The `bdb` module handles basic debugger functions, like setting breakpoints or managing execution via the debugger.

The following exception is defined:

exception `bdb.BdbQuit`

Exception raised by the `Bdb` class for quitting the debugger.

The `bdb` module also defines two classes:

class `bdb.Breakpoint`(*self*, *file*, *line*, *temporary=0*, *cond=None*, *funcname=None*)

This class implements temporary breakpoints, ignore counts, disabling and (re-)enabling, and conditionals.

Breakpoints are indexed by number through a list called `bpbynumber` and by (`file`, `line`) pairs through `bp1ist`. The former points to a single instance of class `Breakpoint`. The latter points to a list of such instances since there may be more than one breakpoint per line.

When creating a breakpoint, its associated filename should be in canonical form. If a *funcname* is defined, a breakpoint hit will be counted when the first line of that function is executed. A conditional breakpoint always counts a hit.

`Breakpoint` instances have the following methods:

`deleteMe()`

Delete the breakpoint from the list associated to a file/line. If it is the last breakpoint in that position, it also deletes the entry for the file/line.

enable()

Mark the breakpoint as enabled.

disable()

Mark the breakpoint as disabled.

bpformat()

Return a string with all the information about the breakpoint, nicely formatted:

- The breakpoint number.
- If it is temporary or not.
- Its file,line position.
- The condition that causes a break.
- If it must be ignored the next N times.
- The breakpoint hit count.

New in version 3.2.

bpprint(out=None)

Print the output of **bpformat()** to the file *out*, or if it is **None**, to standard output.

class **bdb.Bdb(skip=None)**

The **Bdb** class acts as a generic Python debugger base class.

This class takes care of the details of the trace facility; a derived class should implement user interaction. The standard debugger class (**pdb.Pdb**) is an example.

The *skip* argument, if given, must be an iterable of glob-style

module name patterns. The debugger will not step into frames that originate in a module that matches one of these patterns. Whether a frame is considered to originate in a certain module is determined by the `__name__` in the frame globals.

New in version 3.1: The `skip` argument.

The following methods of `Bdb` normally don't need to be overridden.

`canonic(filename)`

Auxiliary method for getting a filename in a canonical form, that is, as a case-normalized (on case-insensitive filesystems) absolute path, stripped of surrounding angle brackets.

`reset()`

Set the `botframe`, `stopframe`, `returnframe` and `quitting` attributes with values ready to start debugging.

`trace_dispatch(frame, event, arg)`

This function is installed as the trace function of debugged frames. Its return value is the new trace function (in most cases, that is, itself).

The default implementation decides how to dispatch a frame, depending on the type of event (passed as a string) that is about to be executed. `event` can be one of the following:

- `"line"`: A new line of code is going to be executed.
- `"call"`: A function is about to be called, or another code block entered.
- `"return"`: A function or other code block is about to return.
- `"exception"`: An exception has occurred.

- `"c_call"`: A C function is about to be called.
- `"c_return"`: A C function has returned.
- `"c_exception"`: A C function has raised an exception.

For the Python events, specialized functions (see below) are called. For the C events, no action is taken.

The `arg` parameter depends on the previous event.

See the documentation for `sys.settrace()` for more information on the trace function. For more information on code and frame objects, refer to *The standard type hierarchy*.

`dispatch_line(frame)`

If the debugger should stop on the current line, invoke the `user_line()` method (which should be overridden in subclasses). Raise a `BdbQuit` exception if the `Bdb.quitting` flag is set (which can be set from `user_line()`). Return a reference to the `trace_dispatch()` method for further tracing in that scope.

`dispatch_call(frame, arg)`

If the debugger should stop on this function call, invoke the `user_call()` method (which should be overridden in subclasses). Raise a `BdbQuit` exception if the `Bdb.quitting` flag is set (which can be set from `user_call()`). Return a reference to the `trace_dispatch()` method for further tracing in that scope.

`dispatch_return(frame, arg)`

If the debugger should stop on this function return, invoke the `user_return()` method (which should be overridden in subclasses). Raise a `BdbQuit` exception if the `Bdb.quitting` flag is set (which can be set from `user_return()`). Return a

reference to the `trace_dispatch()` method for further tracing in that scope.

dispatch_exception(*frame*, *arg*)

If the debugger should stop at this exception, invokes the `user_exception()` method (which should be overridden in subclasses). Raise a `BdbQuit` exception if the `Bdb.quitting` flag is set (which can be set from `user_exception()`). Return a reference to the `trace_dispatch()` method for further tracing in that scope.

Normally derived classes don't override the following methods, but they may if they want to redefine the definition of stopping and breakpoints.

stop_here(*frame*)

This method checks if the *frame* is somewhere below `botframe` in the call stack. `botframe` is the frame in which debugging started.

break_here(*frame*)

This method checks if there is a breakpoint in the filename and line belonging to *frame* or, at least, in the current function. If the breakpoint is a temporary one, this method deletes it.

break_anywhere(*frame*)

This method checks if there is a breakpoint in the filename of the current frame.

Derived classes should override these methods to gain control over debugger operation.

user_call(*frame*, *argument_list*)

This method is called from `dispatch_call()` when there is the

possibility that a break might be necessary anywhere inside the called function.

user_line(*frame*)

This method is called from `dispatch_line()` when either `stop_here()` or `break_here()` yields True.

user_return(*frame*, *return_value*)

This method is called from `dispatch_return()` when `stop_here()` yields True.

user_exception(*frame*, *exc_info*)

This method is called from `dispatch_exception()` when `stop_here()` yields True.

do_clear(*arg*)

Handle how a breakpoint must be removed when it is a temporary one.

This method must be implemented by derived classes.

Derived classes and clients can call the following methods to affect the stepping state.

set_step()

Stop after one line of code.

set_next(*frame*)

Stop on the next line in or below the given frame.

set_return(*frame*)

Stop when returning from the given frame.

set_until(*frame*)

Stop when the line with the line no greater than the current

one is reached or when returning from current frame

set_trace([*frame*])

Start debugging from *frame*. If *frame* is not specified, debugging starts from caller's frame.

set_continue()

Stop only at breakpoints or when finished. If there are no breakpoints, set the system trace function to None.

set_quit()

Set the `quitting` attribute to True. This raises `BdbQuit` in the next call to one of the `dispatch_*`() methods.

Derived classes and clients can call the following methods to manipulate breakpoints. These methods return a string containing an error message if something went wrong, or `None` if all is well.

set_break(*filename*, *lineno*, *temporary=0*, *cond*, *funcname*)

Set a new breakpoint. If the *lineno* line doesn't exist for the *filename* passed as argument, return an error message. The *filename* should be in canonical form, as described in the `canonic()` method.

clear_break(*filename*, *lineno*)

Delete the breakpoints in *filename* and *lineno*. If none were set, an error message is returned.

clear_bpbynumber(*arg*)

Delete the breakpoint which has the index *arg* in the `Breakpoint.bpbynumber`. If *arg* is not numeric or out of range, return an error message.

clear_all_file_breaks(filename)

Delete all breakpoints in *filename*. If none were set, an error message is returned.

clear_all_breaks()

Delete all existing breakpoints.

get_bpbynumber(arg)

Return a breakpoint specified by the given number. If *arg* is a string, it will be converted to a number. If *arg* is a non-numeric string, if the given breakpoint never existed or has been deleted, a **ValueError** is raised.

New in version 3.2.

get_break(filename, lineno)

Check if there is a breakpoint for *lineno* of *filename*.

get_breaks(filename, lineno)

Return all breakpoints for *lineno* in *filename*, or an empty list if none are set.

get_file_breaks(filename)

Return all breakpoints in *filename*, or an empty list if none are set.

get_all_breaks()

Return all breakpoints that are set.

Derived classes and clients can call the following methods to get a data structure representing a stack trace.

get_stack(f, t)

Get a list of records for a frame and all higher (calling) and lower frames, and the size of the higher part.

format_stack_entry(*frame_lineno*, *lprefix*=': ')

Return a string with information about a stack entry, identified by a (*frame*, *lineno*) tuple:

- The canonical form of the filename which contains the frame.
- The function name, or "<lambda>".
- The input arguments.
- The return value.
- The line of code (if it exists).

The following two methods can be called by clients to use a debugger to debug a *statement*, given as a string.

run(*cmd*, *globals*=None, *locals*=None)

Debug a statement executed via the `exec()` function. *globals* defaults to `__main__.__dict__`, *locals* defaults to *globals*.

runeval(*expr*, *globals*=None, *locals*=None)

Debug an expression executed via the `eval()` function. *globals* and *locals* have the same meaning as in `run()`.

runctx(*cmd*, *globals*, *locals*)

For backwards compatibility. Calls the `run()` method.

runcall(*func*, **args*, ***kws*)

Debug a single function call, and return its result.

Finally, the module defines the following functions:

`bdb.checkfuncname`(*b*, *frame*)

Check whether we should break here, depending on the way the breakpoint *b* was set.

If it was set via line number, it checks if `b.line` is the same as the

one in the frame also passed as argument. If the breakpoint was set via function name, we have to check we are in the right frame (the right function) and if we are in its first executable line.

`bdb.effective(file, line, frame)`

Determine if there is an effective (active) breakpoint at this line of code. Return a tuple of the breakpoint and a boolean that indicates if it is ok to delete a temporary breakpoint. Return `(None, None)` if there is no matching breakpoint.

`bdb.set_trace()`

Start debugging with a `Bdb` instance from caller's frame.

26.2. pdb — The Python Debugger

The module `pdb` defines an interactive source code debugger for Python programs. It supports setting (conditional) breakpoints and single stepping at the source line level, inspection of stack frames, source code listing, and evaluation of arbitrary Python code in the context of any stack frame. It also supports post-mortem debugging and can be called under program control.

The debugger is extensible – it is actually defined as the class `Pdb`. This is currently undocumented but easily understood by reading the source. The extension interface uses the modules `bdb` and `cmd`.

The debugger's prompt is `(Pdb)`. Typical usage to run a program under control of the debugger is:

```
>>> import pdb
>>> import mymodule
>>> pdb.run('mymodule.test()')
> <string>(0)?()
(Pdb) continue
> <string>(1)?()
(Pdb) continue
NameError: 'spam'
> <string>(1)?()
(Pdb)
```

`pdb.py` can also be invoked as a script to debug other scripts. For example:

```
python3 -m pdb myscript.py
```

When invoked as a script, `pdb` will automatically enter post-mortem debugging if the program being debugged exits abnormally. After post-mortem debugging (or after normal exit of the program), `pdb` will restart the program. Automatic restarting preserves `pdb`'s state (such

as breakpoints) and in most cases is more useful than quitting the debugger upon program's exit.

New in version 3.2: `pdb.py` now accepts a `-c` option that executes commands as if given in a `.pdbrc` file, see [Debugger Commands](#).

The typical usage to break into the debugger from a running program is to insert

```
import pdb; pdb.set_trace()
```

at the location you want to break into the debugger. You can then step through the code following this statement, and continue running without the debugger using the `continue` command.

The typical usage to inspect a crashed program is:

```
>>> import pdb
>>> import mymodule
>>> mymodule.test()
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
  File "./mymodule.py", line 4, in test
    test2()
  File "./mymodule.py", line 3, in test2
    print(spam)
NameError: spam
>>> pdb.pm()
> ./mymodule.py(3)test2()
-> print(spam)
(Pdb)
```

The module defines the following functions; each enters the debugger in a slightly different way:

`pdb.run(statement, globals=None, locals=None)`

Execute the *statement* (given as a string or a code object) under debugger control. The debugger prompt appears before any code

is executed; you can set breakpoints and type `continue`, or you can step through the statement using `step` or `next` (all these commands are explained below). The optional *globals* and *locals* arguments specify the environment in which the code is executed; by default the dictionary of the module `__main__` is used. (See the explanation of the built-in `exec()` or `eval()` functions.)

`pdb.runeval(expression, globals=None, locals=None)`

Evaluate the *expression* (given as a string or a code object) under debugger control. When `runeval()` returns, it returns the value of the expression. Otherwise this function is similar to `run()`.

`pdb.runcall(function, *args, **kwargs)`

Call the *function* (a function or method object, not a string) with the given arguments. When `runcall()` returns, it returns whatever the function call returned. The debugger prompt appears as soon as the function is entered.

`pdb.set_trace()`

Enter the debugger at the calling stack frame. This is useful to hard-code a breakpoint at a given point in a program, even if the code is not otherwise being debugged (e.g. when an assertion fails).

`pdb.post_mortem(traceback=None)`

Enter post-mortem debugging of the given *traceback* object. If no *traceback* is given, it uses the one of the exception that is currently being handled (an exception must be being handled if the default is to be used).

`pdb.pm()`

Enter post-mortem debugging of the traceback found in

`sys.last_traceback.`

The `run*` functions and `set_trace()` are aliases for instantiating the `Pdb` class and calling the method of the same name. If you want to access further features, you have to do this yourself:

```
class pdb.Pdb(completekey='tab', stdin=None, stdout=None,
skip=None, nosigint=False)
```

`Pdb` is the debugger class.

The `completekey`, `stdin` and `stdout` arguments are passed to the underlying `cmd.Cmd` class; see the description there.

The `skip` argument, if given, must be an iterable of glob-style module name patterns. The debugger will not step into frames that originate in a module that matches one of these patterns. [1]

By default, `Pdb` sets a handler for the SIGINT signal (which is sent when the user presses Ctrl-C on the console) when you give a `continue` command. This allows you to break into the debugger again by pressing Ctrl-C. If you want `Pdb` not to touch the SIGINT handler, set `nosigint` to true.

Example call to enable tracing with `skip`:

```
import pdb; pdb.Pdb(skip=['django.*']).set_trace()
```

New in version 3.1: The `skip` argument.

New in version 3.2: The `nosigint` argument. Previously, a SIGINT handler was never set by `Pdb`.

`run(statement, globals=None, locals=None)`

`runeval(expression, globals=None, locals=None)`

`runcall(function, *args, **kwargs)`

set_trace()

See the documentation for the functions explained above.

26.2.1. Debugger Commands

The commands recognized by the debugger are listed below. Most commands can be abbreviated to one or two letters as indicated; e.g. `h(e1p)` means that either `h` or `he1p` can be used to enter the help command (but not `he` or `he1`, nor `H` or `He1p` or `HELP`). Arguments to commands must be separated by whitespace (spaces or tabs). Optional arguments are enclosed in square brackets (`[]`) in the command syntax; the square brackets must not be typed. Alternatives in the command syntax are separated by a vertical bar (`|`).

Entering a blank line repeats the last command entered. Exception: if the last command was a `list` command, the next 11 lines are listed.

Commands that the debugger doesn't recognize are assumed to be Python statements and are executed in the context of the program being debugged. Python statements can also be prefixed with an exclamation point (`!`). This is a powerful way to inspect the program being debugged; it is even possible to change a variable or call a function. When an exception occurs in such a statement, the exception name is printed but the debugger's state is not changed.

The debugger supports *aliases*. Aliases can have parameters which allows one a certain level of adaptability to the context under examination.

Multiple commands may be entered on a single line, separated by `;;`. (A single `;` is not used as it is the separator for multiple commands in a line that is passed to the Python parser.) No intelligence is applied to separating the commands; the input is split at the first `;;` pair, even if it is in the middle of a quoted string.

If a file `.pdbrc` exists in the user's home directory or in the current directory, it is read in and executed as if it had been typed at the debugger prompt. This is particularly useful for aliases. If both files exist, the one in the home directory is read first and aliases defined there can be overridden by the local file.

Changed in version 3.2: `.pdbrc` can now contain commands that continue debugging, such as `continue` or `next`. Previously, these commands had no effect.

h(e1p) [command]

Without argument, print the list of available commands. With a *command* as argument, print help about that command. `help pdb` displays the full documentation (the docstring of the `pdb` module). Since the *command* argument must be an identifier, `help exec` must be entered to get help on the `!` command.

w(herE)

Print a stack trace, with the most recent frame at the bottom. An arrow indicates the current frame, which determines the context of most commands.

d(own) [count]

Move the current frame *count* (default one) levels down in the stack trace (to a newer frame).

u(p) [count]

Move the current frame *count* (default one) levels up in the stack trace (to an older frame).

b(reak) [(*[filename:]lineno* | *function*) [, *condition*]]

With a *lineno* argument, set a break there in the current file. With a *function* argument, set a break at the first executable statement within that function. The line number may be prefixed with a filename and a colon, to specify a breakpoint in another file

(probably one that hasn't been loaded yet). The file is searched on `sys.path`. Note that each breakpoint is assigned a number to which all the other breakpoint commands refer.

If a second argument is present, it is an expression which must evaluate to true before the breakpoint is honored.

Without argument, list all breaks, including for each breakpoint, the number of times that breakpoint has been hit, the current ignore count, and the associated condition if any.

tbreak `[(filename:lineno | function) [, condition]]`

Temporary breakpoint, which is removed automatically when it is first hit. The arguments are the same as for `break`.

cl(ear) `[filename:lineno | bnumber [bnumber ...]]`

With a *filename:lineno* argument, clear all the breakpoints at this line. With a space separated list of breakpoint numbers, clear those breakpoints. Without argument, clear all breaks (but first ask confirmation).

disable `[bnumber [bnumber ...]]`

Disable the breakpoints given as a space separated list of breakpoint numbers. Disabling a breakpoint means it cannot cause the program to stop execution, but unlike clearing a breakpoint, it remains in the list of breakpoints and can be (re-)enabled.

enable `[bnumber [bnumber ...]]`

Enable the breakpoints specified.

ignore `bnumber [count]`

Set the ignore count for the given breakpoint number. If count is omitted, the ignore count is set to 0. A breakpoint becomes active when the ignore count is zero. When non-zero, the count is decremented each time the breakpoint is reached and the

breakpoint is not disabled and any associated condition evaluates to true.

condition *bpnumber* [*condition*]

Set a new *condition* for the breakpoint, an expression which must evaluate to true before the breakpoint is honored. If *condition* is absent, any existing condition is removed; i.e., the breakpoint is made unconditional.

commands [*bpnumber*]

Specify a list of commands for breakpoint number *bpnumber*. The commands themselves appear on the following lines. Type a line containing just `end` to terminate the commands. An example:

```
(Pdb) commands 1
(com) print some_variable
(com) end
(Pdb)
```

To remove all commands from a breakpoint, type `commands` and follow it immediately with `end`; that is, give no commands.

With no *bpnumber* argument, `commands` refers to the last breakpoint set.

You can use breakpoint commands to start your program up again. Simply use the `continue` command, or `step`, or any other command that resumes execution.

Specifying any command resuming execution (currently `continue`, `step`, `next`, `return`, `jump`, `quit` and their abbreviations) terminates the command list (as if that command was immediately followed by `end`). This is because any time you resume execution (even with a simple `next` or `step`), you may encounter another breakpoint—which could have its own command list, leading to ambiguities about which list to execute.

If you use the 'silent' command in the command list, the usual message about stopping at a breakpoint is not printed. This may be desirable for breakpoints that are to print a specific message and then continue. If none of the other commands print anything, you see no sign that the breakpoint was reached.

s(step)

Execute the current line, stop at the first possible occasion (either in a function that is called or on the next line in the current function).

n(ext)

Continue execution until the next line in the current function is reached or it returns. (The difference between **next** and **step** is that **step** stops inside a called function, while **next** executes called functions at (nearly) full speed, only stopping at the next line in the current function.)

unt(il) [lineno]

Without argument, continue execution until the line with a number greater than the current one is reached.

With a line number, continue execution until a line with a number greater or equal to that is reached. In both cases, also stop when the current frame returns.

Changed in version 3.2: Allow giving an explicit line number.

r(eturn)

Continue execution until the current function returns.

c(ontinue)

Continue execution, only stop when a breakpoint is encountered.

j(ump) lineno

Set the next line that will be executed. Only available in the

bottom-most frame. This lets you jump back and execute code again, or jump forward to skip code that you don't want to run.

It should be noted that not all jumps are allowed – for instance it is not possible to jump into the middle of a `for` loop or out of a `finally` clause.

l(ist) [first[, last]]

List source code for the current file. Without arguments, list 11 lines around the current line or continue the previous listing. With `.` as argument, list 11 lines around the current line. With one argument, list 11 lines around at that line. With two arguments, list the given range; if the second argument is less than the first, it is interpreted as a count.

The current line in the current frame is indicated by `->`. If an exception is being debugged, the line where the exception was originally raised or propagated is indicated by `>>`, if it differs from the current line.

New in version 3.2: The `>>` marker.

ll | `longlist`

List all source code for the current function or frame. Interesting lines are marked as for `list`.

New in version 3.2.

a(rgs)

Print the argument list of the current function.

p(rint) `expression`

Evaluate the *expression* in the current context and print its value.

pp `expression`

Like the `print` command, except the value of the expression is

pretty-printed using the `pprint` module.

whatis *expression*

Print the type of the *expression*.

source *expression*

Try to get source code for the given object and display it.

New in version 3.2.

display [*expression*]

Display the value of the *expression* if it changed, each time execution stops in the current frame.

Without *expression*, list all display expressions for the current frame.

New in version 3.2.

undisplay [*expression*]

Do not display the *expression* any more in the current frame. Without *expression*, clear all display expressions for the current frame.

New in version 3.2.

interact

Start an interactive interpreter (using the `code` module) whose global namespace contains all the (global and local) names found in the current scope.

New in version 3.2.

alias [*name* [*command*]]

Create an alias called *name* that executes *command*. The *command* must *not* be enclosed in quotes. Replaceable parameters can be indicated by `%1`, `%2`, and so on, while `%*` is

replaced by all the parameters. If no command is given, the current alias for *name* is shown. If no arguments are given, all aliases are listed.

Aliases may be nested and can contain anything that can be legally typed at the pdb prompt. Note that internal pdb commands *can* be overridden by aliases. Such a command is then hidden until the alias is removed. Aliasing is recursively applied to the first word of the command line; all other words in the line are left alone.

As an example, here are two useful aliases (especially when placed in the `.pdbrc` file):

```
# Print instance variables (usage "pi classInst")
alias pi for k in %1.__dict__.keys(): print("%1.",k,"=",%1._
# Print instance variables in self
alias ps pi self
```

unalias name

Delete the specified alias.

! statement

Execute the (one-line) *statement* in the context of the current stack frame. The exclamation point can be omitted unless the first word of the statement resembles a debugger command. To set a global variable, you can prefix the assignment command with a **global** statement on the same line, e.g.:

```
(Pdb) global list_options; list_options = ['-1']
(Pdb)
```

run [args ...]

restart [args ...]

Restart the debugged Python program. If an argument is supplied, it is split with **shlex** and the result is used as the new

`sys.argv`. History, breakpoints, actions and debugger options are preserved. `restart` is an alias for `run`.

q(uit)

Quit from the debugger. The program being executed is aborted.

Footnotes

[1] Whether a frame is considered to originate in a certain module is determined by the `__name__` in the frame globals.

 [Python v3.2 documentation](#) » [The Python Standard Library](#) [previous](#) | [next](#) | [modules](#) | [index](#)

» [26. Debugging and Profiling](#) »

26.3. The Python Profilers

Source code: [Lib/profile.py](#) and [Lib/pstats.py](#)

26.3.1. Introduction to the profilers

A *profiler* is a program that describes the run time performance of a program, providing a variety of statistics. This documentation describes the profiler functionality provided in the modules `cProfile`, `profile` and `pstats`. This profiler provides *deterministic profiling* of Python programs. It also provides a series of report generation tools to allow users to rapidly examine the results of a profile operation.

The Python standard library provides two different profilers:

1. `cProfile` is recommended for most users; it's a C extension with reasonable overhead that makes it suitable for profiling long-running programs. Based on `lsprof`, contributed by Brett Rosen and Ted Czotter.
2. `profile`, a pure Python module whose interface is imitated by `cProfile`. Adds significant overhead to profiled programs. If you're trying to extend the profiler in some way, the task might be easier with this module. Copyright © 1994, by InfoSeek Corporation.

The `profile` and `cProfile` modules export the same interface, so they are mostly interchangeable; `cProfile` has a much lower overhead but is newer and might not be available on all systems. `cProfile` is really a compatibility layer on top of the internal `_lsprof` module.

Note: The profiler modules are designed to provide an execution profile for a given program, not for benchmarking purposes (for that, there is `timeit` for reasonably accurate results). This particularly applies to benchmarking Python code against C code: the profilers introduce overhead for Python code, but not for C-

level functions, and so the C code would seem faster than any Python one.

26.3.2. Instant User's Manual

This section is provided for users that “don't want to read the manual.” It provides a very brief overview, and allows a user to rapidly perform profiling on an existing application.

To profile an application with a main entry point of `foo()`, you would add the following to your module:

```
import cProfile
cProfile.run('foo()')
```

(Use `profile` instead of `cProfile` if the latter is not available on your system.)

The above action would cause `foo()` to be run, and a series of informative lines (the profile) to be printed. The above approach is most useful when working with the interpreter. If you would like to save the results of a profile into a file for later examination, you can supply a file name as the second argument to the `run()` function:

```
import cProfile
cProfile.run('foo()', 'fooprof')
```

The file `cProfile.py` can also be invoked as a script to profile another script. For example:

```
python -m cProfile myscript.py
```

`cProfile.py` accepts two optional arguments on the command line:

```
cProfile.py [-o output_file] [-s sort_order]
```

`-s` only applies to standard output (`-o` is not supplied). Look in the

`stats` documentation for valid sort values.

When you wish to review the profile, you should use the methods in the `pstats` module. Typically you would load the statistics data as follows:

```
import pstats
p = pstats.Stats('fooprof')
```

The class `stats` (the above code just created an instance of this class) has a variety of methods for manipulating and printing the data that was just read into `p`. When you ran `cProfile.run()` above, what was printed was the result of three method calls:

```
p.strip_dirs().sort_stats(-1).print_stats()
```

The first method removed the extraneous path from all the module names. The second method sorted all the entries according to the standard module/line/name string that is printed. The third method printed out all the statistics. You might try the following sort calls:

```
p.sort_stats('name')
p.print_stats()
```

The first call will actually sort the list by function name, and the second call will print out the statistics. The following are some interesting calls to experiment with:

```
p.sort_stats('cumulative').print_stats(10)
```

This sorts the profile by cumulative time in a function, and then only prints the ten most significant lines. If you want to understand what algorithms are taking time, the above line is what you would use.

If you were looking to see what functions were looping a lot, and taking a lot of time, you would do:

```
p.sort_stats('time').print_stats(10)
```

to sort according to time spent within each function, and then print the statistics for the top ten functions.

You might also try:

```
p.sort_stats('file').print_stats('__init__')
```

This will sort all the statistics by file name, and then print out statistics for only the class init methods (since they are spelled with `__init__` in them). As one final example, you could try:

```
p.sort_stats('time', 'cum').print_stats(.5, 'init')
```

This line sorts statistics with a primary key of time, and a secondary key of cumulative time, and then prints out some of the statistics. To be specific, the list is first culled down to 50% (re: `.5`) of its original size, then only lines containing `init` are maintained, and that sub-sub-list is printed.

If you wondered what functions called the above functions, you could now (`p` is still sorted according to the last criteria) do:

```
p.print_callers(.5, 'init')
```

and you would get a list of callers for each of the listed functions.

If you want more functionality, you're going to have to read the manual, or guess what the following functions do:

```
p.print_callees()  
p.add('fooprof')
```

Invoked as a script, the `pstats` module is a statistics browser for reading and examining profile dumps. It has a simple line-oriented

interface (implemented using `cmd`) and interactive help.

26.3.3. What Is Deterministic Profiling?

Deterministic profiling is meant to reflect the fact that all *function call*, *function return*, and *exception* events are monitored, and precise timings are made for the intervals between these events (during which time the user's code is executing). In contrast, *statistical profiling* (which is not done by this module) randomly samples the effective instruction pointer, and deduces where time is being spent. The latter technique traditionally involves less overhead (as the code does not need to be instrumented), but provides only relative indications of where time is being spent.

In Python, since there is an interpreter active during execution, the presence of instrumented code is not required to do deterministic profiling. Python automatically provides a *hook* (optional callback) for each event. In addition, the interpreted nature of Python tends to add so much overhead to execution, that deterministic profiling tends to only add small processing overhead in typical applications. The result is that deterministic profiling is not that expensive, yet provides extensive run time statistics about the execution of a Python program.

Call count statistics can be used to identify bugs in code (surprising counts), and to identify possible inline-expansion points (high call counts). Internal time statistics can be used to identify "hot loops" that should be carefully optimized. Cumulative time statistics should be used to identify high level errors in the selection of algorithms. Note that the unusual handling of cumulative times in this profiler allows statistics for recursive implementations of algorithms to be directly compared to iterative implementations.

26.3.4. Reference Manual – `profile` and `cProfile`

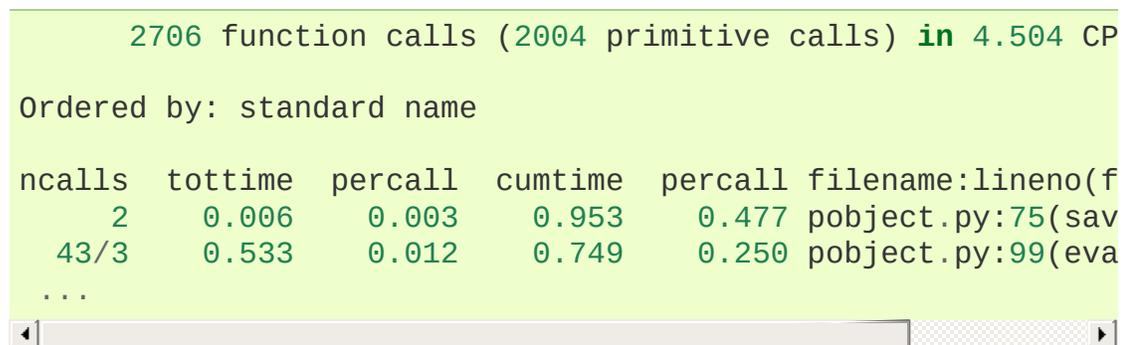

The primary entry point for the profiler is the global function `profile.run()` (resp. `cProfile.run()`). It is typically used to create any profile information. The reports are formatted and printed using methods of the class `pstats.Stats`. The following is a description of all of these standard entry points and functions. For a more in-depth view of some of the code, consider reading the later section on Profiler Extensions, which includes discussion of how to derive “better” profilers from the classes presented, or reading the source code for these modules.

`cProfile.run(command, filename=None, sort=-1)`

This function takes a single argument that can be passed to the `exec()` function, and an optional file name. In all cases this routine attempts to `exec()` its first argument, and gather profiling statistics from the execution. If no file name is present, then this function automatically prints a simple profiling report, sorted by the standard name string (file/line/function-name) that is presented in each line. The following is a typical output from such a call:

```
2706 function calls (2004 primitive calls) in 4.504 CP
Ordered by: standard name
ncalls  tottime  percall  cumtime  percall  filename:lineno(f
    2    0.006   0.003    0.953    0.477  pobject.py:75(sav
  43/3   0.533   0.012    0.749    0.250  pobject.py:99(eva
...

```

The first line indicates that 2706 calls were monitored. Of those calls, 2004 were *primitive*. We define *primitive* to mean that the

call was not induced via recursion. The next line: `Ordered by: standard name`, indicates that the text string in the far right column was used to sort the output. The column headings include:

`ncalls`

for the number of calls,

`totime`

for the total time spent in the given function (and excluding time made in calls to sub-functions),

`percall`

is the quotient of `totime` divided by `ncalls`

`cumtime`

is the total time spent in this and all subfunctions (from invocation till exit). This figure is accurate *even* for recursive functions.

`percall`

is the quotient of `cumtime` divided by primitive calls

`filename:lineno(function)`

provides the respective data of each function

When there are two numbers in the first column (for example, `43/3`), then the latter is the number of primitive calls, and the former is the actual number of calls. Note that when the function does not recurse, these two values are the same, and only the single figure is printed.

If `sort` is given, it can be one of `'stdname'` (sort by `filename:lineno`), `'calls'` (sort by number of calls), `'time'` (sort by total time) or `'cumulative'` (sort by cumulative time). The default is `'stdname'`.

`cProfile.runctx(command, globals, locals, filename=None)`

This function is similar to `run()`, with added arguments to supply the globals and locals dictionaries for the *command* string.

Analysis of the profiler data is done using the `pstats.Stats` class.

```
class pstats.Stats(*filenames, stream=sys.stdout)
```

This class constructor creates an instance of a “statistics object” from a *filename* (or set of filenames). `Stats` objects are manipulated by methods, in order to print useful reports. You may specify an alternate output stream by giving the keyword argument, `stream`.

The file selected by the above constructor must have been created by the corresponding version of `profile` or `cProfile`. To be specific, there is *no* file compatibility guaranteed with future versions of this profiler, and there is no compatibility with files produced by other profilers. If several files are provided, all the statistics for identical functions will be coalesced, so that an overall view of several processes can be considered in a single report. If additional files need to be combined with data in an existing `stats` object, the `add()` method can be used.

26.3.4.1. The `stats` Class

`stats` objects have the following methods:

```
stats.strip_dirs()
```

This method for the `stats` class removes all leading path information from file names. It is very useful in reducing the size of the printout to fit within (close to) 80 columns. This method modifies the object, and the stripped information is lost. After performing a strip operation, the object is considered to have its entries in a “random” order, as it was just after object initialization and loading. If `strip_dirs()` causes two function names to be

indistinguishable (they are on the same line of the same filename, and have the same function name), then the statistics for these two entries are accumulated into a single entry.

`stats.add(*filenames)`

This method of the `stats` class accumulates additional profiling information into the current profiling object. Its arguments should refer to filenames created by the corresponding version of `profile.run()` or `cProfile.run()`. Statistics for identically named (re: file, line, name) functions are automatically accumulated into single function statistics.

`stats.dump_stats(filename)`

Save the data loaded into the `stats` object to a file named *filename*. The file is created if it does not exist, and is overwritten if it already exists. This is equivalent to the method of the same name on the `profile.Profile` and `cProfile.Profile` classes.

`stats.sort_stats(*keys)`

This method modifies the `stats` object by sorting it according to the supplied criteria. The argument is typically a string identifying the basis of a sort (example: `'time'` or `'name'`).

When more than one key is provided, then additional keys are used as secondary criteria when there is equality in all keys selected before them. For example, `sort_stats('name', 'file')` will sort all the entries according to their function name, and resolve all ties (identical function names) by sorting by file name.

Abbreviations can be used for any key names, as long as the abbreviation is unambiguous. The following are the keys currently defined:

Valid Arg	Meaning

'calls'	call count
'cumulative'	cumulative time
'file'	file name
'module'	file name
'pcalls'	primitive call count
'line'	line number
'name'	function name
'nfl'	name/file/line
'stdname'	standard name
'time'	internal time

Note that all sorts on statistics are in descending order (placing most time consuming items first), where as name, file, and line number searches are in ascending order (alphabetical). The subtle distinction between 'nfl' and 'stdname' is that the standard name is a sort of the name as printed, which means that the embedded line numbers get compared in an odd way. For example, lines 3, 20, and 40 would (if the file names were the same) appear in the string order 20, 3 and 40. In contrast, 'nfl' does a numeric compare of the line numbers. In fact, `sort_stats('nfl')` is the same as `sort_stats('name', 'file', 'line')`.

For backward-compatibility reasons, the numeric arguments -1, 0, 1, and 2 are permitted. They are interpreted as 'stdname', 'calls', 'time', and 'cumulative' respectively. If this old style format (numeric) is used, only one sort key (the numeric key) will be used, and additional arguments will be silently ignored.

`stats.reverse_order()`

This method for the `Stats` class reverses the ordering of the basic list within the object. Note that by default ascending vs descending order is properly selected based on the sort key of

choice.

`stats.print_stats(*restrictions)`

This method for the `Stats` class prints out a report as described in the `profile.run()` definition.

The order of the printing is based on the last `sort_stats()` operation done on the object (subject to caveats in `add()` and `strip_dirs()`).

The arguments provided (if any) can be used to limit the list down to the significant entries. Initially, the list is taken to be the complete set of profiled functions. Each restriction is either an integer (to select a count of lines), or a decimal fraction between 0.0 and 1.0 inclusive (to select a percentage of lines), or a regular expression (to pattern match the standard name that is printed; as of Python 1.5b1, this uses the Perl-style regular expression syntax defined by the `re` module). If several restrictions are provided, then they are applied sequentially. For example:

```
print_stats(.1, 'foo:')
```

would first limit the printing to first 10% of list, and then only print functions that were part of filename `.*foo:.` In contrast, the command:

```
print_stats('foo:', .1)
```

would limit the list to all functions having file names `.*foo:`, and then proceed to only print the first 10% of them.

`stats.print_callers(*restrictions)`

This method for the `Stats` class prints a list of all functions that called each function in the profiled database. The ordering is

identical to that provided by `print_stats()`, and the definition of the restricting argument is also identical. Each caller is reported on its own line. The format differs slightly depending on the profiler that produced the stats:

- With `profile`, a number is shown in parentheses after each caller to show how many times this specific call was made. For convenience, a second non-parenthesized number repeats the cumulative time spent in the function at the right.
- With `cProfile`, each caller is preceded by three numbers: the number of times this specific call was made, and the total and cumulative times spent in the current function while it was invoked by this specific caller.

`Stats.print callees(*restrictions)`

This method for the `Stats` class prints a list of all function that were called by the indicated function. Aside from this reversal of direction of calls (re: called vs was called by), the arguments and ordering are identical to the `print callers()` method.

26.3.5. Limitations

One limitation has to do with accuracy of timing information. There is a fundamental problem with deterministic profilers involving accuracy. The most obvious restriction is that the underlying “clock” is only ticking at a rate (typically) of about .001 seconds. Hence no measurements will be more accurate than the underlying clock. If enough measurements are taken, then the “error” will tend to average out. Unfortunately, removing this first error induces a second source of error.

The second problem is that it “takes a while” from when an event is dispatched until the profiler’s call to get the time actually *gets* the state of the clock. Similarly, there is a certain lag when exiting the profiler event handler from the time that the clock’s value was obtained (and then squirreled away), until the user’s code is once again executing. As a result, functions that are called many times, or call many functions, will typically accumulate this error. The error that accumulates in this fashion is typically less than the accuracy of the clock (less than one clock tick), but it *can* accumulate and become very significant.

The problem is more important with `profile` than with the lower-overhead `cProfile`. For this reason, `profile` provides a means of calibrating itself for a given platform so that this error can be probabilistically (on the average) removed. After the profiler is calibrated, it will be more accurate (in a least square sense), but it will sometimes produce negative numbers (when call counts are exceptionally low, and the gods of probability work against you :-).) Do *not* be alarmed by negative numbers in the profile. They should *only* appear if you have calibrated your profiler, and the results are actually better than without calibration.

26.3.6. Calibration

The profiler of the `profile` module subtracts a constant from each event handling time to compensate for the overhead of calling the time function, and socking away the results. By default, the constant is 0. The following procedure can be used to obtain a better constant for a given platform (see discussion in section Limitations above).

```
import profile
pr = profile.Profile()
for i in range(5):
    print(pr.calibrate(10000))
```

The method executes the number of Python calls given by the argument, directly and again under the profiler, measuring the time for both. It then computes the hidden overhead per profiler event, and returns that as a float. For example, on an 800 MHz Pentium running Windows 2000, and using Python's `time.clock()` as the timer, the magical number is about $12.5e-6$.

The object of this exercise is to get a fairly consistent result. If your computer is *very* fast, or your timer function has poor resolution, you might have to pass 100000, or even 1000000, to get consistent results.

When you have a consistent answer, there are three ways you can use it:

```
import profile

# 1. Apply computed bias to all Profile instances created herea
profile.Profile.bias = your_computed_bias

# 2. Apply computed bias to a specific Profile instance.
pr = profile.Profile()
pr.bias = your_computed_bias
```

```
# 3. Specify computed bias in instance constructor.  
pr = profile.Profile(bias=your_computed_bias)
```

If you have a choice, you are better off choosing a smaller constant, and then your results will “less often” show up as negative in profile statistics.

26.3.7. Extensions — Deriving Better Profilers

The `Profile` class of both modules, `profile` and `cProfile`, were written so that derived classes could be developed to extend the profiler. The details are not described here, as doing this successfully requires an expert understanding of how the `Profile` class works internally. Study the source code of the module carefully if you want to pursue this.

If all you want to do is change how current time is determined (for example, to force use of wall-clock time or elapsed process time), pass the timing function you want to the `Profile` class constructor:

```
pr = profile.Profile(your_time_func)
```

The resulting profiler will then call `your_time_func()`.

`profile.Profile`

`your_time_func()` should return a single number, or a list of numbers whose sum is the current time (like what `os.times()` returns). If the function returns a single time number, or the list of returned numbers has length 2, then you will get an especially fast version of the dispatch routine.

Be warned that you should calibrate the profiler class for the timer function that you choose. For most machines, a timer that returns a lone integer value will provide the best results in terms of low overhead during profiling. (`os.times()` is *pretty* bad, as it returns a tuple of floating point values). If you want to substitute a better timer in the cleanest fashion, derive a class and hardwire a replacement dispatch method that best handles your timer call, along with the appropriate calibration constant.

cProfile.Profile

`your_time_func()` should return a single number. If it returns integers, you can also invoke the class constructor with a second argument specifying the real duration of one unit of time. For example, if `your_integer_time_func()` returns times measured in thousands of seconds, you would construct the `Profile` instance as follows:

```
pr = profile.Profile(your_integer_time_func, 0.001)
```

As the `cProfile.Profile` class cannot be calibrated, custom timer functions should be used with care and should be as fast as possible. For the best results with a custom timer, it might be necessary to hard-code it in the C source of the internal `_isprof` module.

26.3.8. Copyright and License Notices

Copyright © 1994, by InfoSeek Corporation, all rights reserved.

Permission to use, copy, modify, and distribute this Python software and its associated documentation for any purpose (subject to the restriction in the following sentence) without fee is hereby granted, provided that the above copyright notice appears in all copies, and that both that copyright notice and this permission notice appear in supporting documentation, and that the name of InfoSeek not be used in advertising or publicity pertaining to distribution of the software without specific, written prior permission. 26.4. `timeit` — Measure execution time of small code snippets

Source code: [Lib/timeit.py](#)

This module provides a simple way to time small bits of Python code. It has both command line as well as callable interfaces. It avoids a number of common traps for measuring execution times. See also Tim Peters' introduction to the "Algorithms" chapter in the Python Cookbook, published by O'Reilly.

The module defines the following public class:

```
class timeit.Timer(stmt='pass', setup='pass', timer=<timer function>)
```

Class for timing execution speed of small code snippets.

The constructor takes a statement to be timed, an additional statement used for setup, and a timer function. Both statements default to `'pass'`; the timer function is platform-dependent (see the module doc string). *stmt* and *setup* may also contain multiple statements separated by `;` or newlines, as long as they don't contain multi-line string literals.

To measure the execution time of the first statement, use the `timeit()` method. The `repeat()` method is a convenience to call `timeit()` multiple times and return a list of results.

