallow and deep copy operations
- pprint — Data pretty printer
  - PrettyPrinter Objects
  - pprint Example
- repr — Alternate repr implementation
  - Repr Objects
  - Subclassing Repr Objects

- Numeric and Mathematical Modules
  - numbers — Numeric abstract base classes
    - The numeric tower
    - Notes for type implementors
      - Adding More Numeric ABCs
      - Implementing the arithmetic operations
  - math — Mathematical functions
- **cmath** — Mathematical functions for complex numbers
  - Complex coordinates
  - cmath functions
- **decimal** — Decimal fixed point and floating point arithmetic
  - Quick-start Tutorial
  - Decimal objects
    - Logical operands
  - Context objects
  - Signals
  - Floating Point Notes
    - Mitigating round-off error with increased precision
    - Special values
  - Working with threads
  - Recipes
  - Decimal FAQ
- **fractions** — Rational numbers
- **random** — Generate pseudo-random numbers
- **itertools** — Functions creating iterators for efficient looping
  - Itertool functions
  - Examples
  - Recipes
- **functools** — Higher order functions and operations on callable objects
  - partial Objects
- **operator** — Standard operators as functions
  - Mapping Operators to Functions
- **File and Directory Access**
  - **os.path** — Common pathname manipulations
  - **fileinput** — Iterate over lines from multiple input streams
- **stat** — Interpreting stat results
- **statvfs** — Constants used with `os.statvfs`
- **fcmp** — File and Directory Comparisons
  - The `dircmp` class
- **tempfile** — Generate temporary files and directories
- **glob** — Unix style pathname pattern expansion
- **fnmatch** — Unix filename pattern matching
- **linecache** — Random access to text lines
- **shutil** — High-level file operations
  - Example
- **dircache** — Cached directory listings
- **macpath** — Mac OS 9 path manipulation functions

**Data Persistence**
- **pickle** — Python object serialization
  - Relationship to other Python modules
  - Data stream format
  - Usage
  - What can be pickled and unpickled?
  - The pickle protocol
    - Pickling and unpickling normal class instances
    - Pickling and unpickling extension types
    - Pickling and unpickling external objects
  - Subclassing Unpicklers
  - Example
- **cPickle** — A faster pickle
- **copy_reg** — Register pickle support functions
- **shelve** — Python object persistence
  - Restrictions
  - Example
- **marshal** — Internal Python object serialization
- **anydbm** — Generic access to DBM-style databases
- **whichdb** — Guess which DBM module created a
database
- **dbm** — Simple “database” interface
- **gdbm** — GNU’s reinterpretation of dbm
- **dbhash** — DBM-style interface to the BSD database library
  - Database Objects
- **bsddb** — Interface to Berkeley DB library
  - Hash, BTree and Record Objects
- **dumbdbm** — Portable DBM implementation
  - Dumbdbm Objects
- **sqlite3** — DB-API 2.0 interface for SQLite databases
  - Module functions and constants
  - Connection Objects
  - Cursor Objects
  - SQLite and Python types
    - Introduction
    - Using adapters to store additional Python types in SQLite databases
      - Letting your object adapt itself
      - Registering an adapter callable
    - Converting SQLite values to custom Python types
  - Default adapters and converters
- **Controlling Transactions**
- **Using pymysql efficiently**
  - Using shortcut methods
  - Accessing columns by name instead of by index
  - Using the connection as a context manager

Data Compression and Archiving
- **zlib** — Compression compatible with gzip
- **gzip** — Support for gzip files
  - Examples of usage
- **bz2** — Compression compatible with **bzip2**
  - (De)compression of files
  - Sequential (de)compression
  - One-shot (de)compression
- **zipfile** — Work with ZIP archives
  - ZipFile Objects
  - PyZipFile Objects
  - ZipInfo Objects
- **tarfile** — Read and write tar archive files
  - TarFile Objects
  - TarInfo Objects
  - Examples
  - Supported tar formats
  - Unicode issues

  - File Formats
  - **csv** — CSV File Reading and Writing
    - Module Contents
    - Dialects and Formatting Parameters
    - Reader Objects
    - Writer Objects
    - Examples
  - **ConfigParser** — Configuration file parser
    - RawConfigParser Objects
    - ConfigParser Objects
    - SafeConfigParser Objects
    - Examples
  - **robotparser** — Parser for robots.txt
  - **netrc** — netrc file processing
    - netrc Objects
  - **xdrlib** — Encode and decode XDR data
    - Packer Objects
    - Unpacker Objects
    - Exceptions
- **plistlib** — Generate and parse Mac OS X .plist files
  - Examples
- **Cryptographic Services**
  - **hashlib** — Secure hashes and message digests
  - **hmac** — Keyed-Hashing for Message Authentication
  - **md5** — MD5 message digest algorithm
  - **sha** — SHA-1 message digest algorithm
- **Generic Operating System Services**
  - **os** — Miscellaneous operating system interfaces
    - Process Parameters
    - File Object Creation
    - File Descriptor Operations
    - Files and Directories
    - Process Management
    - Miscellaneous System Information
    - Miscellaneous Functions
  - **io** — Core tools for working with streams
    - Module Interface
    - I/O Base Classes
    - Raw File I/O
    - Buffered Streams
    - Text I/O
  - **time** — Time access and conversions
  - **optparse** — More powerful command line option parser
    - Background
      - Terminology
      - What are options for?
      - What are positional arguments for?
    - Tutorial
      - Understanding option actions
      - The store action
      - Handling boolean (flag) options
- Other actions
- Default values
- Generating help
- Printing a version string
- How `optparse` handles errors
- Putting it all together

- Reference Guide
  - Creating the parser
  - Populating the parser
  - Defining options
  - Standard option actions
  - Option attributes
  - Standard option types
  - Parsing arguments
  - Querying and manipulating your option parser
  - Conflicts between options
  - Cleanup
  - Other methods

- Option Callbacks
  - Defining a callback option
  - How callbacks are called
  - Raising errors in a callback
  - Callback example 1: trivial callback
  - Callback example 2: check option order
  - Callback example 3: check option order (generalized)
  - Callback example 4: check arbitrary condition
  - Callback example 5: fixed arguments
  - Callback example 6: variable arguments

- Extending `optparse`
  - Adding new types
  - Adding new actions

- `getopt` — Parser for command line options
- `logging` — Logging facility for Python
- Logging tutorial
  - Simple examples
  - Loggers
  - Handlers
  - Formatters
  - Configuring Logging
  - Configuring Logging for a Library
- Logging Levels
- Logger Objects
- Basic example
- Logging to multiple destinations
- Adding contextual information to your logging output
- Sending and receiving logging events across a network
- Handler Objects
  - StreamHandler
  - FileHandler
  - WatchedFileHandler
  - RotatingFileHandler
  - TimedRotatingFileHandler
  - SocketHandler
  - DatagramHandler
  - SysLogHandler
  - NTEventLogHandler
  - SMTPHandler
  - MemoryHandler
  - HTTPHandler
- Formatter Objects
- Filter Objects
- LogRecord Objects
- LoggerAdapter Objects
- Thread Safety
- Configuration
- Configuration functions
- Configuration file format
- Configuration server example
- More examples
  - Multiple handlers and formatters
  - Using logging in multiple modules
- `getpass` — Portable password input
- `curses` — Terminal handling for character-cell displays
  - Functions
  - Window Objects
  - Constants
- `curses.textpad` — Text input widget for curses programs
  - Textbox objects
- `curses.wrapper` — Terminal handler for curses programs
- `curses.ascii` — Utilities for ASCII characters
- `curses.panel` — A panel stack extension for curses.
  - Functions
  - Panel Objects
- `platform` — Access to underlying platform’s identifying data.
  - Cross Platform
  - Java Platform
  - Windows Platform
    - Win95/98 specific
  - Mac OS Platform
  - Unix Platforms
- `errno` — Standard errno system symbols
- `ctypes` — A foreign function library for Python.
  - ctypes tutorial
    - Loading dynamic link libraries
    - Accessing functions from loaded dlls
• Calling functions
• Fundamental data types
• Calling functions, continued
• Calling functions with your own custom data types
• Specifying the required argument types (function prototypes)
• Return types
• Passing pointers (or: passing parameters by reference)
• Structures and unions
• Structure/union alignment and byte order
• Bit fields in structures and unions
• Arrays
• Pointers
• Type conversions
• Incomplete Types
• Callback functions
• Accessing values exported from dlls
• Surprises
• Variable-sized data types

• ctypes reference
  • Finding shared libraries
  • Loading shared libraries
  • Foreign functions
  • Function prototypes
  • Utility functions
  • Data types
  • Fundamental data types
  • Structured data types
  • Arrays and pointers

• Optional Operating System Services
  • select — Waiting for I/O completion
    • Edge and Level Trigger Polling (epoll) Objects
- Polling Objects
- Kqueue Objects
- Kevent Objects
  - threading — Higher-level threading interface
    - Lock Objects
    - RLock Objects
    - Condition Objects
    - Semaphore Objects
      - Semaphore Example
    - Event Objects
    - Thread Objects
    - Timer Objects
    - Using locks, conditions, and semaphores in the with statement
    - Importing in threaded code
  - thread — Multiple threads of control
  - dummy_threading — Drop-in replacement for the threading module
  - dummy_thread — Drop-in replacement for the thread module
  - multiprocessing — Process-based “threading” interface
    - Introduction
      - The Process class
      - Exchanging objects between processes
      - Synchronization between processes
      - Sharing state between processes
      - Using a pool of workers
  - Reference
    - Process and exceptions
    - Pipes and Queues
    - Miscellaneous
    - Connection Objects
- Synchronization primitives
- Shared ctypes Objects
  - The `multiprocessing.sharedctypes` module
- Managers
  - Namespace objects
  - Customized managers
  - Using a remote manager
- Proxy Objects
  - Cleanup
- Process Pools
- Listeners and Clients
  - Address Formats
- Authentication keys
- Logging
  - The `multiprocessing.dummy` module
- Programming guidelines
  - All platforms
  - Windows
- Examples
  - `mmap` — Memory-mapped file support
  - `readline` — GNU readline interface
    - Example
  - `rlcompleter` — Completion function for GNU readline
    - Completer Objects
- Interprocess Communication and Networking
  - `subprocess` — Subprocess management
    - Using the subprocess Module
      - Convenience Functions
      - Exceptions
      - Security
    - Popen Objects
    - Replacing Older Functions with the subprocess
Module
- Replacing /bin/sh shell backquote
- Replacing shell pipe line
- Replacing os.system()
- Replacing os.spawn*
- Replacing os.popen*
- Replacing popen2.*

- socket — Low-level networking interface
  - Socket Objects
  - Example

- ssl — SSL wrapper for socket objects
  - Functions, Constants, and Exceptions
  - SSLSocket Objects
  - Certificates
  - Examples
    - Testing for SSL support
    - Client-side operation
    - Server-side operation

- signal — Set handlers for asynchronous events
  - Example

- popen2 — Subprocesses with accessible I/O streams
  - Popen3 and Popen4 Objects
  - Flow Control Issues

- asyncore — Asynchronous socket handler
  - asyncore Example basic HTTP client

- asynchat — Asynchronous socket command/response handler
  - asynchat - Auxiliary Classes and Functions
  - asynchat Example

Internet Data Handling
- email — An email and MIME handling package
  - email: Representing an email message
  - email: Parsing email messages
FeedParser API
 Parser class API
 Additional notes
 - email: Generating MIME documents
 - email: Creating email and MIME objects from scratch
 - email: Internationalized headers
 - email: Representing character sets
 - email: Encoders
 - email: Exception and Defect classes
 - email: Miscellaneous utilities
 - email: Iterators
 - email: Examples
 Package History
 Differences from mimelib
 - json — JSON encoder and decoder
   - Basic Usage
   - Encoders and decoders
 - mailcap — Mailcap file handling
 - mailbox — Manipulate mailboxes in various formats
   - Mailbox objects
     - Maildir
     - mbox
     - MH
     - Babyl
     - MMDF
   - Message objects
     - MaildirMessage
     - mboxMessage
     - MHMessage
     - BabylMessage
- **MMDFMessage**
  - Exceptions
  - Deprecated classes and methods
  - Examples
- **mhlib** — Access to MH mailboxes
  - MH Objects
  - Folder Objects
  - Message Objects
- **mimetypes** — Map filenames to MIME types
  - MimeTypes Objects
- **MimeWriter** — Generic MIME file writer
  - MimeWriter Objects
- **mimify** — MIME processing of mail messages
- **multifile** — Support for files containing distinct parts
  - MultiFile Objects
  - MultiFile Example
- **rfc822** — Parse RFC 2822 mail headers
  - Message Objects
  - AddressList Objects
- **base64** — RFC 3548: Base16, Base32, Base64 Data Encodings
- **binhex** — Encode and decode binhex4 files
  - Notes
- **binascii** — Convert between binary and ASCII
- **quopri** — Encode and decode MIME quoted-printable data
- **uu** — Encode and decode uuencode files
- **Structured Markup Processing Tools**
  - **HTMLParser** — Simple HTML and XHTML parser
    - Example HTML Parser Application
- **sgmllib** — Simple SGML parser
- **htmllib** — A parser for HTML documents
  - HTMLParser Objects
- **htmlentitydefs** — Definitions of HTML general entities
- **xml.parsers.expat** — Fast XML parsing using Expat
  - XMLParser Objects
  - ExpatError Exceptions
  - Example
  - Content Model Descriptions
  - Expat error constants
- **xml.dom** — The Document Object Model API
  - Module Contents
  - Objects in the DOM
    - DOMImplementation Objects
    - Node Objects
    - NodeList Objects
    - DocumentType Objects
    - Document Objects
    - Element Objects
    - Attr Objects
    - NamedNodeMap Objects
    - Comment Objects
    - Text and CDATASection Objects
    - ProcessingInstruction Objects
    - Exceptions
  - Conformance
    - Type Mapping
    - Accessor Methods
- **xml.dom.minidom** — Lightweight DOM implementation
  - DOM Objects
  - DOM Example
  - minidom and the DOM standard
- **xml.dom.pulldom** — Support for building partial DOM
trees
- DOMEventStream Objects
- **xml.sax** — Support for SAX2 parsers
  - SAXException Objects
- **xml.sax.handler** — Base classes for SAX handlers
  - ContentHandler Objects
  - DTDHandler Objects
  - EntityResolver Objects
  - ErrorHandler Objects
- **xml.sax.saxutils** — SAX Utilities
- **xml.sax.xmlreader** — Interface for XML parsers
  - XMLReader Objects
  - IncrementalParser Objects
  - Locator Objects
  - InputSource Objects
  - The **Attributes** Interface
  - The **AttributesNS** Interface
- **xml.etree.ElementTree** — The ElementTree XML API
  - Functions
  - The Element Interface
  - ElementTree Objects
  - QName Objects
  - TreeBuilder Objects
  - XMLTreeBuilder Objects

- Internet Protocols and Support
  - **webbrowser** — Convenient Web-browser controller
    - Browser Controller Objects
  - **cgi** — Common Gateway Interface support.
    - Introduction
    - Using the **cgi** module
    - Higher Level Interface
    - Old classes
    - Functions
- Caring about security
- Installing your CGI script on a Unix system
- Testing your CGI script
- Debugging CGI scripts
- Common problems and solutions
- `cgitb` — Traceback manager for CGI scripts
- `wsgiref` — WSGI Utilities and Reference Implementation
  - `wsgiref.util` — WSGI environment utilities
  - `wsgiref.headers` — WSGI response header tools
  - `wsgiref.simple_server` — a simple WSGI HTTP server
  - `wsgiref.validate` — WSGI conformance checker
  - `wsgiref.handlers` — server/gateway base classes
- Examples
- `urllib` — Open arbitrary resources by URL
  - High-level interface
  - Utility functions
  - URL Opener objects
- `urllib` Restrictions
- Examples
- `urllib2` — extensible library for opening URLs
  - Request Objects
  - OpenerDirector Objects
  - BaseHandler Objects
  - HTTPRedirectHandler Objects
  - HTTPCookieProcessor Objects
  - ProxyHandler Objects
  - HTTPPasswordMgr Objects
  - AbstractBasicAuthHandler Objects
  - HTTPBasicAuthHandler Objects
  - ProxyBasicAuthHandler Objects
  - AbstractDigestAuthHandler Objects
- HTTPDigestAuthHandler Objects
- ProxyDigestAuthHandler Objects
- HTTPHandler Objects
- HTTPSHandler Objects
- FileHandler Objects
- FTPHandler Objects
- CacheFTPHandler Objects
- UnknownHandler Objects
- HTTPErrorProcessor Objects
- Examples
  - **httplib** — HTTP protocol client
    - HTTPConnection Objects
    - HTTPResponse Objects
    - Examples
  - **ftplib** — FTP protocol client
    - FTP Objects
  - **poplib** — POP3 protocol client
    - POP3 Objects
    - POP3 Example
  - **imaplib** — IMAP4 protocol client
    - IMAP4 Objects
    - IMAP4 Example
  - **nntplib** — NNTP protocol client
    - NNTP Objects
  - **smtplib** — SMTP protocol client
    - SMTP Objects
    - SMTP Example
  - **smtpd** — SMTP Server
    - SMPTServer Objects
    - DebuggingServer Objects
    - PureProxy Objects
    - MailmanProxy Objects
  - **telnetlib** — Telnet client
- Telnet Objects
- Telnet Example
- **uuid** — UUID objects according to RFC 4122
  - Example
- **urllparse** — Parse URLs into components
  - Results of **urllparse** and **urllsplit**
- **SocketServer** — A framework for network servers
  - Server Creation Notes
  - Server Objects
  - RequestHandler Objects
  - Examples
    - **SocketServer.TCPServer** Example
    - **SocketServer.UDPServer** Example
  - Asynchronous Mixins
- **BaseHTTPServer** — Basic HTTP server
- **SimpleHTTPServer** — Simple HTTP request handler
- **CGIHTTPServer** — CGI-capable HTTP request handler
- **cookielib** — Cookie handling for HTTP clients
  - CookieJar and FileCookieJar Objects
  - FileCookieJar subclasses and co-operation with web browsers
  - CookiePolicy Objects
  - DefaultCookiePolicy Objects
  - Cookie Objects
  - Examples
- **Cookie** — HTTP state management
  - Cookie Objects
  - Morsel Objects
  - Example
- **xmlrpcclib** — XML-RPC client access
  - ServerProxy Objects
  - Boolean Objects
  - DateTime Objects
- Binary Objects
- Fault Objects
- ProtocolError Objects
- MultiCall Objects
- Convenience Functions
- Example of Client Usage
- Example of Client and Server Usage
  - SimpleXMLRPCServer — Basic XML-RPC server
    - SimpleXMLRPCServer Objects
      - SimpleXMLRPCServer Example
    - CGIXMLRPCRequestHandler
  - DocXMLRPCServer — Self-documenting XML-RPC server
    - DocXMLRPCServer Objects
    - DocCGIXMLRPCRequestHandler
- Multimedia Services
  - audioop — Manipulate raw audio data
  - imageop — Manipulate raw image data
  - aifc — Read and write AIFF and AIFC files
  - sunau — Read and write Sun AU files
    - AU_read Objects
    - AU_write Objects
  - wave — Read and write WAV files
    - Wave_read Objects
    - Wave_write Objects
  - chunk — Read IFF chunked data
  - colorsys — Conversions between color systems
  - imghdr — Determine the type of an image
  - sndhdr — Determine type of sound file
  - ossaudiodev — Access to OSS-compatible audio devices
    - Audio Device Objects
    - Mixer Device Objects
- Internationalization
- gettext — Multilingual internationalization services
  - GNU gettext API
  - Class-based API
    - The NullTranslations class
    - The GNUTranslations class
    - Solaris message catalog support
    - The Catalog constructor
  - Internationalizing your programs and modules
    - Localizing your module
    - Localizing your application
    - Changing languages on the fly
    - Deferred translations
    - gettext vs. lgettext
  - Acknowledgements
- locale — Internationalization services
  - Background, details, hints, tips and caveats
  - For extension writers and programs that embed Python
  - Access to message catalogs
  - Program Frameworks
    - cmd — Support for line-oriented command interpreters
      - Cmd Objects
    - shlex — Simple lexical analysis
      - shlex Objects
      - Parsing Rules
  - Graphical User Interfaces with Tk
    - Tkinter — Python interface to Tcl/Tk
      - Tkinter Modules
      - Tkinter Life Preserver
        - How To Use This Section
        - A Simple Hello World Program
      - A (Very) Quick Look at Tcl/Tk
      - Mapping Basic Tk into Tkinter
- How Tk and Tkinter are Related
- Handy Reference
  - Setting Options
  - The Packer
  - Packer Options
  - Coupling Widget Variables
  - The Window Manager
  - Tk Option Data Types
  - Bindings and Events
  - The index Parameter
  - Images
- **Tix** — Extension widgets for Tk
  - Using Tix
  - Tix Widgets
    - Basic Widgets
    - File Selectors
    - Hierarchical ListBox
    - Tabular ListBox
    - Manager Widgets
    - Image Types
    - Miscellaneous Widgets
    - Form Geometry Manager
- **ScrolledText** — Scrolled Text Widget
- **turtle** — Turtle graphics for Tk
  - Introduction
  - Overview over available Turtle and Screen methods
    - Turtle methods
    - Methods of TurtleScreen/Screen
  - Methods of RawTurtle/Turtle and corresponding functions
    - Turtle motion
    - Tell Turtle’s state
- Settings for measurement
- Pen control
  - Drawing state
  - Color control
  - Filling
  - More drawing control
- Turtle state
  - Visibility
  - Appearance
- Using events
- Special Turtle methods
- Excursus about the use of compound shapes
- Methods of TurtleScreen/Screen and corresponding functions
  - Window control
  - Animation control
  - Using screen events
  - Settings and special methods
  - Methods specific to Screen, not inherited from TurtleScreen
- The public classes of the module turtle
- Help and configuration
  - How to use help
  - Translation of docstrings into different languages
  - How to configure Screen and Turtles
- Demo scripts
- IDLE
  - Menus
    - File menu
    - Edit menu
    - Windows menu
    - Debug menu (in the Python Shell window only)
Basic editing and navigation
  - Automatic indentation
  - Python Shell window
- Syntax colors
  - Command line usage
- Other Graphical User Interface Packages