The *stmt* and *setup* parameters can also take objects that are callable without arguments. This will embed calls to them in a timer function that will then be executed by `timeit()`. Note that the timing overhead is a little larger in this case because of the

extra function calls.

`Timer.print_exc(file=None)`

Helper to print a traceback from the timed code.

Typical use:

```
t = Timer(...)          # outside the try/except
try:
    t.timeit(...)      # or t.repeat(...)
except:
    t.print_exc()
```

The advantage over the standard traceback is that source lines in the compiled template will be displayed. The optional *file* argument directs where the traceback is sent; it defaults to `sys.stderr`.

`Timer.repeat(repeat=3, number=1000000)`

Call `timeit()` a few times.

This is a convenience function that calls the `timeit()` repeatedly, returning a list of results. The first argument specifies how many times to call `timeit()`. The second argument specifies the *number* argument for `timeit()`.

Note: It's tempting to calculate mean and standard deviation from the result vector and report these. However, this is not very useful. In a typical case, the lowest value gives a lower bound for how fast your machine can run the given code snippet; higher values in the result vector are typically not caused by variability in Python's speed, but by other processes interfering with your timing accuracy. So the `min()` of the result is probably the only number you should be interested in. After that, you should look at the entire vector and apply common

sense rather than statistics.

`Timer.timeit(number=1000000)`

Time *number* executions of the main statement. This executes the setup statement once, and then returns the time it takes to execute the main statement a number of times, measured in seconds as a float. The argument is the number of times through the loop, defaulting to one million. The main statement, the setup statement and the timer function to be used are passed to the constructor.

Note: By default, `timeit()` temporarily turns off *garbage collection* during the timing. The advantage of this approach is that it makes independent timings more comparable. This disadvantage is that GC may be an important component of the performance of the function being measured. If so, GC can be re-enabled as the first statement in the *setup* string. For example:

```
timeit.Timer('for i in range(10): oct(i)', 'gc.enable()').timeit()
```

The module also defines two convenience functions:

`timeit.repeat(stmt='pass', setup='pass', timer=<default timer>, repeat=3, number=1000000)`

Create a `Timer` instance with the given statement, setup code and timer function and run its `repeat()` method with the given repeat count and *number* executions.

`timeit.timeit(stmt='pass', setup='pass', timer=<default timer>, number=1000000)`

Create a `Timer` instance with the given statement, setup code and timer function and run its `timeit()` method with *number*

executions.

26.4.1. Command Line Interface

When called as a program from the command line, the following form is used:

```
python -m timeit [-n N] [-r N] [-s S] [-t] [-c] [-h] [statement]
```

Where the following options are understood:

- n N, --number=N**
how many times to execute 'statement'
- r N, --repeat=N**
how many times to repeat the timer (default 3)
- s S, --setup=S**
statement to be executed once initially (default `pass`)
- t, --time**
use `time.time()` (default on all platforms but Windows)
- c, --clock**
use `time.clock()` (default on Windows)
- v, --verbose**
print raw timing results; repeat for more digits precision
- h, --help**
print a short usage message and exit

A multi-line statement may be given by specifying each line as a separate statement argument; indented lines are possible by enclosing an argument in quotes and using leading spaces. Multiple `-s` options are treated similarly.

If `-n` is not given, a suitable number of loops is calculated by trying successive powers of 10 until the total time is at least 0.2 seconds.

The default timer function is platform dependent. On Windows, `time.clock()` has microsecond granularity but `time.time()`'s granularity is 1/60th of a second; on Unix, `time.clock()` has 1/100th of a second granularity and `time.time()` is much more precise. On either platform, the default timer functions measure wall clock time, not the CPU time. This means that other processes running on the same computer may interfere with the timing. The best thing to do when accurate timing is necessary is to repeat the timing a few times and use the best time. The `-r` option is good for this; the default of 3 repetitions is probably enough in most cases. On Unix, you can use `time.clock()` to measure CPU time.

Note: There is a certain baseline overhead associated with executing a pass statement. The code here doesn't try to hide it, but you should be aware of it. The baseline overhead can be measured by invoking the program without arguments.

The baseline overhead differs between Python versions! Also, to fairly compare older Python versions to Python 2.3, you may want to use Python's `-O` option for the older versions to avoid timing `SET_LINENO` instructions.

26.4.2. Examples

Here are two example sessions (one using the command line, one using the module interface) that compare the cost of using `hasattr()` vs. `try/except` to test for missing and present object attributes.

```
% timeit.py 'try:' ' str.__bool__' 'except AttributeError:' '
100000 loops, best of 3: 15.7 usec per loop
% timeit.py 'if hasattr(str, "__bool__"): pass'
100000 loops, best of 3: 4.26 usec per loop
% timeit.py 'try:' ' int.__bool__' 'except AttributeError:' '
1000000 loops, best of 3: 1.43 usec per loop
% timeit.py 'if hasattr(int, "__bool__"): pass'
100000 loops, best of 3: 2.23 usec per loop
```

```
>>> import timeit
>>> s = """\
... try:
...     str.__bool__
... except AttributeError:
...     pass
... """
>>> t = timeit.Timer(stmt=s)
>>> print("%.2f usec/pass" % (1000000 * t.timeit(number=100000))
17.09 usec/pass
>>> s = """\
... if hasattr(str, '__bool__'): pass
... """
>>> t = timeit.Timer(stmt=s)
>>> print("%.2f usec/pass" % (1000000 * t.timeit(number=100000))
4.85 usec/pass
>>> s = """\
... try:
...     int.__bool__
... except AttributeError:
...     pass
... """
>>> t = timeit.Timer(stmt=s)
>>> print("%.2f usec/pass" % (1000000 * t.timeit(number=100000))
1.97 usec/pass
>>> s = """\
```

```
... if hasattr(int, '__bool__'): pass
... """
>>> t = timeit.Timer(stmt=s)
>>> print("%.2f usec/pass" % (1000000 * t.timeit(number=100000))
3.15 usec/pass
```

To give the `timeit` module access to functions you define, you can pass a `setup` parameter which contains an import statement:

```
def test():
    "Stupid test function"
    L = [i for i in range(100)]

if __name__=='__main__':
    from timeit import Timer
    t = Timer("test()", "from __main__ import test")
    print(t.timeit())
```

26.5. `trace` — Trace or track Python statement execution

Source code: [Lib/trace.py](#)

The `trace` module allows you to trace program execution, generate annotated statement coverage listings, print caller/callee relationships and list functions executed during a program run. It can be used in another program or from the command line.

26.5.1. Command-Line Usage

The `trace` module can be invoked from the command line. It can be as simple as

```
python -m trace --count -C . somefile.py ...
```

The above will execute `somefile.py` and generate annotated listings of all Python modules imported during the execution into the current directory.

--help

Display usage and exit.

--version

Display the version of the module and exit.

26.5.1.1. Main options

At least one of the following options must be specified when invoking `trace`. The `--listfuncs` option is mutually exclusive with the `--trace` and `--counts` options. When `--listfuncs` is provided, neither `--counts` nor `--trace` are accepted, and vice versa.

-c , --count

Produce a set of annotated listing files upon program completion that shows how many times each statement was executed. See also `--coverdir`, `--file` and `--no-report` below.

-t , --trace

Display lines as they are executed.

-l , --listfuncs

Display the functions executed by running the program.

-r , --report

Produce an annotated list from an earlier program run that used the `--count` and `--file` option. This does not execute any code.

-T , --trackcalls

Display the calling relationships exposed by running the program.

26.5.1.2. Modifiers

-f , --file=<file>

Name of a file to accumulate counts over several tracing runs. Should be used with the `--count` option.

-C , --coverdir=<dir>

Directory where the report files go. The coverage report for `package.module` is written to file `dir/package/module.cover`.

-m , --missing

When generating annotated listings, mark lines which were not executed with `>>>>>>`.

-s , --summary

When using `--count` or `--report`, write a brief summary to stdout for each file processed.

-R , --no-report

Do not generate annotated listings. This is useful if you intend to make several runs with `--count`, and then produce a single set of annotated listings at the end.

-g , --timing

Prefix each line with the time since the program started. Only used while tracing.

26.5.1.3. Filters

These options may be repeated multiple times.

--ignore-module=<mod>

Ignore each of the given module names and its submodules (if it is a package). The argument can be a list of names separated by a comma.

--ignore-dir=<dir>

Ignore all modules and packages in the named directory and subdirectories. The argument can be a list of directories separated by `os.pathsep`.

26.5.2. Programmatic Interface

```
class trace.Trace(count=1, trace=1, countfuncs=0, countcallers=0,  
ignoremods=(), ignoredirs=(), infile=None, outfile=None,  
timing=False)
```

Create an object to trace execution of a single statement or expression. All parameters are optional. *count* enables counting of line numbers. *trace* enables line execution tracing. *countfuncs* enables listing of the functions called during the run. *countcallers* enables call relationship tracking. *ignoremods* is a list of modules or packages to ignore. *ignoredirs* is a list of directories whose modules or packages should be ignored. *infile* is the name of the file from which to read stored count information. *outfile* is the name of the file in which to write updated count information. *timing* enables a timestamp relative to when tracing was started to be displayed.

run(*cmd*)

Execute the command and gather statistics from the execution with the current tracing parameters. *cmd* must be a string or code object, suitable for passing into `exec()`.

runtx(*cmd*, *globals*=None, *locals*=None)

Execute the command and gather statistics from the execution with the current tracing parameters, in the defined global and local environments. If not defined, *globals* and *locals* default to empty dictionaries.

runfunc(*func*, **args*, ***kwds*)

Call *func* with the given arguments under control of the **Trace** object with the current tracing parameters.

results()

Return a **CoverageResults** object that contains the cumulative results of all previous calls to `run`, `runcctx` and `runfunc` for the given **Trace** instance. Does not reset the accumulated trace results.

class **trace.CoverageResults**

A container for coverage results, created by **Trace.results()**. Should not be created directly by the user.

update(*other*)

Merge in data from another **CoverageResults** object.

write_results(*show_missing=True*, *summary=False*, *coverdir=None*)

Write coverage results. Set *show_missing* to show lines that had no hits. Set *summary* to include in the output the coverage summary per module. *coverdir* specifies the directory into which the coverage result files will be output. If **None**, the results for each source file are placed in its directory.

A simple example demonstrating the use of the programmatic interface:

```
import sys
import trace

# create a Trace object, telling it what to ignore, and whether
# do tracing or line-counting or both.
tracer = trace.Trace(
    ignoredirs=[sys.prefix, sys.exec_prefix],
    trace=0,
    count=1)

# run the new command using the given tracer
tracer.run('main()')
```

```
# make a report, placing output in /tmp  
r = tracer.results()  
r.write_results(show_missing=True, coverdir="/tmp")
```

27. Python Runtime Services

The modules described in this chapter provide a wide range of services related to the Python interpreter and its interaction with its environment. Here's an overview:

- 27.1. `sys` — System-specific parameters and functions
- 27.2. `sysconfig` — Provide access to Python's configuration information
 - 27.2.1. Configuration variables
 - 27.2.2. Installation paths
 - 27.2.3. Other functions
 - 27.2.4. Using `sysconfig` as a script
- 27.3. `builtins` — Built-in objects
- 27.4. `__main__` — Top-level script environment
- 27.5. `warnings` — Warning control
 - 27.5.1. Warning Categories
 - 27.5.2. The Warnings Filter
 - 27.5.2.1. Default Warning Filters
 - 27.5.3. Temporarily Suppressing Warnings
 - 27.5.4. Testing Warnings
 - 27.5.5. Updating Code For New Versions of Python
 - 27.5.6. Available Functions
 - 27.5.7. Available Context Managers
- 27.6. `contextlib` — Utilities for `with`-statement contexts
- 27.7. `abc` — Abstract Base Classes
- 27.8. `atexit` — Exit handlers
 - 27.8.1. `atexit` Example
- 27.9. `traceback` — Print or retrieve a stack traceback
 - 27.9.1. Traceback Examples
- 27.10. `__future__` — Future statement definitions
- 27.11. `gc` — Garbage Collector interface

- 27.12. `inspect` — Inspect live objects
 - 27.12.1. Types and members
 - 27.12.2. Retrieving source code
 - 27.12.3. Classes and functions
 - 27.12.4. The interpreter stack
 - 27.12.5. Fetching attributes statically
 - 27.12.6. Current State of a Generator
- 27.13. `site` — Site-specific configuration hook
- 27.14. `fpect1` — Floating point exception control
 - 27.14.1. Example
 - 27.14.2. Limitations and other considerations
- 27.15. `distutils` — Building and installing Python modules

27.1. `sys` — System-specific parameters and functions

This module provides access to some variables used or maintained by the interpreter and to functions that interact strongly with the interpreter. It is always available.

`sys.abiflags`

On POSIX systems where Python is build with the standard `configure` script, this contains the ABI flags as specified by [PEP 3149](#).

New in version 3.2.

`sys.argv`

The list of command line arguments passed to a Python script. `argv[0]` is the script name (it is operating system dependent whether this is a full pathname or not). If the command was executed using the `-c` command line option to the interpreter, `argv[0]` is set to the string `'-c'`. If no script name was passed to the Python interpreter, `argv[0]` is the empty string.

To loop over the standard input, or the list of files given on the command line, see the `fileinput` module.

`sys.byteorder`

An indicator of the native byte order. This will have the value `'big'` on big-endian (most-significant byte first) platforms, and `'little'` on little-endian (least-significant byte first) platforms.

`sys.subversion`

A triple (repo, branch, version) representing the Subversion information of the Python interpreter. `repo` is the name of the

repository, 'CPython'. *branch* is a string of one of the forms 'trunk', 'branches/name' or 'tags/name'. *version* is the output of `svnversion`, if the interpreter was built from a Subversion checkout; it contains the revision number (range) and possibly a trailing 'M' if there were local modifications. If the tree was exported (or `svnversion` was not available), it is the revision of `Include/patchlevel.h` if the branch is a tag. Otherwise, it is `None`.

`sys.builtin_module_names`

A tuple of strings giving the names of all modules that are compiled into this Python interpreter. (This information is not available in any other way — `modules.keys()` only lists the imported modules.)

`sys.call_tracing(func, args)`

Call `func(*args)`, while tracing is enabled. The tracing state is saved, and restored afterwards. This is intended to be called from a debugger from a checkpoint, to recursively debug some other code.

`sys.copyright`

A string containing the copyright pertaining to the Python interpreter.

`sys._clear_type_cache()`

Clear the internal type cache. The type cache is used to speed up attribute and method lookups. Use the function *only* to drop unnecessary references during reference leak debugging.

This function should be used for internal and specialized purposes only.

`sys._current_frames()`

Return a dictionary mapping each thread's identifier to the topmost stack frame currently active in that thread at the time the

function is called. Note that functions in the `traceback` module can build the call stack given such a frame.

This is most useful for debugging deadlock: this function does not require the deadlocked threads' cooperation, and such threads' call stacks are frozen for as long as they remain deadlocked. The frame returned for a non-deadlocked thread may bear no relationship to that thread's current activity by the time calling code examines the frame.

This function should be used for internal and specialized purposes only.

`sys.dllhandle`

Integer specifying the handle of the Python DLL. Availability: Windows.

`sys.displayhook(value)`

If *value* is not `None`, this function prints `repr(value)` to `sys.stdout`, and saves *value* in `builtins._`. If `repr(value)` is not encodable to `sys.stdout.encoding` with `sys.stdout.errors` error handler (which is probably `'strict'`), encode it to `sys.stdout.encoding` with `'backslashreplace'` error handler.

`sys.displayhook` is called on the result of evaluating an *expression* entered in an interactive Python session. The display of these values can be customized by assigning another one-argument function to `sys.displayhook`.

Pseudo-code:

```
def displayhook(value):
    if value is None:
        return
    # Set '_' to None to avoid recursion
    builtins._ = None
```

```
text = repr(value)
try:
    sys.stdout.write(text)
except UnicodeEncodeError:
    bytes = text.encode(sys.stdout.encoding, 'backslashr
    if hasattr(sys.stdout, 'buffer'):
        sys.stdout.buffer.write(bytes)
    else:
        text = bytes.decode(sys.stdout.encoding, 'strict
        sys.stdout.write(text)
sys.stdout.write("\n")
builtins._ = value
```

Changed in version 3.2: Use `'backslashreplace'` error handler on `UnicodeEncodeError`.

`sys.excepthook(type, value, traceback)`

This function prints out a given traceback and exception to `sys.stderr`.

When an exception is raised and uncaught, the interpreter calls `sys.excepthook` with three arguments, the exception class, exception instance, and a traceback object. In an interactive session this happens just before control is returned to the prompt; in a Python program this happens just before the program exits. The handling of such top-level exceptions can be customized by assigning another three-argument function to `sys.excepthook`.

`sys.__displayhook__`

`sys.__excepthook__`

These objects contain the original values of `displayhook` and `excepthook` at the start of the program. They are saved so that `displayhook` and `excepthook` can be restored in case they happen to get replaced with broken objects.

`sys.exc_info()`

This function returns a tuple of three values that give information

about the exception that is currently being handled. The information returned is specific both to the current thread and to the current stack frame. If the current stack frame is not handling an exception, the information is taken from the calling stack frame, or its caller, and so on until a stack frame is found that is handling an exception. Here, “handling an exception” is defined as “executing an except clause.” For any stack frame, only information about the exception being currently handled is accessible.

If no exception is being handled anywhere on the stack, a tuple containing three `None` values is returned. Otherwise, the values returned are `(type, value, traceback)`. Their meaning is: *type* gets the type of the exception being handled (a subclass of `BaseException`); *value* gets the exception instance (an instance of the exception type); *traceback* gets a traceback object (see the Reference Manual) which encapsulates the call stack at the point where the exception originally occurred.

Warning: Assigning the *traceback* return value to a local variable in a function that is handling an exception will cause a circular reference. Since most functions don't need access to the traceback, the best solution is to use something like `exctype, value = sys.exc_info()[:2]` to extract only the exception type and value. If you do need the traceback, make sure to delete it after use (best done with a `try ... finally` statement) or to call `exc_info()` in a function that does not itself handle an exception.

Such cycles are normally automatically reclaimed when garbage collection is enabled and they become unreachable, but it remains more efficient to avoid creating cycles.

`sys.exec_prefix`

A string giving the site-specific directory prefix where the platform-dependent Python files are installed; by default, this is also `'/usr/local'`. This can be set at build time with the `--exec-prefix` argument to the **configure** script. Specifically, all configuration files (e.g. the `pyconfig.h` header file) are installed in the directory `exec_prefix + '/lib/pythonversion/config'`, and shared library modules are installed in `exec_prefix + '/lib/pythonversion/lib-dynload'`, where *version* is equal to `version[:3]`.

`sys.executable`

A string giving the name of the executable binary for the Python interpreter, on systems where this makes sense.

`sys.exit([arg])`

Exit from Python. This is implemented by raising the **SystemExit** exception, so cleanup actions specified by finally clauses of **try** statements are honored, and it is possible to intercept the exit attempt at an outer level.

The optional argument *arg* can be an integer giving the exit status (defaulting to zero), or another type of object. If it is an integer, zero is considered “successful termination” and any nonzero value is considered “abnormal termination” by shells and the like. Most systems require it to be in the range 0-127, and produce undefined results otherwise. Some systems have a convention for assigning specific meanings to specific exit codes, but these are generally underdeveloped; Unix programs generally use 2 for command line syntax errors and 1 for all other kind of errors. If another type of object is passed, **None** is equivalent to passing zero, and any other object is printed to **stderr** and results in an exit code of 1. In particular, `sys.exit("some error message")` is a quick way to exit a program when an error occurs.

Since `exit()` ultimately “only” raises an exception, it will only exit the process when called from the main thread, and the exception is not intercepted.

sys. flags

The struct sequence `flags` exposes the status of command line flags. The attributes are read only.

attribute	flag
<code>debug</code>	<code>-d</code>
<code>division_warning</code>	<code>-Q</code>
<code>inspect</code>	<code>-i</code>
<code>interactive</code>	<code>-i</code>
<code>optimize</code>	<code>-O</code> or <code>-OO</code>
<code>dont_write_bytecode</code>	<code>-B</code>
<code>no_user_site</code>	<code>-s</code>
<code>no_site</code>	<code>-S</code>
<code>ignore_environment</code>	<code>-E</code>
<code>verbose</code>	<code>-v</code>
<code>bytes_warning</code>	<code>-b</code>
<code>quiet</code>	<code>-q</code>

Changed in version 3.2: Added `quiet` attribute for the new `-q` flag.

sys. float_info

A structseq holding information about the float type. It contains low level information about the precision and internal representation. The values correspond to the various floating-point constants defined in the standard header file `float.h` for the ‘C’ programming language; see section 5.2.4.2.2 of the 1999 ISO/IEC C standard [C99], ‘Characteristics of floating types’, for details.

attribute	float.h macro	explanation

epsilon	DBL_EPSILON	difference between 1 and the least value greater than 1 that is representable as a float
dig	DBL_DIG	maximum number of decimal digits that can be faithfully represented in a float; see below
mant_dig	DBL_MANT_DIG	float precision: the number of base- <code>radix</code> digits in the significand of a float
max	DBL_MAX	maximum representable finite float
max_exp	DBL_MAX_EXP	maximum integer <code>e</code> such that $\text{radix}^{(e-1)}$ is a representable finite float
max_10_exp	DBL_MAX_10_EXP	maximum integer <code>e</code> such that 10^{**e} is in the range of representable finite floats
min	DBL_MIN	minimum positive normalized float
min_exp	DBL_MIN_EXP	minimum integer <code>e</code> such that $\text{radix}^{(e-1)}$ is a normalized float
min_10_exp	DBL_MIN_10_EXP	minimum integer <code>e</code> such that 10^{**e} is a normalized float
radix	FLT_RADIX	radix of exponent representation
rounds	FLT_ROUNDS	constant representing rounding mode used for arithmetic operations

The attribute `sys.float_info.dig` needs further explanation. If `s` is any string representing a decimal number with at most `sys.float_info.dig` significant digits, then converting `s` to a float and back again will recover a string representing the same

decimal value:

```
>>> import sys
>>> sys.float_info.dig
15
>>> s = '3.14159265358979'    # decimal string with 15 signi
>>> format(float(s), '.15g') # convert to float and back ->
'3.14159265358979'
```

But for strings with more than `sys.float_info.dig` significant digits, this isn't always true:

```
>>> s = '9876543211234567'    # 16 significant digits is too
>>> format(float(s), '.16g') # conversion changes value
'9876543211234568'
```

`sys.float_repr_style`

A string indicating how the `repr()` function behaves for floats. If the string has value `'short'` then for a finite float `x`, `repr(x)` aims to produce a short string with the property that `float(repr(x)) == x`. This is the usual behaviour in Python 3.1 and later. Otherwise, `float_repr_style` has value `'legacy'` and `repr(x)` behaves in the same way as it did in versions of Python prior to 3.1.

New in version 3.1.

`sys.getcheckinterval()`

Return the interpreter's "check interval"; see `setcheckinterval()`.

Deprecated since version 3.2: Use `getswitchinterval()` instead.

`sys.getdefaultencoding()`

Return the name of the current default string encoding used by the Unicode implementation.

`sys.getdlopenflags()`

Return the current value of the flags that are used for `dlopen()` calls. The flag constants are defined in the `ctypes` and `DLFCN` modules. Availability: Unix.

`sys.getfilesystemencoding()`

Return the name of the encoding used to convert Unicode filenames into system file names. The result value depends on the operating system:

- On Mac OS X, the encoding is `'utf-8'`.
- On Unix, the encoding is the user's preference according to the result of `nl_langinfo(CODESET)`, or `'utf-8'` if `nl_langinfo(CODESET)` failed.
- On Windows NT+, file names are Unicode natively, so no conversion is performed. `getfilesystemencoding()` still returns `'mbcs'`, as this is the encoding that applications should use when they explicitly want to convert Unicode strings to byte strings that are equivalent when used as file names.
- On Windows 9x, the encoding is `'mbcs'`.

Changed in version 3.2: On Unix, use `'utf-8'` instead of `None` if `nl_langinfo(CODESET)` failed. `getfilesystemencoding()` result cannot be `None`.

`sys.getrefcount(object)`

Return the reference count of the *object*. The count returned is generally one higher than you might expect, because it includes the (temporary) reference as an argument to `getrefcount()`.

`sys.getrecursionlimit()`

Return the current value of the recursion limit, the maximum depth of the Python interpreter stack. This limit prevents infinite

recursion from causing an overflow of the C stack and crashing Python. It can be set by `setrecursionlimit()`.

`sys.getsizeof(object[, default])`

Return the size of an object in bytes. The object can be any type of object. All built-in objects will return correct results, but this does not have to hold true for third-party extensions as it is implementation specific.

If given, *default* will be returned if the object does not provide means to retrieve the size. Otherwise a `TypeError` will be raised.

`getsizeof()` calls the object's `__sizeof__` method and adds an additional garbage collector overhead if the object is managed by the garbage collector.

See [recursive sizeof recipe](#) for an example of using `getsizeof()` recursively to find the size of containers and all their contents.

`sys.getswitchinterval()`

Return the interpreter's "thread switch interval"; see `setswitchinterval()`.

New in version 3.2.

`sys._getframe([depth])`

Return a frame object from the call stack. If optional integer *depth* is given, return the frame object that many calls below the top of the stack. If that is deeper than the call stack, `ValueError` is raised. The default for *depth* is zero, returning the frame at the top of the call stack.

CPython implementation detail: This function should be used for internal and specialized purposes only. It is not guaranteed

to exist in all implementations of Python.

`sys.getprofile()`

Get the profiler function as set by `setprofile()`.

`sys.gettrace()`

Get the trace function as set by `settrace()`.

CPython implementation detail: The `gettrace()` function is intended only for implementing debuggers, profilers, coverage tools and the like. Its behavior is part of the implementation platform, rather than part of the language definition, and thus may not be available in all Python implementations.

`sys.getwindowsversion()`

Return a named tuple describing the Windows version currently running. The named elements are *major*, *minor*, *build*, *platform*, *service_pack*, *service_pack_minor*, *service_pack_major*, *suite_mask*, and *product_type*. *service_pack* contains a string while all other values are integers. The components can also be accessed by name, so `sys.getwindowsversion()[0]` is equivalent to `sys.getwindowsversion().major`. For compatibility with prior versions, only the first 5 elements are retrievable by indexing.

platform may be one of the following values:

Constant	Platform
0 (VER_PLATFORM_WIN32s)	Win32s on Windows 3.1
1 (VER_PLATFORM_WIN32_WINDOWS)	Windows 95/98/ME
2 (VER_PLATFORM_WIN32_NT)	Windows NT/2000/XP/x64

3 (VER_PLATFORM_WIN32_CE)	Windows CE
---------------------------	------------

product_type may be one of the following values:

Constant	Meaning
1 (VER_NT_WORKSTATION)	The system is a workstation.
2 (VER_NT_DOMAIN_CONTROLLER)	The system is a domain controller.
3 (VER_NT_SERVER)	The system is a server, but not a domain controller.

This function wraps the Win32 `GetVersionEx()` function; see the Microsoft documentation on `OSVERSIONINFOEX()` for more information about these fields.

Availability: Windows.

Changed in version 3.2: Changed to a named tuple and added *service_pack_minor*, *service_pack_major*, *suite_mask*, and *product_type*.

sys.hash_info

A structseq giving parameters of the numeric hash implementation. For more details about hashing of numeric types, see [Hashing of numeric types](#).

attribute	explanation
<code>width</code>	width in bits used for hash values
<code>modulus</code>	prime modulus P used for numeric hash scheme
<code>inf</code>	hash value returned for a positive infinity
<code>nan</code>	hash value returned for a nan
<code>imag</code>	multiplier used for the imaginary part of a complex number

New in version 3.2.

sys.hexversion

The version number encoded as a single integer. This is guaranteed to increase with each version, including proper support for non-production releases. For example, to test that the Python interpreter is at least version 1.5.2, use:

```
if sys.hexversion >= 0x010502F0:
    # use some advanced feature
    ...
else:
    # use an alternative implementation or warn the user
    ...
```

This is called `hexversion` since it only really looks meaningful when viewed as the result of passing it to the built-in `hex()` function. The `version_info` value may be used for a more human-friendly encoding of the same information.

sys.int_info

A struct sequence that holds information about Python's internal representation of integers. The attributes are read only.

attribute	explanation
<code>bits_per_digit</code>	number of bits held in each digit. Python integers are stored internally in base $2^{\text{int_info.bits_per_digit}}$
<code>sizeof_digit</code>	size in bytes of the C type used to represent a digit

New in version 3.1.

sys.intern(string)

Enter `string` in the table of “interned” strings and return the interned string – which is `string` itself or a copy. Interning strings is useful to gain a little performance on dictionary lookup – if the keys in a dictionary are interned, and the lookup key is interned, the key comparisons (after hashing) can be done by a pointer

compare instead of a string compare. Normally, the names used in Python programs are automatically interned, and the dictionaries used to hold module, class or instance attributes have interned keys.

Interned strings are not immortal; you must keep a reference to the return value of `intern()` around to benefit from it.

`sys.last_type`

`sys.last_value`

`sys.last_traceback`

These three variables are not always defined; they are set when an exception is not handled and the interpreter prints an error message and a stack traceback. Their intended use is to allow an interactive user to import a debugger module and engage in post-mortem debugging without having to re-execute the command that caused the error. (Typical use is `import pdb; pdb.pm()` to enter the post-mortem debugger; see `pdb` module for more information.)

The meaning of the variables is the same as that of the return values from `exc_info()` above.

`sys.maxsize`

An integer giving the maximum value a variable of type `Py_ssize_t` can take. It's usually `2**31 - 1` on a 32-bit platform and `2**63 - 1` on a 64-bit platform.

`sys.maxunicode`

An integer giving the largest supported code point for a Unicode character. The value of this depends on the configuration option that specifies whether Unicode characters are stored as UCS-2 or UCS-4.

`sys.meta_path`

A list of *finder* objects that have their `find_module()` methods called to see if one of the objects can find the module to be imported. The `find_module()` method is called at least with the absolute name of the module being imported. If the module to be imported is contained in package then the parent package's `__path__` attribute is passed in as a second argument. The method returns `None` if the module cannot be found, else returns a *loader*.

`sys.meta_path` is searched before any implicit default finders or `sys.path`.

See [PEP 302](#) for the original specification.

`sys.modules`

This is a dictionary that maps module names to modules which have already been loaded. This can be manipulated to force reloading of modules and other tricks.

`sys.path`

A list of strings that specifies the search path for modules. Initialized from the environment variable `PYTHONPATH`, plus an installation-dependent default.

As initialized upon program startup, the first item of this list, `path[0]`, is the directory containing the script that was used to invoke the Python interpreter. If the script directory is not available (e.g. if the interpreter is invoked interactively or if the script is read from standard input), `path[0]` is the empty string, which directs Python to search modules in the current directory first. Notice that the script directory is inserted *before* the entries inserted as a result of `PYTHONPATH`.

A program is free to modify this list for its own purposes.

See also: Module `site` This describes how to use `.pth` files to extend `sys.path`.

`sys.path_hooks`

A list of callables that take a path argument to try to create a *finder* for the path. If a finder can be created, it is to be returned by the callable, else raise `ImportError`.

Originally specified in [PEP 302](#).

`sys.path_importer_cache`

A dictionary acting as a cache for *finder* objects. The keys are paths that have been passed to `sys.path_hooks` and the values are the finders that are found. If a path is a valid file system path but no explicit finder is found on `sys.path_hooks` then `None` is stored to represent the implicit default finder should be used. If the path is not an existing path then `imp.NullImporter` is set.

Originally specified in [PEP 302](#).

`sys.platform`

This string contains a platform identifier that can be used to append platform-specific components to `sys.path`, for instance.

For Unix systems, this is the lowercased OS name as returned by `uname -s` with the first part of the version as returned by `uname -r` appended, e.g. `'sunos5'` or `'linux2'`, *at the time when Python was built*. For other systems, the values are:

System	platform value
Windows	'win32'
Windows/Cygwin	'cygwin'
Mac OS X	'darwin'
OS/2	'os2'

OS/2 EMX

'os2emx'

sys.**prefix**

A string giving the site-specific directory prefix where the platform independent Python files are installed; by default, this is the string `'/usr/local'`. This can be set at build time with the `--prefix` argument to the **configure** script. The main collection of Python library modules is installed in the directory `prefix + '/lib/pythonversion'` while the platform independent header files (all except `pyconfig.h`) are stored in `prefix + '/include/pythonversion'`, where *version* is equal to `version[:3]`.

sys.**ps1**

sys.**ps2**

Strings specifying the primary and secondary prompt of the interpreter. These are only defined if the interpreter is in interactive mode. Their initial values in this case are `'>>> '` and `'... '`. If a non-string object is assigned to either variable, its `str()` is re-evaluated each time the interpreter prepares to read a new interactive command; this can be used to implement a dynamic prompt.

sys.**dont_write_bytecode**

If this is true, Python won't try to write `.pyc` or `.pyo` files on the import of source modules. This value is initially set to `True` or `False` depending on the `-B` command line option and the `PYTHONDONTWRITEBYTECODE` environment variable, but you can set it yourself to control bytecode file generation.

sys.**setcheckinterval(interval)**

Set the interpreter's "check interval". This integer value determines how often the interpreter checks for periodic things such as thread switches and signal handlers. The default is `100`,

meaning the check is performed every 100 Python virtual instructions. Setting it to a larger value may increase performance for programs using threads. Setting it to a value `<= 0` checks every virtual instruction, maximizing responsiveness as well as overhead.

Deprecated since version 3.2: This function doesn't have an effect anymore, as the internal logic for thread switching and asynchronous tasks has been rewritten. Use `setswitchinterval()` instead.

`sys.setdlopenflags(n)`

Set the flags used by the interpreter for `dlopen()` calls, such as when the interpreter loads extension modules. Among other things, this will enable a lazy resolving of symbols when importing a module, if called as `sys.setdlopenflags(0)`. To share symbols across extension modules, call as `sys.setdlopenflags(ctypes.RTLD_GLOBAL)`. Symbolic names for the flag modules can be either found in the `ctypes` module, or in the `DLFCN` module. If `DLFCN` is not available, it can be generated from `/usr/include/dlfcn.h` using the `h2py` script. Availability: Unix.

`sys.setprofile(profilefunc)`

Set the system's profile function, which allows you to implement a Python source code profiler in Python. See chapter *The Python Profilers* for more information on the Python profiler. The system's profile function is called similarly to the system's trace function (see `settrace()`), but it isn't called for each executed line of code (only on call and return, but the return event is reported even when an exception has been set). The function is thread-specific, but there is no way for the profiler to know about context switches between threads, so it does not make sense to use this

in the presence of multiple threads. Also, its return value is not used, so it can simply return `None`.

`sys.setrecursionlimit(limit)`

Set the maximum depth of the Python interpreter stack to *limit*. This limit prevents infinite recursion from causing an overflow of the C stack and crashing Python.

The highest possible limit is platform-dependent. A user may need to set the limit higher when she has a program that requires deep recursion and a platform that supports a higher limit. This should be done with care, because a too-high limit can lead to a crash.

`sys.setswitchinterval(interval)`

Set the interpreter's thread switch interval (in seconds). This floating-point value determines the ideal duration of the "timeslices" allocated to concurrently running Python threads. Please note that the actual value can be higher, especially if long-running internal functions or methods are used. Also, which thread becomes scheduled at the end of the interval is the operating system's decision. The interpreter doesn't have its own scheduler.

New in version 3.2.

`sys.settrace(tracefunc)`

Set the system's trace function, which allows you to implement a Python source code debugger in Python. The function is thread-specific; for a debugger to support multiple threads, it must be registered using `settrace()` for each thread being debugged.

Trace functions should have three arguments: *frame*, *event*, and *arg*. *frame* is the current stack frame. *event* is a string: `'call'`, `'line'`, `'return'`, `'exception'`, `'c_call'`, `'c_return'`, or

'`c_exception`'. *arg* depends on the event type.

The trace function is invoked (with *event* set to '`call`') whenever a new local scope is entered; it should return a reference to a local trace function to be used that scope, or `None` if the scope shouldn't be traced.

The local trace function should return a reference to itself (or to another function for further tracing in that scope), or `None` to turn off tracing in that scope.

The events have the following meaning:

'`call`'

A function is called (or some other code block entered). The global trace function is called; *arg* is `None`; the return value specifies the local trace function.

'`line`'

The interpreter is about to execute a new line of code or re-execute the condition of a loop. The local trace function is called; *arg* is `None`; the return value specifies the new local trace function. See `objects/Inotab_notes.txt` for a detailed explanation of how this works.

'`return`'

A function (or other code block) is about to return. The local trace function is called; *arg* is the value that will be returned, or `None` if the event is caused by an exception being raised. The trace function's return value is ignored.

'`exception`'

An exception has occurred. The local trace function is called; *arg* is a tuple (`exception, value, traceback`); the return value specifies the new local trace function.

'c_call'

A C function is about to be called. This may be an extension function or a built-in. *arg* is the C function object.

'c_return'

A C function has returned. *arg* is the C function object.

'c_exception'

A C function has raised an exception. *arg* is the C function object.

Note that as an exception is propagated down the chain of callers, an 'exception' event is generated at each level.

For more information on code and frame objects, refer to [The standard type hierarchy](#).

CPython implementation detail: The `settrace()` function is intended only for implementing debuggers, profilers, coverage tools and the like. Its behavior is part of the implementation platform, rather than part of the language definition, and thus may not be available in all Python implementations.

`sys.settsdump(on_flag)`

Activate dumping of VM measurements using the Pentium timestamp counter, if *on_flag* is true. Deactivate these dumps if *on_flag* is off. The function is available only if Python was compiled with `--with-tsc`. To understand the output of this dump, read `Python/ceval.c` in the Python sources.

CPython implementation detail: This function is intimately bound to CPython implementation details and thus not likely to be implemented elsewhere.

`sys.stdin`
`sys.stdout`
`sys.stderr`

File objects corresponding to the interpreter's standard input, output and error streams. `stdin` is used for all interpreter input except for scripts but including calls to `input()`. `stdout` is used for the output of `print()` and *expression* statements and for the prompts of `input()`. The interpreter's own prompts and (almost all of) its error messages go to `stderr`. `stdout` and `stderr` needn't be built-in file objects: any object is acceptable as long as it has a `write()` method that takes a string argument. (Changing these objects doesn't affect the standard I/O streams of processes executed by `os.popen()`, `os.system()` or the `exec*()` family of functions in the `os` module.)

The standard streams are in text mode by default. To write or read binary data to these, use the underlying binary buffer. For example, to write bytes to `stdout`, use `sys.stdout.buffer.write(b'abc')`. Using `io.TextIOBase.detach()` streams can be made binary by default. This function sets `stdin` and `stdout` to binary:

```
def make_streams_binary():
    sys.stdin = sys.stdin.detach()
    sys.stdout = sys.stdout.detach()
```

Note that the streams can be replaced with objects (like `io.StringIO`) that do not support the `buffer` attribute or the `detach()` method and can raise `AttributeError` or `io.UnsupportedOperation`.

`sys.__stdin__`
`sys.__stdout__`
`sys.__stderr__`

These objects contain the original values of `stdin`, `stderr` and

`stdout` at the start of the program. They are used during finalization, and could be useful to print to the actual standard stream no matter if the `sys.std*` object has been redirected.

It can also be used to restore the actual files to known working file objects in case they have been overwritten with a broken object. However, the preferred way to do this is to explicitly save the previous stream before replacing it, and restore the saved object.

Note: Under some conditions `stdin`, `stdout` and `stderr` as well as the original values `__stdin__`, `__stdout__` and `__stderr__` can be `None`. It is usually the case for Windows GUI apps that aren't connected to a console and Python apps started with **pythonw**.

`sys.tracebacklimit`

When this variable is set to an integer value, it determines the maximum number of levels of traceback information printed when an unhandled exception occurs. The default is `1000`. When set to `0` or less, all traceback information is suppressed and only the exception type and value are printed.

`sys.version`

A string containing the version number of the Python interpreter plus additional information on the build number and compiler used. This string is displayed when the interactive interpreter is started. Do not extract version information out of it, rather, use `version_info` and the functions provided by the `platform` module.

`sys.api_version`

The C API version for this interpreter. Programmers may find this useful when debugging version conflicts between Python and extension modules.

`sys.version_info`

A tuple containing the five components of the version number: *major*, *minor*, *micro*, *releaselevel*, and *serial*. All values except *releaselevel* are integers; the release level is 'alpha', 'beta', 'candidate', or 'final'. The `version_info` value corresponding to the Python version 2.0 is `(2, 0, 0, 'final', 0)`. The components can also be accessed by name, so `sys.version_info[0]` is equivalent to `sys.version_info.major` and so on.

Changed in version 3.1: Added named component attributes.

`sys.warnoptions`

This is an implementation detail of the warnings framework; do not modify this value. Refer to the `warnings` module for more information on the warnings framework.

`sys.winver`

The version number used to form registry keys on Windows platforms. This is stored as string resource 1000 in the Python DLL. The value is normally the first three characters of `version`. It is provided in the `sys` module for informational purposes; modifying this value has no effect on the registry keys used by Python. Availability: Windows.

`sys._xoptions`

A dictionary of the various implementation-specific flags passed through the `-X` command-line option. Option names are either mapped to their values, if given explicitly, or to `True`. Example:

```
$ ./python -Xa=b -Xc
Python 3.2a3+ (py3k, Oct 16 2010, 20:14:50)
[GCC 4.4.3] on linux2
Type "help", "copyright", "credits" or "license" for more in
>>> import sys
>>> sys._xoptions
```

```
{'a': 'b', 'c': True}
```

CPython implementation detail: This is a CPython-specific way of accessing options passed through `-X`. Other implementations may export them through other means, or not at all.

New in version 3.2.

27.2. `sysconfig` — Provide access to Python's configuration information

Source code: [Lib/sysconfig.py](#)

New in version 3.2.

The `sysconfig` module provides access to Python's configuration information like the list of installation paths and the configuration variables relevant for the current platform.

27.2.1. Configuration variables

A Python distribution contains a `Makefile` and a `pyconfig.h` header file that are necessary to build both the Python binary itself and third-party C extensions compiled using `distutils`.

`sysconfig` puts all variables found in these files in a dictionary that can be accessed using `get_config_vars()` or `get_config_var()`.

Notice that on Windows, it's a much smaller set.

`sysconfig.get_config_vars(*args)`

With no arguments, return a dictionary of all configuration variables relevant for the current platform.

With arguments, return a list of values that result from looking up each argument in the configuration variable dictionary.

For each argument, if the value is not found, return `None`.

`sysconfig.get_config_var(name)`

Return the value of a single variable *name*. Equivalent to `get_config_vars().get(name)`.

If *name* is not found, return `None`.

Example of usage:

```
>>> import sysconfig
>>> sysconfig.get_config_var('Py_ENABLE_SHARED')
0
>>> sysconfig.get_config_var('LIBDIR')
'/usr/local/lib'
>>> sysconfig.get_config_vars('AR', 'CXX')
['ar', 'g++']
```

27.2.2. Installation paths

Python uses an installation scheme that differs depending on the platform and on the installation options. These schemes are stored in `sysconfig` under unique identifiers based on the value returned by `os.name`.

Every new component that is installed using `distutils` or a Distutils-based system will follow the same scheme to copy its file in the right places.

Python currently supports seven schemes:

- *posix_prefix*: scheme for Posix platforms like Linux or Mac OS X. This is the default scheme used when Python or a component is installed.
- *posix_home*: scheme for Posix platforms used when a *home* option is used upon installation. This scheme is used when a component is installed through Distutils with a specific home prefix.
- *posix_user*: scheme for Posix platforms used when a component is installed through Distutils and the *user* option is used. This scheme defines paths located under the user home directory.
- *nt*: scheme for NT platforms like Windows.
- *nt_user*: scheme for NT platforms, when the *user* option is used.
- *os2*: scheme for OS/2 platforms.
- *os2_home*: scheme for OS/2 platforms, when the *user* option is used.

Each scheme is itself composed of a series of paths and each path has a unique identifier. Python currently uses eight paths:

- *stdlib*: directory containing the standard Python library files that

are not platform-specific.

- *platstdlib*: directory containing the standard Python library files that are platform-specific.
- *platlib*: directory for site-specific, platform-specific files.
- *purelib*: directory for site-specific, non-platform-specific files.
- *include*: directory for non-platform-specific header files.
- *platinclude*: directory for platform-specific header files.
- *scripts*: directory for script files.
- *data*: directory for data files.

sysconfig provides some functions to determine these paths.

`sysconfig.get_scheme_names()`

Return a tuple containing all schemes currently supported in **sysconfig**.

`sysconfig.get_path_names()`

Return a tuple containing all path names currently supported in **sysconfig**.

`sysconfig.get_path(name[, scheme[, vars[, expand]]])`

Return an installation path corresponding to the path *name*, from the install scheme named *scheme*.

name has to be a value from the list returned by `get_path_names()`.

sysconfig stores installation paths corresponding to each path name, for each platform, with variables to be expanded. For instance the *stdlib* path for the *nt* scheme is: `{base}/Lib`.

`get_path()` will use the variables returned by `get_config_vars()` to expand the path. All variables have default values for each platform so one may call this function and get the default value.

If *scheme* is provided, it must be a value from the list returned by `get_path_names()`. Otherwise, the default scheme for the current platform is used.

If *vars* is provided, it must be a dictionary of variables that will update the dictionary return by `get_config_vars()`.

If *expand* is set to `False`, the path will not be expanded using the variables.

If *name* is not found, return `None`.

`sysconfig.get_paths([scheme[, vars[, expand]]])`

Return a dictionary containing all installation paths corresponding to an installation scheme. See `get_path()` for more information.

If *scheme* is not provided, will use the default scheme for the current platform.

If *vars* is provided, it must be a dictionary of variables that will update the dictionary used to expand the paths.

If *expand* is set to `False`, the paths will not be expanded.

If *scheme* is not an existing scheme, `get_paths()` will raise a `KeyError`.

27.2.3. Other functions

`sysconfig.get_python_version()`

Return the MAJOR.MINOR Python version number as a string.
Similar to `sys.version[:3]`.

`sysconfig.get_platform()`

Return a string that identifies the current platform.

This is used mainly to distinguish platform-specific build directories and platform-specific built distributions. Typically includes the OS name and version and the architecture (as supplied by `os.uname()`), although the exact information included depends on the OS; e.g. for IRIX the architecture isn't particularly important (IRIX only runs on SGI hardware), but for Linux the kernel version isn't particularly important.

Examples of returned values:

- linux-i586
- linux-alpha (?)
- solaris-2.6-sun4u
- irix-5.3
- irix64-6.2

Windows will return one of:

- win-amd64 (64bit Windows on AMD64 (aka x86_64, Intel64, EM64T, etc))
- win-ia64 (64bit Windows on Itanium)
- win32 (all others - specifically, `sys.platform` is returned)

Mac OS X can return:

- macosx-10.6-ppc

- macosx-10.4-ppc64
- macosx-10.3-i386
- macosx-10.4-fat

For other non-POSIX platforms, currently just returns `sys.platform`.

`sysconfig.is_python_build()`

Return `True` if the current Python installation was built from source.

`sysconfig.parse_config_h(fp[, vars])`

Parse a `config.h`-style file.

`fp` is a file-like object pointing to the `config.h`-like file.

A dictionary containing name/value pairs is returned. If an optional dictionary is passed in as the second argument, it is used instead of a new dictionary, and updated with the values read in the file.

`sysconfig.get_config_h_filename()`

Return the path of `pyconfig.h`.

`sysconfig.get_makefile_filename()`

Return the path of `Makefile`.

27.2.4. Using `sysconfig` as a script

You can use `sysconfig` as a script with Python's `-m` option:

```
$ python -m sysconfig
Platform: "macosx-10.4-i386"
Python version: "3.2"
Current installation scheme: "posix_prefix"

Paths:
    data = "/usr/local"
    include = "/Users/tarek/Dev/svn.python.org/py3k/Include"
    platinclude = "."
    platlib = "/usr/local/lib/python3.2/site-packages"
    platstdlib = "/usr/local/lib/python3.2"
    purelib = "/usr/local/lib/python3.2/site-packages"
    scripts = "/usr/local/bin"
    stdlib = "/usr/local/lib/python3.2"

Variables:
    AC_APPLE_UNIVERSAL_BUILD = "0"
    AIX_GENUINE_CPLUSPLUS = "0"
    AR = "ar"
    ARFLAGS = "rc"
    ASDLGEN = "./Parser/asdl_c.py"
    ...
```

This call will print in the standard output the information returned by `get_platform()`, `get_python_version()`, `get_path()` and `get_config_vars()`.

27.3. `builtins` — Built-in objects

This module provides direct access to all ‘built-in’ identifiers of Python; for example, `builtins.open` is the full name for the built-in function `open()`.

This module is not normally accessed explicitly by most applications, but can be useful in modules that provide objects with the same name as a built-in value, but in which the built-in of that name is also needed. For example, in a module that wants to implement an `open()` function that wraps the built-in `open()`, this module can be used directly:

```
import builtins

def open(path):
    f = builtins.open(path, 'r')
    return UpperCaser(f)

class UpperCaser:
    '''Wrapper around a file that converts output to upper-case'''

    def __init__(self, f):
        self._f = f

    def read(self, count=-1):
        return self._f.read(count).upper()

    # ...
```

As an implementation detail, most modules have the name `__builtins__` made available as part of their globals. The value of `__builtins__` is normally either this module or the value of this module’s `__dict__` attribute. Since this is an implementation detail, it may not be used by alternate implementations of Python.

27.4. `__main__` — Top-level script environment

This module represents the (otherwise anonymous) scope in which the interpreter’s main program executes — commands read either from standard input, from a script file, or from an interactive prompt. It is this environment in which the idiomatic “conditional script” stanza causes a script to run:

```
if __name__ == "__main__":  
    main()
```

27.5. warnings — Warning control

Source code: [Lib/warnings.py](#)

Warning messages are typically issued in situations where it is useful to alert the user of some condition in a program, where that condition (normally) doesn't warrant raising an exception and terminating the program. For example, one might want to issue a warning when a program uses an obsolete module.

Python programmers issue warnings by calling the `warn()` function defined in this module. (C programmers use `PyErr_WarnEx()`; see *Exception Handling* for details).

Warning messages are normally written to `sys.stderr`, but their disposition can be changed flexibly, from ignoring all warnings to turning them into exceptions. The disposition of warnings can vary based on the warning category (see below), the text of the warning message, and the source location where it is issued. Repetitions of a particular warning for the same source location are typically suppressed.

There are two stages in warning control: first, each time a warning is issued, a determination is made whether a message should be issued or not; next, if a message is to be issued, it is formatted and printed using a user-settable hook.

The determination whether to issue a warning message is controlled by the warning filter, which is a sequence of matching rules and actions. Rules can be added to the filter by calling `filterwarnings()` and reset to its default state by calling `resetwarnings()`.

The printing of warning messages is done by calling `showwarning()`,

which may be overridden; the default implementation of this function formats the message by calling `formatwarning()`, which is also available for use by custom implementations.

27.5.1. Warning Categories

There are a number of built-in exceptions that represent warning categories. This categorization is useful to be able to filter out groups of warnings. The following warnings category classes are currently defined:

Class	Description
<code>Warning</code>	This is the base class of all warning category classes. It is a subclass of <code>Exception</code> .
<code>UserWarning</code>	The default category for <code>warn()</code> .
<code>DeprecationWarning</code>	Base category for warnings about deprecated features (ignored by default).
<code>SyntaxWarning</code>	Base category for warnings about dubious syntactic features.
<code>RuntimeWarning</code>	Base category for warnings about dubious runtime features.
<code>FutureWarning</code>	Base category for warnings about constructs that will change semantically in the future.
<code>PendingDeprecationWarning</code>	Base category for warnings about features that will be deprecated in the future (ignored by default).
<code>ImportWarning</code>	Base category for warnings triggered during the process of importing a module (ignored by default).
<code>UnicodeWarning</code>	Base category for warnings related to Unicode.
<code>BytesWarning</code>	Base category for warnings related to <code>bytes</code> and <code>buffer</code> .
<code>ResourceWarning</code>	Base category for warnings related to resource usage.

While these are technically built-in exceptions, they are documented here, because conceptually they belong to the warnings mechanism.

User code can define additional warning categories by subclassing one of the standard warning categories. A warning category must always be a subclass of the `Warning` class.

27.5.2. The Warnings Filter

The warnings filter controls whether warnings are ignored, displayed, or turned into errors (raising an exception).

Conceptually, the warnings filter maintains an ordered list of filter specifications; any specific warning is matched against each filter specification in the list in turn until a match is found; the match determines the disposition of the match. Each entry is a tuple of the form (*action*, *message*, *category*, *module*, *lineno*), where:

- *action* is one of the following strings:

Value	Disposition
"error"	turn matching warnings into exceptions
"ignore"	never print matching warnings
"always"	always print matching warnings
"default"	print the first occurrence of matching warnings for each location where the warning is issued
"module"	print the first occurrence of matching warnings for each module where the warning is issued
"once"	print only the first occurrence of matching warnings, regardless of location

- *message* is a string containing a regular expression that the warning message must match (the match is compiled to always be case-insensitive).
- *category* is a class (a subclass of `Warning`) of which the warning category must be a subclass in order to match.
- *module* is a string containing a regular expression that the module name must match (the match is compiled to be case-

sensitive).

- *lineno* is an integer that the line number where the warning occurred must match, or `0` to match all line numbers.

Since the `Warning` class is derived from the built-in `Exception` class, to turn a warning into an error we simply raise `category(message)`.

The warnings filter is initialized by `-W` options passed to the Python interpreter command line. The interpreter saves the arguments for all `-W` options without interpretation in `sys.warnoptions`; the `warnings` module parses these when it is first imported (invalid options are ignored, after printing a message to `sys.stderr`).

27.5.2.1. Default Warning Filters

By default, Python installs several warning filters, which can be overridden by the command-line options passed to `-W` and calls to `filterwarnings()`.

- `DeprecationWarning` and `PendingDeprecationWarning`, and `ImportWarning` are ignored.
- `BytesWarning` is ignored unless the `-b` option is given once or twice; in this case this warning is either printed (`-b`) or turned into an exception (`-bb`).
- `ResourceWarning` is ignored unless Python was built in debug mode.

Changed in version 3.2: `DeprecationWarning` is now ignored by default in addition to `PendingDeprecationWarning`.

27.5.3. Temporarily Suppressing Warnings

If you are using code that you know will raise a warning, such as a deprecated function, but do not want to see the warning, then it is possible to suppress the warning using the `catch_warnings` context manager:

```
import warnings

def fxn():
    warnings.warn("deprecated", DeprecationWarning)

with warnings.catch_warnings():
    warnings.simplefilter("ignore")
    fxn()
```

While within the context manager all warnings will simply be ignored. This allows you to use known-deprecated code without having to see the warning while not suppressing the warning for other code that might not be aware of its use of deprecated code. Note: this can only be guaranteed in a single-threaded application. If two or more threads use the `catch_warnings` context manager at the same time, the behavior is undefined.

27.5.4. Testing Warnings

To test warnings raised by code, use the `catch_warnings` context manager. With it you can temporarily mutate the warnings filter to facilitate your testing. For instance, do the following to capture all raised warnings to check:

```
import warnings

def fxn():
    warnings.warn("deprecated", DeprecationWarning)

with warnings.catch_warnings(record=True) as w:
    # Cause all warnings to always be triggered.
    warnings.simplefilter("always")
    # Trigger a warning.
    fxn()
    # Verify some things
    assert len(w) == 1
    assert isinstance(w[-1].category, DeprecationWarning)
    assert "deprecated" in str(w[-1].message)
```

One can also cause all warnings to be exceptions by using `error` instead of `always`. One thing to be aware of is that if a warning has already been raised because of a `once/default` rule, then no matter what filters are set the warning will not be seen again unless the warnings registry related to the warning has been cleared.

Once the context manager exits, the warnings filter is restored to its state when the context was entered. This prevents tests from changing the warnings filter in unexpected ways between tests and leading to indeterminate test results. The `showwarning()` function in the module is also restored to its original value. Note: this can only be guaranteed in a single-threaded application. If two or more threads use the `catch_warnings` context manager at the same time, the behavior is undefined.

When testing multiple operations that raise the same kind of warning, it is important to test them in a manner that confirms each operation is raising a new warning (e.g. set warnings to be raised as exceptions and check the operations raise exceptions, check that the length of the warning list continues to increase after each operation, or else delete the previous entries from the warnings list before each new operation).

27.5.5. Updating Code For New Versions of Python

Warnings that are only of interest to the developer are ignored by default. As such you should make sure to test your code with typically ignored warnings made visible. You can do this from the command-line by passing `-Wd` to the interpreter (this is shorthand for `-W default`). This enables default handling for all warnings, including those that are ignored by default. To change what action is taken for encountered warnings you simply change what argument is passed to `-W`, e.g. `-W error`. See the `-W` flag for more details on what is possible.

To programmatically do the same as `-Wd`, use:

```
warnings.simplefilter('default')
```

Make sure to execute this code as soon as possible. This prevents the registering of what warnings have been raised from unexpectedly influencing how future warnings are treated.

Having certain warnings ignored by default is done to prevent a user from seeing warnings that are only of interest to the developer. As you do not necessarily have control over what interpreter a user uses to run their code, it is possible that a new version of Python will be released between your release cycles. The new interpreter release could trigger new warnings in your code that were not there in an older interpreter, e.g. `DeprecationWarning` for a module that you are using. While you as a developer want to be notified that your code is using a deprecated module, to a user this information is essentially noise and provides no benefit to them.

The `unittest` module has been also updated to use the `'default'`

filter while running tests.

27.5.6. Available Functions

`warnings.warn(message, category=None, stacklevel=1)`

Issue a warning, or maybe ignore it or raise an exception. The *category* argument, if given, must be a warning category class (see above); it defaults to `UserWarning`. Alternatively *message* can be a `Warning` instance, in which case *category* will be ignored and `message.__class__` will be used. In this case the message text will be `str(message)`. This function raises an exception if the particular warning issued is changed into an error by the warnings filter see above. The *stacklevel* argument can be used by wrapper functions written in Python, like this:

```
def deprecation(message):  
    warnings.warn(message, DeprecationWarning, stacklevel=2)
```

This makes the warning refer to `deprecation()`'s caller, rather than to the source of `deprecation()` itself (since the latter would defeat the purpose of the warning message).

`warnings.warn_explicit(message, category, filename, lineno, module=None, registry=None, module_globals=None)`

This is a low-level interface to the functionality of `warn()`, passing in explicitly the message, category, filename and line number, and optionally the module name and the registry (which should be the `__warningregistry__` dictionary of the module). The module name defaults to the filename with `.py` stripped; if no registry is passed, the warning is never suppressed. *message* must be a string and *category* a subclass of `Warning` or *message* may be a `Warning` instance, in which case *category* will be ignored.

module_globals, if supplied, should be the global namespace in use by the code for which the warning is issued. (This argument is used to support displaying source for modules found in zipfiles or other non-filesystem import sources).

warnings.**showwarning**(*message*, *category*, *filename*, *lineno*, *file=None*, *line=None*)

Write a warning to a file. The default implementation calls `formatwarning(message, category, filename, lineno, line)` and writes the resulting string to *file*, which defaults to `sys.stderr`. You may replace this function with an alternative implementation by assigning to `warnings.showwarning`. *line* is a line of source code to be included in the warning message; if *line* is not supplied, `showwarning()` will try to read the line specified by *filename* and *lineno*.

warnings.**formatwarning**(*message*, *category*, *filename*, *lineno*, *line=None*)

Format a warning the standard way. This returns a string which may contain embedded newlines and ends in a newline. *line* is a line of source code to be included in the warning message; if *line* is not supplied, `formatwarning()` will try to read the line specified by *filename* and *lineno*.

warnings.**filterwarnings**(*action*, *message=""*, *category=Warning*, *module=""*, *lineno=0*, *append=False*)

Insert an entry into the list of *warnings filter specifications*. The entry is inserted at the front by default; if *append* is true, it is inserted at the end. This checks the types of the arguments, compiles the *message* and *module* regular expressions, and inserts them as a tuple in the list of warnings filters. Entries closer to the front of the list override entries later in the list, if both match a particular warning. Omitted arguments default to a value that matches everything.

warnings.**simplefilter**(*action*, *category=Warning*, *lineno=0*,
append=False)

Insert a simple entry into the list of *warnings filter specifications*. The meaning of the function parameters is as for **filterwarnings()**, but regular expressions are not needed as the filter inserted always matches any message in any module as long as the category and line number match.

warnings.**resetwarnings**()

Reset the warnings filter. This discards the effect of all previous calls to **filterwarnings()**, including that of the *-W* command line options and calls to **simplefilter()**.

27.5.7. Available Context Managers

`class warnings.catch_warnings(*, record=False, module=None)`

A context manager that copies and, upon exit, restores the warnings filter and the `showwarning()` function. If the `record` argument is `False` (the default) the context manager returns `None` on entry. If `record` is `True`, a list is returned that is progressively populated with objects as seen by a custom `showwarning()` function (which also suppresses output to `sys.stdout`). Each object in the list has attributes with the same names as the arguments to `showwarning()`.

The `module` argument takes a module that will be used instead of the module returned when you import `warnings` whose filter will be protected. This argument exists primarily for testing the `warnings` module itself.

Note: The `catch_warnings` manager works by replacing and then later restoring the module's `showwarning()` function and internal list of filter specifications. This means the context manager is modifying global state and therefore is not thread-safe.

27.6. contextlib — Utilities for with-statement contexts

Source code: [Lib/contextlib.py](#)

This module provides utilities for common tasks involving the `with` statement. For more information see also *Context Manager Types* and *With Statement Context Managers*.

Functions provided:

`@contextlib.contextmanager`

This function is a *decorator* that can be used to define a factory function for `with` statement context managers, without needing to create a class or separate `__enter__()` and `__exit__()` methods.

A simple example (this is not recommended as a real way of generating HTML!):

```
from contextlib import contextmanager

@contextmanager
def tag(name):
    print("<%s>" % name)
    yield
    print("</%s>" % name)

>>> with tag("h1"):
...     print("foo")
...
<h1>
foo
</h1>
```

The function being decorated must return a *generator*-iterator when called. This iterator must yield exactly one value, which will

be bound to the targets in the `with` statement's `as` clause, if any.

At the point where the generator yields, the block nested in the `with` statement is executed. The generator is then resumed after the block is exited. If an unhandled exception occurs in the block, it is reraised inside the generator at the point where the yield occurred. Thus, you can use a `try...except...finally` statement to trap the error (if any), or ensure that some cleanup takes place. If an exception is trapped merely in order to log it or to perform some action (rather than to suppress it entirely), the generator must reraise that exception. Otherwise the generator context manager will indicate to the `with` statement that the exception has been handled, and execution will resume with the statement immediately following the `with` statement.

contextmanager uses `ContextDecorator` so the context managers it creates can be used as decorators as well as in `with` statements.

Changed in version 3.2: Use of `ContextDecorator`.

`contextlib.closing(thing)`

Return a context manager that closes *thing* upon completion of the block. This is basically equivalent to:

```
from contextlib import contextmanager

@contextmanager
def closing(thing):
    try:
        yield thing
    finally:
        thing.close()
```

And lets you write code like this:

```
from contextlib import closing
```

```
from urllib.request import urlopen

with closing(urlopen('http://www.python.org')) as page:
    for line in page:
        print(line)
```

without needing to explicitly close `page`. Even if an error occurs, `page.close()` will be called when the `with` block is exited.

`class contextlib.ContextDecorator`

A base class that enables a context manager to also be used as a decorator.

Context managers inheriting from `ContextDecorator` have to implement `__enter__` and `__exit__` as normal. `__exit__` retains its optional exception handling even when used as a decorator.

`ContextDecorator` is used by `contextmanager()`, so you get this functionality automatically.

Example of `ContextDecorator`:

```
from contextlib import ContextDecorator

class mycontext(ContextDecorator):
    def __enter__(self):
        print('Starting')
        return self

    def __exit__(self, *exc):
        print('Finishing')
        return False

>>> @mycontext()
... def function():
...     print('The bit in the middle')
...
>>> function()
Starting
The bit in the middle
Finishing
```

```
>>> with mycontext():
...     print('The bit in the middle')
...
Starting
The bit in the middle
Finishing
```

This change is just syntactic sugar for any construct of the following form:

```
def f():
    with cm():
        # Do stuff
```

`ContextDecorator` lets you instead write:

```
@cm()
def f():
    # Do stuff
```

It makes it clear that the `cm` applies to the whole function, rather than just a piece of it (and saving an indentation level is nice, too).

Existing context managers that already have a base class can be extended by using `ContextDecorator` as a mixin class:

```
from contextlib import ContextDecorator

class mycontext(ContextBaseClass, ContextDecorator):
    def __enter__(self):
        return self

    def __exit__(self, *exc):
        return False
```

New in version 3.2.

 [Python v3.2 documentation](#) » [The Python Standard Library](#) [previous](#) | [next](#) | [modules](#) | [index](#)
» [27. Python Runtime Services](#) »

27.7. abc — Abstract Base Classes

Source code: [Lib/abc.py](#)

This module provides the infrastructure for defining an *abstract base class* (ABCs) in Python, as outlined in [PEP 3119](#); see the PEP for why this was added to Python. (See also [PEP 3141](#) and the [numbers](#) module regarding a type hierarchy for numbers based on ABCs.)

The [collections](#) module has some concrete classes that derive from ABCs; these can, of course, be further derived. In addition the [collections](#) module has some ABCs that can be used to test whether a class or instance provides a particular interface, for example, is it hashable or a mapping.

This module provides the following class:

```
class abc.ABCMeta
```

Metaclass for defining Abstract Base Classes (ABCs).

Use this metaclass to create an ABC. An ABC can be subclassed directly, and then acts as a mix-in class. You can also register unrelated concrete classes (even built-in classes) and unrelated ABCs as “virtual subclasses” – these and their descendants will be considered subclasses of the registering ABC by the built-in [issubclass\(\)](#) function, but the registering ABC won’t show up in their MRO (Method Resolution Order) nor will method implementations defined by the registering ABC be callable (not even via [super\(\)](#)). [1]

Classes created with a metaclass of [ABCMeta](#) have the following method:

`register(subclass)`

Register *subclass* as a “virtual subclass” of this ABC. For example:

```
from abc import ABCMeta

class MyABC(metaclass=ABCMeta):
    pass

MyABC.register(tuple)

assert issubclass(tuple, MyABC)
assert isinstance((), MyABC)
```

You can also override this method in an abstract base class:

`__subclasshook__(subclass)`

(Must be defined as a class method.)

Check whether *subclass* is considered a subclass of this ABC. This means that you can customize the behavior of `issubclass` further without the need to call `register()` on every class you want to consider a subclass of the ABC. (This class method is called from the `__subclasscheck__()` method of the ABC.)

This method should return `True`, `False` or `NotImplemented`. If it returns `True`, the *subclass* is considered a subclass of this ABC. If it returns `False`, the *subclass* is not considered a subclass of this ABC, even if it would normally be one. If it returns `NotImplemented`, the subclass check is continued with the usual mechanism.

For a demonstration of these concepts, look at this example ABC definition:

```
class Foo:
```

```

def __getitem__(self, index):
    ...
def __len__(self):
    ...
def get_iterator(self):
    return iter(self)

class MyIterable(metaclass=ABCMeta):

    @abstractmethod
    def __iter__(self):
        while False:
            yield None

    def get_iterator(self):
        return self.__iter__()

    @classmethod
    def __subclasshook__(cls, C):
        if cls is MyIterable:
            if any("__iter__" in B.__dict__ for B in C.__mro__):
                return True
            return NotImplemented

MyIterable.register(Foo)

```

The ABC `MyIterable` defines the standard iterable method, `__iter__()`, as an abstract method. The implementation given here can still be called from subclasses. The `get_iterator()` method is also part of the `MyIterable` abstract base class, but it does not have to be overridden in non-abstract derived classes.

The `__subclasshook__()` class method defined here says that any class that has an `__iter__()` method in its `__dict__` (or in that of one of its base classes, accessed via the `__mro__` list) is considered a `MyIterable` too.

Finally, the last line makes `Foo` a virtual subclass of `MyIterable`, even though it does not define an `__iter__()` method (it uses the old-style iterable protocol, defined in terms of `__len__()` and

`__getitem__()`). Note that this will not make `get_iterator` available as a method of `Foo`, so it is provided separately.

It also provides the following decorators:

`@abc.abstractmethod(function)`

A decorator indicating abstract methods.

Using this decorator requires that the class's metaclass is `ABCMeta` or is derived from it. A class that has a metaclass derived from `ABCMeta` cannot be instantiated unless all of its abstract methods and properties are overridden. The abstract methods can be called using any of the normal 'super' call mechanisms.

Dynamically adding abstract methods to a class, or attempting to modify the abstraction status of a method or class once it is created, are not supported. The `abstractmethod()` only affects subclasses derived using regular inheritance; "virtual subclasses" registered with the ABC's `register()` method are not affected.

Usage:

```
class C(metaclass=ABCMeta):
    @abstractmethod
    def my_abstract_method(self, ...):
        ...
```

Note: Unlike Java abstract methods, these abstract methods may have an implementation. This implementation can be called via the `super()` mechanism from the class that overrides it. This could be useful as an end-point for a super-call in a framework that uses cooperative multiple-inheritance.

`@abc.abstractclassmethod(function)`

A subclass of the built-in `classmethod()`, indicating an abstract

classmethod. Otherwise it is similar to `abstractmethod()`.

Usage:

```
class C(metaclass=ABCMeta):
    @abstractmethod
    def my_abstract_classmethod(cls, ...):
        ...
```

New in version 3.2.

`@abc.abstractmethod(function)`

A subclass of the built-in `staticmethod()`, indicating an abstract staticmethod. Otherwise it is similar to `abstractmethod()`.

Usage:

```
class C(metaclass=ABCMeta):
    @abstractmethod
    def my_abstract_staticmethod(...):
        ...
```

New in version 3.2.

`abc.abstractproperty(fget=None, fset=None, fdel=None, doc=None)`

A subclass of the built-in `property()`, indicating an abstract property.

Using this function requires that the class's metaclass is `ABCMeta` or is derived from it. A class that has a metaclass derived from `ABCMeta` cannot be instantiated unless all of its abstract methods and properties are overridden. The abstract properties can be called using any of the normal 'super' call mechanisms.

Usage:

```
class C(metaclass=ABCMeta):
    @abstractproperty
    def my_abstract_property(self):
        ...
```

This defines a read-only property; you can also define a read-write abstract property using the ‘long’ form of property declaration:

```
class C(metaclass=ABCMeta):
    def getx(self): ...
    def setx(self, value): ...
    x = abstractproperty(getx, setx)
```

Footnotes

- [1] C++ programmers should note that Python’s virtual base class concept is not the same as C++’s.

27.8. `atexit` — Exit handlers

The `atexit` module defines functions to register and unregister cleanup functions. Functions thus registered are automatically executed upon normal interpreter termination.

Note: the functions registered via this module are not called when the program is killed by a signal not handled by Python, when a Python fatal internal error is detected, or when `os._exit()` is called.

`atexit.register(func, *args, **kwargs)`

Register *func* as a function to be executed at termination. Any optional arguments that are to be passed to *func* must be passed as arguments to `register()`.

At normal program termination (for instance, if `sys.exit()` is called or the main module's execution completes), all functions registered are called in last in, first out order. The assumption is that lower level modules will normally be imported before higher level modules and thus must be cleaned up later.

If an exception is raised during execution of the exit handlers, a traceback is printed (unless `SystemExit` is raised) and the exception information is saved. After all exit handlers have had a chance to run the last exception to be raised is re-raised.

This function returns *func* which makes it possible to use it as a decorator without binding the original name to `None`.

`atexit.unregister(func)`

Remove a function *func* from the list of functions to be run at interpreter- shutdown. After calling `unregister()`, *func* is guaranteed not to be called when the interpreter shuts down.

See also:

Module `readline`

Useful example of `atexit` to read and write `readline` history files.

27.8.1. atexit Example

The following simple example demonstrates how a module can initialize a counter from a file when it is imported and save the counter's updated value automatically when the program terminates without relying on the application making an explicit call into this module at termination.

```
try:
    _count = int(open("/tmp/counter").read())
except IOError:
    _count = 0

def incrcounter(n):
    global _count
    _count = _count + n

def savecounter():
    open("/tmp/counter", "w").write("%d" % _count)

import atexit
atexit.register(savecounter)
```

Positional and keyword arguments may also be passed to `register()` to be passed along to the registered function when it is called:

```
def goodbye(name, adjective):
    print('Goodbye, %s, it was %s to meet you.' % (name, adject

import atexit
atexit.register(goodbye, 'Donny', 'nice')

# or:
atexit.register(goodbye, adjective='nice', name='Donny')
```

Usage as a *decorator*:

```
import atexit

@atexit.register
def goodbye():
    print("You are now leaving the Python sector.")
```

This obviously only works with functions that don't take arguments.

 [Python v3.2 documentation](#) » [The Python Standard Library](#) [previous](#) | [next](#) | [modules](#) | [index](#)
» [27. Python Runtime Services](#) »

27.9. `traceback` — Print or retrieve a stack traceback

This module provides a standard interface to extract, format and print stack traces of Python programs. It exactly mimics the behavior of the Python interpreter when it prints a stack trace. This is useful when you want to print stack traces under program control, such as in a “wrapper” around the interpreter.

The module uses `traceback` objects — this is the object type that is stored in the `sys.last_traceback` variable and returned as the third item from `sys.exc_info()`.

The module defines the following functions:

`traceback.print_tb(traceback, limit=None, file=None)`

Print up to *limit* stack trace entries from *traceback*. If *limit* is omitted or `None`, all entries are printed. If *file* is omitted or `None`, the output goes to `sys.stderr`; otherwise it should be an open file or file-like object to receive the output.

`traceback.print_exception(type, value, traceback, limit=None, file=None, chain=True)`

Print exception information and up to *limit* stack trace entries from *traceback* to *file*. This differs from `print_tb()` in the following ways:

- if *traceback* is not `None`, it prints a header `Traceback (most recent call last):`
- it prints the exception *type* and *value* after the stack trace
- if *type* is `SyntaxError` and *value* has the appropriate format, it prints the line where the syntax error occurred with a caret

indicating the approximate position of the error.

If *chain* is true (the default), then chained exceptions (the `__cause__` or `__context__` attributes of the exception) will be printed as well, like the interpreter itself does when printing an unhandled exception.

`traceback.print_exc(limit=None, file=None, chain=True)`

This is a shorthand for `print_exception(*sys.exc_info())`.

`traceback.print_last(limit=None, file=None, chain=True)`

This is a shorthand for `print_exception(sys.last_type, sys.last_value, sys.last_traceback, limit, file)`. In general it will work only after an exception has reached an interactive prompt (see `sys.last_type`).

`traceback.print_stack(f=None, limit=None, file=None)`

This function prints a stack trace from its invocation point. The optional *f* argument can be used to specify an alternate stack frame to start. The optional *limit* and *file* arguments have the same meaning as for `print_exception()`.

`traceback.extract_tb(traceback, limit=None)`

Return a list of up to *limit* “pre-processed” stack trace entries extracted from the traceback object *traceback*. It is useful for alternate formatting of stack traces. If *limit* is omitted or **None**, all entries are extracted. A “pre-processed” stack trace entry is a quadruple (*filename*, *line number*, *function name*, *text*) representing the information that is usually printed for a stack trace. The *text* is a string with leading and trailing whitespace stripped; if the source is not available it is **None**.

`traceback.extract_stack(f=None, limit=None)`

Extract the raw traceback from the current stack frame. The

return value has the same format as for `extract_tb()`. The optional *f* and *limit* arguments have the same meaning as for `print_stack()`.

`traceback.format_list(list)`

Given a list of tuples as returned by `extract_tb()` or `extract_stack()`, return a list of strings ready for printing. Each string in the resulting list corresponds to the item with the same index in the argument list. Each string ends in a newline; the strings may contain internal newlines as well, for those items whose source text line is not `None`.

`traceback.format_exception_only(type, value)`

Format the exception part of a traceback. The arguments are the exception type and value such as given by `sys.last_type` and `sys.last_value`. The return value is a list of strings, each ending in a newline. Normally, the list contains a single string; however, for `SyntaxError` exceptions, it contains several lines that (when printed) display detailed information about where the syntax error occurred. The message indicating which exception occurred is the always last string in the list.

`traceback.format_exception(type, value, tb, limit=None, chain=True)`

Format a stack trace and the exception information. The arguments have the same meaning as the corresponding arguments to `print_exception()`. The return value is a list of strings, each ending in a newline and some containing internal newlines. When these lines are concatenated and printed, exactly the same text is printed as does `print_exception()`.

`traceback.format_exc(limit=None, chain=True)`

This is like `print_exc(limit)` but returns a string instead of

printing to a file.

`traceback.format_tb(tb, limit=None)`

A shorthand for `format_list(extract_tb(tb, limit))`.

`traceback.format_stack(f=None, limit=None)`

A shorthand for `format_list(extract_stack(f, limit))`.

27.9.1. Traceback Examples

This simple example implements a basic read-eval-print loop, similar to (but less useful than) the standard Python interactive interpreter loop. For a more complete implementation of the interpreter loop, refer to the `code` module.

```
import sys, traceback

def run_user_code(envdir):
    source = input(">>> ")
    try:
        exec(source, envdir)
    except:
        print("Exception in user code:")
        print("-"*60)
        traceback.print_exc(file=sys.stdout)
        print("-"*60)

envdir = {}
while True:
    run_user_code(envdir)
```

The following example demonstrates the different ways to print and format the exception and traceback:

```
import sys, traceback

def lumberjack():
    bright_side_of_death()

def bright_side_of_death():
    return tuple()[0]

try:
    lumberjack()
except IndexError:
    exc_type, exc_value, exc_traceback = sys.exc_info()
    print("*** print_tb:")
    traceback.print_tb(exc_traceback, limit=1, file=sys.stdout)
    print("*** print_exception:")
```

```

    traceback.print_exception(exc_type, exc_value, exc_traceback
                             limit=2, file=sys.stdout)

    print("*** print_exc:")
    traceback.print_exc()
    print("*** format_exc, first and last line:")
    formatted_lines = traceback.format_exc().splitlines()
    print(formatted_lines[0])
    print(formatted_lines[-1])
    print("*** format_exception:")
    print(repr(traceback.format_exception(exc_type, exc_value,
                                         exc_traceback)))

    print("*** extract_tb:")
    print(repr(traceback.extract_tb(exc_traceback)))
    print("*** format_tb:")
    print(repr(traceback.format_tb(exc_traceback)))
    print("*** tb_lineno:", exc_traceback.tb_lineno)

```

The output for the example would look similar to this:

```

*** print_tb:
  File "<doctest...>", line 10, in <module>
    lumberjack()
*** print_exception:
Traceback (most recent call last):
  File "<doctest...>", line 10, in <module>
    lumberjack()
  File "<doctest...>", line 4, in lumberjack
    bright_side_of_death()
IndexError: tuple index out of range
*** print_exc:
Traceback (most recent call last):
  File "<doctest...>", line 10, in <module>
    lumberjack()
  File "<doctest...>", line 4, in lumberjack
    bright_side_of_death()
IndexError: tuple index out of range
*** format_exc, first and last line:
Traceback (most recent call last):
IndexError: tuple index out of range
*** format_exception:
['Traceback (most recent call last):\n',
 '  File "<doctest...>", line 10, in <module>\n    lumberjack()\n',
 '  File "<doctest...>", line 4, in lumberjack\n    bright_side\n',
 '  File "<doctest...>", line 7, in bright_side_of_death\n    r\n',
 'IndexError: tuple index out of range\n']

```

```

*** extract_tb:
[('<doctest...>', 10, '<module>', 'lumberjack()'),
 ('<doctest...>', 4, 'lumberjack', 'bright_side_of_death()'),
 ('<doctest...>', 7, 'bright_side_of_death', 'return tuple()[0]
*** format_tb:
[' File "<doctest...>", line 10, in <module>\n    lumberjack()
' File "<doctest...>", line 4, in lumberjack\n    bright_side
' File "<doctest...>", line 7, in bright_side_of_death\n    r
*** tb_lineno: 10

```

The following example shows the different ways to print and format the stack:

```

>>> import traceback
>>> def another_function():
...     lumberstack()
...
>>> def lumberstack():
...     traceback.print_stack()
...     print(repr(traceback.extract_stack()))
...     print(repr(traceback.format_stack()))
...
>>> another_function()
File "<doctest>", line 10, in <module>
  another_function()
File "<doctest>", line 3, in another_function
  lumberstack()
File "<doctest>", line 6, in lumberstack
  traceback.print_stack()
[('<doctest>', 10, '<module>', 'another_function()'),
 ('<doctest>', 3, 'another_function', 'lumberstack()'),
 ('<doctest>', 7, 'lumberstack', 'print(repr(traceback.extract_
[' File "<doctest>", line 10, in <module>\n    another_funcio
' File "<doctest>", line 3, in another_function\n    lumberst
' File "<doctest>", line 8, in lumberstack\n    print(repr(tr

```

This last example demonstrates the final few formatting functions:

```

>>> import traceback
>>> traceback.format_list([('spam.py', 3, '<module>', 'spam.egg
...     ('eggs.py', 42, 'eggs', 'return "bac
[' File "spam.py", line 3, in <module>\n    spam.eggs()\n',
' File "eggs.py", line 42, in eggs\n    return "bacon"\n']

```

```
>>> an_error = IndexError('tuple index out of range')
>>> traceback.format_exception_only(type(an_error), an_error)
['IndexError: tuple index out of range\n']
```

 [Python v3.2 documentation](#) » [The Python Standard Library](#) [previous](#) | [next](#) | [modules](#) | [index](#)
» [27. Python Runtime Services](#) »

27.10. `__future__` — Future statement definitions

Source code: [Lib/__future__.py](#)

`__future__` is a real module, and serves three purposes:

- To avoid confusing existing tools that analyze import statements and expect to find the modules they're importing.
- To ensure that *future statements* run under releases prior to 2.1 at least yield runtime exceptions (the import of `__future__` will fail, because there was no module of that name prior to 2.1).
- To document when incompatible changes were introduced, and when they will be — or were — made mandatory. This is a form of executable documentation, and can be inspected programmatically via importing `__future__` and examining its contents.

Each statement in `__future__.py` is of the form:

```
FeatureName = _Feature(OptionalRelease, MandatoryRelease,  
                        CompilerFlag)
```

where, normally, *OptionalRelease* is less than *MandatoryRelease*, and both are 5-tuples of the same form as `sys.version_info`:

```
(PY_MAJOR_VERSION, # the 2 in 2.1.0a3; an int  
PY_MINOR_VERSION, # the 1; an int  
PY_MICRO_VERSION, # the 0; an int  
PY_RELEASE_LEVEL, # "alpha", "beta", "candidate" or "final"; s  
PY_RELEASE_SERIAL # the 3; an int  
)
```

OptionalRelease records the first release in which the feature was accepted.

In the case of a *MandatoryRelease* that has not yet occurred, *MandatoryRelease* predicts the release in which the feature will become part of the language.

Else *MandatoryRelease* records when the feature became part of the language; in releases at or after that, modules no longer need a future statement to use the feature in question, but may continue to use such imports.

MandatoryRelease may also be `None`, meaning that a planned feature got dropped.

Instances of class `_Feature` have two corresponding methods, `getOptionalRelease()` and `getMandatoryRelease()`.

CompilerFlag is the (bitfield) flag that should be passed in the fourth argument to the built-in function `compile()` to enable the feature in dynamically compiled code. This flag is stored in the `compiler_flag` attribute on `_Feature` instances.

No feature description will ever be deleted from `__future__`. Since its introduction in Python 2.1 the following features have found their way into the language using this mechanism:

feature	optional in	mandatory in	effect
nested_scopes	2.1.0b1	2.2	PEP 227 : <i>Statically Nested Scopes</i>
generators	2.2.0a1	2.3	PEP 255 : <i>Simple Generators</i>
division	2.2.0a2	3.0	PEP 238 : <i>Changing the Division Operator</i>

absolute_import	2.5.0a1	2.7	PEP 328: <i>Imports: Multi-Line and Absolute/Relative</i>
with_statement	2.5.0a1	2.6	PEP 343: <i>The “with” Statement</i>
print_function	2.6.0a2	3.0	PEP 3105: <i>Make print a function</i>
unicode_literals	2.6.0a2	3.0	PEP 3112: <i>Bytes literals in Python 3000</i>

Future statements

How the compiler treats future imports.

27.11. gc — Garbage Collector interface

This module provides an interface to the optional garbage collector. It provides the ability to disable the collector, tune the collection frequency, and set debugging options. It also provides access to unreachable objects that the collector found but cannot free. Since the collector supplements the reference counting already used in Python, you can disable the collector if you are sure your program does not create reference cycles. Automatic collection can be disabled by calling `gc.disable()`. To debug a leaking program call `gc.set_debug(gc.DEBUG_LEAK)`. Notice that this includes `gc.DEBUG_SAVEALL`, causing garbage-collected objects to be saved in `gc.garbage` for inspection.

The `gc` module provides the following functions:

`gc.enable()`

Enable automatic garbage collection.

`gc.disable()`

Disable automatic garbage collection.

`gc.isenabled()`

Returns true if automatic collection is enabled.

`gc.collect(generations=2)`

With no arguments, run a full collection. The optional argument *generation* may be an integer specifying which generation to collect (from 0 to 2). A `ValueError` is raised if the generation number is invalid. The number of unreachable objects found is returned.