Development Tools
- **pydoc** — Documentation generator and online help system
- **doctest** — Test interactive Python examples
  - Simple Usage: Checking Examples in Docstrings
  - Simple Usage: Checking Examples in a Text File
- How It Works
  - Which Docstrings Are Examined?
  - How are Docstring Examples Recognized?
  - What’s the Execution Context?
  - What About Exceptions?
  - Option Flags and Directives
  - Warnings
- Basic API
- Unittest API
- Advanced API
  - DocTest Objects
  - Example Objects
  - DocTestFinder objects
  - DocTestParser objects
  - DocTestRunner objects
  - OutputChecker objects
- Debugging
- Soapbox
- **unittest** — Unit testing framework
  - Basic example
  - Organizing test code
  - Re-using old test code
- Classes and functions
  - TestCase Objects
  - TestSuite Objects
  - TestResult Objects
  - TestLoader Objects
- 2to3 - Automated Python 2 to 3 code translation
  - Using 2to3
  - lib2to3 - 2to3’s library
- test — Regression tests package for Python
  - Writing Unit Tests for the test package
  - Running tests using test.regrtest
- test.test_support — Utility functions for tests

- Debugging and Profiling
  - bdb — Debugger framework
  - pdb — The Python Debugger
  - Debugger Commands
  - How It Works
  - The Python Profilers
    - Introduction to the profilers
    - Instant User’s Manual
    - What Is Deterministic Profiling?
    - Reference Manual – profile and cProfile
      - The Stats Class
    - Limitations
    - Calibration
    - Extensions — Deriving Better Profilers
  - hotshot — High performance logging profiler
    - Profile Objects
    - Using hotshot data
    - Example Usage
  - timeit — Measure execution time of small code snippets
    - Command Line Interface
Examples

- **trace** — Trace or track Python statement execution
- Command Line Usage
- Programming Interface

**Python Runtime Services**

- **sys** — System-specific parameters and functions
- **__builtin__** — Built-in objects
- **future_builtins** — Python 3 builtins
- **__main__** — Top-level script environment
- **warnings** — Warning control
  - Warning Categories
  - The Warnings Filter
  - Temporarily Suppressing Warnings
  - Testing Warnings
  - Available Functions
  - Available Context Managers
- **contextlib** — Utilities for `with`-statement contexts.
- **abc** — Abstract Base Classes
- **atexit** — Exit handlers
  - `atexit` Example
- **traceback** — Print or retrieve a stack traceback
  - Traceback Examples
- **__future__** — Future statement definitions
- **gc** — Garbage Collector interface
- **inspect** — Inspect live objects
  - Types and members
  - Retrieving source code
  - Classes and functions
  - The interpreter stack
- **site** — Site-specific configuration hook
- **user** — User-specific configuration hook
- **fpexit** — Floating point exception control
• Example
• Limitations and other considerations

○ Custom Python Interpreters
  ■ code — Interpreter base classes
    ■ Interactive Interpreter Objects
    ■ Interactive Console Objects
  ■ codeop — Compile Python code

○ Restricted Execution
  ■ rexec — Restricted execution framework
    ■ RExec Objects
    ■ Defining restricted environments
    ■ An example
  ■ Bastion — Restricting access to objects

○ Importing Modules
  ■ imp — Access the import internals
    ■ Examples
  ■ imputil — Import utilities
    ■ Examples
  ■ zipimport — Import modules from Zip archives
    ■ zipimporter Objects
    ■ Examples
  ■ pkgutil — Package extension utility
  ■ modulefinder — Find modules used by a script
    ■ Example usage of ModuleFinder
  ■ runpy — Locating and executing Python modules

○ Python Language Services
  ■ parser — Access Python parse trees
    ■ Creating ST Objects
    ■ Converting ST Objects
    ■ Queries on ST Objects
    ■ Exceptions and Error Handling
    ■ ST Objects
    ■ Examples
- Emulation of `compile`
- Information Discovery
- Abstract Syntax Trees
  - Node classes
  - Abstract Grammar
  - `ast` Helpers
- `symtable` — Access to the compiler’s symbol tables
  - Generating Symbol Tables
  - Examining Symbol Tables
- `symbol` — Constants used with Python parse trees
- `token` — Constants used with Python parse trees
- `keyword` — Testing for Python keywords
- `tokenize` — Tokenizer for Python source
- `tabnanny` — Detection of ambiguous indentation
- `pyclbr` — Python class browser support
  - Class Objects
  - Function Objects
- `py_compile` — Compile Python source files
- `compileall` — Byte-compile Python libraries
- `dis` — Disassembler for Python bytecode
  - Python Bytecode Instructions
- `pickletools` — Tools for pickle developers.
- `distutils` — Building and installing Python modules

- Python compiler package
  - The basic interface

- Miscellaneous Services
- **formatter** — Generic output formatting
  - The Formatter Interface
  - Formatter Implementations
  - The Writer Interface
  - Writer Implementations
- **MS Windows Specific Services**
  - **msilib** — Read and write Microsoft Installer files
    - Database Objects
    - View Objects
    - Summary Information Objects
    - Record Objects
    - Errors
    - CAB Objects
    - Directory Objects
    - Features
    - GUI classes
    - Precomputed tables
  - **msvcrt** — Useful routines from the MS VC++ runtime
    - File Operations
    - Console I/O
    - Other Functions
  - **_winreg** — Windows registry access
    - Registry Handle Objects
  - **winsound** — Sound-playing interface for Windows
- **Unix Specific Services**
  - **posix** — The most common POSIX system calls
    - Large File Support
    - Notable Module Contents
  - **pwd** — The password database
  - **spwd** — The shadow password database
  - **grp** — The group database
  - **crypt** — Function to check Unix passwords
  - **dl** — Call C functions in shared objects
- DI Objects
  - `termios` — POSIX style tty control
    - Example
  - `tty` — Terminal control functions
  - `pty` — Pseudo-terminal utilities
  - `fcntl` — The `fcntl` and `ioctl` system calls
  - `pipes` — Interface to shell pipelines
    - Template Objects
  - `posixfile` — File-like objects with locking support
  - `resource` — Resource usage information
    - Resource Limits
    - Resource Usage
  - `nis` — Interface to Sun’s NIS (Yellow Pages)
  - `syslog` — Unix syslog library routines
  - `commands` — Utilities for running commands
- Mac OS X specific services
  - `ic` — Access to the Mac OS X Internet Config
    - IC Objects
  - `MacOS` — Access to Mac OS interpreter features
  - `macostools` — Convenience routines for file manipulation
  - `findertools` — The `finder`'s Apple Events interface
  - `EasyDialogs` — Basic Macintosh dialogs
    - ProgressBar Objects
  - `FrameWork` — Interactive application framework
    - Application Objects
    - Window Objects
    - ControlsWindow Object
    - ScrolledWindow Object
    - DialogWindow Objects
  - `autoGIL` — Global Interpreter Lock handling in event loops
Mac OS Toolbox Modules
- Carbon.AE — Apple Events
- Carbon.AH — Apple Help
- Carbon.App — Appearance Manager
- Carbon.CF — Core Foundation
- Carbon.CG — Core Graphics
- Carbon.CarbonEvt — Carbon Event Manager
- Carbon.Cm — Component Manager
- Carbon.Ctl — Control Manager
- Carbon.Dlg — Dialog Manager
- Carbon.Evt — Event Manager
- Carbon.Fm — Font Manager
- Carbon.Folder — Folder Manager
- Carbon.Help — Help Manager
- Carbon.List — List Manager
- Carbon.Menu — Menu Manager
- Carbon.Mlte — MultiLingual Text Editor
- Carbon.Qd — QuickDraw
- Carbon.Qdoffs — QuickDraw Offscreen
- Carbon.Qt — QuickTime
- Carbon.Res — Resource Manager and Handles
- Carbon.Scrap — Scrap Manager
- Carbon.Snd — Sound Manager
- Carbon.TE — TextEdit
- Carbon.Win — Window Manager

- ColorPicker — Color selection dialog

MacPython OSA Modules
- gensuitemodule — Generate OSA stub packages
- aetools — OSA client support
- aepack — Conversion between Python variables and AppleEvent data containers
- aetypes — AppleEvent objects
- MiniAEFrame — Open Scripting Architecture server support
  - AEServer Objects
- SGI IRIX Specific Services
  - al — Audio functions on the SGI
    - Configuration Objects
    - Port Objects
  - AL — Constants used with the al module
  - cd — CD-ROM access on SGI systems

Python is an easy to learn, powerful programming language. It has efficient high-level data structures and a simple but effective approach to object-oriented programming. Python’s elegant syntax and dynamic typing, together with its interpreted nature, make it an ideal language for scripting and rapid application development in many areas on most platforms.