The free lists maintained for a number of built-in types are cleared whenever a full collection or collection of the highest generation (2) is run. Not all items in some free lists may be freed due to the particular implementation, in particular `float`.

gc. **set_debug**(*flags*)

Set the garbage collection debugging flags. Debugging information will be written to `sys.stderr`. See below for a list of debugging flags which can be combined using bit operations to control debugging.

gc. **get_debug**()

Return the debugging flags currently set.

gc. **get_objects**()

Returns a list of all objects tracked by the collector, excluding the list returned.

gc. **set_threshold**(*threshold0*[, *threshold1*[, *threshold2*]])

Set the garbage collection thresholds (the collection frequency). Setting *threshold0* to zero disables collection.

The GC classifies objects into three generations depending on how many collection sweeps they have survived. New objects are placed in the youngest generation (generation 0). If an object survives a collection it is moved into the next older generation. Since generation 2 is the oldest generation, objects in that generation remain there after a collection. In order to decide when to run, the collector keeps track of the number object allocations and deallocations since the last collection. When the number of allocations minus the number of deallocations exceeds *threshold0*, collection starts. Initially only generation 0 is examined. If generation 0 has been examined more than *threshold1* times since generation 1 has been examined, then

generation 1 is examined as well. Similarly, *threshold2* controls the number of collections of generation 1 before collecting generation 2.

gc.**get_count()**

Return the current collection counts as a tuple of (count0, count1, count2).

gc.**get_threshold()**

Return the current collection thresholds as a tuple of (threshold0, threshold1, threshold2).

gc.**get_referrers(*objs)**

Return the list of objects that directly refer to any of *objs*. This function will only locate those containers which support garbage collection; extension types which do refer to other objects but do not support garbage collection will not be found.

Note that objects which have already been dereferenced, but which live in cycles and have not yet been collected by the garbage collector can be listed among the resulting referrers. To get only currently live objects, call `collect()` before calling `get_referrers()`.

Care must be taken when using objects returned by `get_referrers()` because some of them could still be under construction and hence in a temporarily invalid state. Avoid using `get_referrers()` for any purpose other than debugging.

gc.**get_referents(*objs)**

Return a list of objects directly referred to by any of the arguments. The referents returned are those objects visited by the arguments' C-level `tp_traverse` methods (if any), and may not be all objects actually directly reachable. `tp_traverse`

methods are supported only by objects that support garbage collection, and are only required to visit objects that may be involved in a cycle. So, for example, if an integer is directly reachable from an argument, that integer object may or may not appear in the result list.

`gc.is_tracked(obj)`

Returns True if the object is currently tracked by the garbage collector, False otherwise. As a general rule, instances of atomic types aren't tracked and instances of non-atomic types (containers, user-defined objects...) are. However, some type-specific optimizations can be present in order to suppress the garbage collector footprint of simple instances (e.g. dicts containing only atomic keys and values):

```
>>> gc.is_tracked(0)
False
>>> gc.is_tracked("a")
False
>>> gc.is_tracked([])
True
>>> gc.is_tracked({})
False
>>> gc.is_tracked({"a": 1})
False
>>> gc.is_tracked({"a": []})
True
```

New in version 3.1.

The following variable is provided for read-only access (you can mutate its value but should not rebind it):

`gc.garbage`

A list of objects which the collector found to be unreachable but could not be freed (uncollectable objects). By default, this list contains only objects with `__del__()` methods. Objects that have `__del__()` methods and are part of a reference cycle cause the

entire reference cycle to be uncollectable, including objects not necessarily in the cycle but reachable only from it. Python doesn't collect such cycles automatically because, in general, it isn't possible for Python to guess a safe order in which to run the `__del__()` methods. If you know a safe order, you can force the issue by examining the *garbage* list, and explicitly breaking cycles due to your objects within the list. Note that these objects are kept alive even so by virtue of being in the *garbage* list, so they should be removed from *garbage* too. For example, after breaking cycles, do `del gc.garbage[:]` to empty the list. It's generally better to avoid the issue by not creating cycles containing objects with `__del__()` methods, and *garbage* can be examined in that case to verify that no such cycles are being created.

If `DEBUG_SAVEALL` is set, then all unreachable objects will be added to this list rather than freed.

Changed in version 3.2: If this list is non-empty at interpreter shutdown, a `ResourceWarning` is emitted, which is silent by default. If `DEBUG_UNCOLLECTABLE` is set, in addition all uncollectable objects are printed.

The following constants are provided for use with `set_debug()`:

`gc.DEBUG_STATS`

Print statistics during collection. This information can be useful when tuning the collection frequency.

`gc.DEBUG_COLLECTABLE`

Print information on collectable objects found.

`gc.DEBUG_UNCOLLECTABLE`

Print information of uncollectable objects found (objects which are not reachable but cannot be freed by the collector). These

objects will be added to the `garbage` list.

Changed in version 3.2: Also print the contents of the `garbage` list at interpreter shutdown, if it isn't empty.

gc. **DEBUG_SAVEALL**

When set, all unreachable objects found will be appended to *garbage* rather than being freed. This can be useful for debugging a leaking program.

gc. **DEBUG_LEAK**

The debugging flags necessary for the collector to print information about a leaking program (equal to `DEBUG_COLLECTABLE` | `DEBUG_UNCOLLECTABLE` | `DEBUG_SAVEALL`).

27.12. `inspect` — Inspect live objects

Source code: [Lib/inspect.py](#)

The `inspect` module provides several useful functions to help get information about live objects such as modules, classes, methods, functions, tracebacks, frame objects, and code objects. For example, it can help you examine the contents of a class, retrieve the source code of a method, extract and format the argument list for a function, or get all the information you need to display a detailed traceback.

There are four main kinds of services provided by this module: type checking, getting source code, inspecting classes and functions, and examining the interpreter stack.

27.12.1. Types and members

The `getmembers()` function retrieves the members of an object such as a class or module. The sixteen functions whose names begin with “is” are mainly provided as convenient choices for the second argument to `getmembers()`. They also help you determine when you can expect to find the following special attributes:

Type	Attribute	Description
module	<code>__doc__</code>	documentation string
	<code>__file__</code>	filename (missing for built-in modules)
class	<code>__doc__</code>	documentation string
	<code>__module__</code>	name of module in which this class was defined
method	<code>__doc__</code>	documentation string
	<code>__name__</code>	name with which this method was defined
	<code>__func__</code>	function object containing implementation of method
	<code>__self__</code>	instance to which this method is bound, or <code>None</code>
function	<code>__doc__</code>	documentation string
	<code>__name__</code>	name with which this function was defined
	<code>__code__</code>	code object containing compiled function <i>bytecode</i>
	<code>__defaults__</code>	tuple of any default values for arguments
	<code>__globals__</code>	global namespace in which this function was defined
traceback	<code>tb_frame</code>	frame object at this level
	<code>tb_lasti</code>	index of last attempted

		instruction in bytecode
	tb_lineno	current line number in Python source code
	tb_next	next inner traceback object (called by this level)
frame	f_back	next outer frame object (this frame's caller)
	f_builtins	builtins namespace seen by this frame
	f_code	code object being executed in this frame
	f_globals	global namespace seen by this frame
	f_lasti	index of last attempted instruction in bytecode
	f_lineno	current line number in Python source code
	f_locals	local namespace seen by this frame
	f_restricted	0 or 1 if frame is in restricted execution mode
	f_trace	tracing function for this frame, or None
code	co_argcount	number of arguments (not including * or ** args)
	co_code	string of raw compiled bytecode
	co_consts	tuple of constants used in the bytecode
	co_filename	name of file in which this code object was created
	co_firstlineno	number of first line in Python source code
	co_flags	bitmap: 1=optimized 2=newlocals 4=*arg 8=**arg
		encoded mapping of line

	<code>co_inotab</code>	numbers to bytecode indices
	<code>co_name</code>	name with which this code object was defined
	<code>co_names</code>	tuple of names of local variables
	<code>co_nlocals</code>	number of local variables
	<code>co_stacksize</code>	virtual machine stack space required
	<code>co_varnames</code>	tuple of names of arguments and local variables
<code>builtin</code>	<code>__doc__</code>	documentation string
	<code>__name__</code>	original name of this function or method
	<code>__self__</code>	instance to which a method is bound, or <code>None</code>

`inspect.getmembers(object[, predicate])`

Return all the members of an object in a list of (name, value) pairs sorted by name. If the optional *predicate* argument is supplied, only members for which the predicate returns a true value are included.

Note: `getmembers()` does not return metaclass attributes when the argument is a class (this behavior is inherited from the `dir()` function).

`inspect.getmoduleinfo(path)`

Returns a *named tuple* `ModuleInfo(name, suffix, mode, module_type)` of values that describe how Python will interpret the file identified by *path* if it is a module, or `None` if it would not be identified as a module. In that tuple, *name* is the name of the module without the name of any enclosing package, *suffix* is the trailing part of the file name (which may not be a dot-delimited

extension), *mode* is the `open()` mode that would be used ('r' or 'rb'), and *module_type* is an integer giving the type of the module. *module_type* will have a value which can be compared to the constants defined in the `imp` module; see the documentation for that module for more information on module types.

`inspect.getmodulename(path)`

Return the name of the module named by the file *path*, without including the names of enclosing packages. This uses the same algorithm as the interpreter uses when searching for modules. If the name cannot be matched according to the interpreter's rules, `None` is returned.

`inspect.ismodule(object)`

Return true if the object is a module.

`inspect.isclass(object)`

Return true if the object is a class, whether built-in or created in Python code.

`inspect.ismethod(object)`

Return true if the object is a bound method written in Python.

`inspect.isfunction(object)`

Return true if the object is a Python function, which includes functions created by a *lambda* expression.

`inspect.isgeneratorfunction(object)`

Return true if the object is a Python generator function.

`inspect.isgenerator(object)`

Return true if the object is a generator.

`inspect.istraceback(object)`

Return true if the object is a traceback.

`inspect.isframe(object)`

Return true if the object is a frame.

`inspect.iscode(object)`

Return true if the object is a code.

`inspect.isbuiltin(object)`

Return true if the object is a built-in function or a bound built-in method.

`inspect.isroutine(object)`

Return true if the object is a user-defined or built-in function or method.

`inspect.isabstract(object)`

Return true if the object is an abstract base class.

`inspect.ismethoddescriptor(object)`

Return true if the object is a method descriptor, but not if `ismethod()`, `isclass()`, `isfunction()` or `isbuiltin()` are true.

This, for example, is true of `int.__add__`. An object passing this test has a `__get__` attribute but not a `__set__` attribute, but beyond that the set of attributes varies. `__name__` is usually sensible, and `__doc__` often is.

Methods implemented via descriptors that also pass one of the other tests return false from the `ismethoddescriptor()` test, simply because the other tests promise more – you can, e.g., count on having the `__func__` attribute (etc) when an object passes `ismethod()`.

`inspect.isdatadescriptor(object)`

Return true if the object is a data descriptor.

Data descriptors have both a `__get__` and a `__set__` attribute. Examples are properties (defined in Python), getsets, and members. The latter two are defined in C and there are more specific tests available for those types, which is robust across Python implementations. Typically, data descriptors will also have `__name__` and `__doc__` attributes (properties, getsets, and members have both of these attributes), but this is not guaranteed.

`inspect.isgetsetdescriptor(object)`

Return true if the object is a getset descriptor.

CPython implementation detail: getsets are attributes defined in extension modules via `PyGetSetDef` structures. For Python implementations without such types, this method will always return `False`.

`inspect.ismemberdescriptor(object)`

Return true if the object is a member descriptor.

CPython implementation detail: Member descriptors are attributes defined in extension modules via `PyMemberDef` structures. For Python implementations without such types, this method will always return `False`.

27.12.2. Retrieving source code

`inspect.getdoc(object)`

Get the documentation string for an object, cleaned up with `cleandoc()`.

`inspect.getcomments(object)`

Return in a single string any lines of comments immediately preceding the object's source code (for a class, function, or method), or at the top of the Python source file (if the object is a module).

`inspect.getfile(object)`

Return the name of the (text or binary) file in which an object was defined. This will fail with a `TypeError` if the object is a built-in module, class, or function.

`inspect.getmodule(object)`

Try to guess which module an object was defined in.

`inspect.getsourcefile(object)`

Return the name of the Python source file in which an object was defined. This will fail with a `TypeError` if the object is a built-in module, class, or function.

`inspect.getsourcelines(object)`

Return a list of source lines and starting line number for an object. The argument may be a module, class, method, function, traceback, frame, or code object. The source code is returned as a list of the lines corresponding to the object and the line number indicates where in the original source file the first line of code was found. An `IOError` is raised if the source code cannot be retrieved.

`inspect.getsource(object)`

Return the text of the source code for an object. The argument may be a module, class, method, function, traceback, frame, or code object. The source code is returned as a single string. An **IOError** is raised if the source code cannot be retrieved.

`inspect.cleandoc(doc)`

Clean up indentation from docstrings that are indented to line up with blocks of code. Any whitespace that can be uniformly removed from the second line onwards is removed. Also, all tabs are expanded to spaces.

27.12.3. Classes and functions

`inspect.getclasstree(classes, unique=False)`

Arrange the given list of classes into a hierarchy of nested lists. Where a nested list appears, it contains classes derived from the class whose entry immediately precedes the list. Each entry is a 2-tuple containing a class and a tuple of its base classes. If the *unique* argument is true, exactly one entry appears in the returned structure for each class in the given list. Otherwise, classes using multiple inheritance and their descendants will appear multiple times.

`inspect.getargspec(func)`

Get the names and default values of a Python function's arguments. A *named tuple* `ArgSpec(args, varargs, keywords, defaults)` is returned. *args* is a list of the argument names. *varargs* and *keywords* are the names of the `*` and `**` arguments or `None`. *defaults* is a tuple of default argument values or `None` if there are no default arguments; if this tuple has *n* elements, they correspond to the last *n* elements listed in *args*.

Deprecated since version 3.0: Use `getfullargspec()` instead, which provides information about keyword-only arguments and annotations.

`inspect.getfullargspec(func)`

Get the names and default values of a Python function's arguments. A *named tuple* is returned:

`FullArgSpec(args, varargs, varkw, defaults, kwonlyargs, kwonlydefaults, annotations)`

args is a list of the argument names. *varargs* and *varkw* are the names of the `*` and `**` arguments or `None`. *defaults* is an n-tuple of the default values of the last n arguments. *kwoonlyargs* is a list of keyword-only argument names. *kwoonlydefaults* is a dictionary mapping names from *kwoonlyargs* to defaults. *annotations* is a dictionary mapping argument names to annotations.

The first four items in the tuple correspond to `getargspec()`.

`inspect.getargvalues(frame)`

Get information about arguments passed into a particular frame. A *named tuple* `ArgInfo(args, varargs, keywords, locals)` is returned. *args* is a list of the argument names. *varargs* and *keywords* are the names of the `*` and `**` arguments or `None`. *locals* is the locals dictionary of the given frame.

`inspect.formatargspec(args[, varargs, varkw, defaults, formatarg, formatvarargs, formatvarkw, formatvalue])`

Format a pretty argument spec from the four values returned by `getargspec()`. The `format*` arguments are the corresponding optional formatting functions that are called to turn names and values into strings.

`inspect.formatargvalues(args[, varargs, varkw, locals, formatarg, formatvarargs, formatvarkw, formatvalue])`

Format a pretty argument spec from the four values returned by `getargvalues()`. The `format*` arguments are the corresponding optional formatting functions that are called to turn names and values into strings.

`inspect.getmro(cls)`

Return a tuple of class `cls`'s base classes, including `cls`, in method resolution order. No class appears more than once in this

tuple. Note that the method resolution order depends on `cls`'s type. Unless a very peculiar user-defined metatype is in use, `cls` will be the first element of the tuple.

`inspect.getcallargs(func[, *args][, **kwargs])`

Bind the `args` and `kwargs` to the argument names of the Python function or method `func`, as if it was called with them. For bound methods, bind also the first argument (typically named `self`) to the associated instance. A dict is returned, mapping the argument names (including the names of the `*` and `**` arguments, if any) to their values from `args` and `kwargs`. In case of invoking `func` incorrectly, i.e. whenever `func(*args, **kwargs)` would raise an exception because of incompatible signature, an exception of the same type and the same or similar message is raised. For example:

```
>>> from inspect import getcallargs
>>> def f(a, b=1, *pos, **named):
...     pass
>>> getcallargs(f, 1, 2, 3)
{'a': 1, 'named': {}, 'b': 2, 'pos': (3,)}
>>> getcallargs(f, a=2, x=4)
{'a': 2, 'named': {'x': 4}, 'b': 1, 'pos': ()}
>>> getcallargs(f)
Traceback (most recent call last):
...
TypeError: f() takes at least 1 argument (0 given)
```

New in version 3.2.

27.12.4. The interpreter stack

When the following functions return “frame records,” each record is a tuple of six items: the frame object, the filename, the line number of the current line, the function name, a list of lines of context from the source code, and the index of the current line within that list.

Note: Keeping references to frame objects, as found in the first element of the frame records these functions return, can cause your program to create reference cycles. Once a reference cycle has been created, the lifespan of all objects which can be accessed from the objects which form the cycle can become much longer even if Python’s optional cycle detector is enabled. If such cycles must be created, it is important to ensure they are explicitly broken to avoid the delayed destruction of objects and increased memory consumption which occurs.

Though the cycle detector will catch these, destruction of the frames (and local variables) can be made deterministic by removing the cycle in a `finally` clause. This is also important if the cycle detector was disabled when Python was compiled or using `gc.disable()`. For example:

```
def handle_stackframe_without_leak():
    frame = inspect.currentframe()
    try:
        # do something with the frame
    finally:
        del frame
```

The optional *context* argument supported by most of these functions specifies the number of lines of context to return, which are centered around the current line.

`inspect.getframeinfo(frame, context=1)`

Get information about a frame or traceback object. A *named tuple* `Traceback(filename, lineno, function, code_context, index)` is returned.

`inspect.getouterframes(frame, context=1)`

Get a list of frame records for a frame and all outer frames. These frames represent the calls that lead to the creation of *frame*. The first entry in the returned list represents *frame*; the last entry represents the outermost call on *frame*'s stack.

`inspect.getinnerframes(traceback, context=1)`

Get a list of frame records for a traceback's frame and all inner frames. These frames represent calls made as a consequence of *frame*. The first entry in the list represents *traceback*; the last entry represents where the exception was raised.

`inspect.currentframe()`

Return the frame object for the caller's stack frame.

CPython implementation detail: This function relies on Python stack frame support in the interpreter, which isn't guaranteed to exist in all implementations of Python. If running in an implementation without Python stack frame support this function returns `None`.

`inspect.stack(context=1)`

Return a list of frame records for the caller's stack. The first entry in the returned list represents the caller; the last entry represents the outermost call on the stack.

`inspect.trace(context=1)`

Return a list of frame records for the stack between the current

frame and the frame in which an exception currently being handled was raised in. The first entry in the list represents the caller; the last entry represents where the exception was raised.

27.12.5. Fetching attributes statically

Both `getattr()` and `hasattr()` can trigger code execution when fetching or checking for the existence of attributes. Descriptors, like properties, will be invoked and `__getattr__()` and `__getattribute__()` may be called.

For cases where you want passive introspection, like documentation tools, this can be inconvenient. `getattr_static` has the same signature as `getattr()` but avoids executing code when it fetches attributes.

```
inspect.getattr_static(obj, attr, default=None)
```

Retrieve attributes without triggering dynamic lookup via the descriptor protocol, `__getattr__` or `__getattribute__`.

Note: this function may not be able to retrieve all attributes that `getattr` can fetch (like dynamically created attributes) and may find attributes that `getattr` can't (like descriptors that raise `AttributeError`). It can also return descriptors objects instead of instance members.

New in version 3.2.

The only known case that can cause `getattr_static` to trigger code execution, and cause it to return incorrect results (or even break), is where a class uses `__slots__` and provides a `__dict__` member using a property or descriptor. If you find other cases please report them so they can be fixed or documented.

`getattr_static` does not resolve descriptors, for example slot descriptors or getset descriptors on objects implemented in C. The descriptor object is returned instead of the underlying attribute.

You can handle these with code like the following. Note that for

arbitrary getset descriptors invoking these may trigger code execution:

```
# example code for resolving the builtin descriptor types
class _foo:
    __slots__ = ['foo']

slot_descriptor = type(_foo.foo)
getset_descriptor = type(type(open(__file__)).name)
wrapper_descriptor = type(str.__dict__[ '__add__' ])
descriptor_types = (slot_descriptor, getset_descriptor, wrapper_descriptor)

result = getattr_static(some_object, 'foo')
if type(result) in descriptor_types:
    try:
        result = result.__get__()
    except AttributeError:
        # descriptors can raise AttributeError to
        # indicate there is no underlying value
        # in which case the descriptor itself will
        # have to do
        pass
```

27.12.6. Current State of a Generator

When implementing coroutine schedulers and for other advanced uses of generators, it is useful to determine whether a generator is currently executing, is waiting to start or resume or execution, or has already terminated. `getgeneratorstate()` allows the current state of a generator to be determined easily.

```
inspect.getgeneratorstate(generator)
```

Get current state of a generator-iterator.

Possible states are:

- `GEN_CREATED`: Waiting to start execution.
- `GEN_RUNNING`: Currently being executed by the interpreter.
- `GEN_SUSPENDED`: Currently suspended at a yield expression.
- `GEN_CLOSED`: Execution has completed.

New in version 3.2.

27.13. `site` — Site-specific configuration hook

Source code: [Lib/site.py](#)

This module is automatically imported during initialization. The automatic import can be suppressed using the interpreter's `-S` option.

Importing this module will append site-specific paths to the module search path.

It starts by constructing up to four directories from a head and a tail part. For the head part, it uses `sys.prefix` and `sys.exec_prefix`; empty heads are skipped. For the tail part, it uses the empty string and then `lib/site-packages` (on Windows) or `lib/python|version|/site-packages` and then `lib/site-python` (on Unix and Macintosh). For each of the distinct head-tail combinations, it sees if it refers to an existing directory, and if so, adds it to `sys.path` and also inspects the newly added path for configuration files.

A path configuration file is a file whose name has the form `package.pth` and exists in one of the four directories mentioned above; its contents are additional items (one per line) to be added to `sys.path`. Non-existing items are never added to `sys.path`, but no check is made that the item refers to a directory (rather than a file). No item is added to `sys.path` more than once. Blank lines and lines beginning with `#` are skipped. Lines starting with `import` (followed by space or tab) are executed.

For example, suppose `sys.prefix` and `sys.exec_prefix` are set to

`/usr/local`. The Python `X.Y` library is then installed in `/usr/local/lib/pythonX.Y` (where only the first three characters of `sys.version` are used to form the installation path name). Suppose this has a subdirectory `/usr/local/lib/pythonX.Y/site-packages` with three subsubdirectories, `foo`, `bar` and `spam`, and two path configuration files, `foo.pth` and `bar.pth`. Assume `foo.pth` contains the following:

```
# foo package configuration
```

```
foo  
bar  
bletch
```

and `bar.pth` contains:

```
# bar package configuration
```

```
bar
```

Then the following version-specific directories are added to `sys.path`, in this order:

```
/usr/local/lib/pythonX.Y/site-packages/bar  
/usr/local/lib/pythonX.Y/site-packages/foo
```

Note that `bletch` is omitted because it doesn't exist; the `bar` directory precedes the `foo` directory because `bar.pth` comes alphabetically before `foo.pth`; and `spam` is omitted because it is not mentioned in either path configuration file.

After these path manipulations, an attempt is made to import a module named `sitecustomize`, which can perform arbitrary site-specific customizations. If this import fails with an `ImportError` exception, it is silently ignored.

Note that for some non-Unix systems, `sys.prefix` and `sys.exec_prefix` are empty, and the path manipulations are skipped; however the import of `sitecustomize` is still attempted.

`site.PREFIXES`

A list of prefixes for site package directories

`site.ENABLE_USER_SITE`

Flag showing the status of the user site directory. True means the user site directory is enabled and added to `sys.path`. When the flag is None the user site directory is disabled for security reasons.

`site.USER_SITE`

Path to the user site directory for the current Python version or None

`site.USER_BASE`

Path to the base directory for user site directories

PYTHONNOUSERSITE

PYTHONUSERBASE

`site.addsitedir(sitedir, known_paths=None)`

Adds a directory to `sys.path` and processes its pth files.

`site.getsitepackages()`

Returns a list containing all global site-packages directories (and possibly site-python).

New in version 3.2.

`site.getuserbase()`

Returns the “user base” directory path.

The “user base” directory can be used to store data. If the global

variable `USER_BASE` is not initialized yet, this function will also set it.

New in version 3.2.

`site.getusersitepackages()`

Returns the user-specific site-packages directory path.

If the global variable `USER_SITE` is not initialized yet, this function will also set it.

New in version 3.2.

27.14. `fpect1` — Floating point exception control

Platforms: Unix

Note: The `fpect1` module is not built by default, and its usage is discouraged and may be dangerous except in the hands of experts. See also the section *Limitations and other considerations* on limitations for more details.

Most computers carry out floating point operations in conformance with the so-called IEEE-754 standard. On any real computer, some floating point operations produce results that cannot be expressed as a normal floating point value. For example, try

```
>>> import math
>>> math.exp(1000)
inf
>>> math.exp(1000) / math.exp(1000)
nan
```

(The example above will work on many platforms. DEC Alpha may be one exception.) “Inf” is a special, non-numeric value in IEEE-754 that stands for “infinity”, and “nan” means “not a number.” Note that, other than the non-numeric results, nothing special happened when you asked Python to carry out those calculations. That is in fact the default behaviour prescribed in the IEEE-754 standard, and if it works for you, stop reading now.

In some circumstances, it would be better to raise an exception and stop processing at the point where the faulty operation was attempted. The `fpect1` module is for use in that situation. It provides control over floating point units from several hardware

manufacturers, allowing the user to turn on the generation of **SIGFPE** whenever any of the IEEE-754 exceptions Division by Zero, Overflow, or Invalid Operation occurs. In tandem with a pair of wrapper macros that are inserted into the C code comprising your python system, **SIGFPE** is trapped and converted into the Python **FloatingPointError** exception.

The **fpect1** module defines the following functions and may raise the given exception:

fpect1.turnon_sigfpe()

Turn on the generation of **SIGFPE**, and set up an appropriate signal handler.

fpect1.turnoff_sigfpe()

Reset default handling of floating point exceptions.

exception **fpect1.FloatingPointError**

After **turnon_sigfpe()** has been executed, a floating point operation that raises one of the IEEE-754 exceptions Division by Zero, Overflow, or Invalid operation will in turn raise this standard Python exception.

27.14.1. Example

The following example demonstrates how to start up and test operation of the `fpectl` module.

```
>>> import fpectl
>>> import fpetest
>>> fpectl.turnon_sigfpe()
>>> fpetest.test()
overflow          PASS
FloatingPointError: Overflow

div by 0          PASS
FloatingPointError: Division by zero
[ more output from test elided ]
>>> import math
>>> math.exp(1000)
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
FloatingPointError: in math_1
```

27.14.2. Limitations and other considerations

Setting up a given processor to trap IEEE-754 floating point errors currently requires custom code on a per-architecture basis. You may have to modify `fpect1` to control your particular hardware.

Conversion of an IEEE-754 exception to a Python exception requires that the wrapper macros `PyFPE_START_PROTECT` and `PyFPE_END_PROTECT` be inserted into your code in an appropriate fashion. Python itself has been modified to support the `fpect1` module, but many other codes of interest to numerical analysts have not.

The `fpect1` module is not thread-safe.

See also: Some files in the source distribution may be interesting in learning more about how this module operates. The include file `Include/pyfpe.h` discusses the implementation of this module at some length. `Modules/fpetestmodule.c` gives several examples of use. Many additional examples can be found in `Objects/floatobject.c`.

27.15. `distutils` — Building and installing Python modules

The `distutils` package provides support for building and installing additional modules into a Python installation. The new modules may be either 100%-pure Python, or may be extension modules written in C, or may be collections of Python packages which include modules coded in both Python and C.

This package is discussed in two separate chapters:

See also:

Distributing Python Modules

The manual for developers and packagers of Python modules. This describes how to prepare `distutils`-based packages so that they may be easily installed into an existing Python installation.

Installing Python Modules

An “administrators” manual which includes information on installing modules into an existing Python installation. You do not need to be a Python programmer to read this manual.

28. Custom Python Interpreters

The modules described in this chapter allow writing interfaces similar to Python's interactive interpreter. If you want a Python interpreter that supports some special feature in addition to the Python language, you should look at the `code` module. (The `codeop` module is lower-level, used to support compiling a possibly-incomplete chunk of Python code.)

The full list of modules described in this chapter is:

- 28.1. `code` — Interpreter base classes
 - 28.1.1. Interactive Interpreter Objects
 - 28.1.2. Interactive Console Objects
- 28.2. `codeop` — Compile Python code

28.1. `code` — Interpreter base classes

The `code` module provides facilities to implement read-eval-print loops in Python. Two classes and convenience functions are included which can be used to build applications which provide an interactive interpreter prompt.

```
class code.InteractiveInterpreter(locals=None)
```

This class deals with parsing and interpreter state (the user's namespace); it does not deal with input buffering or prompting or input file naming (the filename is always passed in explicitly). The optional *locals* argument specifies the dictionary in which code will be executed; it defaults to a newly created dictionary with key `'__name__'` set to `'__console__'` and key `'__doc__'` set to `None`.

```
class code.InteractiveConsole(locals=None, filename="<console>")
```

Closely emulate the behavior of the interactive Python interpreter. This class builds on `InteractiveInterpreter` and adds prompting using the familiar `sys.ps1` and `sys.ps2`, and input buffering.

```
code.interact(banner=None, readfunc=None, local=None)
```

Convenience function to run a read-eval-print loop. This creates a new instance of `InteractiveConsole` and sets *readfunc* to be used as the `raw_input()` method, if provided. If *local* is provided, it is passed to the `InteractiveConsole` constructor for use as the default namespace for the interpreter loop. The `interact()` method of the instance is then run with *banner* passed as the banner to use, if provided. The console object is discarded after use.

```
code.compile_command(source, filename="<input>",  
symbol="single")
```

This function is useful for programs that want to emulate Python's interpreter main loop (a.k.a. the read-eval-print loop). The tricky part is to determine when the user has entered an incomplete command that can be completed by entering more text (as opposed to a complete command or a syntax error). This function *almost* always makes the same decision as the real interpreter main loop.

source is the source string; *filename* is the optional filename from which source was read, defaulting to '`<input>`'; and *symbol* is the optional grammar start symbol, which should be either '`single`' (the default) or '`eval`'.

Returns a code object (the same as `compile(source, filename, symbol)`) if the command is complete and valid; `None` if the command is incomplete; raises `SyntaxError` if the command is complete and contains a syntax error, or raises `OverflowError` or `ValueError` if the command contains an invalid literal.

28.1.1. Interactive Interpreter Objects

`InteractiveInterpreter.runsource(source, filename="<input>", symbol="single")`

Compile and run some source in the interpreter. Arguments are the same as for `compile_command()`; the default for `filename` is `'<input>'`, and for `symbol` is `'single'`. One several things can happen:

- The input is incorrect; `compile_command()` raised an exception (`SyntaxError` or `OverflowError`). A syntax traceback will be printed by calling the `showsyntaxerror()` method. `runsource()` returns `False`.
- The input is incomplete, and more input is required; `compile_command()` returned `None`. `runsource()` returns `True`.
- The input is complete; `compile_command()` returned a code object. The code is executed by calling the `runcode()` (which also handles run-time exceptions, except for `SystemExit`). `runsource()` returns `False`.

The return value can be used to decide whether to use `sys.ps1` or `sys.ps2` to prompt the next line.

`InteractiveInterpreter.runcode(code)`

Execute a code object. When an exception occurs, `showtraceback()` is called to display a traceback. All exceptions are caught except `SystemExit`, which is allowed to propagate.

A note about `KeyboardInterrupt`: this exception may occur elsewhere in this code, and may not always be caught. The caller should be prepared to deal with it.

`InteractiveInterpreter`. **`showsyntaxerror(filename=None)`**

Display the syntax error that just occurred. This does not display a stack trace because there isn't one for syntax errors. If *filename* is given, it is stuffed into the exception instead of the default filename provided by Python's parser, because it always uses '<string>' when reading from a string. The output is written by the `write()` method.

`InteractiveInterpreter`. **`showtraceback()`**

Display the exception that just occurred. We remove the first stack item because it is within the interpreter object implementation. The output is written by the `write()` method.

`InteractiveInterpreter`. **`write(data)`**

Write a string to the standard error stream (`sys.stderr`). Derived classes should override this to provide the appropriate output handling as needed.

28.1.2. Interactive Console Objects

The `InteractiveConsole` class is a subclass of `InteractiveInterpreter`, and so offers all the methods of the interpreter objects as well as the following additions.

`InteractiveConsole.interact(banner=None)`

Closely emulate the interactive Python console. The optional banner argument specify the banner to print before the first interaction; by default it prints a banner similar to the one printed by the standard Python interpreter, followed by the class name of the console object in parentheses (so as not to confuse this with the real interpreter – since it's so close!).

`InteractiveConsole.push(line)`

Push a line of source text to the interpreter. The line should not have a trailing newline; it may have internal newlines. The line is appended to a buffer and the interpreter's `runsource()` method is called with the concatenated contents of the buffer as source. If this indicates that the command was executed or invalid, the buffer is reset; otherwise, the command is incomplete, and the buffer is left as it was after the line was appended. The return value is `True` if more input is required, `False` if the line was dealt with in some way (this is the same as `runsource()`).

`InteractiveConsole.resetbuffer()`

Remove any unhandled source text from the input buffer.

`InteractiveConsole.raw_input(prompt="")`

Write a prompt and read a line. The returned line does not include the trailing newline. When the user enters the EOF key sequence, `EOFError` is raised. The base implementation reads

from `sys.stdin`; a subclass may replace this with a different implementation.

» 28. Custom Python Interpreters »

28.2. `codeop` — Compile Python code

The `codeop` module provides utilities upon which the Python read-eval-print loop can be emulated, as is done in the `code` module. As a result, you probably don't want to use the module directly; if you want to include such a loop in your program you probably want to use the `code` module instead.

There are two parts to this job:

1. Being able to tell if a line of input completes a Python statement: in short, telling whether to print '>>>' or '...' next.
2. Remembering which future statements the user has entered, so subsequent input can be compiled with these in effect.

The `codeop` module provides a way of doing each of these things, and a way of doing them both.

To do just the former:

```
codeop.compile_command(source, filename="<input>",  
symbol="single")
```

Tries to compile *source*, which should be a string of Python code and return a code object if *source* is valid Python code. In that case, the filename attribute of the code object will be *filename*, which defaults to '<input>'. Returns `None` if *source* is *not* valid Python code, but is a prefix of valid Python code.

If there is a problem with *source*, an exception will be raised. `SyntaxError` is raised if there is invalid Python syntax, and `OverflowError` or `ValueError` if there is an invalid literal.

The *symbol* argument determines whether *source* is compiled as a statement (`'single'`, the default) or as an *expression* (`'eval'`). Any other value will cause `ValueError` to be raised.

Note: It is possible (but not likely) that the parser stops parsing with a successful outcome before reaching the end of the source; in this case, trailing symbols may be ignored instead of causing an error. For example, a backslash followed by two newlines may be followed by arbitrary garbage. This will be fixed once the API for the parser is better.

`class codeop.Compile`

Instances of this class have `__call__()` methods identical in signature to the built-in function `compile()`, but with the difference that if the instance compiles program text containing a `__future__` statement, the instance ‘remembers’ and compiles all subsequent program texts with the statement in force.

`class codeop.CommandCompiler`

Instances of this class have `__call__()` methods identical in signature to `compile_command()`; the difference is that if the instance compiles program text containing a `__future__` statement, the instance ‘remembers’ and compiles all subsequent program texts with the statement in force.

29. Importing Modules

The modules described in this chapter provide new ways to import other Python modules and hooks for customizing the import process.

The full list of modules described in this chapter is:

- 29.1. `imp` — Access the `import` internals
 - 29.1.1. Examples
- 29.2. `zipimport` — Import modules from Zip archives
 - 29.2.1. `zipimporter` Objects
 - 29.2.2. Examples
- 29.3. `pkgutil` — Package extension utility
- 29.4. `modulefinder` — Find modules used by a script
 - 29.4.1. Example usage of `ModuleFinder`
- 29.5. `runpy` — Locating and executing Python modules
- 29.6. `importlib` – An implementation of `import`
 - 29.6.1. Introduction
 - 29.6.2. Functions
 - 29.6.3. `importlib.abc` – Abstract base classes related to `import`
 - 29.6.4. `importlib.machinery` – Importers and path hooks
 - 29.6.5. `importlib.util` – Utility code for importers

29.1. `imp` — Access the `import` internals

This module provides an interface to the mechanisms used to implement the `import` statement. It defines the following constants and functions:

`imp.get_magic()`

Return the magic string value used to recognize byte-compiled code files (`.pyc` files). (This value may be different for each Python version.)

`imp.get_suffixes()`

Return a list of 3-element tuples, each describing a particular type of module. Each triple has the form `(suffix, mode, type)`, where *suffix* is a string to be appended to the module name to form the filename to search for, *mode* is the mode string to pass to the built-in `open()` function to open the file (this can be `'r'` for text files or `'rb'` for binary files), and *type* is the file type, which has one of the values `PY_SOURCE`, `PY_COMPILED`, or `C_EXTENSION`, described below.

`imp.find_module(name[, path])`

Try to find the module *name*. If *path* is omitted or `None`, the list of directory names given by `sys.path` is searched, but first a few special places are searched: the function tries to find a built-in module with the given name (`C_BUILTIN`), then a frozen module (`PY_FROZEN`), and on some systems some other places are looked in as well (on Windows, it looks in the registry which may point to a specific file).

Otherwise, *path* must be a list of directory names; each directory is searched for files with any of the suffixes returned by `get_suffixes()` above. Invalid names in the list are silently ignored (but all list items must be strings).

If search is successful, the return value is a 3-element tuple (`file`, `pathname`, `description`):

file is an open *file object* positioned at the beginning, *pathname* is the pathname of the file found, and *description* is a 3-element tuple as contained in the list returned by `get_suffixes()` describing the kind of module found.

If the module does not live in a file, the returned *file* is `None`, *pathname* is the empty string, and the *description* tuple contains empty strings for its suffix and mode; the module type is indicated as given in parentheses above. If the search is unsuccessful, `ImportError` is raised. Other exceptions indicate problems with the arguments or environment.

If the module is a package, *file* is `None`, *pathname* is the package path and the last item in the *description* tuple is `PKG_DIRECTORY`.

This function does not handle hierarchical module names (names containing dots). In order to find *P.*M**, that is, submodule *M* of package *P*, use `find_module()` and `load_module()` to find and load package *P*, and then use `find_module()` with the *path* argument set to `P.__path__`. When *P* itself has a dotted name, apply this recipe recursively.

`imp.load_module(name, file, pathname, description)`

Load a module that was previously found by `find_module()` (or by an otherwise conducted search yielding compatible results). This function does more than importing the module: if the module was

already imported, it will reload the module! The *name* argument indicates the full module name (including the package name, if this is a submodule of a package). The *file* argument is an open file, and *pathname* is the corresponding file name; these can be `None` and `''`, respectively, when the module is a package or not being loaded from a file. The *description* argument is a tuple, as would be returned by `get_suffixes()`, describing what kind of module must be loaded.

If the load is successful, the return value is the module object; otherwise, an exception (usually `ImportError`) is raised.

Important: the caller is responsible for closing the *file* argument, if it was not `None`, even when an exception is raised. This is best done using a `try ... finally` statement.

`imp.new_module(name)`

Return a new empty module object called *name*. This object is *not* inserted in `sys.modules`.

`imp.lock_held()`

Return `True` if the import lock is currently held, else `False`. On platforms without threads, always return `False`.

On platforms with threads, a thread executing an import holds an internal lock until the import is complete. This lock blocks other threads from doing an import until the original import completes, which in turn prevents other threads from seeing incomplete module objects constructed by the original thread while in the process of completing its import (and the imports, if any, triggered by that).

`imp.acquire_lock()`

Acquire the interpreter's import lock for the current thread. This

lock should be used by import hooks to ensure thread-safety when importing modules.

Once a thread has acquired the import lock, the same thread may acquire it again without blocking; the thread must release it once for each time it has acquired it.

On platforms without threads, this function does nothing.

`imp.release_lock()`

Release the interpreter's import lock. On platforms without threads, this function does nothing.

`imp.reload(module)`

Reload a previously imported *module*. The argument must be a module object, so it must have been successfully imported before. This is useful if you have edited the module source file using an external editor and want to try out the new version without leaving the Python interpreter. The return value is the module object (the same as the *module* argument).

When `reload(module)` is executed:

- Python modules' code is recompiled and the module-level code reexecuted, defining a new set of objects which are bound to names in the module's dictionary. The `init` function of extension modules is not called a second time.
- As with all other objects in Python the old objects are only reclaimed after their reference counts drop to zero.
- The names in the module namespace are updated to point to any new or changed objects.
- Other references to the old objects (such as names external to the module) are not rebound to refer to the new objects and must be updated in each namespace where they occur if that is desired.

There are a number of other caveats:

If a module is syntactically correct but its initialization fails, the first `import` statement for it does not bind its name locally, but does store a (partially initialized) module object in `sys.modules`. To reload the module you must first `import` it again (this will bind the name to the partially initialized module object) before you can `reload()` it.

When a module is reloaded, its dictionary (containing the module's global variables) is retained. Redefinitions of names will override the old definitions, so this is generally not a problem. If the new version of a module does not define a name that was defined by the old version, the old definition remains. This feature can be used to the module's advantage if it maintains a global table or cache of objects — with a `try` statement it can test for the table's presence and skip its initialization if desired:

```
try:
    cache
except NameError:
    cache = {}
```

It is legal though generally not very useful to reload built-in or dynamically loaded modules, except for `sys`, `__main__` and `__builtin__`. In many cases, however, extension modules are not designed to be initialized more than once, and may fail in arbitrary ways when reloaded.

If a module imports objects from another module using `from ... import ...`, calling `reload()` for the other module does not redefine the objects imported from it — one way around this is to re-execute the `from` statement, another is to use `import` and qualified names (`module.*name*`) instead.

If a module instantiates instances of a class, reloading the module that defines the class does not affect the method definitions of the instances — they continue to use the old class definition. The same is true for derived classes.

The following functions are conveniences for handling **PEP 3147** byte-compiled file paths.

New in version 3.2.

`imp.cache_from_source(path, debug_override=None)`

Return the **PEP 3147** path to the byte-compiled file associated with the source *path*. For example, if *path* is `/foo/bar/baz.py` the return value would be `/foo/bar/__pycache__/baz.cpython-32.pyc` for Python 3.2. The `cpython-32` string comes from the current magic tag (see `get_tag()`). The returned path will end in `.pyc` when `__debug__` is True or `.pyo` for an optimized Python (i.e. `__debug__` is False). By passing in True or False for *debug_override* you can override the system's value for `__debug__` for extension selection.

path need not exist.