The Python interpreter and the extensive standard library are freely available in source or binary form for all major platforms from the Python Web site, http://www.python.org/, and may be freely distributed. The same site also contains distributions of and pointers to many free third party Python modules, programs and tools, and additional documentation.

The Python interpreter is easily extended with new functions and data types implemented in C or C++ (or other languages callable from C). Python is also suitable as an extension language for customizable applications.

This tutorial introduces the reader informally to the basic concepts and features of the Python language and system. It helps to have a Python interpreter handy for hands-on experience, but all examples are self-contained, so the tutorial can be read off-line as well.

For a description of standard objects and modules, see the Python Library Reference document. The Python Reference Manual gives a more formal definition of the language. To write extensions in C or C++, read Extending and Embedding the Python Interpreter and Python/C API Reference. There are also several books covering Python in depth.
This tutorial does not attempt to be comprehensive and cover every single feature, or even every commonly used feature. Instead, it introduces many of Python’s most noteworthy features, and will give you a good idea of the language’s flavor and style. After reading it, you will be able to read and write Python modules and programs, and you will be ready to learn more about the various Python library modules described in the Python Library Reference.

The Glossary is also worth going through.

This reference manual describes the syntax and “core semantics” of the language. It is terse, but attempts to be exact and complete. The semantics of non-essential built-in object types and of the built-in functions and modules are described in *The Python Standard Library*. For an informal introduction to the language, see *The Python Tutorial*. For C or C++ programmers, two additional manuals exist: *Extending and Embedding the Python Interpreter* describes the high-level picture of how to write a Python extension module, and the *Python/C API Reference Manual* describes the interfaces available to C/C++ programmers in detail.

- Full Grammar specification
While *The Python Language Reference* describes the exact syntax and semantics of the Python language, this library reference manual describes the standard library that is distributed with Python. It also describes some of the optional components that are commonly included in Python distributions.

Python's standard library is very extensive, offering a wide range of facilities as indicated by the long table of contents listed below. The library contains built-in modules (written in C) that provide access to system functionality such as file I/O that would otherwise be inaccessible to Python programmers, as well as modules written in Python that provide standardized solutions for many problems that occur in everyday programming. Some of these modules are explicitly designed to encourage and enhance the portability of Python programs by abstracting away platform-specifocs into platform-neutral APIs.

The Python installers for the Windows platform usually includes the entire standard library and often also include many additional components. For Unix-like operating systems Python is normally provided as a collection of packages, so it may be necessary to use the packaging tools provided with the operating system to obtain some or all of the optional components.

In addition to the standard library, there is a growing collection of several thousand components (from individual programs and modules to packages and entire application development frameworks), available from the Python Package Index.

- Introduction
- Built-in Functions
- Non-essential Built-in Functions

- Built-in Constants
  - Constants added by the `site` module

- Built-in Objects

- Built-in Types
  - Truth Value Testing
  - Boolean Operations — `and`, `or`, `not`
  - Comparisons
  - Numeric Types — `int`, `float`, `long`, `complex`
  - Iterator Types
  - Sequence Types — `str`, `unicode`, `list`, `tuple`, `buffer`, `xrange`
  - Set Types — `set`, `frozenset`
  - Mapping Types — `dict`

- File Objects
- Context Manager Types
- Other Built-in Types
- Special Attributes

- Built-in Exceptions

- String Services
  - `string` — Common string operations
  - `re` — Regular expression operations
  - `struct` — Interpret strings as packed binary data
  - `difflib` — Helpers for computing deltas
  - `StringIO` — Read and write strings as files
  - `cStringIO` — Faster version of `StringIO`
  - `textwrap` — Text wrapping and filling
  - `codecs` — Codec registry and base classes
• **unicodedata** — Unicode Database  
• **stringprep** — Internet String Preparation  
• **fpformat** — Floating point conversions

• **Data Types**  
  • **datetime** — Basic date and time types  
  • **calendar** — General calendar-related functions  
  • **collections** — High-performance container datatypes  
  • **heapq** — Heap queue algorithm  
  • **bisect** — Array bisection algorithm  
  • **array** — Efficient arrays of numeric values  
  • **sets** — Unordered collections of unique elements  
  • **sched** — Event scheduler  
  • **mutex** — Mutual exclusion support  
  • **queue** — A synchronized queue class  
  • **weakref** — Weak references  
  • **UserDict** — Class wrapper for dictionary objects  
  • **UserList** — Class wrapper for list objects  
  • **UserString** — Class wrapper for string objects  
  • **types** — Names for built-in types  
  • **new** — Creation of runtime internal objects  
  • **copy** — Shallow and deep copy operations  
  • **pprint** — Data pretty printer  
  • **repr** — Alternate `repr` implementation

• **Numeric and Mathematical Modules**  
  • **numbers** — Numeric abstract base classes  
  • **math** — Mathematical functions  
  • **cmath** — Mathematical functions for complex numbers  
  • **decimal** — Decimal fixed point and floating point arithmetic  
  • **fractions** — Rational numbers
- `random` — Generate pseudo-random numbers
- `itertools` — Functions creating iterators for efficient looping
- `functools` — Higher order functions and operations on callable objects
- `operator` — Standard operators as functions

**File and Directory Access**
- `os.path` — Common pathname manipulations
- `fileinput` — Iterate over lines from multiple input streams
- `stat` — Interpreting `stat` results
- `statvfs` — Constants used with `os.statvfs`
- `filecmp` — File and Directory Comparisons
- `tempfile` — Generate temporary files and directories
- `glob` — Unix style pathname pattern expansion
- `fnmatch` — Unix filename pattern matching
- `linecache` — Random access to text lines
- `shutil` — High-level file operations
- `dircache` — Cached directory listings
- `macpath` — Mac OS 9 path manipulation functions

**Data Persistence**
- `pickle` — Python object serialization
- `cPickle` — A faster `pickle`
- `copy_reg` — Register `pickle` support functions
- `shelve` — Python object persistence
- `marshal` — Internal Python object serialization
- `anydbm` — Generic access to DBM-style databases
- `whichdb` — Guess which DBM module created a database
- `dbm` — Simple “database” interface
- `gdbm` — GNU’s reinterpretation of `dbm`
- `dbhash` — DBM-style interface to the BSD database library
- **bsddb** — Interface to Berkeley DB library
- **dumbdbm** — Portable DBM implementation
- **sqlite3** — DB-API 2.0 interface for SQLite databases

**Data Compression and Archiving**
- **zlib** — Compression compatible with **gzip**
- **gzip** — Support for **gzip** files
- **bz2** — Compression compatible with **bzip2**
- **zipfile** — Work with ZIP archives
- **tarfile** — Read and write tar archive files

**File Formats**
- **csv** — CSV File Reading and Writing
- **ConfigParser** — Configuration file parser
- **robotparser** — Parser for robots.txt
- **netrc** — netrc file processing
- **xdrlib** — Encode and decode XDR data
- **plistlib** — Generate and parse Mac OS X .plist files

**Cryptographic Services**
- **hashlib** — Secure hashes and message digests
- **hmac** — Keyed-Hashing for Message Authentication
- **md5** — MD5 message digest algorithm
- **sha** — SHA-1 message digest algorithm

**Generic Operating System Services**
- **os** — Miscellaneous operating system interfaces
- **io** — Core tools for working with streams
- **time** — Time access and conversions
- **optparse** — More powerful command line option parser
- **getopt** — Parser for command line options
- **logging** — Logging facility for Python
- `getpass` — Portable password input
- `curses` — Terminal handling for character-cell displays
- `curses.textpad` — Text input widget for curses programs
- `curses.wrapper` — Terminal handler for curses programs
- `curses.ascii` — Utilities for ASCII characters
- `curses.panel` — A panel stack extension for curses.
- `platform` — Access to underlying platform’s identifying data.
- `errno` — Standard errno system symbols
- `ctypes` — A foreign function library for Python.

- **Optional Operating System Services**
  - `select` — Waiting for I/O completion
  - `threading` — Higher-level threading interface
  - `thread` — Multiple threads of control
  - `dummy_threading` — Drop-in replacement for the `threading` module
  - `dummy_thread` — Drop-in replacement for the `thread` module
  - `multiprocessing` — Process-based “threading” interface
  - `mmap` — Memory-mapped file support
  - `readline` — GNU readline interface
  - `rlcompleter` — Completion function for GNU readline

- **Interprocess Communication and Networking**
  - `subprocess` — Subprocess management
  - `socket` — Low-level networking interface
  - `ssl` — SSL wrapper for socket objects
  - `signal` — Set handlers for asynchronous events
  - `popen2` — Subprocesses with accessible I/O streams
  - `asyncore` — Asynchronous socket handler
  - `asynchat` — Asynchronous socket command/response handler
- **Internet Data Handling**
  - **email** — An email and MIME handling package
  - **json** — JSON encoder and decoder
  - **mailcap** — Mailcap file handling
  - **mailbox** — Manipulate mailboxes in various formats
  - **mhlib** — Access to MH mailboxes
  - **mime** — Tools for parsing MIME messages
  - **mimetypes** — Map filenames to MIME types
  - **MimeWriter** — Generic MIME file writer
  - **mimify** — MIME processing of mail messages
  - **multifile** — Support for files containing distinct parts
  - **rfc822** — Parse RFC 2822 mail headers
  - **base64** — RFC 3548: Base16, Base32, Base64 Data Encodings
  - **binhex** — Encode and decode binhex4 files
  - **binascii** — Convert between binary and ASCII
  - **quopri** — Encode and decode MIME quoted-printable data
  - **uu** — Encode and decode uuencode files

- **Structured Markup Processing Tools**
  - **HTMLParser** — Simple HTML and XHTML parser
  - **sgmllib** — Simple SGML parser
  - **htmllib** — A parser for HTML documents
  - **htmlentitydefs** — Definitions of HTML general entities
  - **xml.parsers.expat** — Fast XML parsing using Expat
  - **xml.dom** — The Document Object Model API
  - **xml.dom.minidom** — Lightweight DOM implementation
  - **xml.dom.pulldom** — Support for building partial DOM trees
  - **xml.sax** — Support for SAX2 parsers
  - **xml.sax.handler** — Base classes for SAX handlers
  - **xml.sax.saxutils** — SAX Utilities
• xml.sax.xmlreader — Interface for XML parsers
• xml.etree.ElementTree — The ElementTree XML API

• Internet Protocols and Support
  • webbrowser — Convenient Web-browser controller
  • cgi — Common Gateway Interface support.
  • cgitb — Traceback manager for CGI scripts
  • wsgiref — WSGI Utilities and Reference Implementation
  • urllib — Open arbitrary resources by URL
  • urllib2 — extensible library for opening URLs
  • httplib — HTTP protocol client
  • ftplib — FTP protocol client
  • poplib — POP3 protocol client
  • imaplib — IMAP4 protocol client
  • nntplib — NNTP protocol client
  • smtplib — SMTP protocol client
  • smtpd — SMTP Server
  • telnetlib — Telnet client
  • uuid — UUID objects according to RFC 4122
  • urlparse — Parse URLs into components
  • SocketServer — A framework for network servers
  • BaseHTTPServer — Basic HTTP server
  • SimpleHTTPServer — Simple HTTP request handler
  • CGIHTTPServer — CGI-capable HTTP request handler
  • cookielib — Cookie handling for HTTP clients
  • Cookie — HTTP state management
  • xmlrpclib — XML-RPC client access
  • SimpleXMLRPCServer — Basic XML-RPC server
  • DocXMLRPCServer — Self-documenting XML-RPC server

• Multimedia Services
- **audioop** — Manipulate raw audio data
- **imageop** — Manipulate raw image data
- **aifc** — Read and write AIFF and AIFC files
- **sunau** — Read and write Sun AU files
- **wave** — Read and write WAV files
- **chunk** — Read IFF chunked data
- **colorsys** — Conversions between color systems
- **imghdr** — Determine the type of an image
- **sndhdr** — Determine type of sound file
- **ossaudiodev** — Access to OSS-compatible audio devices

**Internationalization**
- **gettext** — Multilingual internationalization services
- **locale** — Internationalization services

**Program Frameworks**
- **cmd** — Support for line-oriented command interpreters
- **shlex** — Simple lexical analysis

**Graphical User Interfaces with Tk**
- **Tkinter** — Python interface to Tcl/Tk
- **Tix** — Extension widgets for Tk
- **ScrolledText** — Scrolled Text Widget
- **turtle** — Turtle graphics for Tk
- **IDLE**
- **Other Graphical User Interface Packages**

**Development Tools**
- **pydoc** — Documentation generator and online help system
- **doctest** — Test interactive Python examples
- **unittest** — Unit testing framework
- **2to3** - Automated Python 2 to 3 code translation
- **test** — Regression tests package for Python
- **test.test_support** — Utility functions for tests

- **Debugging and Profiling**
  - **bdb** — Debugger framework
  - **pdb** — The Python Debugger
  - **Debugger Commands**
  - **How It Works**
  - **The Python Profilers**
  - **hotshot** — High performance logging profiler
  - **timeit** — Measure execution time of small code snippets
  - **trace** — Trace or track Python statement execution

- **Python Runtime Services**
  - **sys** — System-specific parameters and functions
  - **__builtin__** — Built-in objects
  - **future.builtins** — Python 3 builtins
  - **__main__** — Top-level script environment
  - **warnings** — Warning control
  - **contextlib** — Utilities for with-statement contexts.
  - **abc** — Abstract Base Classes
  - **atexit** — Exit handlers
  - **traceback** — Print or retrieve a stack traceback
  - **__future__** — Future statement definitions
  - **gc** — Garbage Collector interface
  - **inspect** — Inspect live objects
  - **site** — Site-specific configuration hook
  - **user** — User-specific configuration hook
  - **fpectl** — Floating point exception control

- **Custom Python Interpreters**
  - **code** — Interpreter base classes
  - **codeop** — Compile Python code
- **Restricted Execution**
  - `rexe` — Restricted execution framework
  - `Bastion` — Restricting access to objects

- **Importing Modules**
  - `imp` — Access the `import` internals
  - `imputil` — Import utilities
  - `zipimport` — Import modules from Zip archives
  - `pkgutil` — Package extension utility
  - `modulefinder` — Find modules used by a script
  - `runpy` — Locating and executing Python modules

- **Python Language Services**
  - `parser` — Access Python parse trees
  - **Abstract Syntax Trees**
    - `symtable` — Access to the compiler’s symbol tables
    - `symbol` — Constants used with Python parse trees
    - `token` — Constants used with Python parse trees
    - `keyword` — Testing for Python keywords
    - `tokenizer` — Tokenizer for Python source
    - `tabnanny` — Detection of ambiguous indentation
    - `pyclbr` — Python class browser support
    - `py_compile` — Compile Python source files
    - `compileall` — Byte-compile Python libraries
    - `dis` — Disassembler for Python bytecode
    - `pickletools` — Tools for pickle developers.
    - `distutils` — Building and installing Python modules

- **Python compiler package**
  - The basic interface
  - Limitations
  - Python Abstract Syntax
- Using Visitors to Walk ASTs
- Bytecode Generation

**Miscellaneous Services**
- **formatter** — Generic output formatting

**MS Windows Specific Services**
- **msilib** — Read and write Microsoft Installer files
- **msvcrt** – Useful routines from the MS VC++ runtime
- **_winreg** – Windows registry access
- **winsound** — Sound-playing interface for Windows

**Unix Specific Services**
- **posix** — The most common POSIX system calls
- **pwd** — The password database
- **spwd** — The shadow password database
- **grp** — The group database
- **crypt** — Function to check Unix passwords
- **dl** — Call C functions in shared objects
- **termios** — POSIX style tty control
- **tty** — Terminal control functions
- **pty** — Pseudo-terminal utilities
- **fcntl** — The `fcntl` and `ioctl` system calls
- **pipes** — Interface to shell pipelines
- **posixfile** — File-like objects with locking support
- **resource** — Resource usage information
- **nis** — Interface to Sun’s NIS (Yellow Pages)
- **syslog** — Unix syslog library routines
- **commands** — Utilities for running commands

**Mac OS X specific services**
- **ic** — Access to the Mac OS X Internet Config
- **MacOS** — Access to Mac OS interpreter features
- **macostools** — Convenience routines for file manipulation
- **findertools** — The finder's Apple Events interface
- **EasyDialogs** — Basic Macintosh dialogs
- **FrameWork** — Interactive application framework
- **autoGIL** — Global Interpreter Lock handling in event loops

Mac OS Toolbox Modules
- **ColorPicker** — Color selection dialog

MacPython OSA Modules
- **gensuitemodule** — Generate OSA stub packages
- **aetools** — OSA client support
- **aepack** — Conversion between Python variables and AppleEvent data containers
- **aetypes** — AppleEvent objects
- **MiniAEFrame** — Open Scripting Architecture server support

SGI IRIX Specific Services
- **a1** — Audio functions on the SGI
- **AL** — Constants used with the a1 module
- **cd** — CD-ROM access on SGI systems
- **f1** — FORMS library for graphical user interfaces
- **FL** — Constants used with the f1 module
- **flp** — Functions for loading stored FORMS designs
- **fm** — *Font Manager* interface
- **g1** — *Graphics Library* interface
- **DEVICE** — Constants used with the g1 module
- **GL** — Constants used with the g1 module
- **imgfile** — Support for SGI imglib files
- **jpeg** — Read and write JPEG files

SunOS Specific Services
- sunaudiodev — Access to Sun audio hardware
- SUNAUDIODEV — Constants used with sunaudiodev

- Undocumented Modules
  - Miscellaneous useful utilities
  - Platform specific modules
  - Multimedia
  - Undocumented Mac OS modules
  - Obsolete
  - SGI-specific Extension modules
Python HOWTOs

Python HOWTOs are documents that cover a single, specific topic, and attempt to cover it fairly completely. Modelled on the Linux Documentation Project’s HOWTO collection, this collection is an effort to foster documentation that’s more detailed than the Python Library Reference.

Currently, the HOWTOs are:

- Python Advocacy HOWTO
- Porting Extension Modules to 3.0
- Curses Programming with Python
- Idioms and Anti-Idioms in Python
- Functional Programming HOWTO
- Regular Expression HOWTO
- Socket Programming HOWTO
- Unicode HOWTO
- HOWTO Fetch Internet Resources Using urllib2
- HOWTO Use Python in the web
This document describes how to write modules in C or C++ to extend the Python interpreter with new modules. Those modules can define new functions but also new object types and their methods. The document also describes how to embed the Python interpreter in another application, for use as an extension language. Finally, it shows how to compile and link extension modules so that they can be loaded dynamically (at run time) into the interpreter, if the underlying operating system supports this feature.

This document assumes basic knowledge about Python. For an informal introduction to the language, see The Python Tutorial. The Python Language Reference gives a more formal definition of the language. The Python Standard Library documents the existing object types, functions and modules (both built-in and written in Python) that give the language its wide application range.

For a detailed description of the whole Python/C API, see the separate Python/C API Reference Manual.

Installing Python Modules

Author: Greg Ward
Release: 2.6
Date: October 02, 2008

Abstract

This document describes the Python Distribution Utilities ("Distutils") from the end-user's point-of-view, describing how to extend the capabilities of a standard Python installation by building and installing third-party Python modules and extensions.
Introduction

Although Python's extensive standard library covers many programming needs, there often comes a time when you need to add some new functionality to your Python installation in the form of third-party modules. This might be necessary to support your own programming, or to support an application that you want to use and that happens to be written in Python.

In the past, there has been little support for adding third-party modules to an existing Python installation. With the introduction of the Python Distribution Utilities (Distutils for short) in Python 2.0, this changed.