`imp.source_from_cache(path)`

Given the *path* to a **PEP 3147** file name, return the associated source code file path. For example, if *path* is `/foo/bar/__pycache__/baz.cpython-32.pyc` the returned path would be `/foo/bar/baz.py`. *path* need not exist, however if it does not conform to **PEP 3147** format, a `ValueError` is raised.

`imp.get_tag()`

Return the **PEP 3147** magic tag string matching this version of Python's magic number, as returned by `get_magic()`.

The following constants with integer values, defined in this module, are used to indicate the search result of `find_module()`.

`imp.PY_SOURCE`

The module was found as a source file.

`imp.PY_COMPILED`

The module was found as a compiled code object file.

`imp.C_EXTENSION`

The module was found as dynamically loadable shared library.

`imp.PKG_DIRECTORY`

The module was found as a package directory.

`imp.C_BUILTIN`

The module was found as a built-in module.

`imp.PY_FROZEN`

The module was found as a frozen module (see `init_frozen()`).

`class imp.NullImporter(path_string)`

The `NullImporter` type is a [PEP 302](#) import hook that handles non-directory path strings by failing to find any modules. Calling this type with an existing directory or empty string raises `ImportError`. Otherwise, a `NullImporter` instance is returned.

Python adds instances of this type to `sys.path_importer_cache` for any path entries that are not directories and are not handled by any other path hooks on `sys.path_hooks`. Instances have only one method:

`find_module(fullname[, path])`

This method always returns `None`, indicating that the requested module could not be found.

29.1.1. Examples

The following function emulates what was the standard import statement up to Python 1.4 (no hierarchical module names). (This *implementation* wouldn't work in that version, since `find_module()` has been extended and `load_module()` has been added in 1.4.)

```
import imp
import sys

def __import__(name, globals=None, locals=None, fromlist=None):
    # Fast path: see if the module has already been imported.
    try:
        return sys.modules[name]
    except KeyError:
        pass

    # If any of the following calls raises an exception,
    # there's a problem we can't handle -- let the caller handle it.
    fp, pathname, description = imp.find_module(name)

    try:
        return imp.load_module(name, fp, pathname, description)
    finally:
        # Since we may exit via an exception, close fp explicitly.
        if fp:
            fp.close()
```

29.2. `zipimport` — Import modules from Zip archives

This module adds the ability to import Python modules (`*.py`, `*.py[co]`) and packages from ZIP-format archives. It is usually not needed to use the `zipimport` module explicitly; it is automatically used by the built-in `import` mechanism for `sys.path` items that are paths to ZIP archives.

Typically, `sys.path` is a list of directory names as strings. This module also allows an item of `sys.path` to be a string naming a ZIP file archive. The ZIP archive can contain a subdirectory structure to support package imports, and a path within the archive can be specified to only import from a subdirectory. For example, the path `/tmp/example.zip/lib/` would only import from the `lib/` subdirectory within the archive.

Any files may be present in the ZIP archive, but only files `.py` and `.py[co]` are available for import. ZIP import of dynamic modules (`.pyd`, `.so`) is disallowed. Note that if an archive only contains `.py` files, Python will not attempt to modify the archive by adding the corresponding `.pyc` or `.pyo` file, meaning that if a ZIP archive doesn't contain `.pyc` files, importing may be rather slow.

ZIP archives with an archive comment are currently not supported.

See also:

PKZIP Application Note

Documentation on the ZIP file format by Phil Katz, the creator of the format and algorithms used.

PEP 273 - Import Modules from Zip Archives

Written by James C. Ahlstrom, who also provided an implementation. Python 2.3 follows the specification in PEP 273, but uses an implementation written by Just van Rossum that uses the import hooks described in PEP 302.

PEP 302 - New Import Hooks

The PEP to add the import hooks that help this module work.

This module defines an exception:

exception `zipimport.ZipImportError`

Exception raised by zipimporter objects. It's a subclass of `ImportError`, so it can be caught as `ImportError`, too.

29.2.1. zipimporter Objects

`zipimporter` is the class for importing ZIP files.

`class zipimport.zipimporter(archivepath)`

Create a new `zipimporter` instance. *archivepath* must be a path to a ZIP file, or to a specific path within a ZIP file. For example, an *archivepath* of `foo/bar.zip/lib` will look for modules in the `lib` directory inside the ZIP file `foo/bar.zip` (provided that it exists).

`ZipImportError` is raised if *archivepath* doesn't point to a valid ZIP archive.

`find_module(fullname[, path])`

Search for a module specified by *fullname*. *fullname* must be the fully qualified (dotted) module name. It returns the `zipimporter` instance itself if the module was found, or `None` if it wasn't. The optional *path* argument is ignored—it's there for compatibility with the importer protocol.

`get_code(fullname)`

Return the code object for the specified module. Raise `ZipImportError` if the module couldn't be found.

`get_data(pathname)`

Return the data associated with *pathname*. Raise `IOError` if the file wasn't found.

`get_filename(fullname)`

Return the value `__file__` would be set to if the specified module was imported. Raise `ZipImportError` if the module couldn't be found.

New in version 3.1.

get_source(*fullname*)

Return the source code for the specified module. Raise **ZipImportError** if the module couldn't be found, return **None** if the archive does contain the module, but has no source for it.

is_package(*fullname*)

Return True if the module specified by *fullname* is a package. Raise **ZipImportError** if the module couldn't be found.

load_module(*fullname*)

Load the module specified by *fullname*. *fullname* must be the fully qualified (dotted) module name. It returns the imported module, or raises **ZipImportError** if it wasn't found.

archive

The file name of the importer's associated ZIP file, without a possible subpath.

prefix

The subpath within the ZIP file where modules are searched. This is the empty string for zipimporter objects which point to the root of the ZIP file.

The **archive** and **prefix** attributes, when combined with a slash, equal the original *archivepath* argument given to the **zipimporter** constructor.

29.2.2. Examples

Here is an example that imports a module from a ZIP archive - note that the `zipimport` module is not explicitly used.

```
$ unzip -l /tmp/example.zip
Archive:  /tmp/example.zip
 Length   Date    Time    Name
-----
  8467   11-26-02  22:30   jwzthreading.py
-----
  8467                               1 file

$ ./python
Python 2.3 (#1, Aug 1 2003, 19:54:32)
>>> import sys
>>> sys.path.insert(0, '/tmp/example.zip') # Add .zip file to
>>> import jwzthreading
>>> jwzthreading.__file__
'/tmp/example.zip/jwzthreading.py'
```

29.3. pkgutil — Package extension utility

Source code: [Lib/pkgutil.py](#)

This module provides utilities for the import system, in particular package support.

`pkgutil.extend_path(path, name)`

Extend the search path for the modules which comprise a package. Intended use is to place the following code in a package's `__init__.py`:

```
from pkgutil import extend_path
__path__ = extend_path(__path__, __name__)
```

This will add to the package's `__path__` all subdirectories of directories on `sys.path` named after the package. This is useful if one wants to distribute different parts of a single logical package as multiple directories.

It also looks for `*.pkg` files beginning where `*` matches the *name* argument. This feature is similar to `*.pth` files (see the `site` module for more information), except that it doesn't special-case lines starting with `import`. A `*.pkg` file is trusted at face value: apart from checking for duplicates, all entries found in a `*.pkg` file are added to the path, regardless of whether they exist on the filesystem. (This is a feature.)

If the input path is not a list (as is the case for frozen packages) it is returned unchanged. The input path is not modified; an extended copy is returned. Items are only appended to the copy

at the end.

It is assumed that `sys.path` is a sequence. Items of `sys.path` that are not strings referring to existing directories are ignored. Unicode items on `sys.path` that cause errors when used as filenames may cause this function to raise an exception (in line with `os.path.isdir()` behavior).

```
class pkgutil. ImpImporter(dirname=None)
```

PEP 302 Importer that wraps Python's "classic" import algorithm.

If *dirname* is a string, a **PEP 302** importer is created that searches that directory. If *dirname* is `None`, a **PEP 302** importer is created that searches the current `sys.path`, plus any modules that are frozen or built-in.

Note that `ImpImporter` does not currently support being used by placement on `sys.meta_path`.

```
class pkgutil. ImpLoader(fullname, file, filename, etc)
```

PEP 302 Loader that wraps Python's "classic" import algorithm.

```
pkgutil. find_loader(fullname)
```

Find a **PEP 302** "loader" object for *fullname*.

If *fullname* contains dots, path must be the containing package's `__path__`. Returns `None` if the module cannot be found or imported. This function uses `iter_importers()`, and is thus subject to the same limitations regarding platform-specific special import locations such as the Windows registry.

```
pkgutil. get_importer(path_item)
```

Retrieve a **PEP 302** importer for the given *path_item*.

The returned importer is cached in `sys.path_importer_cache` if it was newly created by a path hook.

If there is no importer, a wrapper around the basic import machinery is returned. This wrapper is never inserted into the importer cache (`None` is inserted instead).

The cache (or part of it) can be cleared manually if a rescan of `sys.path_hooks` is necessary.

`pkgutil.get_loader(module_or_name)`

Get a **PEP 302** “loader” object for *module_or_name*.

If the module or package is accessible via the normal import mechanism, a wrapper around the relevant part of that machinery is returned. Returns `None` if the module cannot be found or imported. If the named module is not already imported, its containing package (if any) is imported, in order to establish the package `__path__`.

This function uses `iter_importers()`, and is thus subject to the same limitations regarding platform-specific special import locations such as the Windows registry.

`pkgutil.iter_importers(fullname=“`

Yield **PEP 302** importers for the given module name.

If `fullname` contains a `‘.’`, the importers will be for the package containing `fullname`, otherwise they will be importers for `sys.meta_path`, `sys.path`, and Python’s “classic” import machinery, in that order. If the named module is in a package, that package is imported as a side effect of invoking this function.

Non-**PEP 302** mechanisms (e.g. the Windows registry) used by the standard import machinery to find files in alternative locations

are partially supported, but are searched *after* `sys.path`. Normally, these locations are searched *before* `sys.path`, preventing `sys.path` entries from shadowing them.

For this to cause a visible difference in behaviour, there must be a module or package name that is accessible via both `sys.path` and one of the non-**PEP 302** file system mechanisms. In this case, the emulation will find the former version, while the builtin import mechanism will find the latter.

Items of the following types can be affected by this discrepancy:

`imp.C_EXTENSION`, `imp.PY_SOURCE`, `imp.PY_COMPILED`,
`imp.PKG_DIRECTORY`.

`pkgutil.iter_modules(path=None, prefix="")`

Yields `(module_loader, name, ispkg)` for all submodules on *path*, or, if *path* is `None`, all top-level modules on `sys.path`.

path should be either `None` or a list of paths to look for modules in.

prefix is a string to output on the front of every module name on output.

`pkgutil.walk_packages(path=None, prefix="", onerror=None)`

Yields `(module_loader, name, ispkg)` for all modules recursively on *path*, or, if *path* is `None`, all accessible modules.

path should be either `None` or a list of paths to look for modules in.

prefix is a string to output on the front of every module name on output.

Note that this function must import all *packages* (*not* all modules!)

on the given *path*, in order to access the `__path__` attribute to find submodules.

onerror is a function which gets called with one argument (the name of the package which was being imported) if any exception occurs while trying to import a package. If no *onerror* function is supplied, `ImportErrors` are caught and ignored, while all other exceptions are propagated, terminating the search.

Examples:

```
# list all modules python can access
walk_packages()

# list all submodules of ctypes
walk_packages(ctypes.__path__, ctypes.__name__ + '.')
```

`pkgutil.get_data(package, resource)`

Get a resource from a package.

This is a wrapper for the [PEP 302](#) loader `get_data()` API. The *package* argument should be the name of a package, in standard module format (`foo.bar`). The *resource* argument should be in the form of a relative filename, using `/` as the path separator. The parent directory name `..` is not allowed, and nor is a rooted name (starting with a `/`).

The function returns a binary string that is the contents of the specified resource.

For packages located in the filesystem, which have already been imported, this is the rough equivalent of:

```
d = os.path.dirname(sys.modules[package].__file__)
data = open(os.path.join(d, resource), 'rb').read()
```

If the package cannot be located or loaded, or it uses a **PEP 302** loader which does not support `get_data()`, then `None` is returned.

 Python v3.2 documentation » The Python Standard Library previous | next | modules | index
» 29. Importing Modules »

29.4. `modulefinder` — Find modules used by a script

Source code: [Lib/modulefinder.py](#)

This module provides a `ModuleFinder` class that can be used to determine the set of modules imported by a script. `modulefinder.py` can also be run as a script, giving the filename of a Python script as its argument, after which a report of the imported modules will be printed.

`modulefinder.AddPackagePath(pkg_name, path)`

Record that the package named *pkg_name* can be found in the specified *path*.

`modulefinder.ReplacePackage(oldname, newname)`

Allows specifying that the module named *oldname* is in fact the package named *newname*. The most common usage would be to handle how the `_xmlplus` package replaces the `xml` package.

`class modulefinder.ModuleFinder(path=None, debug=0, excludes=[], replace_paths=[])`

This class provides `run_script()` and `report()` methods to determine the set of modules imported by a script. *path* can be a list of directories to search for modules; if not specified, `sys.path` is used. *debug* sets the debugging level; higher values make the class print debugging messages about what it's doing. *excludes* is a list of module names to exclude from the analysis. *replace_paths* is a list of `(oldpath, newpath)` tuples that will be replaced in module paths.

report()

Print a report to standard output that lists the modules imported by the script and their paths, as well as modules that are missing or seem to be missing.

run_script(*pathname*)

Analyze the contents of the *pathname* file, which must contain Python code.

modules

A dictionary mapping module names to modules. See *Example usage of ModuleFinder*

29.4.1. Example usage of ModuleFinder

The script that is going to get analyzed later on (bacon.py):

```
import re, itertools

try:
    import baconhameggs
except ImportError:
    pass

try:
    import guido.python.ham
except ImportError:
    pass
```

The script that will output the report of bacon.py:

```
from modulefinder import ModuleFinder

finder = ModuleFinder()
finder.run_script('bacon.py')

print('Loaded modules:')
for name, mod in finder.modules.items():
    print('%s: ' % name, end='')
    print(', '.join(list(mod.globalnames.keys())[:3]))

print('-'*50)
print('Modules not imported:')
print('\n'.join(finder.badmodules.keys()))
```

Sample output (may vary depending on the architecture):

```
Loaded modules:
_types:
copyreg:  _inverted_registry, _slotnames, __all__
sre_compile:  isstring, sre, optimize_unicode
_sre:
sre_constants:  REPEAT_ONE, makedict, AT_END_LINE
sys:
```

```
re: __module__, finditer, _expand
itertools:
__main__: re, itertools, baconhameggs
sre_parse: __getslice__, _PATTERNENDERS, SRE_FLAG_UNICODE
array:
types: __module__, IntType, TypeType
-----
Modules not imported:
guido.python.ham
baconhameggs
```

29.5. `runpy` — Locating and executing Python modules

Source code: [Lib/runpy.py](#)

The `runpy` module is used to locate and run Python modules without importing them first. Its main use is to implement the `-m` command line switch that allows scripts to be located using the Python module namespace rather than the filesystem.

The `runpy` module provides two functions:

```
runpy.run_module(mod_name, init_globals=None,  
run_name=None, alter_sys=False)
```

Execute the code of the specified module and return the resulting module globals dictionary. The module's code is first located using the standard import mechanism (refer to [PEP 302](#) for details) and then executed in a fresh module namespace.

If the supplied module name refers to a package rather than a normal module, then that package is imported and the `__main__` submodule within that package is then executed and the resulting module globals dictionary returned.

The optional dictionary argument `init_globals` may be used to pre-populate the module's globals dictionary before the code is executed. The supplied dictionary will not be modified. If any of the special global variables below are defined in the supplied dictionary, those definitions are overridden by `run_module()`.

The special global variables `__name__`, `__file__`, `__cached__`, `__loader__` and `__package__` are set in the globals dictionary

before the module code is executed (Note that this is a minimal set of variables - other variables may be set implicitly as an interpreter implementation detail).

`__name__` is set to `run_name` if this optional argument is not `None`, to `mod_name + '.__main__'` if the named module is a package and to the `mod_name` argument otherwise.

`__file__` is set to the name provided by the module loader. If the loader does not make filename information available, this variable is set to `None`.

`__cached__` will be set to `None`.

`__loader__` is set to the [PEP 302](#) module loader used to retrieve the code for the module (This loader may be a wrapper around the standard import mechanism).

`__package__` is set to `mod_name` if the named module is a package and to `mod_name.rpartition('.')[0]` otherwise.

If the argument `alter_sys` is supplied and evaluates to `True`, then `sys.argv[0]` is updated with the value of `__file__` and `sys.modules[__name__]` is updated with a temporary module object for the module being executed. Both `sys.argv[0]` and `sys.modules[__name__]` are restored to their original values before the function returns.

Note that this manipulation of `sys` is not thread-safe. Other threads may see the partially initialised module, as well as the altered list of arguments. It is recommended that the `sys` module be left alone when invoking this function from threaded code.

Changed in version 3.1: Added ability to execute packages by

looking for a `__main__` submodule.

Changed in version 3.2: Added `__cached__` global variable (see [PEP 3147](#)).

`runpy.run_path(file_path, init_globals=None, run_name=None)`

Execute the code at the named filesystem location and return the resulting module globals dictionary. As with a script name supplied to the CPython command line, the supplied path may refer to a Python source file, a compiled bytecode file or a valid `sys.path` entry containing a `__main__` module (e.g. a zipfile containing a top-level `__main__.py` file).

For a simple script, the specified code is simply executed in a fresh module namespace. For a valid `sys.path` entry (typically a zipfile or directory), the entry is first added to the beginning of `sys.path`. The function then looks for and executes a `__main__` module using the updated path. Note that there is no special protection against invoking an existing `__main__` entry located elsewhere on `sys.path` if there is no such module at the specified location.

The optional dictionary argument `init_globals` may be used to pre-populate the module's globals dictionary before the code is executed. The supplied dictionary will not be modified. If any of the special global variables below are defined in the supplied dictionary, those definitions are overridden by `run_path()`.

The special global variables `__name__`, `__file__`, `__loader__` and `__package__` are set in the globals dictionary before the module code is executed (Note that this is a minimal set of variables - other variables may be set implicitly as an interpreter implementation detail).

`__name__` is set to `run_name` if this optional argument is not `None` and to `'<run_path>'` otherwise.

`__file__` is set to the name provided by the module loader. If the loader does not make filename information available, this variable is set to `None`. For a simple script, this will be set to `file_path`.

`__loader__` is set to the **PEP 302** module loader used to retrieve the code for the module (This loader may be a wrapper around the standard import mechanism). For a simple script, this will be set to `None`.

`__package__` is set to `__name__.rpartition('.')[0]`.

A number of alterations are also made to the `sys` module. Firstly, `sys.path` may be altered as described above. `sys.argv[0]` is updated with the value of `file_path` and `sys.modules[__name__]` is updated with a temporary module object for the module being executed. All modifications to items in `sys` are reverted before the function returns.

Note that, unlike `run_module()`, the alterations made to `sys` are not optional in this function as these adjustments are essential to allowing the execution of `sys.path` entries. As the thread-safety limitations still apply, use of this function in threaded code should be either serialised with the import lock or delegated to a separate process.

New in version 3.2.

29.6. `importlib` – An implementation Of `import`

New in version 3.1.

29.6.1. Introduction

The purpose of the `importlib` package is two-fold. One is to provide an implementation of the `import` statement (and thus, by extension, the `__import__()` function) in Python source code. This provides an implementation of `import` which is portable to any Python interpreter. This also provides a reference implementation which is easier to comprehend than one implemented in a programming language other than Python.

Two, the components to implement `import` are exposed in this package, making it easier for users to create their own custom objects (known generically as an *importer*) to participate in the import process. Details on custom importers can be found in [PEP 302](#).

See also:

The import statement

The language reference for the `import` statement.

Packages specification

Original specification of packages. Some semantics have changed since the writing of this document (e.g. redirecting based on `None` in `sys.modules`).

The `__import__()` function

The `import` statement is syntactic sugar for this function.

29.6.2. Functions

`importlib.__import__(name, globals={}, locals={}, fromlist=list(), level=0)`

An implementation of the built-in `__import__()` function.

`importlib.import_module(name, package=None)`

Import a module. The *name* argument specifies what module to import in absolute or relative terms (e.g. either `pkg.mod` or `..mod`). If the name is specified in relative terms, then the *package* argument must be set to the name of the package which is to act as the anchor for resolving the package name (e.g. `import_module('..mod', 'pkg.subpkg')` will import `pkg.mod`).

The `import_module()` function acts as a simplifying wrapper around `importlib.__import__()`. This means all semantics of the function are derived from `importlib.__import__()`, including requiring the package from which an import is occurring to have been previously imported (i.e., *package* must already be imported). The most important difference is that `import_module()` returns the most nested package or module that was imported (e.g. `pkg.mod`), while `__import__()` returns the top-level package or module (e.g. `pkg`).

29.6.3. `importlib.abc` – Abstract base classes related to import

The `importlib.abc` module contains all of the core abstract base classes used by `import`. Some subclasses of the core abstract base classes are also provided to help in implementing the core ABCs.

`class importlib.abc.Finder`

An abstract base class representing a *finder*. See [PEP 302](#) for the exact definition for a finder.

`find_module(fullname, path=None)`

An abstract method for finding a *loader* for the specified module. If the *finder* is found on `sys.meta_path` and the module to be searched for is a subpackage or module then *path* will be the value of `__path__` from the parent package. If a loader cannot be found, `None` is returned.

`class importlib.abc.Loader`

An abstract base class for a *loader*. See [PEP 302](#) for the exact definition for a loader.

`load_module(fullname)`

An abstract method for loading a module. If the module cannot be loaded, `ImportError` is raised, otherwise the loaded module is returned.

If the requested module already exists in `sys.modules`, that module should be used and reloaded. Otherwise the loader should create a new module and insert it into `sys.modules` before any loading begins, to prevent recursion from the import. If the loader inserted a module and the load fails, it

must be removed by the loader from `sys.modules`; modules already in `sys.modules` before the loader began execution should be left alone. The `importlib.util.module_for_loader()` decorator handles all of these details.

The loader should set several attributes on the module. (Note that some of these attributes can change when a module is reloaded.)

- `__name__`
The name of the module.
- `__file__`
The path to where the module data is stored (not set for built-in modules).
- `__path__`
A list of strings specifying the search path within a package. This attribute is not set on modules.
- `__package__`
The parent package for the module/package. If the module is top-level then it has a value of the empty string. The `importlib.util.set_package()` decorator can handle the details for `__package__`.
- `__loader__`
The loader used to load the module. (This is not set by the built-in import machinery, but it should be set whenever a *loader* is used.)

`class importlib.abc.ResourceLoader`

An abstract base class for a *loader* which implements the

optional **PEP 302** protocol for loading arbitrary resources from the storage back-end.

get_data(*path*)

An abstract method to return the bytes for the data located at *path*. Loaders that have a file-like storage back-end that allows storing arbitrary data can implement this abstract method to give direct access to the data stored. **IOError** is to be raised if the *path* cannot be found. The *path* is expected to be constructed using a module's `__file__` attribute or an item from a package's `__path__`.

`class importlib.abc. InspectLoader`

An abstract base class for a *loader* which implements the optional **PEP 302** protocol for loaders that inspect modules.

get_code(*fullname*)

An abstract method to return the `code` object for a module. `None` is returned if the module does not have a code object (e.g. built-in module). **ImportError** is raised if loader cannot find the requested module.

get_source(*fullname*)

An abstract method to return the source of a module. It is returned as a text string with universal newlines. Returns `None` if no source is available (e.g. a built-in module). Raises **ImportError** if the loader cannot find the module specified.

is_package(*fullname*)

An abstract method to return a true value if the module is a package, a false value otherwise. **ImportError** is raised if the *loader* cannot find the module.

`class importlib.abc. ExecutionLoader`

An abstract base class which inherits from `InspectLoader` that, when implemented, helps a module to be executed as a script. The ABC represents an optional **PEP 302** protocol.

get_filename(*fullname*)

An abstract method that is to return the value of `__file__` for the specified module. If no path is available, `ImportError` is raised.

If source code is available, then the method should return the path to the source file, regardless of whether a bytecode was used to load the module.

`class importlib.abc. SourceLoader`

An abstract base class for implementing source (and optionally bytecode) file loading. The class inherits from both `ResourceLoader` and `ExecutionLoader`, requiring the implementation of:

- `ResourceLoader.get_data()`
- `ExecutionLoader.get_filename()`

Should only return the path to the source file; sourceless loading is not supported.

The abstract methods defined by this class are to add optional bytecode file support. Not implementing these optional methods causes the loader to only work with source code. Implementing the methods allows the loader to work with source *and* bytecode files; it does not allow for *sourceless* loading where only bytecode is provided. Bytecode files are an optimization to speed up loading by removing the parsing step of Python's compiler, and so no bytecode-specific API is exposed.

path_mtime(*self, path*)

Optional abstract method which returns the modification time for the specified path.

set_data(*self*, *path*, *data*)

Optional abstract method which writes the specified bytes to a file path. Any intermediate directories which do not exist are to be created automatically.

When writing to the path fails because the path is read-only (`errno.EACCES`), do not propagate the exception.

get_code(*self*, *fullname*)

Concrete implementation of `InspectLoader.get_code()`.

load_module(*self*, *fullname*)

Concrete implementation of `Loader.load_module()`.

get_source(*self*, *fullname*)

Concrete implementation of `InspectLoader.get_source()`.

is_package(*self*, *fullname*)

Concrete implementation of `InspectLoader.is_package()`. A module is determined to be a package if its file path is a file named `__init__` when the file extension is removed.

`class importlib.abc. PyLoader`

An abstract base class inheriting from `ExecutionLoader` and `ResourceLoader` designed to ease the loading of Python source modules (bytecode is not handled; see `SourceLoader` for a source/bytecode ABC). A subclass implementing this ABC will only need to worry about exposing how the source code is stored; all other details for loading Python source code will be handled by the concrete implementations of key methods.

Deprecated since version 3.2: This class has been deprecated in favor of `SourceLoader` and is slated for removal in Python 3.4. See below for how to create a subclass that is compatible with Python 3.1 onwards.

If compatibility with Python 3.1 is required, then use the following idiom to implement a subclass that will work with Python 3.1 onwards (make sure to implement `ExecutionLoader.get_filename()`):

```
try:
    from importlib.abc import SourceLoader
except ImportError:
    from importlib.abc import PyLoader as SourceLoader

class CustomLoader(SourceLoader):
    def get_filename(self, fullname):
        """Return the path to the source file."""
        # Implement ...

    def source_path(self, fullname):
        """Implement source_path in terms of get_filename."""
        try:
            return self.get_filename(fullname)
        except ImportError:
            return None

    def is_package(self, fullname):
        """Implement is_package by looking for an __init__ f
        name as returned by get_filename."""
        filename = os.path.basename(self.get_filename(fullna
        return os.path.splitext(filename)[0] == '__init__'
```

`source_path(fullname)`

An abstract method that returns the path to the source code for a module. Should return `None` if there is no source code. Raises `ImportError` if the loader knows it cannot handle the module.

`get_filename(fullname)`

A concrete implementation of `importlib.abc.ExecutionLoader.get_filename()` that relies on `source_path()`. If `source_path()` returns `None`, then `ImportError` is raised.

`load_module(fullname)`

A concrete implementation of `importlib.abc.Loader.load_module()` that loads Python source code. All needed information comes from the abstract methods required by this ABC. The only pertinent assumption made by this method is that when loading a package `__path__` is set to `[os.path.dirname(__file__)]`.

`get_code(fullname)`

A concrete implementation of `importlib.abc.InspectLoader.get_code()` that creates code objects from Python source code, by requesting the source code (using `source_path()` and `get_data()`) and compiling it with the built-in `compile()` function.

`get_source(fullname)`

A concrete implementation of `importlib.abc.InspectLoader.get_source()`. Uses `importlib.abc.ResourceLoader.get_data()` and `source_path()` to get the source code. It tries to guess the source encoding using `tokenize.detect_encoding()`.

`class importlib.abc.PyPycLoader`

An abstract base class inheriting from `PyLoader`. This ABC is meant to help in creating loaders that support both Python source and bytecode.

Deprecated since version 3.2: This class has been deprecated in favor of `SourceLoader` and to properly support [PEP 3147](#). If compatibility is required with Python 3.1, implement both `SourceLoader` and `PyLoader`; instructions on how to do so are included in the documentation for `PyLoader`. Do note that this solution will not support sourceless/bytecode-only loading; only source *and* bytecode loading.

`source_mtime(fullname)`

An abstract method which returns the modification time for the source code of the specified module. The modification time should be an integer. If there is no source code, return `None`. If the module cannot be found then `ImportError` is raised.

`bytecode_path(fullname)`

An abstract method which returns the path to the bytecode for the specified module, if it exists. It returns `None` if no bytecode exists (yet). Raises `ImportError` if the loader knows it cannot handle the module.

`get_filename(fullname)`

A concrete implementation of `ExecutionLoader.get_filename()` that relies on `PyLoader.source_path()` and `bytecode_path()`. If `source_path()` returns a path, then that value is returned. Else if `bytecode_path()` returns a path, that path will be returned. If a path is not available from both methods, `ImportError` is raised.

`write_bytecode(fullname, bytecode)`

An abstract method which has the loader write *bytecode* for future use. If the bytecode is written, return `True`. Return

False if the bytecode could not be written. This method should not be called if `sys.dont_write_bytecode` is true. The *bytecode* argument should be a bytes string or bytes array.

29.6.4. `importlib.machinery` – Importers and path hooks

This module contains the various objects that help `import` find and load modules.

`class importlib.machinery.BuiltinImporter`

An *importer* for built-in modules. All known built-in modules are listed in `sys.builtin_module_names`. This class implements the `importlib.abc.Finder` and `importlib.abc.InspectLoader` ABCs.

Only class methods are defined by this class to alleviate the need for instantiation.

`class importlib.machinery.FrozenImporter`

An *importer* for frozen modules. This class implements the `importlib.abc.Finder` and `importlib.abc.InspectLoader` ABCs.

Only class methods are defined by this class to alleviate the need for instantiation.

`class importlib.machinery.PathFinder`

Finder for `sys.path`. This class implements the `importlib.abc.Finder` ABC.

This class does not perfectly mirror the semantics of `import` in terms of `sys.path`. No implicit path hooks are assumed for simplification of the class and its semantics.

Only class methods are defined by this class to alleviate the need for instantiation.

`classmethod find_module(fullname, path=None)`

Class method that attempts to find a *loader* for the module specified by *fullname* on `sys.path` or, if defined, on *path*. For each path entry that is searched, `sys.path_importer_cache` is checked. If a non-`false` object is found then it is used as the *finder* to look for the module being searched for. If no entry is found in `sys.path_importer_cache`, then `sys.path_hooks` is searched for a finder for the path entry and, if found, is stored in `sys.path_importer_cache` along with being queried about the module. If no finder is ever found then `None` is returned.

29.6.5. `importlib.util` – Utility code for importers

This module contains the various objects that help in the construction of an *importer*.

`@importlib.util.module_for_loader`

A *decorator* for a *loader* method, to handle selecting the proper module object to load with. The decorated method is expected to have a call signature taking two positional arguments (e.g. `load_module(self, module)`) for which the second argument will be the module **object** to be used by the loader. Note that the decorator will not work on static methods because of the assumption of two arguments.

The decorated method will take in the **name** of the module to be loaded as expected for a *loader*. If the module is not found in `sys.modules` then a new one is constructed with its `__name__` attribute set. Otherwise the module found in `sys.modules` will be passed into the method. If an exception is raised by the decorated method and a module was added to `sys.modules` it will be removed to prevent a partially initialized module from being left in `sys.modules`. If the module was already in `sys.modules` then it is left alone.

Use of this decorator handles all the details of which module object a loader should initialize as specified by [PEP 302](#).

`@importlib.util.set_loader`

A *decorator* for a *loader* method, to set the `__loader__` attribute on loaded modules. If the attribute is already set the decorator does nothing. It is assumed that the first positional argument to the wrapped method is what `__loader__` should be set to.

@importlib.util.**set_package**

A *decorator* for a *loader* to set the `__package__` attribute on the module returned by the loader. If `__package__` is set and has a value other than `None` it will not be changed. Note that the module returned by the loader is what has the attribute set on and not the module found in `sys.modules`.

Reliance on this decorator is discouraged when it is possible to set `__package__` before the execution of the code is possible. By setting it before the code for the module is executed it allows the attribute to be used at the global level of the module during initialization.

30. Python Language Services

Python provides a number of modules to assist in working with the Python language. These modules support tokenizing, parsing, syntax analysis, bytecode disassembly, and various other facilities.

These modules include:

- 30.1. `parser` — Access Python parse trees
 - 30.1.1. Creating ST Objects
 - 30.1.2. Converting ST Objects
 - 30.1.3. Queries on ST Objects
 - 30.1.4. Exceptions and Error Handling
 - 30.1.5. ST Objects
 - 30.1.6. Example: Emulation of `compile()`
- 30.2. `ast` — Abstract Syntax Trees
 - 30.2.1. Node classes
 - 30.2.2. Abstract Grammar
 - 30.2.3. `ast` Helpers
- 30.3. `symtable` — Access to the compiler's symbol tables
 - 30.3.1. Generating Symbol Tables
 - 30.3.2. Examining Symbol Tables
- 30.4. `symbol` — Constants used with Python parse trees
- 30.5. `token` — Constants used with Python parse trees
- 30.6. `keyword` — Testing for Python keywords
- 30.7. `tokenize` — Tokenizer for Python source
- 30.8. `tabnanny` — Detection of ambiguous indentation
- 30.9. `pyclbr` — Python class browser support
 - 30.9.1. Class Objects
 - 30.9.2. Function Objects
- 30.10. `py_compile` — Compile Python source files
- 30.11. `compileall` — Byte-compile Python libraries

- 30.11.1. Command-line use
- 30.11.2. Public functions
- 30.12. `dis` — Disassembler for Python bytecode
 - 30.12.1. Python Bytecode Instructions
- 30.13. `pickletools` — Tools for pickle developers
 - 30.13.1. Command line usage
 - 30.13.1.1. Command line options
 - 30.13.2. Programmatic Interface

30.1. parser — Access Python parse trees

The `parser` module provides an interface to Python's internal parser and byte-code compiler. The primary purpose for this interface is to allow Python code to edit the parse tree of a Python expression and create executable code from this. This is better than trying to parse and modify an arbitrary Python code fragment as a string because parsing is performed in a manner identical to the code forming the application. It is also faster.

Note: From Python 2.5 onward, it's much more convenient to cut in at the Abstract Syntax Tree (AST) generation and compilation stage, using the `ast` module.

There are a few things to note about this module which are important to making use of the data structures created. This is not a tutorial on editing the parse trees for Python code, but some examples of using the `parser` module are presented.

Most importantly, a good understanding of the Python grammar processed by the internal parser is required. For full information on the language syntax, refer to *The Python Language Reference*. The parser itself is created from a grammar specification defined in the file `Grammar/Grammar` in the standard Python distribution. The parse trees stored in the ST objects created by this module are the actual output from the internal parser when created by the `expr()` or `suite()` functions, described below. The ST objects created by `sequence2st()` faithfully simulate those structures. Be aware that the values of the sequences which are considered "correct" will vary from one version of Python to another as the formal grammar for the language is revised. However, transporting code from one Python

version to another as source text will always allow correct parse trees to be created in the target version, with the only restriction being that migrating to an older version of the interpreter will not support more recent language constructs. The parse trees are not typically compatible from one version to another, whereas source code has always been forward-compatible.

Each element of the sequences returned by `st2list()` or `st2tuple()` has a simple form. Sequences representing non-terminal elements in the grammar always have a length greater than one. The first element is an integer which identifies a production in the grammar. These integers are given symbolic names in the C header file `Include/graminit.h` and the Python module `symbol`. Each additional element of the sequence represents a component of the production as recognized in the input string: these are always sequences which have the same form as the parent. An important aspect of this structure which should be noted is that keywords used to identify the parent node type, such as the keyword `if` in an `if_stmt`, are included in the node tree without any special treatment. For example, the `if` keyword is represented by the tuple `(1, 'if')`, where `1` is the numeric value associated with all `NAME` tokens, including variable and function names defined by the user. In an alternate form returned when line number information is requested, the same token might be represented as `(1, 'if', 12)`, where the `12` represents the line number at which the terminal symbol was found.

Terminal elements are represented in much the same way, but without any child elements and the addition of the source text which was identified. The example of the `if` keyword above is representative. The various types of terminal symbols are defined in the C header file `Include/token.h` and the Python module `token`.

The ST objects are not required to support the functionality of this

module, but are provided for three purposes: to allow an application to amortize the cost of processing complex parse trees, to provide a parse tree representation which conserves memory space when compared to the Python list or tuple representation, and to ease the creation of additional modules in C which manipulate parse trees. A simple “wrapper” class may be created in Python to hide the use of ST objects.

The `parser` module defines functions for a few distinct purposes. The most important purposes are to create ST objects and to convert ST objects to other representations such as parse trees and compiled code objects, but there are also functions which serve to query the type of parse tree represented by an ST object.

See also:

Module `symbol`

Useful constants representing internal nodes of the parse tree.

Module `token`

Useful constants representing leaf nodes of the parse tree and functions for testing node values.

30.1.1. Creating ST Objects

ST objects may be created from source code or from a parse tree. When creating an ST object from source, different functions are used to create the `'eval'` and `'exec'` forms.

`parser.expr(source)`

The `expr()` function parses the parameter *source* as if it were an input to `compile(source, 'file.py', 'eval')`. If the parse succeeds, an ST object is created to hold the internal parse tree representation, otherwise an appropriate exception is raised.

`parser.suite(source)`

The `suite()` function parses the parameter *source* as if it were an input to `compile(source, 'file.py', 'exec')`. If the parse succeeds, an ST object is created to hold the internal parse tree representation, otherwise an appropriate exception is raised.

`parser.sequence2st(sequence)`

This function accepts a parse tree represented as a sequence and builds an internal representation if possible. If it can validate that the tree conforms to the Python grammar and all nodes are valid node types in the host version of Python, an ST object is created from the internal representation and returned to the caller. If there is a problem creating the internal representation, or if the tree cannot be validated, a `ParserError` exception is raised. An ST object created this way should not be assumed to compile correctly; normal exceptions raised by compilation may still be initiated when the ST object is passed to `compilest()`. This may indicate problems not related to syntax (such as a `MemoryError` exception), but may also be due to constructs such as the result of parsing `del f(0)`, which escapes the Python

parser but is checked by the bytecode compiler.

Sequences representing terminal tokens may be represented as either two-element lists of the form `(1, 'name')` or as three-element lists of the form `(1, 'name', 56)`. If the third element is present, it is assumed to be a valid line number. The line number may be specified for any subset of the terminal symbols in the input tree.

`parser.tuple2st(sequence)`

This is the same function as `sequence2st()`. This entry point is maintained for backward compatibility.

30.1.2. Converting ST Objects

ST objects, regardless of the input used to create them, may be converted to parse trees represented as list- or tuple- trees, or may be compiled into executable code objects. Parse trees may be extracted with or without line numbering information.

`parser.st2list(st, line_info=False, col_info=False)`

This function accepts an ST object from the caller in *st* and returns a Python list representing the equivalent parse tree. The resulting list representation can be used for inspection or the creation of a new parse tree in list form. This function does not fail so long as memory is available to build the list representation. If the parse tree will only be used for inspection, `st2tuple()` should be used instead to reduce memory consumption and fragmentation. When the list representation is required, this function is significantly faster than retrieving a tuple representation and converting that to nested lists.

If *line_info* is true, line number information will be included for all terminal tokens as a third element of the list representing the token. Note that the line number provided specifies the line on which the token *ends*. This information is omitted if the flag is false or omitted.

`parser.st2tuple(st, line_info=False, col_info=False)`

This function accepts an ST object from the caller in *st* and returns a Python tuple representing the equivalent parse tree. Other than returning a tuple instead of a list, this function is identical to `st2list()`.

If *line_info* is true, line number information will be included for all terminal tokens as a third element of the list representing the

token. This information is omitted if the flag is false or omitted.

`parser.compilest(st, filename='<syntax-tree>')`

The Python byte compiler can be invoked on an ST object to produce code objects which can be used as part of a call to the built-in `exec()` or `eval()` functions. This function provides the interface to the compiler, passing the internal parse tree from `st` to the parser, using the source file name specified by the `filename` parameter. The default value supplied for `filename` indicates that the source was an ST object.

Compiling an ST object may result in exceptions related to compilation; an example would be a `SyntaxError` caused by the parse tree for `del f(0)`: this statement is considered legal within the formal grammar for Python but is not a legal language construct. The `SyntaxError` raised for this condition is actually generated by the Python byte-compiler normally, which is why it can be raised at this point by the `parser` module. Most causes of compilation failure can be diagnosed programmatically by inspection of the parse tree.

30.1.3. Queries on ST Objects

Two functions are provided which allow an application to determine if an ST was created as an expression or a suite. Neither of these functions can be used to determine if an ST was created from source code via `expr()` or `suite()` or from a parse tree via `sequence2st()`.

`parser.isexpr(st)`

When `st` represents an `'eval'` form, this function returns true, otherwise it returns false. This is useful, since code objects normally cannot be queried for this information using existing built-in functions. Note that the code objects created by `compilest()` cannot be queried like this either, and are identical to those created by the built-in `compile()` function.

`parser.issuite(st)`

This function mirrors `isexpr()` in that it reports whether an ST object represents an `'exec'` form, commonly known as a “suite.” It is not safe to assume that this function is equivalent to `not isexpr(st)`, as additional syntactic fragments may be supported in the future.

30.1.4. Exceptions and Error Handling

The parser module defines a single exception, but may also pass other built-in exceptions from other portions of the Python runtime environment. See each function for information about the exceptions it can raise.

exception parser. **ParserError**

Exception raised when a failure occurs within the parser module. This is generally produced for validation failures rather than the built-in **SyntaxError** raised during normal parsing. The exception argument is either a string describing the reason of the failure or a tuple containing a sequence causing the failure from a parse tree passed to **sequence2st()** and an explanatory string. Calls to **sequence2st()** need to be able to handle either type of exception, while calls to other functions in the module will only need to be aware of the simple string values.

Note that the functions **compilest()**, **expr()**, and **suite()** may raise exceptions which are normally raised by the parsing and compilation process. These include the built in exceptions **MemoryError**, **OverflowError**, **SyntaxError**, and **SystemError**. In these cases, these exceptions carry all the meaning normally associated with them. Refer to the descriptions of each function for detailed information.

30.1.5. ST Objects

Ordered and equality comparisons are supported between ST objects. Pickling of ST objects (using the `pickle` module) is also supported.

`parser.STType`

The type of the objects returned by `expr()`, `suite()` and `sequence2st()`.