This document is aimed primarily at the people who need to install third-party Python modules: end-users and system administrators who just need to get some Python application running, and existing Python programmers who want to add some new goodies to their toolbox. You don't need to know Python to read this document; there will be some brief forays into using Python's interactive mode to explore your installation, but that's it. If you're looking for information on how to distribute your own Python modules so that others may use them, see the *Distributing Python Modules* manual.

Best case: trivial installation

In the best case, someone will have prepared a special version of the module distribution you want to install that is targeted specifically at your platform and is installed just like any other software on your platform. For example, the module developer might make an executable installer available for Windows users, an RPM package for users of RPM-based Linux systems (Red Hat, SuSE, Mandrake, and many others), a Debian package for users of Debian-based
Linux systems, and so forth.

In that case, you would download the installer appropriate to your platform and do the obvious thing with it: run it if it's an executable installer, `rpm --install` it if it's an RPM, etc. You don't need to run Python or a setup script, you don't need to compile anything—you might not even need to read any instructions (although it's always a good idea to do so anyways).

Of course, things will not always be that easy. You might be interested in a module distribution that doesn't have an easy-to-use installer for your platform. In that case, you'll have to start with the source distribution released by the module’s author/maintainer. Installing from a source distribution is not too hard, as long as the modules are packaged in the standard way. The bulk of this document is about building and installing modules from standard source distributions.

The new standard: Distutils

If you download a module source distribution, you can tell pretty quickly if it was packaged and distributed in the standard way, i.e. using the Distutils. First, the distribution's name and version number will be featured prominently in the name of the downloaded archive, e.g. `foo-1.0.tar.gz` or `widget-0.9.7.zip`. Next, the archive will unpack into a similarly-named directory: `foo-1.0` or `widget-0.9.7`. Additionally, the distribution will contain a setup script `setup.py`, and a file named `README.txt` or possibly just `README`, which should explain that building and installing the module distribution is a simple matter of running

```
python setup.py install
```

If all these things are true, then you already know how to build and
install the modules you’ve just downloaded: Run the command above. Unless you need to install things in a non-standard way or customize the build process, you don’t really need this manual. Or rather, the above command is everything you need to get out of this manual.
Standard Build and Install

As described in section The new standard: Distutils, building and installing a module distribution using the Distutils is usually one simple command:

```
python setup.py install
```

On Unix, you’d run this command from a shell prompt; on Windows, you have to open a command prompt window (“DOS box”) and do it there; on Mac OS X, you open a Terminal window to get a shell prompt.

Platform variations

You should always run the setup command from the distribution root directory, i.e. the top-level subdirectory that the module source distribution unpacks into. For example, if you've just downloaded a module source distribution `foo-1.0.tar.gz` onto a Unix system, the normal thing to do is:

```
gunzip -c foo-1.0.tar.gz | tar xf -   # unpacks into directory
cd foo-1.0
python setup.py install
```

On Windows, you’d probably download `foo-1.0.zip`. If you downloaded the archive file to `C:\Temp`, then it would unpack into `C:\Temp\foo-1.0`; you can use either a archive manipulator with a graphical user interface (such as WinZip) or a command-line tool (such as `unzip` or `pkunzip`) to unpack the archive. Then, open a command prompt window (“DOS box”), and run:

```
cd c:\Temp\foo-1.0
python setup.py install
```
Splitting the job up

Running `setup.py install` builds and installs all modules in one run. If you prefer to work incrementally—especially useful if you want to customize the build process, or if things are going wrong—you can use the setup script to do one thing at a time. This is particularly helpful when the build and install will be done by different users—for example, you might want to build a module distribution and hand it off to a system administrator for installation (or do it yourself, with super-user privileges).

For example, you can build everything in one step, and then install everything in a second step, by invoking the setup script twice:

```bash
python setup.py build
python setup.py install
```

If you do this, you will notice that running the `install` command first runs the `build` command, which—in this case—quickly notices that it has nothing to do, since everything in the `build` directory is up-to-date.

You may not need this ability to break things down often if all you do is install modules downloaded off the ‘net, but it’s very handy for more advanced tasks. If you get into distributing your own Python modules and extensions, you’ll run lots of individual Distutils commands on their own.

How building works

As implied above, the `build` command is responsible for putting the files to install into a `build directory`. By default, this is `build` under the distribution root; if you’re excessively concerned with speed, or want
to keep the source tree pristine, you can change the build directory with the --build-base option. For example:

```
python setup.py build --build-base=/tmp/pybuild/foo-1.0
```

(Or you could do this permanently with a directive in your system or personal Distutils configuration file; see section Distutils Configuration Files.) Normally, this isn’t necessary.

The default layout for the build tree is as follows:

```
--- build/ --- lib/
or
--- build/ --- lib.<plat>/
    temp.<plat>/
```

where `<plat>` expands to a brief description of the current OS/hardware platform and Python version. The first form, with just a `lib` directory, is used for “pure module distributions”—that is, module distributions that include only pure Python modules. If a module distribution contains any extensions (modules written in C/C++), then the second form, with two `<plat>` directories, is used. In that case, the `temp.<plat>` directory holds temporary files generated by the compile/link process that don’t actually get installed. In either case, the `lib` (or `lib.<plat>`) directory contains all Python modules (pure Python and extensions) that will be installed.

In the future, more directories will be added to handle Python scripts, documentation, binary executables, and whatever else is needed to handle the job of installing Python modules and applications.

How installation works

After the `build` command runs (whether you run it explicitly, or the `install` command does it for you), the work of the `install` command is
relatively simple: all it has to do is copy everything under `build/lib` (or `build/lib.plat`) to your chosen installation directory.

If you don’t choose an installation directory—i.e., if you just run `setup.py install`—then the `install` command installs to the standard location for third-party Python modules. This location varies by platform and by how you built/installed Python itself. On Unix (and Mac OS X, which is also Unix-based), it also depends on whether the module distribution being installed is pure Python or contains extensions (“non-pure”):

<table>
<thead>
<tr>
<th>Platform</th>
<th>Standard installation location</th>
<th>Default value</th>
</tr>
</thead>
<tbody>
<tr>
<td>Unix (pure)</td>
<td><code>prefix/lib/pythonX.Y/site-packages</code></td>
<td><code>/usr/local/lib/pythonX.Y/site-packages</code></td>
</tr>
<tr>
<td>Unix (non-pure)</td>
<td><code>exec-prefix/lib/pythonX.Y/site-packages</code></td>
<td><code>/usr/local/lib/pythonX.Y/site-packages</code></td>
</tr>
<tr>
<td>Windows</td>
<td><code>prefix</code></td>
<td><code>C:\Python</code></td>
</tr>
</tbody>
</table>

Notes:

1. Most Linux distributions include Python as a standard part of the system, so `prefix` and `exec-prefix` are usually both `/usr` on Linux. If you build Python yourself on Linux (or any Unix-like system), the default `prefix` and `exec-prefix` are `/usr/local`.
2. The default installation directory on Windows was `C:\Program Files\Python` under Python 1.6a1, 1.5.2, and earlier.

`prefix` and `exec-prefix` stand for the directories that Python is installed to, and where it finds its libraries at run-time. They are always the same under Windows, and very often the same under Unix and Mac OS X. You can find out what your Python installation uses for `prefix` and `exec-prefix` by running Python in interactive
mode and typing a few simple commands. Under Unix, just type `python` at the shell prompt. Under Windows, choose Start ▶ Programs ▶ Python X.Y ▶ Python (command line). Once the interpreter is started, you type Python code at the prompt. For example, on my Linux system, I type the three Python statements shown below, and get the output as shown, to find out my `prefix` and `exec-prefix`:

```
>>> import sys
>>> sys.prefix
'/usr'
>>> sys.exec_prefix
'/usr'
```

If you don’t want to install modules to the standard location, or if you don’t have permission to write there, then you need to read about alternate installations in section *Alternate Installation*. If you want to customize your installation directories more heavily, see section *Custom Installation* on custom installations.
Alternate Installation

Often, it is necessary or desirable to install modules to a location other than the standard location for third-party Python modules. For example, on a Unix system you might not have permission to write to the standard third-party module directory. Or you might wish to try out a module before making it a standard part of your local Python installation. This is especially true when upgrading a distribution already present: you want to make sure your existing base of scripts still works with the new version before actually upgrading.

The Distutils install command is designed to make installing module distributions to an alternate location simple and painless. The basic idea is that you supply a base directory for the installation, and the install command picks a set of directories (called an installation scheme) under this base directory in which to install files. The details differ across platforms, so read whichever of the following sections applies to you.

Alternate installation: the home scheme

The idea behind the “home scheme” is that you build and maintain a personal stash of Python modules. This scheme's name is derived from the idea of a “home” directory on Unix, since it's not unusual for a Unix user to make their home directory have a layout similar to /usr/ or /usr/local/. This scheme can be used by anyone, regardless of the operating system their installing for.

Installing a new module distribution is as simple as

```
python setup.py install --home=<dir>
```

where you can supply any directory you like for the --home option.
On Unix, lazy typists can just type a tilde (~); the `install` command will expand this to your home directory:

```
python setup.py install --home=~
```

The `--home` option defines the installation base directory. Files are installed to the following directories under the installation base as follows:

<table>
<thead>
<tr>
<th>Type of file</th>
<th>Installation Directory</th>
<th>Override option</th>
</tr>
</thead>
<tbody>
<tr>
<td>pure module distribution</td>
<td><code>home/lib/python</code></td>
<td><code>--install-purelib</code></td>
</tr>
<tr>
<td>non-pure module distribution</td>
<td><code>home/lib/python</code></td>
<td><code>--install-platlib</code></td>
</tr>
<tr>
<td>scripts</td>
<td><code>home/bin</code></td>
<td><code>--install-scripts</code></td>
</tr>
<tr>
<td>data</td>
<td><code>home/share</code></td>
<td><code>--install-data</code></td>
</tr>
</tbody>
</table>

*Changed in version 2.4:* The `--home` option used to be supported only on Unix.