ST objects have the following methods:

`ST.compile(filename='<syntax-tree>')`

Same as `compilest(st, filename)`.

`ST.isexpr()`

Same as `isexpr(st)`.

`ST.issuite()`

Same as `issuite(st)`.

`ST.tolist(line_info=False, col_info=False)`

Same as `st2list(st, line_info, col_info)`.

`ST.totuple(line_info=False, col_info=False)`

Same as `st2tuple(st, line_info, col_info)`.

30.1.6. Example: Emulation of `compile()`

While many useful operations may take place between parsing and bytecode generation, the simplest operation is to do nothing. For this purpose, using the `parser` module to produce an intermediate data structure is equivalent to the code

```
>>> code = compile('a + 5', 'file.py', 'eval')
>>> a = 5
>>> eval(code)
10
```

The equivalent operation using the `parser` module is somewhat longer, and allows the intermediate internal parse tree to be retained as an ST object:

```
>>> import parser
>>> st = parser.expr('a + 5')
>>> code = st.compile('file.py')
>>> a = 5
>>> eval(code)
10
```

An application which needs both ST and code objects can package this code into readily available functions:

```
import parser

def load_suite(source_string):
    st = parser.suite(source_string)
    return st, st.compile()

def load_expression(source_string):
    st = parser.expr(source_string)
    return st, st.compile()
```

30.2. `ast` — Abstract Syntax Trees

Source code: [Lib/ast.py](#)

The `ast` module helps Python applications to process trees of the Python abstract syntax grammar. The abstract syntax itself might change with each Python release; this module helps to find out programmatically what the current grammar looks like.

An abstract syntax tree can be generated by passing `ast.PyCF_ONLY_AST` as a flag to the `compile()` built-in function, or using the `parse()` helper provided in this module. The result will be a tree of objects whose classes all inherit from `ast.AST`. An abstract syntax tree can be compiled into a Python code object using the built-in `compile()` function.

30.2.1. Node classes

`class ast.AST`

This is the base of all AST node classes. The actual node classes are derived from the `Parser/Python.asdl` file, which is reproduced *below*. They are defined in the `_ast` C module and re-exported in `ast`.

There is one class defined for each left-hand side symbol in the abstract grammar (for example, `ast.stmt` or `ast.expr`). In addition, there is one class defined for each constructor on the right-hand side; these classes inherit from the classes for the left-hand side trees. For example, `ast.BinOp` inherits from `ast.expr`. For production rules with alternatives (aka “sums”), the left-hand side class is abstract: only instances of specific constructor nodes are ever created.

`_fields`

Each concrete class has an attribute `_fields` which gives the names of all child nodes.

Each instance of a concrete class has one attribute for each child node, of the type as defined in the grammar. For example, `ast.BinOp` instances have an attribute `left` of type `ast.expr`.

If these attributes are marked as optional in the grammar (using a question mark), the value might be `None`. If the attributes can have zero-or-more values (marked with an asterisk), the values are represented as Python lists. All possible attributes must be present and have valid values when compiling an AST with `compile()`.

lineno **col_offset**

Instances of `ast.expr` and `ast.stmt` subclasses have `lineno` and `col_offset` attributes. The `lineno` is the line number of source text (1-indexed so the first line is line 1) and the `col_offset` is the UTF-8 byte offset of the first token that generated the node. The UTF-8 offset is recorded because the parser uses UTF-8 internally.

The constructor of a class `ast.T` parses its arguments as follows:

- If there are positional arguments, there must be as many as there are items in `T._fields`; they will be assigned as attributes of these names.
- If there are keyword arguments, they will set the attributes of the same names to the given values.

For example, to create and populate an `ast.UnaryOp` node, you could use

```
node = ast.UnaryOp()  
node.op = ast.USub()  
node.operand = ast.Num()  
node.operand.n = 5  
node.operand.lineno = 0  
node.operand.col_offset = 0  
node.lineno = 0  
node.col_offset = 0
```

or the more compact

```
node = ast.UnaryOp(ast.USub(), ast.Num(5, lineno=0, col_offs  
                    lineno=0, col_offset=0)
```

30.2.2. Abstract Grammar

The module defines a string constant `__version__` which is the decimal Subversion revision number of the file shown below.

The abstract grammar is currently defined as follows:

```
-- ASDL's four builtin types are identifier, int, string, objec
module Python version "$Revision: 82163 $"
{
    mod = Module(stmt* body)
        | Interactive(stmt* body)
        | Expression(expr body)

    -- not really an actual node but useful in Jython's
    | Suite(stmt* body)

    stmt = FunctionDef(identifier name, arguments args,
                        stmt* body, expr* decorator_list, ex
        | ClassDef(identifier name,
                    expr* bases,
                    keyword* keywords,
                    expr? starargs,
                    expr? kwargs,
                    stmt* body,
                    expr* decorator_list)
        | Return(expr? value)

        | Delete(expr* targets)
        | Assign(expr* targets, expr value)
        | AugAssign(expr target, operator op, expr value)

    -- use 'orelse' because else is a keyword in targ
    | For(expr target, expr iter, stmt* body, stmt* o
    | While(expr test, stmt* body, stmt* orelse)
    | If(expr test, stmt* body, stmt* orelse)
    | With(expr context_expr, expr? optional_vars, st

        | Raise(expr? exc, expr? cause)
        | TryExcept(stmt* body, excepthandler* handlers,
        | TryFinally(stmt* body, stmt* finalbody)
        | Assert(expr test, expr? msg)
```

```

| Import(alias* names)

except_handler = ExceptHandler(expr? type, identifier? name,
                               attributes (int lineno, int col_offset))

arguments = (arg* args, identifier? vararg, expr? vararg,
            arg* kwonlyargs, identifier? kwarg,
            expr? kwargannotation, expr* defaults,
            expr* kw_defaults)
arg = (identifier arg, expr? annotation)

-- keyword arguments supplied to call
keyword = (identifier arg, expr value)

-- import name with optional 'as' alias.
alias = (identifier name, identifier? asname)
}

```

30.2.3. ast Helpers

Apart from the node classes, `ast` module defines these utility functions and classes for traversing abstract syntax trees:

`ast.parse(source, filename='<unknown>', mode='exec')`

Parse the source into an AST node. Equivalent to `compile(source, filename, mode, ast.PyCF_ONLY_AST)`.

`ast.literal_eval(node_or_string)`

Safely evaluate an expression node or a string containing a Python expression. The string or node provided may only consist of the following Python literal structures: strings, bytes, numbers, tuples, lists, dicts, sets, booleans, and `None`.

This can be used for safely evaluating strings containing Python expressions from untrusted sources without the need to parse the values oneself.

Changed in version 3.2: Now allows bytes and set literals.

`ast.get_docstring(node, clean=True)`

Return the docstring of the given `node` (which must be a `FunctionDef`, `ClassDef` or `Module` node), or `None` if it has no docstring. If `clean` is true, clean up the docstring's indentation with `inspect.cleandoc()`.

`ast.fix_missing_locations(node)`

When you compile a node tree with `compile()`, the compiler expects `lineno` and `col_offset` attributes for every node that supports them. This is rather tedious to fill in for generated nodes, so this helper adds these attributes recursively where not already set, by setting them to the values of the parent node. It

works recursively starting at *node*.

`ast.increment_lineno(node, n=1)`

Increment the line number of each node in the tree starting at *node* by *n*. This is useful to “move code” to a different location in a file.

`ast.copy_location(new_node, old_node)`

Copy source location (`lineno` and `col_offset`) from *old_node* to *new_node* if possible, and return *new_node*.

`ast.iter_fields(node)`

Yield a tuple of (`fieldname`, `value`) for each field in `node._fields` that is present on *node*.

`ast.iter_child_nodes(node)`

Yield all direct child nodes of *node*, that is, all fields that are nodes and all items of fields that are lists of nodes.

`ast.walk(node)`

Recursively yield all descendant nodes in the tree starting at *node* (including *node* itself), in no specified order. This is useful if you only want to modify nodes in place and don't care about the context.

`class ast.NodeVisitor`

A node visitor base class that walks the abstract syntax tree and calls a visitor function for every node found. This function may return a value which is forwarded by the `visit()` method.

This class is meant to be subclassed, with the subclass adding visitor methods.

`visit(node)`

Visit a node. The default implementation calls the method

called `self.visit_classname` where *classname* is the name of the node class, or `generic_visit()` if that method doesn't exist.

`generic_visit(node)`

This visitor calls `visit()` on all children of the node.

Note that child nodes of nodes that have a custom visitor method won't be visited unless the visitor calls `generic_visit()` or visits them itself.

Don't use the `NodeVisitor` if you want to apply changes to nodes during traversal. For this a special visitor exists (`NodeTransformer`) that allows modifications.

`class ast.NodeTransformer`

A `NodeVisitor` subclass that walks the abstract syntax tree and allows modification of nodes.

The `NodeTransformer` will walk the AST and use the return value of the visitor methods to replace or remove the old node. If the return value of the visitor method is `None`, the node will be removed from its location, otherwise it is replaced with the return value. The return value may be the original node in which case no replacement takes place.

Here is an example transformer that rewrites all occurrences of name lookups (`foo`) to `data['foo']`:

```
class RewriteName(NodeTransformer):  
  
    def visit_Name(self, node):  
        return copy_location(Subscript(  
            value=Name(id='data', ctx=Load()),  
            slice=Index(value=Str(s=node.id)),  
            ctx=node.ctx
```

```
), node)
```

Keep in mind that if the node you're operating on has child nodes you must either transform the child nodes yourself or call the `generic_visit()` method for the node first.

For nodes that were part of a collection of statements (that applies to all statement nodes), the visitor may also return a list of nodes rather than just a single node.

Usually you use the transformer like this:

```
node = YourTransformer().visit(node)
```

`ast.dump(node, annotate_fields=True, include_attributes=False)`

Return a formatted dump of the tree in *node*. This is mainly useful for debugging purposes. The returned string will show the names and the values for fields. This makes the code impossible to evaluate, so if evaluation is wanted *annotate_fields* must be set to `False`. Attributes such as line numbers and column offsets are not dumped by default. If this is wanted, *include_attributes* can be set to `True`.

30.3. `symtable` — Access to the compiler's symbol tables

Symbol tables are generated by the compiler from AST just before bytecode is generated. The symbol table is responsible for calculating the scope of every identifier in the code. `symtable` provides an interface to examine these tables.

30.3.1. Generating Symbol Tables

`symtable.symtable(code, filename, compile_type)`

Return the toplevel `SymbolTable` for the Python source *code*. *filename* is the name of the file containing the code. *compile_type* is like the *mode* argument to `compile()`.

30.3.2. Examining Symbol Tables

`class` `symtable.SymbolTable`

A namespace table for a block. The constructor is not public.

`get_type()`

Return the type of the symbol table. Possible values are `'class'`, `'module'`, and `'function'`.

`get_id()`

Return the table's identifier.

`get_name()`

Return the table's name. This is the name of the class if the table is for a class, the name of the function if the table is for a function, or `'top'` if the table is global (`get_type()` returns `'module'`).

`get_lineno()`

Return the number of the first line in the block this table represents.

`is_optimized()`

Return `True` if the locals in this table can be optimized.

`is_nested()`

Return `True` if the block is a nested class or function.

`has_children()`

Return `True` if the block has nested namespaces within it. These can be obtained with `get_children()`.

`has_exec()`

Return `True` if the block uses `exec`.

has_import_star()

Return `True` if the block uses a starred from-import.

get_identifiers()

Return a list of names of symbols in this table.

lookup(*name*)

Lookup *name* in the table and return a `Symbol` instance.

get_symbols()

Return a list of `Symbol` instances for names in the table.

get_children()

Return a list of the nested symbol tables.

class `symtable`. **Function**

A namespace for a function or method. This class inherits `SymbolTable`.

get_parameters()

Return a tuple containing names of parameters to this function.

get_locals()

Return a tuple containing names of locals in this function.

get_globals()

Return a tuple containing names of globals in this function.

get_frees()

Return a tuple containing names of free variables in this function.

class `symtable.Class`

A namespace of a class. This class inherits `SymbolTable`.

`get_methods()`

Return a tuple containing the names of methods declared in the class.

class `symtable.Symbol`

An entry in a `SymbolTable` corresponding to an identifier in the source. The constructor is not public.

`get_name()`

Return the symbol's name.

`is_referenced()`

Return `true` if the symbol is used in its block.

`is_imported()`

Return `true` if the symbol is created from an import statement.

`is_parameter()`

Return `true` if the symbol is a parameter.

`is_global()`

Return `true` if the symbol is global.

`is_declared_global()`

Return `true` if the symbol is declared global with a global statement.

`is_local()`

Return `true` if the symbol is local to its block.

`is_free()`

Return `True` if the symbol is referenced in its block, but not assigned to.

`is_assigned()`

Return `True` if the symbol is assigned to in its block.

`is_namespace()`

Return `True` if name binding introduces new namespace.

If the name is used as the target of a function or class statement, this will be true.

For example:

```
>>> table = symtable.symtable("def some_func(): pass", "s
>>> table.lookup("some_func").is_namespace()
True
```

Note that a single name can be bound to multiple objects. If the result is `True`, the name may also be bound to other objects, like an `int` or `list`, that does not introduce a new namespace.

`get_namespaces()`

Return a list of namespaces bound to this name.

`get_namespace()`

Return the namespace bound to this name. If more than one namespace is bound, a `ValueError` is raised.

30.4. `symbol` — Constants used with Python parse trees

Source code: [Lib/symbol.py](#)

This module provides constants which represent the numeric values of internal nodes of the parse tree. Unlike most Python constants, these use lower-case names. Refer to the file `Grammar/Grammar` in the Python distribution for the definitions of the names in the context of the language grammar. The specific numeric values which the names map to may change between Python versions.

This module also provides one additional data object:

`symbol.sym_name`

Dictionary mapping the numeric values of the constants defined in this module back to name strings, allowing more human-readable representation of parse trees to be generated.

See also:

Module `parser`

The second example for the `parser` module shows how to use the `symbol` module.

30.5. token — Constants used with Python parse trees

Source code: [Lib/token.py](#)

This module provides constants which represent the numeric values of leaf nodes of the parse tree (terminal tokens). Refer to the file `Grammar/Grammar` in the Python distribution for the definitions of the names in the context of the language grammar. The specific numeric values which the names map to may change between Python versions.

The module also provides a mapping from numeric codes to names and some functions. The functions mirror definitions in the Python C header files.

`token.tok_name`

Dictionary mapping the numeric values of the constants defined in this module back to name strings, allowing more human-readable representation of parse trees to be generated.

`token.ISTERMINAL(x)`

Return true for terminal token values.

`token.ISNONTERMINAL(x)`

Return true for non-terminal token values.

`token.ISEOF(x)`

Return true if `x` is the marker indicating the end of input.

The token constants are:

`token.ENDMARKER`

token. **NAME**
token. **NUMBER**
token. **STRING**
token. **NEWLINE**
token. **INDENT**
token. **DEDENT**
token. **LPAR**
token. **RPAR**
token. **LSQB**
token. **RSQB**
token. **COLON**
token. **COMMA**
token. **SEMI**
token. **PLUS**
token. **MINUS**
token. **STAR**
token. **SLASH**
token. **VBAR**
token. **AMPER**
token. **LESS**
token. **GREATER**
token. **EQUAL**
token. **DOT**
token. **PERCENT**
token. **BACKQUOTE**
token. **LBRACE**
token. **RBRACE**
token. **EQUAL**
token. **NOTEQUAL**
token. **LESSEQUAL**
token. **GREATEREQUAL**
token. **TILDE**
token. **CIRCUMFLEX**
token. **LEFTSHIFT**
token. **RIGHTSHIFT**
token. **DOUBLESTAR**
token. **PLUSEQUAL**
token. **MINEQUAL**
token. **STAREQUAL**
token. **SLASHEQUAL**
token. **PERCENTEQUAL**
token. **AMPEREQUAL**

token.**VBAREQUAL**
token.**CIRCUMFLEXEQUAL**
token.**LEFTSHIFTEQUAL**
token.**RIGHTSHIFTEQUAL**
token.**DOUBLESTAREQUAL**
token.**DOUBLES LASH**
token.**DOUBLES LASH EQUAL**
token.**AT**
token.**OP**
token.**ERRORTOKEN**
token.**N_TOKENS**
token.**NT_OFFSET**

See also:

Module `parser`

The second example for the `parser` module shows how to use the `symbol` module.

30.6. keyword — Testing for Python keywords

Source code: [Lib/keyword.py](#)

This module allows a Python program to determine if a string is a keyword.

`keyword.iskeyword(s)`

Return true if `s` is a Python keyword.

`keyword.kwlist`

Sequence containing all the keywords defined for the interpreter. If any keywords are defined to only be active when particular `__future__` statements are in effect, these will be included as well.

30.7. tokenize — Tokenizer for Python source

Source code: [Lib/tokenize.py](#)

The `tokenize` module provides a lexical scanner for Python source code, implemented in Python. The scanner in this module returns comments as tokens as well, making it useful for implementing “pretty-printers,” including colorizers for on-screen displays.

The primary entry point is a *generator*:

```
tokenize.tokenize(readline)
```

The `tokenize()` generator requires one argument, *readline*, which must be a callable object which provides the same interface as the `io.IOBase.readline()` method of file objects. Each call to the function should return one line of input as bytes.

The generator produces 5-tuples with these members: the token type; the token string; a 2-tuple `(srow, scol)` of ints specifying the row and column where the token begins in the source; a 2-tuple `(erow, ecol)` of ints specifying the row and column where the token ends in the source; and the line on which the token was found. The line passed (the last tuple item) is the *logical* line; continuation lines are included. The 5 tuple is returned as a *named tuple* with the field names: `type string start end line`.

Changed in version 3.1: Added support for named tuples.

`tokenize()` determines the source encoding of the file by looking for a UTF-8 BOM or encoding cookie, according to [PEP 263](#).

All constants from the `token` module are also exported from `tokenize`, as are three additional token type values:

`tokenize.COMMENT`

Token value used to indicate a comment.

`tokenize.NL`

Token value used to indicate a non-terminating newline. The `NEWLINE` token indicates the end of a logical line of Python code; `NL` tokens are generated when a logical line of code is continued over multiple physical lines.

`tokenize.ENCODING`

Token value that indicates the encoding used to decode the source bytes into text. The first token returned by `tokenize()` will always be an `ENCODING` token.

Another function is provided to reverse the tokenization process. This is useful for creating tools that tokenize a script, modify the token stream, and write back the modified script.

`tokenize.untokenize(iterable)`

Converts tokens back into Python source code. The *iterable* must return sequences with at least two elements, the token type and the token string. Any additional sequence elements are ignored.

The reconstructed script is returned as a single string. The result is guaranteed to tokenize back to match the input so that the conversion is lossless and round-trips are assured. The guarantee applies only to the token type and token string as the spacing between tokens (column positions) may change.

It returns bytes, encoded using the `ENCODING` token, which is the first token sequence output by `tokenize()`.

`tokenize()` needs to detect the encoding of source files it tokenizes. The function it uses to do this is available:

`tokenize.detect_encoding(readline)`

The `detect_encoding()` function is used to detect the encoding that should be used to decode a Python source file. It requires one argument, `readline`, in the same way as the `tokenize()` generator.

It will call `readline` a maximum of twice, and return the encoding used (as a string) and a list of any lines (not decoded from bytes) it has read in.

It detects the encoding from the presence of a UTF-8 BOM or an encoding cookie as specified in [PEP 263](#). If both a BOM and a cookie are present, but disagree, a `SyntaxError` will be raised. Note that if the BOM is found, `'utf-8-sig'` will be returned as an encoding.

If no encoding is specified, then the default of `'utf-8'` will be returned.

Use `open()` to open Python source files: it uses `detect_encoding()` to detect the file encoding.

`tokenize.open(filename)`

Open a file in read only mode using the encoding detected by `detect_encoding()`.

New in version 3.2.

Example of a script rewriter that transforms float literals into Decimal objects:

```
from tokenize import tokenize, untokenize, NUMBER, STRING, NAME
```

```

from io import BytesIO

def decistmt(s):
    """Substitute Decimals for floats in a string of statements

    >>> from decimal import Decimal
    >>> s = 'print(+21.3e-5*-.1234/81.7)'
    >>> decistmt(s)
    "print (+Decimal ('21.3e-5')*-Decimal ('.1234')/Decimal ('8

    The format of the exponent is inherited from the platform C
    Known cases are "e-007" (Windows) and "e-07" (not Windows).
    we're only showing 12 digits, and the 13th isn't close to 5
    rest of the output should be platform-independent.

    >>> exec(s) #doctest: +ELLIPSIS
    -3.21716034272e-0...7

    Output from calculations with Decimal should be identical a
    platforms.

    >>> exec(decistmt(s))
    -3.217160342717258261933904529E-7
    """
    result = []
    g = tokenize(BytesIO(s.encode('utf-8')).readline) # tokenize
    for toknum, tokval, _, _, _ in g:
        if toknum == NUMBER and '.' in tokval: # replace NUMBE
            result.extend([
                (NAME, 'Decimal'),
                (OP, '('),
                (STRING, repr(tokval)),
                (OP, ')')
            ])
        else:
            result.append((toknum, tokval))
    return untokenize(result).decode('utf-8')

```

30.8. `tabnanny` — Detection of ambiguous indentation

Source code: [Lib/tabnanny.py](#)

For the time being this module is intended to be called as a script. However it is possible to import it into an IDE and use the function `check()` described below.

Note: The API provided by this module is likely to change in future releases; such changes may not be backward compatible.

`tabnanny.check(file_or_dir)`

If `file_or_dir` is a directory and not a symbolic link, then recursively descend the directory tree named by `file_or_dir`, checking all `.py` files along the way. If `file_or_dir` is an ordinary Python source file, it is checked for whitespace related problems. The diagnostic messages are written to standard output using the `print()` function.

`tabnanny.verbose`

Flag indicating whether to print verbose messages. This is incremented by the `-v` option if called as a script.

`tabnanny.filename_only`

Flag indicating whether to print only the filenames of files containing whitespace related problems. This is set to true by the `-q` option if called as a script.

exception `tabnanny.NannyNag`

Raised by `tokeneater()` if detecting an ambiguous indent.

Captured and handled in `check()`.

`tabnanny.tokenizeater`(*type, token, start, end, line*)

This function is used by `check()` as a callback parameter to the function `tokenize.tokenize()`.

See also:

Module `tokenize`

Lexical scanner for Python source code.

30.9. `pyclbr` — Python class browser support

Source code: [Lib/pyclbr.py](#)

The `pyclbr` module can be used to determine some limited information about the classes, methods and top-level functions defined in a module. The information provided is sufficient to implement a traditional three-pane class browser. The information is extracted from the source code rather than by importing the module, so this module is safe to use with untrusted code. This restriction makes it impossible to use this module with modules not implemented in Python, including all standard and optional extension modules.

`pyclbr.readmodule(module, path=None)`

Read a module and return a dictionary mapping class names to class descriptor objects. The parameter *module* should be the name of a module as a string; it may be the name of a module within a package. The *path* parameter should be a sequence, and is used to augment the value of `sys.path`, which is used to locate module source code.

`pyclbr.readmodule_ex(module, path=None)`

Like `readmodule()`, but the returned dictionary, in addition to mapping class names to class descriptor objects, also maps top-level function names to function descriptor objects. Moreover, if the module being read is a package, the key `'__path__'` in the returned dictionary has as its value a list which contains the package search path.

30.9.1. Class Objects

The `class` objects used as values in the dictionary returned by `readmodule()` and `readmodule_ex()` provide the following data members:

Class.`module`

The name of the module defining the class described by the class descriptor.

Class.`name`

The name of the class.

Class.`super`

A list of `class` objects which describe the immediate base classes of the class being described. Classes which are named as superclasses but which are not discoverable by `readmodule()` are listed as a string with the class name instead of as `class` objects.

Class.`methods`

A dictionary mapping method names to line numbers.

Class.`file`

Name of the file containing the `class` statement defining the class.

Class.`lineno`

The line number of the `class` statement within the file named by `file`.

30.9.2. Function Objects

The `Function` objects used as values in the dictionary returned by `readmodule_ex()` provide the following data members:

`Function.module`

The name of the module defining the function described by the function descriptor.

`Function.name`

The name of the function.

`Function.file`

Name of the file containing the `def` statement defining the function.

`Function.lineno`

The line number of the `def` statement within the file named by `file`.

30.10. `py_compile` — Compile Python source files

Source code: [Lib/py_compile.py](#)

The `py_compile` module provides a function to generate a byte-code file from a source file, and another function used when the module source file is invoked as a script.

Though not often needed, this function can be useful when installing modules for shared use, especially if some of the users may not have permission to write the byte-code cache files in the directory containing the source code.

exception `py_compile.PyCompileError`

Exception raised when an error occurs while attempting to compile the file.

`py_compile.compile(file, cfile=None, dfile=None, doraise=False, optimize=-1)`

Compile a source file to byte-code and write out the byte-code cache file. The source code is loaded from the file name *file*. The byte-code is written to *cfile*, which defaults to the [PEP 3147](#) path, ending in `.pyc` (`.pyo` if optimization is enabled in the current interpreter). For example, if *file* is `/foo/bar/baz.py` *cfile* will default to `/foo/bar/__pycache__/baz.cpython-32.pyc` for Python 3.2. If *dfile* is specified, it is used as the name of the source file in error messages when instead of *file*. If *doraise* is true, a `PyCompileError` is raised when an error is encountered while compiling *file*. If *doraise* is false (the default), an error string is written to `sys.stderr`, but no exception is raised. This function

returns the path to byte-compiled file, i.e. whatever *cfile* value was used.

optimize controls the optimization level and is passed to the built-in `compile()` function. The default of `-1` selects the optimization level of the current interpreter.

Changed in version 3.2: Changed default value of *cfile* to be [PEP 3147](#)-compliant. Previous default was `file + 'c'` (`'o'` if optimization was enabled). Also added the *optimize* parameter.

`py_compile.main(args=None)`

Compile several source files. The files named in *args* (or on the command line, if *args* is `None`) are compiled and the resulting bytecode is cached in the normal manner. This function does not search a directory structure to locate source files; it only compiles files named explicitly. If `'-'` is the only parameter in *args*, the list of files is taken from standard input.

Changed in version 3.2: Added support for `'-'`.

When this module is run as a script, the `main()` is used to compile all the files named on the command line. The exit status is nonzero if one of the files could not be compiled.

See also:

Module `compileall`

Utilities to compile all Python source files in a directory tree.

30.11. `compileall` — Byte-compile Python libraries

This module provides some utility functions to support installing Python libraries. These functions compile Python source files in a directory tree. This module can be used to create the cached byte-code files at library installation time, which makes them available for use even by users who don't have write permission to the library directories.

30.11.1. Command-line use

This module can work as a script (using **python -m compileall**) to compile Python sources.

[directory|file]...

Positional arguments are files to compile or directories that contain source files, traversed recursively. If no argument is given, behave as if the command line was `-l <directories from sys.path>`.

-l

Do not recurse into subdirectories, only compile source code files directly contained in the named or implied directories.

-f

Force rebuild even if timestamps are up-to-date.

-q

Do not print the list of files compiled, print only error messages.

-d `destdir`

Directory prepended to the path to each file being compiled. This will appear in compilation time tracebacks, and is also compiled in to the byte-code file, where it will be used in tracebacks and other messages in cases where the source file does not exist at the time the byte-code file is executed.

-x `regex`

`regex` is used to search the full path to each file considered for compilation, and if the `regex` produces a match, the file is skipped.

-i `list`

Read the file `list` and add each line that it contains to the list of

files and directories to compile. If `list` is `-`, read lines from `stdin`.

-b

Write the byte-code files to their legacy locations and names, which may overwrite byte-code files created by another version of Python. The default is to write files to their **PEP 3147** locations and names, which allows byte-code files from multiple versions of Python to coexist.

Changed in version 3.2: Added the `-i`, `-b` and `-h` options.

30.11.2. Public functions

`compileall.compile_dir(dir, maxlevels=10, ddir=None, force=False, rx=None, quiet=False, legacy=False, optimize=-1)`

Recursively descend the directory tree named by *dir*, compiling all `.py` files along the way.

The *maxlevels* parameter is used to limit the depth of the recursion; it defaults to `10`.

If *ddir* is given, it is prepended to the path to each file being compiled for use in compilation time tracebacks, and is also compiled in to the byte-code file, where it will be used in tracebacks and other messages in cases where the source file does not exist at the time the byte-code file is executed.

If *force* is true, modules are re-compiled even if the timestamps are up to date.

If *rx* is given, its search method is called on the complete path to each file considered for compilation, and if it returns a true value, the file is skipped.

If *quiet* is true, nothing is printed to the standard output unless errors occur.

If *legacy* is true, byte-code files are written to their legacy locations and names, which may overwrite byte-code files created by another version of Python. The default is to write files to their **PEP 3147** locations and names, which allows byte-code files from multiple versions of Python to coexist.

optimize specifies the optimization level for the compiler. It is passed to the built-in `compile()` function.

Changed in version 3.2: Added the *legacy* and *optimize* parameter.

```
compileall.compile_file(fullname, ddir=None, force=False,  
rx=None, quiet=False, legacy=False, optimize=-1)
```

Compile the file with path *fullname*.

If *ddir* is given, it is prepended to the path to the file being compiled for use in compilation time tracebacks, and is also compiled in to the byte-code file, where it will be used in tracebacks and other messages in cases where the source file does not exist at the time the byte-code file is executed.

If *rx* is given, its search method is passed the full path name to the file being compiled, and if it returns a true value, the file is not compiled and `True` is returned.

If *quiet* is true, nothing is printed to the standard output unless errors occur.

If *legacy* is true, byte-code files are written to their legacy locations and names, which may overwrite byte-code files created by another version of Python. The default is to write files to their [PEP 3147](#) locations and names, which allows byte-code files from multiple versions of Python to coexist.

optimize specifies the optimization level for the compiler. It is passed to the built-in `compile()` function.

New in version 3.2.

```
compileall.compile_path(skip_curdir=True, maxlevels=0,  
force=False, legacy=False, optimize=-1)
```

Byte-compile all the `.py` files found along `sys.path`. If *skip_curdir* is true (the default), the current directory is not included in the

search. All other parameters are passed to the `compile_dir()` function. Note that unlike the other compile functions, `maxlevels` defaults to 0.

Changed in version 3.2: Added the *legacy* and *optimize* parameter.

To force a recompile of all the `.py` files in the `Lib/` subdirectory and all its subdirectories:

```
import compileall

compileall.compile_dir('Lib/', force=True)

# Perform same compilation, excluding files in .svn directories
import re
compileall.compile_dir('Lib/', rx=re.compile('/[.]svn'), force=
```

See also:

Module `py_compile`

Byte-compile a single source file.

30.12. `dis` — Disassembler for Python bytecode

Source code: [Lib/dis.py](#)

The `dis` module supports the analysis of CPython *bytecode* by disassembling it. The CPython bytecode which this module takes as an input is defined in the file `Include/opcode.h` and used by the compiler and the interpreter.

CPython implementation detail: Bytecode is an implementation detail of the CPython interpreter. No guarantees are made that bytecode will not be added, removed, or changed between versions of Python. Use of this module should not be considered to work across Python VMs or Python releases.

Example: Given the function `myfunc()`:

```
def myfunc(alist):  
    return len(alist)
```

the following command can be used to get the disassembly of `myfunc()`:

```
>>> dis.dis(myfunc)  
2           0 LOAD_GLOBAL           0 (len)  
           3 LOAD_FAST             0 (alist)  
           6 CALL_FUNCTION         1  
           9 RETURN_VALUE
```

(The “2” is a line number).

The `dis` module defines the following functions and constants:

`dis.code_info(x)`

Return a formatted multi-line string with detailed code object information for the supplied function, method, source code string or code object.

Note that the exact contents of code info strings are highly implementation dependent and they may change arbitrarily across Python VMs or Python releases.

New in version 3.2.

`dis.show_code(x)`

Print detailed code object information for the supplied function, method, source code string or code object to stdout.

This is a convenient shorthand for `print(code_info(x))`, intended for interactive exploration at the interpreter prompt.

New in version 3.2.

`dis.dis(x=None)`

Disassemble the `x` object. `x` can denote either a module, a class, a method, a function, a code object, a string of source code or a byte sequence of raw bytecode. For a module, it disassembles all functions. For a class, it disassembles all methods. For a code object or sequence of raw bytecode, it prints one line per bytecode instruction. Strings are first compiled to code objects with the `compile()` built-in function before being disassembled. If no object is provided, this function disassembles the last traceback.

`dis.distb(tb=None)`

Disassemble the top-of-stack function of a traceback, using the

last traceback if none was passed. The instruction causing the exception is indicated.

`dis.disassemble(code, lasti=-1)`

`dis.disco(code, lasti=-1)`

Disassemble a code object, indicating the last instruction if *lasti* was provided. The output is divided in the following columns:

1. the line number, for the first instruction of each line
2. the current instruction, indicated as `-->`,
3. a labelled instruction, indicated with `>>`,
4. the address of the instruction,
5. the operation code name,
6. operation parameters, and
7. interpretation of the parameters in parentheses.

The parameter interpretation recognizes local and global variable names, constant values, branch targets, and compare operators.

`dis.findlinestarts(code)`

This generator function uses the `co_firstlineno` and `co_lnotab` attributes of the code object *code* to find the offsets which are starts of lines in the source code. They are generated as `(offset, lineno)` pairs.

`dis.findlabels(code)`

Detect all offsets in the code object *code* which are jump targets, and return a list of these offsets.

`dis.opname`

Sequence of operation names, indexable using the bytecode.

`dis.opmap`

Dictionary mapping operation names to bytecodes.

`dis.cmp_op`

Sequence of all compare operation names.

dis. **hasconst**

Sequence of bytecodes that have a constant parameter.

dis. **hasfree**

Sequence of bytecodes that access a free variable.

dis. **hasname**

Sequence of bytecodes that access an attribute by name.

dis. **hasjrel**

Sequence of bytecodes that have a relative jump target.

dis. **hasjabs**

Sequence of bytecodes that have an absolute jump target.

dis. **haslocal**

Sequence of bytecodes that access a local variable.

dis. **hascompare**

Sequence of bytecodes of Boolean operations.

30.12.1. Python Bytecode Instructions

The Python compiler currently generates the following bytecode instructions.

General instructions

STOP_CODE

Indicates end-of-code to the compiler, not used by the interpreter.

NOP

Do nothing code. Used as a placeholder by the bytecode optimizer.

POP_TOP

Removes the top-of-stack (TOS) item.

ROT_TWO

Swaps the two top-most stack items.

ROT_THREE

Lifts second and third stack item one position up, moves top down to position three.

DUP_TOP

Duplicates the reference on top of the stack.

DUP_TOP_TWO

Duplicates the two references on top of the stack, leaving them in the same order.

Unary operations

Unary operations take the top of the stack, apply the operation, and push the result back on the stack.

UNARY_POSITIVE

Implements $TOS = +TOS$.

UNARY_NEGATIVE

Implements $TOS = -TOS$.

UNARY_NOT

Implements $TOS = \text{not } TOS$.

UNARY_INVERT

Implements $TOS = \sim TOS$.

GET_ITER

Implements $TOS = \text{iter}(TOS)$.

Binary operations

Binary operations remove the top of the stack (TOS) and the second top-most stack item (TOS1) from the stack. They perform the operation, and put the result back on the stack.

BINARY_POWER

Implements $TOS = TOS1 ** TOS$.

BINARY_MULTIPLY

Implements $TOS = TOS1 * TOS$.

BINARY_FLOOR_DIVIDE

Implements $TOS = TOS1 // TOS$.

BINARY_TRUE_DIVIDE

Implements $TOS = TOS1 / TOS$.

BINARY_MODULO

Implements $TOS = TOS1 \% TOS$.

BINARY_ADD

Implements $TOS = TOS1 + TOS$.

BINARY_SUBTRACT

Implements $TOS = TOS1 - TOS$.

BINARY_SUBSCR

Implements $TOS = TOS1[TOS]$.

BINARY_LSHIFT

Implements $TOS = TOS1 \ll TOS$.

BINARY_RSHIFT

Implements $TOS = TOS1 \gg TOS$.

BINARY_AND

Implements $TOS = TOS1 \& TOS$.

BINARY_XOR

Implements $TOS = TOS1 \wedge TOS$.

BINARY_OR

Implements $TOS = TOS1 | TOS$.

In-place operations

In-place operations are like binary operations, in that they remove TOS and TOS1, and push the result back on the stack, but the operation is done in-place when TOS1 supports it, and the resulting TOS may be (but does not have to be) the original TOS1.

INPLACE_POWER

Implements in-place $TOS = TOS1 ** TOS$.

INPLACE_MULTIPLY

Implements in-place $TOS = TOS1 * TOS$.

INPLACE_FLOOR_DIVIDE

Implements in-place $TOS = TOS1 // TOS$.

INPLACE_TRUE_DIVIDE

Implements in-place $TOS = TOS1 / TOS$.

INPLACE_MODULO

Implements in-place $TOS = TOS1 \% TOS$.

INPLACE_ADD

Implements in-place $TOS = TOS1 + TOS$.

INPLACE_SUBTRACT

Implements in-place $TOS = TOS1 - TOS$.

INPLACE_LSHIFT

Implements in-place $TOS = TOS1 \ll TOS$.

INPLACE_RSHIFT

Implements in-place $TOS = TOS1 \gg TOS$.

INPLACE_AND

Implements in-place $TOS = TOS1 \& TOS$.

INPLACE_XOR

Implements in-place $TOS = TOS1 \wedge TOS$.

INPLACE_OR

Implements in-place $TOS = TOS1 | TOS$.

STORE_SUBSCR

Implements $TOS1[TOS] = TOS2$.

DELETE_SUBSCR

Implements `del TOS1[TOS]`.

Miscellaneous opcodes

PRINT_EXPR

Implements the expression statement for the interactive mode. TOS is removed from the stack and printed. In non-interactive mode, an expression statement is terminated with `POP_STACK`.

BREAK_LOOP

Terminates a loop due to a `break` statement.

CONTINUE_LOOP(*target*)

Continues a loop due to a `continue` statement. *target* is the address to jump to (which should be a `FOR_ITER` instruction).

SET_ADD(*i*)

Calls `set.add(TOS1[-i], TOS)`. Used to implement set comprehensions.

LIST_APPEND(*i*)

Calls `list.append(TOS[-i], TOS)`. Used to implement list comprehensions.

MAP_ADD(*i*)

Calls `dict.setdefault(TOS1[-i], TOS, TOS1)`. Used to implement dict comprehensions.

For all of the `SET_ADD`, `LIST_APPEND` and `MAP_ADD` instructions, while the added value or key/value pair is popped off, the container object remains on the stack so that it is available for further iterations of the loop.

RETURN_VALUE

Returns with TOS to the caller of the function.

YIELD_VALUE

Pops `TOS` and yields it from a *generator*.

IMPORT_STAR

Loads all symbols not starting with `'_'` directly from the module TOS to the local namespace. The module is popped after loading all names. This opcode implements `from module import *`.

POP_BLOCK

Removes one block from the block stack. Per frame, there is a stack of blocks, denoting nested loops, try statements, and such.

POP_EXCEPT

Removes one block from the block stack. The popped block must be an exception handler block, as implicitly created when entering an except handler. In addition to popping extraneous values from the frame stack, the last three popped values are used to restore the exception state.

END_FINALLY

Terminates a `finally` clause. The interpreter recalls whether the exception has to be re-raised, or whether the function returns, and continues with the outer-next block.

LOAD_BUILD_CLASS

Pushes `builtins.__build_class__()` onto the stack. It is later called by `CALL_FUNCTION` to construct a class.

SETUP_WITH(*delta*)

This opcode performs several operations before a `with` block starts. First, it loads `__exit__()` from the context manager and pushes it onto the stack for later use by `WITH_CLEANUP`. Then, `__enter__()` is called, and a finally block pointing to `delta` is pushed. Finally, the result of calling the `enter` method is pushed onto the stack. The next opcode will either ignore it (`POP_TOP`), or store it in (a) variable(s) (`STORE_FAST`, `STORE_NAME`, or `UNPACK_SEQUENCE`).

WITH_CLEANUP

Cleans up the stack when a `with` statement block exits. TOS is the context manager's `__exit__()` bound method. Below TOS are 1–3 values indicating how/why the finally clause was entered:

- SECOND = `None`
- (SECOND, THIRD) = (`WHY_{RETURN, CONTINUE}`), `retval`
- SECOND = `WHY_*`; no `retval` below it
- (SECOND, THIRD, FOURTH) = `exc_info()`

In the last case, `TOS(SECOND, THIRD, FOURTH)` is called, otherwise `TOS(None, None, None)`. In addition, TOS is removed from the stack.

If the stack represents an exception, *and* the function call returns a 'true' value, this information is “zapped” and replaced with a single `WHY_SILENCED` to prevent `END_FINALLY` from re-raising the exception. (But non-local gotos will still be resumed.)

STORE_LOCALS

Pops TOS from the stack and stores it as the current frame's `f_locals`. This is used in class construction.

All of the following opcodes expect arguments. An argument is two bytes, with the more significant byte last.

STORE_NAME(*namei*)

Implements `name = TOS`. *namei* is the index of *name* in the attribute `co_names` of the code object. The compiler tries to use `STORE_FAST` or `STORE_GLOBAL` if possible.

DELETE_NAME(*namei*)

Implements `del name`, where *namei* is the index into `co_names` attribute of the code object.

UNPACK_SEQUENCE(*count*)

Unpacks TOS into *count* individual values, which are put onto the stack right-to-left.

UNPACK_EX(*counts*)

Implements assignment with a starred target: Unpacks an iterable in TOS into individual values, where the total number of values can be smaller than the number of items in the iterable: one the new values will be a list of all leftover items.

The low byte of *counts* is the number of values before the list value, the high byte of *counts* the number of values after it. The resulting values are put onto the stack right-to-left.

STORE_ATTR(*namei*)

Implements `TOS.name = TOS1`, where *namei* is the index of name in `co_names`.

DELETE_ATTR(*namei*)

Implements `del TOS.name`, using *namei* as index into `co_names`.

STORE_GLOBAL(*namei*)

Works as `STORE_NAME`, but stores the name as a global.

DELETE_GLOBAL(*namei*)

Works as `DELETE_NAME`, but deletes a global name.

LOAD_CONST(*consti*)

Pushes `co_consts[consti]` onto the stack.

LOAD_NAME(*namei*)

Pushes the value associated with `co_names[namei]` onto the stack.

BUILD_TUPLE(*count*)

Creates a tuple consuming *count* items from the stack, and pushes the resulting tuple onto the stack.

BUILD_LIST(*count*)

Works as `BUILD_TUPLE`, but creates a list.

BUILD_SET(*count*)

Works as `BUILD_TUPLE`, but creates a set.

BUILD_MAP(*count*)

Pushes a new dictionary object onto the stack. The dictionary is pre-sized to hold *count* entries.