**Alternate installation: Unix (the prefix scheme)**

The “prefix scheme” is useful when you wish to use one Python installation to perform the build/install (i.e., to run the setup script), but install modules into the third-party module directory of a different Python installation (or something that looks like a different Python installation). If this sounds a trifle unusual, it is—that’s why the “home scheme” comes first. However, there are at least two known cases where the prefix scheme will be useful.

First, consider that many Linux distributions put Python in `/usr`, rather than the more traditional `/usr/local`. This is entirely appropriate, since in those cases Python is part of “the system” rather than a local add-on. However, if you are installing Python
modules from source, you probably want them to go in /usr/local/lib/python2.X rather than /usr/lib/python2.X. This can be done with

```
/usr/bin/python setup.py install --prefix=/usr/local
```

Another possibility is a network filesystem where the name used to write to a remote directory is different from the name used to read it: for example, the Python interpreter accessed as /usr/local/bin/python might search for modules in /usr/local/lib/python2.X, but those modules would have to be installed to, say, /mnt/@server/export/lib/python2.X. This could be done with

```
/usr/local/bin/python setup.py install --prefix=/mnt/@server/export
```

In either case, the --prefix option defines the installation base, and the --exec-prefix option defines the platform-specific installation base, which is used for platform-specific files. (Currently, this just means non-pure module distributions, but could be expanded to C libraries, binary executables, etc.) If --exec-prefix is not supplied, it defaults to --prefix. Files are installed as follows:

<table>
<thead>
<tr>
<th>Type of file</th>
<th>Installation Directory</th>
<th>Override option</th>
</tr>
</thead>
<tbody>
<tr>
<td>pure module distribution</td>
<td><code>prefix/lib/pythonX.Y/site-packages</code></td>
<td><code>--install-purelib</code></td>
</tr>
<tr>
<td>non-pure module distribution</td>
<td><code>exec-prefix/lib/pythonX.Y/site-packages</code></td>
<td><code>--install-platlib</code></td>
</tr>
<tr>
<td>scripts</td>
<td><code>prefix/bin</code></td>
<td><code>--install-scripts</code></td>
</tr>
<tr>
<td>data</td>
<td><code>prefix/share</code></td>
<td><code>--install-data</code></td>
</tr>
</tbody>
</table>

There is no requirement that --prefix or --exec-prefix actually point to an alternate Python installation; if the directories listed above do not
already exist, they are created at installation time.

Incidentally, the real reason the prefix scheme is important is simply that a standard Unix installation uses the prefix scheme, but with --prefix and --exec-prefix supplied by Python itself as sys.prefix and sys.exec_prefix. Thus, you might think you'll never use the prefix scheme, but every time you run python setup.py install without any other options, you're using it.

Note that installing extensions to an alternate Python installation has no effect on how those extensions are built: in particular, the Python header files (Python.h and friends) installed with the Python interpreter used to run the setup script will be used in compiling extensions. It is your responsibility to ensure that the interpreter used to run extensions installed in this way is compatible with the interpreter used to build them. The best way to do this is to ensure that the two interpreters are the same version of Python (possibly different builds, or possibly copies of the same build). (Of course, if your --prefix and --exec-prefix don't even point to an alternate Python installation, this is immaterial.)

**Alternate installation: Windows (the prefix scheme)**

Windows has no concept of a user's home directory, and since the standard Python installation under Windows is simpler than under Unix, the --prefix option has traditionally been used to install additional packages in separate locations on Windows.

```
python setup.py install --prefix="\Temp\Python"
```

to install modules to the \Temp\Python directory on the current drive.

The installation base is defined by the --prefix option; the --exec-prefix option is not supported under Windows. Files are installed as
### Type of file

Custom Installation

Sometimes, the alternate installation schemes described in section *Alternate Installation* just don’t do what you want. You might want to tweak just one or two directories while keeping everything under the same base directory, or you might want to completely redefine the installation scheme. In either case, you’re creating a custom installation scheme.

You probably noticed the column of “override options” in the tables describing the alternate installation schemes above. Those options are how you define a custom installation scheme. These override options can be relative, absolute, or explicitly defined in terms of one of the installation base directories. (There are two installation base directories, and they are normally the same— they only differ when you use the Unix “prefix scheme” and supply different *--prefix* and *--exec-prefix* options.)

For example, say you’re installing a module distribution to your home directory under Unix—but you want scripts to go in ~/scripts rather than ~/bin. As you might expect, you can override this directory with the *--install-scripts* option; in this case, it makes most sense to supply a relative path, which will be interpreted relative to the installation base directory (your home directory, in this case):

```
python setup.py install --home=~ --install-scripts=scripts
```

Another Unix example: suppose your Python installation was built and installed with a prefix of /usr/local/python, so under a standard installation scripts will wind up in /usr/local/python/bin. If you want them in /usr/local/bin instead, you would supply this absolute directory for the *--install-scripts* option:
python setup.py install --install-scripts=/usr/local/bin

(This performs an installation using the “prefix scheme,” where the prefix is whatever your Python interpreter was installed with—/usr/local/python in this case.)

If you maintain Python on Windows, you might want third-party modules to live in a subdirectory of prefix, rather than right in prefix itself. This is almost as easy as customizing the script installation directory—you just have to remember that there are two types of modules to worry about, pure modules and non-pure modules (i.e., modules from a non-pure distribution). For example:

python setup.py install --install-purelib=Site --install-platlib=Site

The specified installation directories are relative to prefix. Of course, you also have to ensure that these directories are in Python's module search path, such as by putting a .pth file in prefix. See section Modifying Python's Search Path to find out how to modify Python’s search path.

If you want to define an entire installation scheme, you just have to supply all of the installation directory options. The recommended way to do this is to supply relative paths; for example, if you want to maintain all Python module-related files under python in your home directory, and you want a separate directory for each platform that you use your home directory from, you might define the following installation scheme:

python setup.py install --home=~ 
    --install-purelib=python/lib 
    --install-platlib=python/lib.$PLAT 
    --install-scripts=python/scripts 
    --install-data=python/data
or, equivalently,

```bash
python setup.py install --home=~/.python \
--install-purelib=lib \
--install-platlib='lib.$PLAT' \
--install-scripts=scripts \
--install-data=data
```

$PLAT is not (necessarily) an environment variable—it will be expanded by the Distutils as it parses your command line options, just as it does when parsing your configuration file(s).

Obviously, specifying the entire installation scheme every time you install a new module distribution would be very tedious. Thus, you can put these options into your Distutils config file (see section Distutils Configuration Files):

```ini
[install]
install-base=$HOME
install-purelib=python/lib
install-platlib=python/lib.$PLAT
install-scripts=python/scripts
install-data=python/data
```

or, equivalently,

```ini
[install]
install-base=$HOME/python
install-purelib=lib
install-platlib=lib.$PLAT
install-scripts=scripts
install-data=data
```

Note that these two are not equivalent if you supply a different installation base directory when you run the setup script. For example,

```bash
python setup.py install --install-base=/tmp
```

would install pure modules to `/tmp/python/lib` in the first case, and
to `/tmp/lib` in the second case. (For the second case, you probably want to supply an installation base of `/tmp/python`.)

You probably noticed the use of `$HOME` and `$PLAT` in the sample configuration file input. These are Distutils configuration variables, which bear a strong resemblance to environment variables. In fact, you can use environment variables in config files on platforms that have such a notion but the Distutils additionally define a few extra variables that may not be in your environment, such as `$PLAT`. (And of course, on systems that don’t have environment variables, such as Mac OS 9, the configuration variables supplied by the Distutils are the only ones you can use.) See section *Distutils Configuration Files* for details.

## Modifying Python’s Search Path

When the Python interpreter executes an `import` statement, it searches for both Python code and extension modules along a search path. A default value for the path is configured into the Python binary when the interpreter is built. You can determine the path by importing the `sys` module and printing the value of `sys.path`.

```bash
$ python
[GCC 2.96 20000731 (Red Hat Linux 7.3 2.96-112)] on linux2
Type ``help'', ``copyright'', ``credits'' or ``license'' for more info
>>> import sys
>>> sys.path
```

The null string in `sys.path` represents the current working directory.

The expected convention for locally installed packages is to put them
in the .../site-packages/ directory, but you may want to install Python modules into some arbitrary directory. For example, your site may have a convention of keeping all software related to the web server under /www. Add-on Python modules might then belong in /www/python, and in order to import them, this directory must be added to sys.path. There are several different ways to add the directory.

The most convenient way is to add a path configuration file to a directory that’s already on Python’s path, usually to the .../site-packages/ directory. Path configuration files have an extension of .pth, and each line must contain a single path that will be appended to sys.path. (Because the new paths are appended to sys.path, modules in the added directories will not override standard modules. This means you can’t use this mechanism for installing fixed versions of standard modules.)

Paths can be absolute or relative, in which case they’re relative to the directory containing the .pth file. See the documentation of the site module for more information.

A slightly less convenient way is to edit the site.py file in Python’s standard library, and modify sys.path. site.py is automatically imported when the Python interpreter is executed, unless the -S switch is supplied to suppress this behaviour. So you could simply edit site.py and add two lines to it:

```python
import sys
sys.path.append('/www/python/')
```

However, if you reinstall the same major version of Python (perhaps when upgrading from 2.2 to 2.2.2, for example) site.py will be overwritten by the stock version. You’d have to remember that it was modified and save a copy before doing the installation.
There are two environment variables that can modify \texttt{sys.path}. \texttt{PYTHONHOME} sets an alternate value for the prefix of the Python installation. For example, if \texttt{PYTHONHOME} is set to \texttt{/www/python}, the search path will be set to ['', '/www/python/lib/pythonX.Y/', '/www/python/lib/pythonX.Y/plat-linux2', ...].

The \texttt{PYTHONPATH} variable can be set to a list of paths that will be added to the beginning of \texttt{sys.path}. For example, if \texttt{PYTHONPATH} is set to \texttt{/www/python:/opt/py}, the search path will begin with [''/www/python', '/opt/py']. (Note that directories must exist in order to be added to \texttt{sys.path}; the \texttt{site} module removes paths that don't exist.)

Finally, \texttt{sys.path} is just a regular Python list, so any Python application can modify it by adding or removing entries.
Distutils Configuration Files

As mentioned above, you can use Distutils configuration files to record personal or site preferences for any Distutils options. That is, any option to any command can be stored in one of two or three (depending on your platform) configuration files, which will be consulted before the command-line is parsed. This means that configuration files will override default values, and the command-line will in turn override configuration files. Furthermore, if multiple configuration files apply, values from “earlier” files are overridden by “later” files.