LOAD_ATTR(*name_i*)

Replaces TOS with `getattr(TOS, co_names[namei])`.

COMPARE_OP(*opname*)

Performs a Boolean operation. The operation name can be found in `cmp_op[opname]`.

IMPORT_NAME(*name_i*)

Imports the module `co_names[namei]`. TOS and TOS1 are popped and provide the *fromlist* and *level* arguments of `__import__()`. The module object is pushed onto the stack. The current namespace is not affected: for a proper import statement, a subsequent `STORE_FAST` instruction modifies the namespace.

IMPORT_FROM(*name_i*)

Loads the attribute `co_names[namei]` from the module found in TOS. The resulting object is pushed onto the stack, to be subsequently stored by a `STORE_FAST` instruction.

JUMP_FORWARD(*delta*)

Increments bytecode counter by *delta*.

POP_JUMP_IF_TRUE(*target*)

If TOS is true, sets the bytecode counter to *target*. TOS is popped.

POP_JUMP_IF_FALSE(*target*)

If TOS is false, sets the bytecode counter to *target*. TOS is popped.

JUMP_IF_TRUE_OR_POP(*target*)

If TOS is true, sets the bytecode counter to *target* and leaves TOS on the stack. Otherwise (TOS is false), TOS is popped.

JUMP_IF_FALSE_OR_POP(*target*)

If TOS is false, sets the bytecode counter to *target* and leaves TOS on the stack. Otherwise (TOS is true), TOS is popped.

JUMP_ABSOLUTE(*target*)

Set bytecode counter to *target*.

FOR_ITER(*delta*)

TOS is an *iterator*. Call its `__next__()` method. If this yields a new value, push it on the stack (leaving the iterator below it). If the iterator indicates it is exhausted TOS is popped, and the byte code counter is incremented by *delta*.

LOAD_GLOBAL(*namei*)**

Loads the global named `co_names[namei]` onto the stack.

SETUP_LOOP(*delta*)

Pushes a block for a loop onto the block stack. The block spans from the current instruction with a size of *delta* bytes.

SETUP_EXCEPT(*delta*)

Pushes a try block from a try-except clause onto the block stack. *delta* points to the first except block.

SETUP_FINALLY(*delta*)

Pushes a try block from a try-except clause onto the block stack. *delta* points to the finally block.

STORE_MAP

Store a key and value pair in a dictionary. Pops the key and value while leaving the dictionary on the stack.

LOAD_FAST(*var_num*)

Pushes a reference to the local `co_varnames[var_num]` onto the stack.

STORE_FAST(*var_num*)

Stores TOS into the local `co_varnames[var_num]`.

DELETE_FAST(*var_num*)

Deletes local `co_varnames[var_num]`.

LOAD_CLOSURE(*i*)

Pushes a reference to the cell contained in slot *i* of the cell and free variable storage. The name of the variable is `co_cellvars[i]` if *i* is less than the length of `co_cellvars`. Otherwise it is `co_freevars[i - len(co_cellvars)]`.

LOAD_DEREF(*i*)

Loads the cell contained in slot *i* of the cell and free variable storage. Pushes a reference to the object the cell contains on the stack.

STORE_DEREF(*i*)

Stores TOS into the cell contained in slot *i* of the cell and free

variable storage.

DELETE_DEREF(*i*)

Empties the cell contained in slot *i* of the cell and free variable storage. Used by the `del` statement.

RAISE_VARARGS(*argc*)

Raises an exception. *argc* indicates the number of parameters to the raise statement, ranging from 0 to 3. The handler will find the traceback as TOS2, the parameter as TOS1, and the exception as TOS.

CALL_FUNCTION(*argc*)

Calls a function. The low byte of *argc* indicates the number of positional parameters, the high byte the number of keyword parameters. On the stack, the opcode finds the keyword parameters first. For each keyword argument, the value is on top of the key. Below the keyword parameters, the positional parameters are on the stack, with the right-most parameter on top. Below the parameters, the function object to call is on the stack. Pops all function arguments, and the function itself off the stack, and pushes the return value.

MAKE_FUNCTION(*argc*)

Pushes a new function object on the stack. TOS is the code associated with the function. The function object is defined to have *argc* default parameters, which are found below TOS.

MAKE_CLOSURE(*argc*)

Creates a new function object, sets its `__closure__` slot, and pushes it on the stack. TOS is the code associated with the function, TOS1 the tuple containing cells for the closure's free variables. The function also has *argc* default parameters, which are found below the cells.

BUILD_SLICE(*argc*)

Pushes a slice object on the stack. *argc* must be 2 or 3. If it is 2, `slice(TOS1, TOS)` is pushed; if it is 3, `slice(TOS2, TOS1, TOS)` is pushed. See the `slice()` built-in function for more information.

EXTENDED_ARG(*ext*)

Prefixes any opcode which has an argument too big to fit into the default two bytes. *ext* holds two additional bytes which, taken together with the subsequent opcode's argument, comprise a four-byte argument, *ext* being the two most-significant bytes.

CALL_FUNCTION_VAR(*argc*)

Calls a function. *argc* is interpreted as in `CALL_FUNCTION`. The top element on the stack contains the variable argument list, followed by keyword and positional arguments.

CALL_FUNCTION_KW(*argc*)

Calls a function. *argc* is interpreted as in `CALL_FUNCTION`. The top element on the stack contains the keyword arguments dictionary, followed by explicit keyword and positional arguments.

CALL_FUNCTION_VAR_KW(*argc*)

Calls a function. *argc* is interpreted as in `CALL_FUNCTION`. The top element on the stack contains the keyword arguments dictionary, followed by the variable-arguments tuple, followed by explicit keyword and positional arguments.

HAVE_ARGUMENT

This is not really an opcode. It identifies the dividing line between opcodes which don't take arguments `< HAVE_ARGUMENT` and those which do `>= HAVE_ARGUMENT`.

30.13. `pickletools` — Tools for pickle developers

Source code: [Lib/pickletools.py](#)

This module contains various constants relating to the intimate details of the `pickle` module, some lengthy comments about the implementation, and a few useful functions for analyzing pickled data. The contents of this module are useful for Python core developers who are working on the `pickle`; ordinary users of the `pickle` module probably won't find the `pickletools` module relevant.

30.13.1. Command line usage

New in version 3.2.

When invoked from the command line, `python -m pickletools` will disassemble the contents of one or more pickle files. Note that if you want to see the Python object stored in the pickle rather than the details of pickle format, you may want to use `-m pickle` instead. However, when the pickle file that you want to examine comes from an untrusted source, `-m pickletools` is a safer option because it does not execute pickle bytecode.

For example, with a tuple `(1, 2)` pickled in file `x.pickle`:

```
$ python -m pickle x.pickle
(1, 2)

$ python -m pickletools x.pickle
 0: \x80 PROTO      3
 2: K   BININT1    1
 4: K   BININT1    2
 6: \x86 TUPLE2
 7: q   BININPUT   0
 9: .   STOP
highest protocol among opcodes = 2
```

30.13.1.1. Command line options

-a, --annotate

Annotate each line with a short opcode description.

-o, --output=<file>

Name of a file where the output should be written.

-l, --indentlevel=<num>

The number of blanks by which to indent a new MARK level.

-m, --memo

When multiple objects are disassembled, preserve memo between disassemblies.

-p, --preamble=<preamble>

When more than one pickle file are specified, print given preamble before each disassembly.

30.13.2. Programmatic Interface

```
pickletools.dis(pickle, out=None, memo=None, indentlevel=4,  
annotate=0)
```

Outputs a symbolic disassembly of the pickle to the file-like object *out*, defaulting to `sys.stdout`. *pickle* can be a string or a file-like object. *memo* can be a Python dictionary that will be used as the pickle's memo; it can be used to perform disassemblies across multiple pickles created by the same pickler. Successive levels, indicated by `MARK` opcodes in the stream, are indented by *indentlevel* spaces. If a nonzero value is given to *annotate*, each opcode in the output is annotated with a short description. The value of *annotate* is used as a hint for the column where annotation should start.

New in version 3.2: The *annotate* argument.

```
pickletools.genops(pickle)
```

Provides an *iterator* over all of the opcodes in a pickle, returning a sequence of `(opcode, arg, pos)` triples. *opcode* is an instance of an `OpcodeInfo` class; *arg* is the decoded value, as a Python object, of the opcode's argument; *pos* is the position at which this opcode is located. *pickle* can be a string or a file-like object.

```
pickletools.optimize(picklestring)
```

Returns a new equivalent pickle string after eliminating unused `PUT` opcodes. The optimized pickle is shorter, takes less transmission time, requires less storage space, and unpickles more efficiently.

31. Miscellaneous Services

The modules described in this chapter provide miscellaneous services that are available in all Python versions. Here's an overview:

- **31.1. `formatter`** — Generic output formatting
 - 31.1.1. The Formatter Interface
 - 31.1.2. Formatter Implementations
 - 31.1.3. The Writer Interface
 - 31.1.4. Writer Implementations

31.1. `formatter` — Generic output formatting

This module supports two interface definitions, each with multiple implementations: The *formatter* interface, and the *writer* interface which is required by the formatter interface.

Formatter objects transform an abstract flow of formatting events into specific output events on writer objects. Formatters manage several stack structures to allow various properties of a writer object to be changed and restored; writers need not be able to handle relative changes nor any sort of “change back” operation. Specific writer properties which may be controlled via formatter objects are horizontal alignment, font, and left margin indentations. A mechanism is provided which supports providing arbitrary, non-exclusive style settings to a writer as well. Additional interfaces facilitate formatting events which are not reversible, such as paragraph separation.

Writer objects encapsulate device interfaces. Abstract devices, such as file formats, are supported as well as physical devices. The provided implementations all work with abstract devices. The interface makes available mechanisms for setting the properties which formatter objects manage and inserting data into the output.

31.1.1. The Formatter Interface

Interfaces to create formatters are dependent on the specific formatter class being instantiated. The interfaces described below are the required interfaces which all formatters must support once initialized.

One data element is defined at the module level:

`formatter.AS_IS`

Value which can be used in the font specification passed to the `push_font()` method described below, or as the new value to any other `push_property()` method. Pushing the `AS_IS` value allows the corresponding `pop_property()` method to be called without having to track whether the property was changed.

The following attributes are defined for formatter instance objects:

`formatter.writer`

The writer instance with which the formatter interacts.

`formatter.end_paragraph(blanklines)`

Close any open paragraphs and insert at least *blanklines* before the next paragraph.

`formatter.add_line_break()`

Add a hard line break if one does not already exist. This does not break the logical paragraph.

`formatter.add_hor_rule(*args, **kw)`

Insert a horizontal rule in the output. A hard break is inserted if there is data in the current paragraph, but the logical paragraph is not broken. The arguments and keywords are passed on to the writer's `send_line_break()` method.

`formatter.add_flowling_data(data)`

Provide data which should be formatted with collapsed whitespace. Whitespace from preceding and successive calls to `add_flowling_data()` is considered as well when the whitespace collapse is performed. The data which is passed to this method is expected to be word-wrapped by the output device. Note that any word-wrapping still must be performed by the writer object due to the need to rely on device and font information.

`formatter.add_literal_data(data)`

Provide data which should be passed to the writer unchanged. Whitespace, including newline and tab characters, are considered legal in the value of *data*.

`formatter.add_label_data(format, counter)`

Insert a label which should be placed to the left of the current left margin. This should be used for constructing bulleted or numbered lists. If the *format* value is a string, it is interpreted as a format specification for *counter*, which should be an integer. The result of this formatting becomes the value of the label; if *format* is not a string it is used as the label value directly. The label value is passed as the only argument to the writer's `send_label_data()` method. Interpretation of non-string label values is dependent on the associated writer.

Format specifications are strings which, in combination with a counter value, are used to compute label values. Each character in the format string is copied to the label value, with some characters recognized to indicate a transform on the counter value. Specifically, the character `'1'` represents the counter value formatter as an Arabic number, the characters `'A'` and `'a'` represent alphabetic representations of the counter value in upper and lower case, respectively, and `'I'` and `'i'` represent the counter value in Roman numerals, in upper and lower case.

Note that the alphabetic and roman transforms require that the counter value be greater than zero.

`formatter.flush_softspace()`

Send any pending whitespace buffered from a previous call to `add_flowling_data()` to the associated writer object. This should be called before any direct manipulation of the writer object.

`formatter.push_alignment(align)`

Push a new alignment setting onto the alignment stack. This may be `AS_IS` if no change is desired. If the alignment value is changed from the previous setting, the writer's `new_alignment()` method is called with the *align* value.

`formatter.pop_alignment()`

Restore the previous alignment.

`formatter.push_font((size, italic, bold, teletype))`

Change some or all font properties of the writer object. Properties which are not set to `AS_IS` are set to the values passed in while others are maintained at their current settings. The writer's `new_font()` method is called with the fully resolved font specification.

`formatter.pop_font()`

Restore the previous font.

`formatter.push_margin(margin)`

Increase the number of left margin indentations by one, associating the logical tag *margin* with the new indentation. The initial margin level is 0. Changed values of the logical tag must be true values; false values other than `AS_IS` are not sufficient to change the margin.

`formatter.pop_margin()`

Restore the previous margin.

`formatter.push_style(*styles)`

Push any number of arbitrary style specifications. All styles are pushed onto the styles stack in order. A tuple representing the entire stack, including **AS_IS** values, is passed to the writer's `new_styles()` method.

`formatter.pop_style(n=1)`

Pop the last *n* style specifications passed to `push_style()`. A tuple representing the revised stack, including **AS_IS** values, is passed to the writer's `new_styles()` method.

`formatter.set_spacing(spacing)`

Set the spacing style for the writer.

`formatter.assert_line_data(flag=1)`

Inform the formatter that data has been added to the current paragraph out-of-band. This should be used when the writer has been manipulated directly. The optional *flag* argument can be set to false if the writer manipulations produced a hard line break at the end of the output.

31.1.2. Formatter Implementations

Two implementations of formatter objects are provided by this module. Most applications may use one of these classes without modification or subclassing.

class `formatter.NullFormatter(writer=None)`

A formatter which does nothing. If *writer* is omitted, a `NullWriter` instance is created. No methods of the writer are called by `NullFormatter` instances. Implementations should inherit from this class if implementing a writer interface but don't need to inherit any implementation.

class `formatter.AbstractFormatter(writer)`

The standard formatter. This implementation has demonstrated wide applicability to many writers, and may be used directly in most circumstances. It has been used to implement a full-featured World Wide Web browser.

31.1.3. The Writer Interface

Interfaces to create writers are dependent on the specific writer class being instantiated. The interfaces described below are the required interfaces which all writers must support once initialized. Note that while most applications can use the `AbstractFormatter` class as a formatter, the writer must typically be provided by the application.

`writer.flush()`

Flush any buffered output or device control events.

`writer.new_alignment(align)`

Set the alignment style. The *align* value can be any object, but by convention is a string or `None`, where `None` indicates that the writer's "preferred" alignment should be used. Conventional *align* values are `'left'`, `'center'`, `'right'`, and `'justify'`.

`writer.new_font(font)`

Set the font style. The value of *font* will be `None`, indicating that the device's default font should be used, or a tuple of the form `(size, italic, bold, teletype)`. Size will be a string indicating the size of font that should be used; specific strings and their interpretation must be defined by the application. The *italic*, *bold*, and *teletype* values are Boolean values specifying which of those font attributes should be used.

`writer.new_margin(margin, level)`

Set the margin level to the integer *level* and the logical tag to *margin*. Interpretation of the logical tag is at the writer's discretion; the only restriction on the value of the logical tag is that it not be a false value for non-zero values of *level*.

`writer.new_spacing(spacing)`

Set the spacing style to *spacing*.

`writer.new_styles(styles)`

Set additional styles. The *styles* value is a tuple of arbitrary values; the value `AS_IS` should be ignored. The *styles* tuple may be interpreted either as a set or as a stack depending on the requirements of the application and writer implementation.

`writer.send_line_break()`

Break the current line.

`writer.send_paragraph(blankline)`

Produce a paragraph separation of at least *blankline* blank lines, or the equivalent. The *blankline* value will be an integer. Note that the implementation will receive a call to `send_line_break()` before this call if a line break is needed; this method should not include ending the last line of the paragraph. It is only responsible for vertical spacing between paragraphs.

`writer.send_hor_rule(*args, **kw)`

Display a horizontal rule on the output device. The arguments to this method are entirely application- and writer-specific, and should be interpreted with care. The method implementation may assume that a line break has already been issued via `send_line_break()`.

`writer.send_flow_data(data)`

Output character data which may be word-wrapped and re-flowed as needed. Within any sequence of calls to this method, the writer may assume that spans of multiple whitespace characters have been collapsed to single space characters.

`writer.send_literal_data(data)`

Output character data which has already been formatted for

display. Generally, this should be interpreted to mean that line breaks indicated by newline characters should be preserved and no new line breaks should be introduced. The data may contain embedded newline and tab characters, unlike data provided to the `send_formatted_data()` interface.

`writer.send_label_data(data)`

Set *data* to the left of the current left margin, if possible. The value of *data* is not restricted; treatment of non-string values is entirely application- and writer-dependent. This method will only be called at the beginning of a line.

31.1.4. Writer Implementations

Three implementations of the writer object interface are provided as examples by this module. Most applications will need to derive new writer classes from the `NullWriter` class.

`class formatter.NullWriter`

A writer which only provides the interface definition; no actions are taken on any methods. This should be the base class for all writers which do not need to inherit any implementation methods.

`class formatter.AbstractWriter`

A writer which can be used in debugging formatters, but not much else. Each method simply announces itself by printing its name and arguments on standard output.

`class formatter.DumbWriter(file=None, maxcol=72)`

Simple writer class which writes output on the *file object* passed in as *file* or, if *file* is omitted, on standard output. The output is simply word-wrapped to the number of columns specified by *maxcol*. This class is suitable for reflowing a sequence of paragraphs.

32. MS Windows Specific Services

This chapter describes modules that are only available on MS Windows platforms.

- 32.1. `msilib` — Read and write Microsoft Installer files
 - 32.1.1. Database Objects
 - 32.1.2. View Objects
 - 32.1.3. Summary Information Objects
 - 32.1.4. Record Objects
 - 32.1.5. Errors
 - 32.1.6. CAB Objects
 - 32.1.7. Directory Objects
 - 32.1.8. Features
 - 32.1.9. GUI classes
 - 32.1.10. Precomputed tables
- 32.2. `msvcrt` – Useful routines from the MS VC++ runtime
 - 32.2.1. File Operations
 - 32.2.2. Console I/O
 - 32.2.3. Other Functions
- 32.3. `winreg` – Windows registry access
 - 32.3.1. Constants
 - 32.3.1.1. HKEY_* Constants
 - 32.3.1.2. Access Rights
 - 32.3.1.2.1. 64-bit Specific
 - 32.3.1.3. Value Types
 - 32.3.2. Registry Handle Objects
- 32.4. `winsound` — Sound-playing interface for Windows

32.1. `msilib` — Read and write Microsoft Installer files

Platforms: Windows

The `msilib` supports the creation of Microsoft Installer (`.msi`) files. Because these files often contain an embedded “cabinet” file (`.cab`), it also exposes an API to create CAB files. Support for reading `.cab` files is currently not implemented; read support for the `.msi` database is possible.

This package aims to provide complete access to all tables in an `.msi` file, therefore, it is a fairly low-level API. Two primary applications of this package are the `distutils` command `bdist_msi`, and the creation of Python installer package itself (although that currently uses a different version of `msilib`).

The package contents can be roughly split into four parts: low-level CAB routines, low-level MSI routines, higher-level MSI routines, and standard table structures.

`msilib.FCICreate(cabname, files)`

Create a new CAB file named *cabname*. *files* must be a list of tuples, each containing the name of the file on disk, and the name of the file inside the CAB file.

The files are added to the CAB file in the order they appear in the list. All files are added into a single CAB file, using the MSZIP compression algorithm.

Callbacks to Python for the various steps of MSI creation are currently not exposed.

`msilib.UuidCreate()`

Return the string representation of a new unique identifier. This wraps the Windows API functions `UuidCreate()` and `UuidToString()`.

`msilib.OpenDatabase(path, persist)`

Return a new database object by calling `MsiOpenDatabase`. *path* is the file name of the MSI file; *persist* can be one of the constants `MSIDBOPEN_CREATEDIRECT`, `MSIDBOPEN_CREATE`, `MSIDBOPEN_DIRECT`, `MSIDBOPEN_READONLY`, OR `MSIDBOPEN_TRANSACT`, and may include the flag `MSIDBOPEN_PATCHFILE`. See the Microsoft documentation for the meaning of these flags; depending on the flags, an existing database is opened, or a new one created.

`msilib.CreateRecord(count)`

Return a new record object by calling `MSICreateRecord()`. *count* is the number of fields of the record.

`msilib.init_database(name, schema, ProductName, ProductCode, ProductVersion, Manufacturer)`

Create and return a new database *name*, initialize it with *schema*, and set the properties *ProductName*, *ProductCode*, *ProductVersion*, and *Manufacturer*.

schema must be a module object containing `tables` and `_validation_records` attributes; typically, `msilib.schema` should be used.

The database will contain just the schema and the validation records when this function returns.

`msilib.add_data(database, table, records)`

Add all *records* to the table named *table* in *database*.

The *table* argument must be one of the predefined tables in the MSI schema, e.g. 'Feature', 'File', 'Component', 'Dialog', 'Control', etc.

records should be a list of tuples, each one containing all fields of a record according to the schema of the table. For optional fields, **None** can be passed.

Field values can be int or long numbers, strings, or instances of the Binary class.

`class msilib.Binary(filename)`

Represents entries in the Binary table; inserting such an object using `add_data()` reads the file named *filename* into the table.

`msilib.add_tables(database, module)`

Add all table content from *module* to *database*. *module* must contain an attribute *tables* listing all tables for which content should be added, and one attribute per table that has the actual content.

This is typically used to install the sequence tables.

`msilib.add_stream(database, name, path)`

Add the file *path* into the `_Stream` table of *database*, with the stream name *name*.

`msilib.gen_uuid()`

Return a new UUID, in the format that MSI typically requires (i.e. in curly braces, and with all hexdigits in upper-case).

See also: [FCICreateFile](#) [UuidCreate](#) [UuidToString](#)

32.1.1. Database Objects

Database.**OpenView**(*sql*)

Return a view object, by calling `MSIDatabaseOpenView()`. *sql* is the SQL statement to execute.

Database.**Commit**()

Commit the changes pending in the current transaction, by calling `MSIDatabaseCommit()`.

Database.**GetSummaryInformation**(*count*)

Return a new summary information object, by calling `MsiGetSummaryInformation()`. *count* is the maximum number of updated values.

See also: [MSIDatabaseOpenView](#) [MSIDatabaseCommit](#)
[MsiGetSummaryInformation](#)

32.1.2. View Objects

View.**Execute**(*params*)

Execute the SQL query of the view, through `MSIViewExecute()`. If *params* is not `None`, it is a record describing actual values of the parameter tokens in the query.

View.**GetColumnInfo**(*kind*)

Return a record describing the columns of the view, through calling `MsiViewGetColumnInfo()`. *kind* can be either `MSICOLINFO_NAMES` or `MSICOLINFO_TYPES`.

View.**Fetch**()

Return a result record of the query, through calling `MsiViewFetch()`.

View.**Modify**(*kind*, *data*)

Modify the view, by calling `MsiViewModify()`. *kind* can be one of `MSIMODIFY_SEEK`, `MSIMODIFY_REFRESH`, `MSIMODIFY_INSERT`, `MSIMODIFY_UPDATE`, `MSIMODIFY_ASSIGN`, `MSIMODIFY_REPLACE`, `MSIMODIFY_MERGE`, `MSIMODIFY_DELETE`, `MSIMODIFY_INSERT_TEMPORARY`, `MSIMODIFY_VALIDATE`, `MSIMODIFY_VALIDATE_NEW`, `MSIMODIFY_VALIDATE_FIELD`, or `MSIMODIFY_VALIDATE_DELETE`.

data must be a record describing the new data.

View.**Close**()

Close the view, through `MsiViewClose()`.

See also: [MsiViewExecute](#) [MSIViewGetColumnInfo](#)
[MsiViewFetch](#) [MsiViewModify](#) [MsiViewClose](#)

32.1.3. Summary Information Objects

`SummaryInformation.GetProperty(field)`

Return a property of the summary, through `MsiSummaryInfoGetProperty()`. *field* is the name of the property, and can be one of the constants `PID_CODEPAGE`, `PID_TITLE`, `PID_SUBJECT`, `PID_AUTHOR`, `PID_KEYWORDS`, `PID_COMMENTS`, `PID_TEMPLATE`, `PID_LASTAUTHOR`, `PID_REVNUMBER`, `PID_LASTPRINTED`, `PID_CREATE_DTM`, `PID_LASTSAVE_DTM`, `PID_PAGECOUNT`, `PID_WORDCOUNT`, `PID_CHARCOUNT`, `PID_APPNAME`, OR `PID_SECURITY`.

`SummaryInformation.GetPropertyCount()`

Return the number of summary properties, through `MsiSummaryInfoGetPropertyCount()`.

`SummaryInformation.SetProperty(field, value)`

Set a property through `MsiSummaryInfoSetProperty()`. *field* can have the same values as in `GetProperty()`, *value* is the new value of the property. Possible value types are integer and string.

`SummaryInformation.Persist()`

Write the modified properties to the summary information stream, using `MsiSummaryInfoPersist()`.

See also: [MsiSummaryInfoGetProperty](#)
[MsiSummaryInfoGetPropertyCount](#) [MsiSummaryInfoSetProperty](#)
[MsiSummaryInfoPersist](#)

32.1.4. Record Objects

Record. **GetFieldCount()**

Return the number of fields of the record, through `MsiRecordGetFieldCount()`.

Record. **GetInteger(*field*)**

Return the value of *field* as an integer where possible. *field* must be an integer.

Record. **GetString(*field*)**

Return the value of *field* as a string where possible. *field* must be an integer.

Record. **SetString(*field*, *value*)**

Set *field* to *value* through `MsiRecordSetString()`. *field* must be an integer; *value* a string.

Record. **SetStream(*field*, *value*)**

Set *field* to the contents of the file named *value*, through `MsiRecordSetStream()`. *field* must be an integer; *value* a string.

Record. **SetInteger(*field*, *value*)**

Set *field* to *value* through `MsiRecordSetInteger()`. Both *field* and *value* must be an integer.

Record. **ClearData()**

Set all fields of the record to 0, through `MsiRecordClearData()`.

See also: [MsiRecordGetFieldCount](#) [MsiRecordSetString](#)
[MsiRecordSetStream](#) [MsiRecordSetInteger](#) [MsiRecordClear](#)

32.1.5. Errors

All wrappers around MSI functions raise `MsiError`; the string inside the exception will contain more detail.

32.1.6. CAB Objects

`class msilib.CAB(name)`

The class `CAB` represents a CAB file. During MSI construction, files will be added simultaneously to the `Files` table, and to a CAB file. Then, when all files have been added, the CAB file can be written, then added to the MSI file.

name is the name of the CAB file in the MSI file.

`append(full, file, logical)`

Add the file with the pathname *full* to the CAB file, under the name *logical*. If there is already a file named *logical*, a new file name is created.

Return the index of the file in the CAB file, and the new name of the file inside the CAB file.

`commit(database)`

Generate a CAB file, add it as a stream to the MSI file, put it into the `Media` table, and remove the generated file from the disk.

32.1.7. Directory Objects

```
class msilib.Directory(database, cab, basedir, physical, logical,  
default[, componentflags])
```

Create a new directory in the Directory table. There is a current component at each point in time for the directory, which is either explicitly created through `start_component()`, or implicitly when files are added for the first time. Files are added into the current component, and into the cab file. To create a directory, a base directory object needs to be specified (can be `None`), the path to the physical directory, and a logical directory name. `default` specifies the DefaultDir slot in the directory table. `componentflags` specifies the default flags that new components get.

```
start_component(component=None, feature=None,  
flags=None, keyfile=None, uuid=None)
```

Add an entry to the Component table, and make this component the current component for this directory. If no component name is given, the directory name is used. If no `feature` is given, the current feature is used. If no `flags` are given, the directory's default flags are used. If no `keyfile` is given, the KeyPath is left null in the Component table.

```
add_file(file, src=None, version=None, language=None)
```

Add a file to the current component of the directory, starting a new one if there is no current component. By default, the file name in the source and the file table will be identical. If the `src` file is specified, it is interpreted relative to the current directory. Optionally, a `version` and a `language` can be specified for the entry in the File table.

```
glob(pattern, exclude=None)
```

Add a list of files to the current component as specified in the glob pattern. Individual files can be excluded in the *exclude* list.

remove_pyc()

Remove `.pyc/.pyo` files on uninstall.

See also: [Directory Table](#) [File Table](#) [Component Table](#)
[FeatureComponents Table](#)

32.1.8. Features

```
class msilib.Feature(db, id, title, desc, display, level=1,  
parent=None, directory=None, attributes=0)
```

Add a new record to the `Feature` table, using the values `id`, `parent.id`, `title`, `desc`, `display`, `level`, `directory`, and `attributes`. The resulting feature object can be passed to the `start_component()` method of `Directory`.

```
set_current()
```

Make this feature the current feature of `msilib`. New components are automatically added to the default feature, unless a feature is explicitly specified.

See also: [Feature Table](#)

32.1.9. GUI classes

`msilib` provides several classes that wrap the GUI tables in an MSI database. However, no standard user interface is provided; use `bdist_msi` to create MSI files with a user-interface for installing Python packages.

`class msilib.Control(dlg, name)`

Base class of the dialog controls. *dlg* is the dialog object the control belongs to, and *name* is the control's name.

`event(event, argument, condition=1, ordering=None)`

Make an entry into the `controlEvent` table for this control.

`mapping(event, attribute)`

Make an entry into the `EventMapping` table for this control.

`condition(action, condition)`

Make an entry into the `controlCondition` table for this control.

`class msilib.RadioButtonGroup(dlg, name, property)`

Create a radio button control named *name*. *property* is the installer property that gets set when a radio button is selected.

`add(name, x, y, width, height, text, value=None)`

Add a radio button named *name* to the group, at the coordinates *x*, *y*, *width*, *height*, and with the label *text*. If *value* is `None`, it defaults to *name*.

`class msilib.Dialog(db, name, x, y, w, h, attr, title, first, default, cancel)`

Return a new `Dialog` object. An entry in the `Dialog` table is made, with the specified coordinates, dialog attributes, title, name of the

first, default, and cancel controls.

control(*name, type, x, y, width, height, attributes, property, text, control_next, help*)

Return a new **control** object. An entry in the `control` table is made with the specified parameters.

This is a generic method; for specific types, specialized methods are provided.

text(*name, x, y, width, height, attributes, text*)

Add and return a `Text` control.

bitmap(*name, x, y, width, height, text*)

Add and return a `Bitmap` control.

line(*name, x, y, width, height*)

Add and return a `Line` control.

pushbutton(*name, x, y, width, height, attributes, text, next_control*)

Add and return a `PushButton` control.

radiogroup(*name, x, y, width, height, attributes, property, text, next_control*)

Add and return a `RadioButtonGroup` control.

checkbox(*name, x, y, width, height, attributes, property, text, next_control*)

Add and return a `CheckBox` control.

See also: [Dialog Table Control Table Control Types](#)
[ControlCondition Table ControlEvent Table EventMapping Table](#)
[RadioButton Table](#)

32.1.10. Precomputed tables

`msilib` provides a few subpackages that contain only schema and table definitions. Currently, these definitions are based on MSI version 2.0.

`msilib.schema`

This is the standard MSI schema for MSI 2.0, with the *tables* variable providing a list of table definitions, and *_Validation_records* providing the data for MSI validation.

`msilib.sequence`

This module contains table contents for the standard sequence tables: *AdminExecuteSequence*, *AdminUISequence*, *AdvtExecuteSequence*, *InstallExecuteSequence*, and *InstallUISequence*.

`msilib.text`

This module contains definitions for the *UIText* and *ActionText* tables, for the standard installer actions.

32.2. `msvcrt` – Useful routines from the MS VC++ runtime

Platforms: Windows

These functions provide access to some useful capabilities on Windows platforms. Some higher-level modules use these functions to build the Windows implementations of their services. For example, the `getpass` module uses this in the implementation of the `getpass()` function.

Further documentation on these functions can be found in the Platform API documentation.

The module implements both the normal and wide char variants of the console I/O api. The normal API deals only with ASCII characters and is of limited use for internationalized applications. The wide char API should be used where ever possible

32.2.1. File Operations

`msvcrt.locking(fd, mode, nbytes)`

Lock part of a file based on file descriptor *fd* from the C runtime. Raises `IOError` on failure. The locked region of the file extends from the current file position for *nbytes* bytes, and may continue beyond the end of the file. *mode* must be one of the `LK_*` constants listed below. Multiple regions in a file may be locked at the same time, but may not overlap. Adjacent regions are not merged; they must be unlocked individually.

`msvcrt.LK_LOCK`

`msvcrt.LK_RLCK`

Locks the specified bytes. If the bytes cannot be locked, the program immediately tries again after 1 second. If, after 10 attempts, the bytes cannot be locked, `IOError` is raised.

`msvcrt.LK_NBLCK`

`msvcrt.LK_NBRLCK`

Locks the specified bytes. If the bytes cannot be locked, `IOError` is raised.

`msvcrt.LK_UNLCK`

Unlocks the specified bytes, which must have been previously locked.

`msvcrt.setmode(fd, flags)`

Set the line-end translation mode for the file descriptor *fd*. To set it to text mode, *flags* should be `os.O_TEXT`; for binary, it should be `os.O_BINARY`.

`msvcrt.open_osfhandle(handle, flags)`

Create a C runtime file descriptor from the file handle *handle*. The

flags parameter should be a bitwise OR of `os.O_APPEND`, `os.O_RDONLY`, and `os.O_TEXT`. The returned file descriptor may be used as a parameter to `os.fdopen()` to create a file object.

`msvcrt.get_osfhandle(fd)`

Return the file handle for the file descriptor *fd*. Raises `IOError` if *fd* is not recognized.

32.2.2. Console I/O

`msvcrt.kbhit()`

Return true if a keypress is waiting to be read.

`msvcrt.getch()`

Read a keypress and return the resulting character as a byte string. Nothing is echoed to the console. This call will block if a keypress is not already available, but will not wait for `Enter` to be pressed. If the pressed key was a special function key, this will return `'\000'` or `'\xe0'`; the next call will return the keycode. The `Control-C` keypress cannot be read with this function.

`msvcrt.getwch()`

Wide char variant of `getch()`, returning a Unicode value.

`msvcrt.getche()`

Similar to `getch()`, but the keypress will be echoed if it represents a printable character.

`msvcrt.getwche()`

Wide char variant of `getche()`, returning a Unicode value.

`msvcrt.putch(char)`

Print the byte string `char` to the console without buffering.

`msvcrt.putwch(unicode_char)`

Wide char variant of `putch()`, accepting a Unicode value.

`msvcrt.ungetch(char)`

Cause the byte string `char` to be “pushed back” into the console buffer; it will be the next character read by `getch()` or `getche()`.

msvcrt. **ungetwch**(*unicode_char*)

Wide char variant of **ungetch()**, accepting a Unicode value.

32.2.3. Other Functions

`msvcrt.heapmin()`

Force the `malloc()` heap to clean itself up and return unused blocks to the operating system. On failure, this raises `IOError`.

32.3. winreg – Windows registry access

Platforms: Windows

These functions expose the Windows registry API to Python. Instead of using an integer as the registry handle, a *handle object* is used to ensure that the handles are closed correctly, even if the programmer neglects to explicitly close them.

This module offers the following functions:

`winreg.CloseKey(hkey)`

Closes a previously opened registry key. The *hkey* argument specifies a previously opened key.

Note: If *hkey* is not closed using this method (or via `hkey.Close()`), it is closed when the *hkey* object is destroyed by Python.

`winreg.ConnectRegistry(computer_name, key)`

Establishes a connection to a predefined registry handle on another computer, and returns a *handle object*.

computer_name is the name of the remote computer, of the form `r"\\computername"`. If **None**, the local computer is used.

key is the predefined handle to connect to.

The return value is the handle of the opened key. If the function fails, a **WindowsError** exception is raised.

`winreg.CreateKey(key, sub_key)`

Creates or opens the specified key, returning a *handle object*.

key is an already open key, or one of the predefined *HKEY_* constants*.

sub_key is a string that names the key this method opens or creates.

If *key* is one of the predefined keys, *sub_key* may be `None`. In that case, the handle returned is the same key handle passed in to the function.

If the key already exists, this function opens the existing key.

The return value is the handle of the opened key. If the function fails, a `WindowsError` exception is raised.

```
winreg.CreateKeyEx(key, sub_key, reserved=0,  
access=KEY_ALL_ACCESS)
```

Creates or opens the specified key, returning a *handle object*.

key is an already open key, or one of the predefined *HKEY_* constants*.

sub_key is a string that names the key this method opens or creates.

res is a reserved integer, and must be zero. The default is zero.

sam is an integer that specifies an access mask that describes the desired security access for the key. Default is `KEY_ALL_ACCESS`. See *Access Rights* for other allowed values.

If *key* is one of the predefined keys, *sub_key* may be `None`. In that case, the handle returned is the same key handle passed in to the function.

If the key already exists, this function opens the existing key.

The return value is the handle of the opened key. If the function fails, a `WindowsError` exception is raised.

New in version 3.2.

`winreg.DeleteKey(key, sub_key)`

Deletes the specified key.

`key` is an already open key, or one of the predefined `HKEY_* constants`.

`sub_key` is a string that must be a subkey of the key identified by the `key` parameter. This value must not be `None`, and the key may not have subkeys.

This method can not delete keys with subkeys.

If the method succeeds, the entire key, including all of its values, is removed. If the method fails, a `WindowsError` exception is raised.

`winreg.DeleteKeyEx(key, sub_key, access=KEY_ALL_ACCESS, reserved=0)`

Deletes the specified key.

Note: The `DeleteKeyEx()` function is implemented with the `RegDeleteKeyEx` Windows API function, which is specific to 64-bit versions of Windows. See the [RegDeleteKeyEx documentation](#).

`key` is an already open key, or one of the predefined `HKEY_* constants`.

`sub_key` is a string that must be a subkey of the key identified by

the *key* parameter. This value must not be `None`, and the key may not have subkeys.

res is a reserved integer, and must be zero. The default is zero.

sam is an integer that specifies an access mask that describes the desired security access for the key. Default is `KEY_ALL_ACCESS`. See [Access Rights](#) for other allowed values.

This method can not delete keys with subkeys.

If the method succeeds, the entire key, including all of its values, is removed. If the method fails, a `WindowsError` exception is raised.

On unsupported Windows versions, `NotImplementedError` is raised.

New in version 3.2.

`winreg.DeleteValue(key, value)`

Removes a named value from a registry key.

key is an already open key, or one of the predefined [HKEY_* constants](#).

value is a string that identifies the value to remove.

`winreg.EnumKey(key, index)`

Enumerates subkeys of an open registry key, returning a string.

key is an already open key, or one of the predefined [HKEY_* constants](#).

index is an integer that identifies the index of the key to retrieve.

The function retrieves the name of one subkey each time it is called. It is typically called repeatedly until a `WindowsError` exception is raised, indicating, no more values are available.

`winreg.EnumValue(key, index)`

Enumerates values of an open registry key, returning a tuple.

key is an already open key, or one of the predefined `HKEY_* constants`.

index is an integer that identifies the index of the value to retrieve.

The function retrieves the name of one subkey each time it is called. It is typically called repeatedly, until a `WindowsError` exception is raised, indicating no more values.

The result is a tuple of 3 items:

Index	Meaning
0	A string that identifies the value name
1	An object that holds the value data, and whose type depends on the underlying registry type
2	An integer that identifies the type of the value data (see table in docs for <code>SetValueEx()</code>)

`winreg.ExpandEnvironmentStrings(str)`

Expands environment variable placeholders `%NAME%` in strings like `REG_EXPAND_SZ`:

```
>>> ExpandEnvironmentStrings('%windir%')
'C:\\Windows'
```

`winreg.FlushKey(key)`

Writes all the attributes of a key to the registry.

key is an already open key, or one of the predefined *HKEY_* constants*.

It is not necessary to call **FlushKey()** to change a key. Registry changes are flushed to disk by the registry using its lazy flusher. Registry changes are also flushed to disk at system shutdown. Unlike **CloseKey()**, the **FlushKey()** method returns only when all the data has been written to the registry. An application should only call **FlushKey()** if it requires absolute certainty that registry changes are on disk.

Note: If you don't know whether a **FlushKey()** call is required, it probably isn't.

winreg. **LoadKey**(*key*, *sub_key*, *file_name*)

Creates a subkey under the specified key and stores registration information from a specified file into that subkey.

key is a handle returned by **ConnectRegistry()** or one of the constants **HKEY_USERS** or **HKEY_LOCAL_MACHINE**.

sub_key is a string that identifies the subkey to load.

file_name is the name of the file to load registry data from. This file must have been created with the **SaveKey()** function. Under the file allocation table (FAT) file system, the filename may not have an extension.

A call to **LoadKey()** fails if the calling process does not have the **SE_RESTORE_PRIVILEGE** privilege. Note that privileges are different from permissions – see the [RegLoadKey documentation](#) for more details.

If *key* is a handle returned by **ConnectRegistry()**, then the path

specified in *file_name* is relative to the remote computer.

winreg. **OpenKey**(*key*, *sub_key*, *reserved*=0,
access=KEY_ALL_ACCESS)

Opens the specified key, returning a *handle object*.

key is an already open key, or one of the predefined *HKEY_* constants*.

sub_key is a string that identifies the *sub_key* to open.

res is a reserved integer, and must be zero. The default is zero.

sam is an integer that specifies an access mask that describes the desired security access for the key. Default is **KEY_READ**. See *Access Rights* for other allowed values.

The result is a new handle to the specified key.

If the function fails, **WindowsError** is raised.

Changed in version 3.2: Allow the use of named arguments.

winreg. **OpenKeyEx**()

The functionality of **OpenKeyEx()** is provided via **OpenKey()**, by the use of default arguments.

winreg. **QueryInfoKey**(*key*)

Returns information about a key, as a tuple.

key is an already open key, or one of the predefined *HKEY_* constants*.

The result is a tuple of 3 items:

Index	Meaning

0	An integer giving the number of sub keys this key has.
1	An integer giving the number of values this key has.
2	An integer giving when the key was last modified (if available) as 100's of nanoseconds since Jan 1, 1600.

winreg. **QueryValue**(key, sub_key)

Retrieves the unnamed value for a key, as a string.

key is an already open key, or one of the predefined *HKEY_* constants*.

sub_key is a string that holds the name of the subkey with which the value is associated. If this parameter is **None** or empty, the function retrieves the value set by the **SetValue()** method for the key identified by *key*.