Location and names of config files

The names and locations of the configuration files vary slightly across platforms. On Unix and Mac OS X, the three configuration files (in the order they are processed) are:

<table>
<thead>
<tr>
<th>Type of file</th>
<th>Location and filename</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>system</td>
<td>prefix/lib/pythonver/distutils/distutils.cfg</td>
<td>(1)</td>
</tr>
<tr>
<td>personal</td>
<td>$HOME/.pydistutils.cfg</td>
<td>(2)</td>
</tr>
<tr>
<td>local</td>
<td>setup.cfg</td>
<td>(3)</td>
</tr>
</tbody>
</table>

And on Windows, the configuration files are:

<table>
<thead>
<tr>
<th>Type of file</th>
<th>Location and filename</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>system</td>
<td>prefix\Lib\distutils\distutils.cfg</td>
<td>(4)</td>
</tr>
<tr>
<td>personal</td>
<td>%HOME%\pydistutils.cfg</td>
<td>(5)</td>
</tr>
<tr>
<td>local</td>
<td>setup.cfg</td>
<td>(3)</td>
</tr>
</tbody>
</table>

Notes:
1. Strictly speaking, the system-wide configuration file lives in the directory where the Distutils are installed; under Python 1.6 and later on Unix, this is as shown. For Python 1.5.2, the Distutils will normally be installed to \texttt{\texttt{prefix/lib/python1.5/site-packages/distutils}}, so the system configuration file should be put there under Python 1.5.2.

2. On Unix, if the \texttt{HOME} environment variable is not defined, the user's home directory will be determined with the \texttt{getpwuid()} function from the standard \texttt{pwd} module.

3. i.e., in the current directory (usually the location of the setup script).

4. (See also note (1).) Under Python 1.6 and later, Python's default "installation prefix" is \texttt{C:\Python}, so the system configuration file is normally \texttt{C:\Python\Lib\distutils\distutils.cfg}. Under Python 1.5.2, the default prefix was \texttt{C:\Program Files\Python}, and the Distutils were not part of the standard library—so the system configuration file would be \texttt{C:\Program Files\Python\distutils\distutils.cfg} in a standard Python 1.5.2 installation under Windows.

5. On Windows, if the \texttt{HOME} environment variable is not defined, no personal configuration file will be found or used. (In other words, the Distutils make no attempt to guess your home directory on Windows.)

### Syntax of config files

The Distutils configuration files all have the same syntax. The config files are grouped into sections. There is one section for each Distutils command, plus a \texttt{global} section for global options that affect every command. Each section consists of one option per line, specified as \texttt{option=value}.

For example, the following is a complete config file that just forces all
commands to run quietly by default:

```
[global]
verbose=0
```

If this is installed as the system config file, it will affect all processing of any Python module distribution by any user on the current system. If it is installed as your personal config file (on systems that support them), it will affect only module distributions processed by you. And if it is used as the `setup.cfg` for a particular module distribution, it affects only that distribution.

You could override the default “build base” directory and make the `build*` commands always forcibly rebuild all files with the following:

```
[build]
build-base=blib
force=1
```

which corresponds to the command-line arguments

```
python setup.py build --build-base=blib --force
```

except that including the `build` command on the command-line means that command will be run. Including a particular command in config files has no such implication; it only means that if the command is run, the options in the config file will apply. (Or if other commands that derive values from it are run, they will use the values in the config file.)

You can find out the complete list of options for any command using the `--help` option, e.g.:

```
python setup.py build --help
```

and you can find out the complete list of global options by using `--help` without a command:
python setup.py --help

See also the “Reference” section of the “Distributing Python Modules” manual.
Building Extensions: Tips and Tricks

Whenever possible, the Distutils try to use the configuration information made available by the Python interpreter used to run the `setup.py` script. For example, the same compiler and linker flags used to compile Python will also be used for compiling extensions. Usually this will work well, but in complicated situations this might be inappropriate. This section discusses how to override the usual Distutils behaviour.

Tweaking compiler/linker flags

Compiling a Python extension written in C or C++ will sometimes require specifying custom flags for the compiler and linker in order to use a particular library or produce a special kind of object code. This is especially true if the extension hasn’t been tested on your platform, or if you’re trying to cross-compile Python.

In the most general case, the extension author might have foreseen that compiling the extensions would be complicated, and provided a `Setup` file for you to edit. This will likely only be done if the module distribution contains many separate extension modules, or if they often require elaborate sets of compiler flags in order to work.

A `setup` file, if present, is parsed in order to get a list of extensions to build. Each line in a `Setup` describes a single module. Lines have the following structure:

```
module ... [sourcefile ...] [cpparg ...] [library ...]
```

Let’s examine each of the fields in turn.

- `module` is the name of the extension module to be built, and
should be a valid Python identifier. You can’t just change this in order to rename a module (edits to the source code would also be needed), so this should be left alone.

- sourcefile is anything that's likely to be a source code file, at least judging by the filename. Filenames ending in .c are assumed to be written in C, filenames ending in .cc, and .c++ are assumed to be C++, and filenames ending in .m or .mm are assumed to be in Objective C.
- cpparg is an argument for the C preprocessor, and is anything starting with -I, -D, -U or -C.
- library is anything ending in .a or beginning with -l or -L.

If a particular platform requires a special library on your platform, you can add it by editing the Setup file and running python setup.py build. For example, if the module defined by the line

```
foo foomodule.c
```

must be linked with the math library libm.a on your platform, simply add -lm to the line:

```
foo foomodule.c -lm
```

Arbitrary switches intended for the compiler or the linker can be supplied with the -Xcompiler arg and -Xlinker arg options:

```
foo foomodule.c -Xcompiler -o32 -Xlinker -shared -lm
```

The next option after -Xcompiler and -Xlinker will be appended to the proper command line, so in the above example the compiler will be passed the -o32 option, and the linker will be passed -shared. If a compiler option requires an argument, you’ll have to supply multiple -Xcompiler options; for example, to pass -x c++ the Setup file would have to contain -Xcompiler -x -Xcompiler c++. 
Compiler flags can also be supplied through setting the **CFLAGS** environment variable. If set, the contents of **CFLAGS** will be added to the compiler flags specified in the setup file.

### Using non-Microsoft compilers on Windows

#### Borland/CodeGear C++

This subsection describes the necessary steps to use Distutils with the Borland C++ compiler version 5.5. First you have to know that Borland’s object file format (OMF) is different from the format used by the Python version you can download from the Python or ActiveState Web site. (Python is built with Microsoft Visual C++, which uses COFF as the object file format.) For this reason you have to convert Python’s library `python25.lib` into the Borland format. You can do this as follows:

```
coff2omf python25.lib python25_bcpp.lib
```

The `coff2omf` program comes with the Borland compiler. The file `python25.lib` is in the `Libs` directory of your Python installation. If your extension uses other libraries (zlib, ...) you have to convert them too.

The converted files have to reside in the same directories as the normal libraries.

How does Distutils manage to use these libraries with their changed names? If the extension needs a library (eg. `foo`) Distutils checks first if it finds a library with suffix `_bcpp` (eg. `foo_bcpp.lib`) and then uses this library. In the case it doesn’t find such a special library it uses the default name (`foo.lib.`) [1]

To let Distutils compile your extension with Borland C++ you now
have to type:

```
python setup.py build --compiler=bcpp
```

If you want to use the Borland C++ compiler as the default, you could specify this in your personal or system-wide configuration file for Distutils (see section *Distutils Configuration Files.*)

---

**GNU C / Cygwin / MinGW**

These instructions only apply if you’re using a version of Python prior to 2.4.1 with a MinGW prior to 3.0.0 (with binutils-2.13.90-20030111-1).

This section describes the necessary steps to use Distutils with the GNU C/C++ compilers in their Cygwin and MinGW distributions. [2] For a Python interpreter that was built with Cygwin, everything should work without any of these following steps.

These compilers require some special libraries. This task is more complex than for Borland’s C++, because there is no program to convert the library. First you have to create a list of symbols which the Python DLL exports. (You can find a good program for this task at http://www.emmestech.com/software/cygwin/pexports-0.43/download_pexports.html)
pexports python25.dll >python25.def

The location of an installed `python25.dll` will depend on the installation options and the version and language of Windows. In a “just for me” installation, it will appear in the root of the installation directory. In a shared installation, it will be located in the system directory.

Then you can create from these information an import library for gcc.

```
/cygwin/bin/dlltool --dllname python25.dll --def python25.def
```

The resulting library has to be placed in the same directory as `python25.lib`. (Should be the `libs` directory under your Python installation directory.)

If your extension uses other libraries (zlib,...) you might have to convert them too. The converted files have to reside in the same directories as the normal libraries do.

To let Distutils compile your extension with Cygwin you now have to type

```
python setup.py build --compiler=cygwin
```

and for Cygwin in no-cygwin mode [3] or for MinGW type:

```
python setup.py build --compiler=mingw32
```

If you want to use any of these options/compilers as default, you should consider to write it in your personal or system-wide configuration file for Distutils (see section Distutils Configuration Files.)

Building Python modules on MS Windows platform with MinGW

Information about building the required libraries for the MinGW environment.

Footnotes

[1] This also means you could replace all existing COFF-libraries with OMF-libraries of the same name.

[3] Then you have no POSIX emulation available, but you also don't need cygwin1.dll.
This document describes the Python Distribution Utilities ("Distutils") from the module developer’s point of view, describing how to use the Distutils to make Python modules and extensions easily available to a wider audience with very little overhead for build/release/install mechanics.

The Python language has a substantial body of documentation, much of it contributed by various authors. The markup used for the Python documentation is reStructuredText, developed by the docutils project, amended by custom directives and using a toolset named Sphinx to postprocess the HTML output.

This document describes the style guide for our documentation, the custom reStructuredText markup introduced to support Python documentation and how it should be used, as well as the Sphinx build system.

If you’re interested in contributing to Python’s documentation, there’s no need to write reStructuredText if you’re not so inclined; plain text contributions are more than welcome as well.