Values in the registry have name, type, and data components. This method retrieves the data for a key's first value that has a NULL name. But the underlying API call doesn't return the type, so always use **QueryValueEx()** if possible.

winreg. **QueryValueEx**(key, value_name)

Retrieves the type and data for a specified value name associated with an open registry key.

key is an already open key, or one of the predefined *HKEY_* constants*.

value_name is a string indicating the value to query.

The result is a tuple of 2 items:

Index	Meaning
0	The value of the registry item.
1	An integer giving the registry type for this value (see

table in docs for [SetValueEx\(\)](#)

`winreg.SaveKey(key, file_name)`

Saves the specified key, and all its subkeys to the specified file.

key is an already open key, or one of the predefined [HKEY_* constants](#).

file_name is the name of the file to save registry data to. This file cannot already exist. If this filename includes an extension, it cannot be used on file allocation table (FAT) file systems by the [LoadKey\(\)](#) method.

If *key* represents a key on a remote computer, the path described by *file_name* is relative to the remote computer. The caller of this method must possess the `SeBackupPrivilege` security privilege. Note that privileges are different than permissions – see the [Conflicts Between User Rights and Permissions](#) documentation for more details.

This function passes NULL for *security_attributes* to the API.

`winreg.SetValue(key, sub_key, type, value)`

Associates a value with a specified key.

key is an already open key, or one of the predefined [HKEY_* constants](#).

sub_key is a string that names the subkey with which the value is associated.

type is an integer that specifies the type of the data. Currently this must be `REG_SZ`, meaning only strings are supported. Use the [SetValueEx\(\)](#) function for support for other data types.

value is a string that specifies the new value.

If the key specified by the *sub_key* parameter does not exist, the SetValue function creates it.

Value lengths are limited by available memory. Long values (more than 2048 bytes) should be stored as files with the filenames stored in the configuration registry. This helps the registry perform efficiently.

The key identified by the *key* parameter must have been opened with **KEY_SET_VALUE** access.

`winreg.SetValueEx(key, value_name, reserved, type, value)`

Stores data in the value field of an open registry key.

key is an already open key, or one of the predefined *HKEY_* constants*.

value_name is a string that names the subkey with which the value is associated.

type is an integer that specifies the type of the data. See *Value Types* for the available types.

reserved can be anything – zero is always passed to the API.

value is a string that specifies the new value.

This method can also set additional value and type information for the specified key. The key identified by the key parameter must have been opened with **KEY_SET_VALUE** access.

To open the key, use the **CreateKey()** or **OpenKey()** methods.

Value lengths are limited by available memory. Long values (more than 2048 bytes) should be stored as files with the filenames stored in the configuration registry. This helps the

registry perform efficiently.

winreg. **DisableReflectionKey**(*key*)

Disables registry reflection for 32-bit processes running on a 64-bit operating system.

key is an already open key, or one of the predefined *HKEY_* constants*.

Will generally raise **NotImplemented** if executed on a 32-bit operating system.

If the key is not on the reflection list, the function succeeds but has no effect. Disabling reflection for a key does not affect reflection of any subkeys.

winreg. **EnableReflectionKey**(*key*)

Restores registry reflection for the specified disabled key.

key is an already open key, or one of the predefined *HKEY_* constants*.

Will generally raise **NotImplemented** if executed on a 32-bit operating system.

Restoring reflection for a key does not affect reflection of any subkeys.

winreg. **QueryReflectionKey**(*key*)

Determines the reflection state for the specified key.

key is an already open key, or one of the predefined *HKEY_* constants*.

Returns **True** if reflection is disabled.

Will generally raise `NotImplemented` if executed on a 32-bit operating system.

32.3.1. Constants

The following constants are defined for use in many `_winreg` functions.

32.3.1.1. HKEY_* Constants

`winreg.HKEY_CLASSES_ROOT`

Registry entries subordinate to this key define types (or classes) of documents and the properties associated with those types. Shell and COM applications use the information stored under this key.

`winreg.HKEY_CURRENT_USER`

Registry entries subordinate to this key define the preferences of the current user. These preferences include the settings of environment variables, data about program groups, colors, printers, network connections, and application preferences.

`winreg.HKEY_LOCAL_MACHINE`

Registry entries subordinate to this key define the physical state of the computer, including data about the bus type, system memory, and installed hardware and software.

`winreg.HKEY_USERS`

Registry entries subordinate to this key define the default user configuration for new users on the local computer and the user configuration for the current user.

`winreg.HKEY_PERFORMANCE_DATA`

Registry entries subordinate to this key allow you to access performance data. The data is not actually stored in the registry; the registry functions cause the system to collect the data from its source.

winreg. **HKEY_CURRENT_CONFIG**

Contains information about the current hardware profile of the local computer system.

winreg. **HKEY_DYN_DATA**

This key is not used in versions of Windows after 98.

32.3.1.2. Access Rights

For more information, see [Registry Key Security and Access](#).

winreg. **KEY_ALL_ACCESS**

Combines the **STANDARD_RIGHTS_REQUIRED**, **KEY_QUERY_VALUE**, **KEY_SET_VALUE**, **KEY_CREATE_SUB_KEY**, **KEY_ENUMERATE_SUB_KEYS**, **KEY_NOTIFY**, and **KEY_CREATE_LINK** access rights.

winreg. **KEY_WRITE**

Combines the **STANDARD_RIGHTS_WRITE**, **KEY_SET_VALUE**, and **KEY_CREATE_SUB_KEY** access rights.

winreg. **KEY_READ**

Combines the **STANDARD_RIGHTS_READ**, **KEY_QUERY_VALUE**, **KEY_ENUMERATE_SUB_KEYS**, and **KEY_NOTIFY** values.

winreg. **KEY_EXECUTE**

Equivalent to **KEY_READ**.

winreg. **KEY_QUERY_VALUE**

Required to query the values of a registry key.

winreg. **KEY_SET_VALUE**

Required to create, delete, or set a registry value.

winreg. **KEY_CREATE_SUB_KEY**

Required to create a subkey of a registry key.

winreg. **KEY_ENUMERATE_SUB_KEYS**

Required to enumerate the subkeys of a registry key.

winreg. **KEY_NOTIFY**

Required to request change notifications for a registry key or for subkeys of a registry key.

winreg. **KEY_CREATE_LINK**

Reserved for system use.

32.3.1.2.1. 64-bit Specific

For more information, see [Accessing an Alternate Registry View](#).

winreg. **KEY_WOW64_64KEY**

Indicates that an application on 64-bit Windows should operate on the 64-bit registry view.

winreg. **KEY_WOW64_32KEY**

Indicates that an application on 64-bit Windows should operate on the 32-bit registry view.

32.3.1.3. Value Types

For more information, see [Registry Value Types](#).

winreg. **REG_BINARY**

Binary data in any form.

winreg. **REG_DWORD**

32-bit number.

winreg. **REG_DWORD_LITTLE_ENDIAN**

A 32-bit number in little-endian format.

winreg. **REG_DWORD_BIG_ENDIAN**

A 32-bit number in big-endian format.

winreg.**REG_EXPAND_SZ**

Null-terminated string containing references to environment variables (%PATH%).

winreg.**REG_LINK**

A Unicode symbolic link.

winreg.**REG_MULTI_SZ**

A sequence of null-terminated strings, terminated by two null characters. (Python handles this termination automatically.)

winreg.**REG_NONE**

No defined value type.

winreg.**REG_RESOURCE_LIST**

A device-driver resource list.

winreg.**REG_FULL_RESOURCE_DESCRIPTOR**

A hardware setting.

winreg.**REG_RESOURCE_REQUIREMENTS_LIST**

A hardware resource list.

winreg.**REG_SZ**

A null-terminated string.

32.3.2. Registry Handle Objects

This object wraps a Windows HKEY object, automatically closing it when the object is destroyed. To guarantee cleanup, you can call either the `close()` method on the object, or the `closeKey()` function.

All registry functions in this module return one of these objects.

All registry functions in this module which accept a handle object also accept an integer, however, use of the handle object is encouraged.

Handle objects provide semantics for `__bool__()` – thus

```
if handle:  
    print("Yes")
```

will print `Yes` if the handle is currently valid (has not been closed or detached).

The object also support comparison semantics, so handle objects will compare true if they both reference the same underlying Windows handle value.

Handle objects can be converted to an integer (e.g., using the built-in `int()` function), in which case the underlying Windows handle value is returned. You can also use the `Detach()` method to return the integer handle, and also disconnect the Windows handle from the handle object.

`PyHKEY.close()`

Closes the underlying Windows handle.

If the handle is already closed, no error is raised.

PyHKEY. **Detach()**

Detaches the Windows handle from the handle object.

The result is an integer that holds the value of the handle before it is detached. If the handle is already detached or closed, this will return zero.

After calling this function, the handle is effectively invalidated, but the handle is not closed. You would call this function when you need the underlying Win32 handle to exist beyond the lifetime of the handle object.

PyHKEY. **__enter__()**

PyHKEY. **__exit__(*exc_info)**

The HKEY object implements `__enter__()` and `__exit__()` and thus supports the context protocol for the `with` statement:

```
with OpenKey(HKEY_LOCAL_MACHINE, "foo") as key:  
    ... # work with key
```

will automatically close `key` when control leaves the `with` block.

32.4. winsound — Sound-playing interface for Windows

Platforms: Windows

The `winsound` module provides access to the basic sound-playing machinery provided by Windows platforms. It includes functions and several constants.

`winsound.Beep(frequency, duration)`

Beep the PC's speaker. The *frequency* parameter specifies frequency, in hertz, of the sound, and must be in the range 37 through 32,767. The *duration* parameter specifies the number of milliseconds the sound should last. If the system is not able to beep the speaker, `RuntimeError` is raised.

`winsound.PlaySound(sound, flags)`

Call the underlying `PlaySound()` function from the Platform API. The *sound* parameter may be a filename, audio data as a string, or `None`. Its interpretation depends on the value of *flags*, which can be a bitwise ORed combination of the constants described below. If the *sound* parameter is `None`, any currently playing waveform sound is stopped. If the system indicates an error, `RuntimeError` is raised.

`winsound.MessageBeep(type=MB_OK)`

Call the underlying `MessageBeep()` function from the Platform API. This plays a sound as specified in the registry. The *type* argument specifies which sound to play; possible values are `-1`, `MB_ICONASTERISK`, `MB_ICONEXCLAMATION`, `MB_ICONHAND`, `MB_ICONQUESTION`, and `MB_OK`, all described below. The value `-1` produces a “simple beep”; this is the final fallback if a sound

cannot be played otherwise.

winsound.SND_FILENAME

The *sound* parameter is the name of a WAV file. Do not use with **SND_ALIAS**.

winsound.SND_ALIAS

The *sound* parameter is a sound association name from the registry. If the registry contains no such name, play the system default sound unless **SND_NODEFAULT** is also specified. If no default sound is registered, raise **RuntimeError**. Do not use with **SND_FILENAME**.

All Win32 systems support at least the following; most systems support many more:

PlaySound() name	Corresponding Control Panel Sound name
'SystemAsterisk'	Asterisk
'SystemExclamation'	Exclamation
'SystemExit'	Exit Windows
'SystemHand'	Critical Stop
'SystemQuestion'	Question

For example:

```
import winsound
# Play Windows exit sound.
winsound.PlaySound("SystemExit", winsound.SND_ALIAS)

# Probably play Windows default sound, if any is registered
# "*" probably isn't the registered name of any sound).
winsound.PlaySound("*", winsound.SND_ALIAS)
```

winsound.SND_LOOP

Play the sound repeatedly. The **SND_ASYNC** flag must also be used

to avoid blocking. Cannot be used with `SND_MEMORY`.

`winsound.SND_MEMORY`

The *sound* parameter to `PlaySound()` is a memory image of a WAV file, as a string.

Note: This module does not support playing from a memory image asynchronously, so a combination of this flag and `SND_ASYNC` will raise `RuntimeError`.

`winsound.SND_PURGE`

Stop playing all instances of the specified sound.

Note: This flag is not supported on modern Windows platforms.

`winsound.SND_ASYNC`

Return immediately, allowing sounds to play asynchronously.

`winsound.SND_NODEFAULT`

If the specified sound cannot be found, do not play the system default sound.

`winsound.SND_NOSTOP`

Do not interrupt sounds currently playing.

`winsound.SND_NOWAIT`

Return immediately if the sound driver is busy.

`winsound.MB_ICONASTERISK`

Play the `SystemDefault` sound.

`winsound.MB_ICONEXCLAMATION`

Play the `SystemExclamation` sound.

`winsound.MB_ICONHAND`

Play the `systemHand` sound.

`winsound.MB_ICONQUESTION`

Play the `systemQuestion` sound.

`winsound.MB_OK`

Play the `systemDefault` sound.

33. Unix Specific Services

The modules described in this chapter provide interfaces to features that are unique to the Unix operating system, or in some cases to some or many variants of it. Here's an overview:

- 33.1. `posix` — The most common POSIX system calls
 - 33.1.1. Large File Support
 - 33.1.2. Notable Module Contents
- 33.2. `pwd` — The password database
- 33.3. `spwd` — The shadow password database
- 33.4. `grp` — The group database
- 33.5. `crypt` — Function to check Unix passwords
- 33.6. `termios` — POSIX style tty control
 - 33.6.1. Example
- 33.7. `tty` — Terminal control functions
- 33.8. `pty` — Pseudo-terminal utilities
 - 33.8.1. Example
- 33.9. `fcntl` — The `fcntl()` and `ioctl()` system calls
- 33.10. `pipes` — Interface to shell pipelines
 - 33.10.1. Template Objects
- 33.11. `resource` — Resource usage information
 - 33.11.1. Resource Limits
 - 33.11.2. Resource Usage
- 33.12. `nis` — Interface to Sun's NIS (Yellow Pages)
- 33.13. `syslog` — Unix syslog library routines
 - 33.13.1. Examples
 - 33.13.1.1. Simple example

33.1. `posix` — The most common POSIX system calls

Platforms: Unix

This module provides access to operating system functionality that is standardized by the C Standard and the POSIX standard (a thinly disguised Unix interface).

Do not import this module directly. Instead, import the module `os`, which provides a *portable* version of this interface. On Unix, the `os` module provides a superset of the `posix` interface. On non-Unix operating systems the `posix` module is not available, but a subset is always available through the `os` interface. Once `os` is imported, there is *no* performance penalty in using it instead of `posix`. In addition, `os` provides some additional functionality, such as automatically calling `putenv()` when an entry in `os.environ` is changed.

Errors are reported as exceptions; the usual exceptions are given for type errors, while errors reported by the system calls raise `OSError`.

33.1.1. Large File Support

Several operating systems (including AIX, HP-UX, Irix and Solaris) provide support for files that are larger than 2 GB from a C programming model where `int` and `long` are 32-bit values. This is typically accomplished by defining the relevant size and offset types as 64-bit values. Such files are sometimes referred to as *large files*.

Large file support is enabled in Python when the size of an `off_t` is larger than a `long` and the `long long` type is available and is at least as large as an `off_t`. It may be necessary to configure and compile Python with certain compiler flags to enable this mode. For example, it is enabled by default with recent versions of Irix, but with Solaris 2.6 and 2.7 you need to do something like:

```
CFLAGS="`getconf LFS_CFLAGS`" OPT="-g -O2 $CFLAGS" \  
./configure
```

On large-file-capable Linux systems, this might work:

```
CFLAGS='-D_LARGEFILE64_SOURCE -D_FILE_OFFSET_BITS=64' OPT="-g -  
./configure
```

33.1.2. Notable Module Contents

In addition to many functions described in the `os` module documentation, `posix` defines the following data item:

`posix.environ`

A dictionary representing the string environment at the time the interpreter was started. Keys and values are bytes on Unix and `str` on Windows. For example, `environ[b'HOME']` (`environ['HOME']` on Windows) is the pathname of your home directory, equivalent to `getenv("HOME")` in C.

Modifying this dictionary does not affect the string environment passed on by `execv()`, `popen()` or `system()`; if you need to change the environment, pass `environ` to `execve()` or add variable assignments and export statements to the command string for `system()` or `popen()`.

Changed in version 3.2: On Unix, keys and values are bytes.

Note: The `os` module provides an alternate implementation of `environ` which updates the environment on modification. Note also that updating `os.environ` will render this dictionary obsolete. Use of the `os` module version of this is recommended over direct access to the `posix` module.

33.2. `pwd` — The password database

Platforms: Unix

This module provides access to the Unix user account and password database. It is available on all Unix versions.

Password database entries are reported as a tuple-like object, whose attributes correspond to the members of the `passwd` structure (Attribute field below, see `<pwd.h>`):

Index	Attribute	Meaning
0	<code>pw_name</code>	Login name
1	<code>pw_passwd</code>	Optional encrypted password
2	<code>pw_uid</code>	Numerical user ID
3	<code>pw_gid</code>	Numerical group ID
4	<code>pw_gecos</code>	User name or comment field
5	<code>pw_dir</code>	User home directory
6	<code>pw_shell</code>	User command interpreter

The `uid` and `gid` items are integers, all others are strings. `KeyError` is raised if the entry asked for cannot be found.

Note: In traditional Unix the field `pw_passwd` usually contains a password encrypted with a DES derived algorithm (see module `crypt`). However most modern unices use a so-called *shadow password* system. On those unices the `pw_passwd` field only contains an asterisk (`'*'`) or the letter `'x'` where the encrypted password is stored in a file `/etc/shadow` which is not world readable. Whether the `pw_passwd` field contains anything useful is

system-dependent. If available, the `spwd` module should be used where access to the encrypted password is required.

It defines the following items:

`pwd.getpwnid(uid)`

Return the password database entry for the given numeric user ID.

`pwd.getpwnam(name)`

Return the password database entry for the given user name.

`pwd.getpwall()`

Return a list of all available password database entries, in arbitrary order.

See also:

Module `grp`

An interface to the group database, similar to this.

Module `spwd`

An interface to the shadow password database, similar to this.

33.3. `spwd` — The shadow password database

Platforms: Unix

This module provides access to the Unix shadow password database. It is available on various Unix versions.

You must have enough privileges to access the shadow password database (this usually means you have to be root).

Shadow password database entries are reported as a tuple-like object, whose attributes correspond to the members of the `spwd` structure (Attribute field below, see `<shadow.h>`):

Index	Attribute	Meaning
0	<code>sp_nam</code>	Login name
1	<code>sp_pwd</code>	Encrypted password
2	<code>sp_lstchg</code>	Date of last change
3	<code>sp_min</code>	Minimal number of days between changes
4	<code>sp_max</code>	Maximum number of days between changes
5	<code>sp_warn</code>	Number of days before password expires to warn user about it
6	<code>sp_inact</code>	Number of days after password expires until account is blocked
7	<code>sp_expire</code>	Number of days since 1970-01-01 until account is disabled
8	<code>sp_flag</code>	Reserved

The `sp_nam` and `sp_pwd` items are strings, all others are integers. **KeyError** is raised if the entry asked for cannot be found.

The following functions are defined:

`spwd.getspnam(name)`

Return the shadow password database entry for the given user name.

`spwd.getspall()`

Return a list of all available shadow password database entries, in arbitrary order.

See also:

Module `grp`

An interface to the group database, similar to this.

Module `pwd`

An interface to the normal password database, similar to this.

33.4. grp — The group database

Platforms: Unix

This module provides access to the Unix group database. It is available on all Unix versions.

Group database entries are reported as a tuple-like object, whose attributes correspond to the members of the `group` structure (Attribute field below, see `<pwd.h>`):

Index	Attribute	Meaning
0	<code>gr_name</code>	the name of the group
1	<code>gr_passwd</code>	the (encrypted) group password; often empty
2	<code>gr_gid</code>	the numerical group ID
3	<code>gr_mem</code>	all the group member's user names

The `gid` is an integer, name and password are strings, and the member list is a list of strings. (Note that most users are not explicitly listed as members of the group they are in according to the password database. Check both databases to get complete membership information. Also note that a `gr_name` that starts with a `+` or `-` is likely to be a YP/NIS reference and may not be accessible via `getgrnam()` or `getgrgid()`.)

It defines the following items:

`grp.getgrgid(gid)`

Return the group database entry for the given numeric group ID. `KeyError` is raised if the entry asked for cannot be found.

`grp.getgrnam(name)`

Return the group database entry for the given group name.

`KeyError` is raised if the entry asked for cannot be found.

`grp.getgrall()`

Return a list of all available group entries, in arbitrary order.

See also:

Module `pwd`

An interface to the user database, similar to this.

Module `spwd`

An interface to the shadow password database, similar to this.

33.5. `crypt` — Function to check Unix passwords

Platforms: Unix

This module implements an interface to the `crypt(3)` routine, which is a one-way hash function based upon a modified DES algorithm; see the Unix man page for further details. Possible uses include allowing Python scripts to accept typed passwords from the user, or attempting to crack Unix passwords with a dictionary.

Notice that the behavior of this module depends on the actual implementation of the `crypt(3)` routine in the running system. Therefore, any extensions available on the current implementation will also be available on this module.

`crypt.crypt(word, salt)`

`word` will usually be a user's password as typed at a prompt or in a graphical interface. `salt` is usually a random two-character string which will be used to perturb the DES algorithm in one of 4096 ways. The characters in `salt` must be in the set `[./a-zA-Z0-9]`. Returns the hashed password as a string, which will be composed of characters from the same alphabet as the salt (the first two characters represent the salt itself).

Since a few `crypt(3)` extensions allow different values, with different sizes in the `salt`, it is recommended to use the full crypted password as salt when checking for a password.

A simple example illustrating typical use:

```
import crypt, getpass, pwd

def login():
```

```
username = input('Python login:')
cryptepasswd = pwd.getpwnam(username)[1]
if cryptepasswd:
    if cryptepasswd == 'x' or cryptepasswd == '*':
        raise "Sorry, currently no support for shadow passwd
    cleartext = getpass.getpass()
    return crypt.crypt(cleartext, cryptepasswd) == cryptep
else:
    return 1
```

33.6. `termios` — POSIX style tty control

Platforms: Unix

This module provides an interface to the POSIX calls for tty I/O control. For a complete description of these calls, see the POSIX or Unix manual pages. It is only available for those Unix versions that support POSIX *termios* style tty I/O control (and then only if configured at installation time).

All functions in this module take a file descriptor *fd* as their first argument. This can be an integer file descriptor, such as returned by `sys.stdin.fileno()`, or a *file object*, such as `sys.stdin` itself.

This module also defines all the constants needed to work with the functions provided here; these have the same name as their counterparts in C. Please refer to your system documentation for more information on using these terminal control interfaces.

The module defines the following functions:

`termios.tcgetattr(fd)`

Return a list containing the tty attributes for file descriptor *fd*, as follows: `[iflag, oflag, cflag, lflag, ispeed, ospeed, cc]` where `cc` is a list of the tty special characters (each a string of length 1, except the items with indices `VMIN` and `VTIME`, which are integers when these fields are defined). The interpretation of the flags and the speeds as well as the indexing in the `cc` array must be done using the symbolic constants defined in the `termios` module.

`termios.tcsetattr(fd, when, attributes)`

Set the tty attributes for file descriptor *fd* from the *attributes*, which is a list like the one returned by `tcgetattr()`. The *when* argument determines when the attributes are changed: **TCSANOW** to change immediately, **TCSADRAIN** to change after transmitting all queued output, or **TCSAFLUSH** to change after transmitting all queued output and discarding all queued input.

`termios.tcsendbreak(fd, duration)`

Send a break on file descriptor *fd*. A zero *duration* sends a break for 0.25 –0.5 seconds; a nonzero *duration* has a system dependent meaning.

`termios.tcdrain(fd)`

Wait until all output written to file descriptor *fd* has been transmitted.

`termios.tcflush(fd, queue)`

Discard queued data on file descriptor *fd*. The *queue* selector specifies which queue: **TCIFLUSH** for the input queue, **TCOFLUSH** for the output queue, or **TCIOFLUSH** for both queues.

`termios.tcflow(fd, action)`

Suspend or resume input or output on file descriptor *fd*. The *action* argument can be **TCOOFF** to suspend output, **TCOON** to restart output, **TCIOFF** to suspend input, or **TCION** to restart input.

See also:

Module `tty`

Convenience functions for common terminal control operations.

33.6.1. Example

Here's a function that prompts for a password with echoing turned off. Note the technique using a separate `tcgetattr()` call and a `try ... finally` statement to ensure that the old tty attributes are restored exactly no matter what happens:

```
def getpass(prompt="Password: "):
    import termios, sys
    fd = sys.stdin.fileno()
    old = termios.tcgetattr(fd)
    new = termios.tcgetattr(fd)
    new[3] = new[3] & ~termios.ECHO           # lflags
    try:
        termios.tcsetattr(fd, termios.TCSADRAIN, new)
        passwd = input(prompt)
    finally:
        termios.tcsetattr(fd, termios.TCSADRAIN, old)
    return passwd
```

33.7. `tty` — Terminal control functions

Platforms: Unix

The `tty` module defines functions for putting the tty into cbreak and raw modes.

Because it requires the `termios` module, it will work only on Unix.

The `tty` module defines the following functions:

`tty.setraw(fd, when=termios.TCSAFLUSH)`

Change the mode of the file descriptor *fd* to raw. If *when* is omitted, it defaults to `termios.TCSAFLUSH`, and is passed to `termios.tcsetattr()`.

`tty.setcbreak(fd, when=termios.TCSAFLUSH)`

Change the mode of file descriptor *fd* to cbreak. If *when* is omitted, it defaults to `termios.TCSAFLUSH`, and is passed to `termios.tcsetattr()`.

See also:

Module `termios`

Low-level terminal control interface.

33.8. `pty` — Pseudo-terminal utilities

Platforms: Linux

The `pty` module defines operations for handling the pseudo-terminal concept: starting another process and being able to write to and read from its controlling terminal programmatically.

Because pseudo-terminal handling is highly platform dependent, there is code to do it only for Linux. (The Linux code is supposed to work on other platforms, but hasn't been tested yet.)

The `pty` module defines the following functions:

`pty.fork()`

Fork. Connect the child's controlling terminal to a pseudo-terminal. Return value is `(pid, fd)`. Note that the child gets `pid 0`, and the `fd` is *invalid*. The parent's return value is the `pid` of the child, and `fd` is a file descriptor connected to the child's controlling terminal (and also to the child's standard input and output).

`pty.openpty()`

Open a new pseudo-terminal pair, using `os.openpty()` if possible, or emulation code for generic Unix systems. Return a pair of file descriptors `(master, slave)`, for the master and the slave end, respectively.

`pty.spawn(argv[, master_read[, stdin_read]])`

Spawn a process, and connect its controlling terminal with the current process's standard io. This is often used to baffle programs which insist on reading from the controlling terminal.

The functions *master_read* and *stdin_read* should be functions which read from a file descriptor. The defaults try to read 1024 bytes each time they are called.

33.8.1. Example

The following program acts like the Unix command *script(1)*, using a pseudo-terminal to record all input and output of a terminal session in a “typescript”.

```
import sys, os, time, getopt
import pty

mode = 'wb'
shell = 'sh'
filename = 'typescript'
if 'SHELL' in os.environ:
    shell = os.environ['SHELL']

try:
    opts, args = getopt.getopt(sys.argv[1:], 'ap')
except getopt.error as msg:
    print('%s: %s' % (sys.argv[0], msg))
    sys.exit(2)

for opt, arg in opts:
    # option -a: append to typescript file
    if opt == '-a':
        mode = 'ab'
    # option -p: use a Python shell as the terminal command
    elif opt == '-p':
        shell = sys.executable
if args:
    filename = args[0]

script = open(filename, mode)

def read(fd):
    data = os.read(fd, 1024)
    script.write(data)
    return data

sys.stdout.write('Script started, file is %s\n' % filename)
script.write(('Script started on %s\n' % time.asctime()).encode())
pty.spawn(shell, read)
script.write(('Script done on %s\n' % time.asctime()).encode())
sys.stdout.write('Script done, file is %s\n' % filename)
```

 [Python v3.2 documentation](#) » [The Python Standard Library](#) [previous](#) | [next](#) | [modules](#) | [index](#)
» [33. Unix Specific Services](#) »

33.9. `fcntl` — The `fcntl()` and `ioctl()` system calls

Platforms: Unix

This module performs file control and I/O control on file descriptors. It is an interface to the `fcntl()` and `ioctl()` Unix routines.

All functions in this module take a file descriptor `fd` as their first argument. This can be an integer file descriptor, such as returned by `sys.stdin.fileno()`, or a `io.IOBase` object, such as `sys.stdin` itself, which provides a `fileno()` that returns a genuine file descriptor.

The module defines the following functions:

`fcntl.fcntl(fd, op[, arg])`

Perform the requested operation on file descriptor `fd` (file objects providing a `fileno()` method are accepted as well). The operation is defined by `op` and is operating system dependent. These codes are also found in the `fcntl` module. The argument `arg` is optional, and defaults to the integer value `0`. When present, it can either be an integer value, or a string. With the argument missing or an integer value, the return value of this function is the integer return value of the C `fcntl()` call. When the argument is a string it represents a binary structure, e.g. created by `struct.pack()`. The binary data is copied to a buffer whose address is passed to the C `fcntl()` call. The return value after a successful call is the contents of the buffer, converted to a string object. The length of the returned string will be the same as the length of the `arg` argument. This is limited to 1024 bytes. If the information returned in the buffer by the operating system is larger than 1024 bytes, this is most likely to result in a

segmentation violation or a more subtle data corruption.

If the `fcntl()` fails, an `IOError` is raised.

`fcntl.ioctl(fd, op[, arg[, mutate_flag]])`

This function is identical to the `fcntl()` function, except that the argument handling is even more complicated.

The `op` parameter is limited to values that can fit in 32-bits.

The parameter `arg` can be one of an integer, absent (treated identically to the integer `0`), an object supporting the read-only buffer interface (most likely a plain Python string) or an object supporting the read-write buffer interface.

In all but the last case, behaviour is as for the `fcntl()` function.

If a mutable buffer is passed, then the behaviour is determined by the value of the `mutate_flag` parameter.

If it is false, the buffer's mutability is ignored and behaviour is as for a read-only buffer, except that the 1024 byte limit mentioned above is avoided – so long as the buffer you pass is as least as long as what the operating system wants to put there, things should work.

If `mutate_flag` is true (the default), then the buffer is (in effect) passed to the underlying `ioctl()` system call, the latter's return code is passed back to the calling Python, and the buffer's new contents reflect the action of the `ioctl()`. This is a slight simplification, because if the supplied buffer is less than 1024 bytes long it is first copied into a static buffer 1024 bytes long which is then passed to `ioctl()` and copied back into the supplied buffer.

An example:

```
>>> import array, fcntl, struct, termios, os
>>> os.getpgrp()
13341
>>> struct.unpack('h', fcntl.ioctl(0, termios.TIOCGPGRP, "
13341
>>> buf = array.array('h', [0])
>>> fcntl.ioctl(0, termios.TIOCGPGRP, buf, 1)
0
>>> buf
array('h', [13341])
```

`fcntl.flock(fd, op)`

Perform the lock operation *op* on file descriptor *fd* (file objects providing a `fileno()` method are accepted as well). See the Unix manual `flock(2)` for details. (On some systems, this function is emulated using `fcntl()`.)

`fcntl.lockf(fd, operation[, length[, start[, whence]]])`

This is essentially a wrapper around the `fcntl()` locking calls. *fd* is the file descriptor of the file to lock or unlock, and *operation* is one of the following values:

- `LOCK_UN` – unlock
- `LOCK_SH` – acquire a shared lock
- `LOCK_EX` – acquire an exclusive lock

When *operation* is `LOCK_SH` or `LOCK_EX`, it can also be bitwise ORed with `LOCK_NB` to avoid blocking on lock acquisition. If `LOCK_NB` is used and the lock cannot be acquired, an `IOError` will be raised and the exception will have an `errno` attribute set to `EACCES` or `EAGAIN` (depending on the operating system; for portability, check for both values). On at least some systems, `LOCK_EX` can only be used if the file descriptor refers to a file

opened for writing.

length is the number of bytes to lock, *start* is the byte offset at which the lock starts, relative to *whence*, and *whence* is as with `fileobj.seek()`, specifically:

- 0 – relative to the start of the file (`SEEK_SET`)
- 1 – relative to the current buffer position (`SEEK_CUR`)
- 2 – relative to the end of the file (`SEEK_END`)

The default for *start* is 0, which means to start at the beginning of the file. The default for *length* is 0 which means to lock to the end of the file. The default for *whence* is also 0.

Examples (all on a SVR4 compliant system):

```
import struct, fcntl, os

f = open(...)
rv = fcntl.fcntl(f, fcntl.F_SETFL, os.O_NDELAY)

lockdata = struct.pack('hhllhh', fcntl.F_WRLCK, 0, 0, 0, 0, 0)
rv = fcntl.fcntl(f, fcntl.F_SETLKW, lockdata)
```

Note that in the first example the return value variable *rv* will hold an integer value; in the second example it will hold a string value. The structure lay-out for the *lockdata* variable is system dependent — therefore using the `flock()` call may be better.

See also:

Module `os`

If the locking flags `o_SHLOCK` and `o_EXLOCK` are present in the `os` module (on BSD only), the `os.open()` function provides an alternative to the `lockf()` and `flock()` functions.

33.10. pipes — Interface to shell pipelines

Platforms: Unix

Source code: [Lib/pipes.py](#)

The `pipes` module defines a class to abstract the concept of a *pipeline* — a sequence of converters from one file to another.

Because the module uses `/bin/sh` command lines, a POSIX or compatible shell for `os.system()` and `os.popen()` is required.

The `pipes` module defines the following class:

```
class pipes.Template
```

 An abstraction of a pipeline.

Example:

```
>>> import pipes
>>> t=pipes.Template()
>>> t.append('tr a-z A-Z', '--')
>>> f=t.open('/tmp/1', 'w')
>>> f.write('hello world')
>>> f.close()
>>> open('/tmp/1').read()
'HELLO WORLD'
```

33.10.1. Template Objects

Template objects following methods:

Template.**reset()**

Restore a pipeline template to its initial state.

Template.**clone()**

Return a new, equivalent, pipeline template.

Template.**debug(flag)**

If *flag* is true, turn debugging on. Otherwise, turn debugging off. When debugging is on, commands to be executed are printed, and the shell is given `set -x` command to be more verbose.

Template.**append(cmd, kind)**

Append a new action at the end. The *cmd* variable must be a valid bourne shell command. The *kind* variable consists of two letters.

The first letter can be either of `'-'` (which means the command reads its standard input), `'f'` (which means the commands reads a given file on the command line) or `'.'` (which means the commands reads no input, and hence must be first.)

Similarly, the second letter can be either of `'-'` (which means the command writes to standard output), `'f'` (which means the command writes a file on the command line) or `'.'` (which means the command does not write anything, and hence must be last.)

Template.**prepend(cmd, kind)**

Add a new action at the beginning. See [append\(\)](#) for explanations of the arguments.

Template.**open**(*file*, *mode*)

Return a file-like object, open to *file*, but read from or written to by the pipeline. Note that only one of 'r', 'w' may be given.

Template.**copy**(*infile*, *outfile*)

Copy *infile* to *outfile* through the pipe.

33.11. resource — Resource usage information

Platforms: Unix

This module provides basic mechanisms for measuring and controlling system resources utilized by a program.

Symbolic constants are used to specify particular system resources and to request usage information about either the current process or its children.

A single exception is defined for errors:

exception resource.**error**

The functions described below may raise this error if the underlying system call failures unexpectedly.

33.11.1. Resource Limits

Resources usage can be limited using the `setrlimit()` function described below. Each resource is controlled by a pair of limits: a soft limit and a hard limit. The soft limit is the current limit, and may be lowered or raised by a process over time. The soft limit can never exceed the hard limit. The hard limit can be lowered to any value greater than the soft limit, but not raised. (Only processes with the effective UID of the super-user can raise a hard limit.)

The specific resources that can be limited are system dependent. They are described in the `getrlimit(2)` man page. The resources listed below are supported when the underlying operating system supports them; resources which cannot be checked or controlled by the operating system are not defined in this module for those platforms.

`resource.getrlimit(resource)`

Returns a tuple `(soft, hard)` with the current soft and hard limits of *resource*. Raises `ValueError` if an invalid resource is specified, or `error` if the underlying system call fails unexpectedly.

`resource.setrlimit(resource, limits)`

Sets new limits of consumption of *resource*. The *limits* argument must be a tuple `(soft, hard)` of two integers describing the new limits. A value of `-1` can be used to specify the maximum possible upper limit.

Raises `ValueError` if an invalid resource is specified, if the new soft limit exceeds the hard limit, or if a process tries to raise its hard limit (unless the process has an effective UID of super-user). Can also raise `error` if the underlying system call fails.

These symbols define resources whose consumption can be controlled using the `setrlimit()` and `getrlimit()` functions described below. The values of these symbols are exactly the constants used by C programs.

The Unix man page for *getrlimit(2)* lists the available resources. Note that not all systems use the same symbol or same value to denote the same resource. This module does not attempt to mask platform differences — symbols not defined for a platform will not be available from this module on that platform.

resource. **RLIMIT_CORE**

The maximum size (in bytes) of a core file that the current process can create. This may result in the creation of a partial core file if a larger core would be required to contain the entire process image.

resource. **RLIMIT_CPU**

The maximum amount of processor time (in seconds) that a process can use. If this limit is exceeded, a `SIGXCPU` signal is sent to the process. (See the `signal` module documentation for information about how to catch this signal and do something useful, e.g. flush open files to disk.)

resource. **RLIMIT_FSIZE**

The maximum size of a file which the process may create. This only affects the stack of the main thread in a multi-threaded process.

resource. **RLIMIT_DATA**

The maximum size (in bytes) of the process's heap.

resource. **RLIMIT_STACK**

The maximum size (in bytes) of the call stack for the current process.

resource. **RLIMIT_RSS**

The maximum resident set size that should be made available to the process.

resource. **RLIMIT_NPROC**

The maximum number of processes the current process may create.

resource. **RLIMIT_NOFILE**

The maximum number of open file descriptors for the current process.

resource. **RLIMIT_OFILE**

The BSD name for [RLIMIT_NOFILE](#).

resource. **RLIMIT_MEMLOCK**

The maximum address space which may be locked in memory.

resource. **RLIMIT_VMEM**

The largest area of mapped memory which the process may occupy.

resource. **RLIMIT_AS**

The maximum area (in bytes) of address space which may be taken by the process.

33.11.2. Resource Usage

These functions are used to retrieve resource usage information:

`resource.getrusage(who)`

This function returns an object that describes the resources consumed by either the current process or its children, as specified by the *who* parameter. The *who* parameter should be specified using one of the `RUSAGE_*` constants described below.

The fields of the return value each describe how a particular system resource has been used, e.g. amount of time spent running in user mode or number of times the process was swapped out of main memory. Some values are dependent on the clock tick interval, e.g. the amount of memory the process is using.

For backward compatibility, the return value is also accessible as a tuple of 16 elements.

The fields `ru_utime` and `ru_stime` of the return value are floating point values representing the amount of time spent executing in user mode and the amount of time spent executing in system mode, respectively. The remaining values are integers. Consult the `getrusage(2)` man page for detailed information about these values. A brief summary is presented here:

Index	Field	Resource
0	<code>ru_utime</code>	time in user mode (float)
1	<code>ru_stime</code>	time in system mode (float)
2	<code>ru_maxrss</code>	maximum resident set size
3	<code>ru_ixrss</code>	shared memory size
4	<code>ru_idrss</code>	unshared memory size

5	<code>ru_isrss</code>	unshared stack size
6	<code>ru_minflt</code>	page faults not requiring I/O
7	<code>ru_majflt</code>	page faults requiring I/O
8	<code>ru_nswap</code>	number of swap outs
9	<code>ru_inblock</code>	block input operations
10	<code>ru_oublock</code>	block output operations
11	<code>ru_msgsnd</code>	messages sent
12	<code>ru_msgrcv</code>	messages received
13	<code>ru_nsignals</code>	signals received
14	<code>ru_nvcsw</code>	voluntary context switches
15	<code>ru_nivcsw</code>	involuntary context switches

This function will raise a `ValueError` if an invalid *who* parameter is specified. It may also raise `error` exception in unusual circumstances.

`resource.getpagesize()`

Returns the number of bytes in a system page. (This need not be the same as the hardware page size.) This function is useful for determining the number of bytes of memory a process is using. The third element of the tuple returned by `getrusage()` describes memory usage in pages; multiplying by page size produces number of bytes.

The following `RUSAGE_*` symbols are passed to the `getrusage()` function to specify which processes information should be provided for.

`resource.RUSAGE_SELF`

Pass to `getrusage()` to request resources consumed by the calling process, which is the sum of resources used by all threads in the process.

`resource.RUSAGE_CHILDREN`

Pass to `getrusage()` to request resources consumed by child processes of the calling process which have been terminated and waited for.

resource.**RUSAGE_BOTH**

Pass to `getrusage()` to request resources consumed by both the current process and child processes. May not be available on all systems.

resource.**RUSAGE_THREAD**

Pass to `getrusage()` to request resources consumed by the current thread. May not be available on all systems.

New in version 3.2.

33.12. `nis` — Interface to Sun's NIS (Yellow Pages)

Platforms: Unix

The `nis` module gives a thin wrapper around the NIS library, useful for central administration of several hosts.

Because NIS exists only on Unix systems, this module is only available for Unix.

The `nis` module defines the following functions:

`nis.match(key, mapname[, domain=default_domain])`

Return the match for *key* in map *mapname*, or raise an error (`nis.error`) if there is none. Both should be strings, *key* is 8-bit clean. Return value is an arbitrary array of bytes (may contain `NULL` and other joys).

Note that *mapname* is first checked if it is an alias to another name.

The *domain* argument allows to override the NIS domain used for the lookup. If unspecified, lookup is in the default NIS domain.

`nis.cat(mapname[, domain=default_domain])`

Return a dictionary mapping *key* to *value* such that `match(key, mapname)==value`. Note that both keys and values of the dictionary are arbitrary arrays of bytes.

Note that *mapname* is first checked if it is an alias to another name.

The *domain* argument allows to override the NIS domain used for the lookup. If unspecified, lookup is in the default NIS domain.

```
nis.maps([domain=default_domain])
```

Return a list of all valid maps.

The *domain* argument allows to override the NIS domain used for the lookup. If unspecified, lookup is in the default NIS domain.

```
nis.get_default_domain()
```

Return the system default NIS domain.

The `nis` module defines the following exception:

```
exception nis.error
```

An error raised when a NIS function returns an error code.

33.13. `syslog` — Unix `syslog` library routines

Platforms: Unix

This module provides an interface to the Unix `syslog` library routines. Refer to the Unix manual pages for a detailed description of the `syslog` facility.

This module wraps the system `syslog` family of routines. A pure Python library that can speak to a syslog server is available in the `logging.handlers` module as `SysLogHandler`.

The module defines the following functions:

`syslog.syslog([priority], message)`

Send the string *message* to the system logger. A trailing newline is added if necessary. Each message is tagged with a priority composed of a *facility* and a *level*. The optional *priority* argument, which defaults to `LOG_INFO`, determines the message priority. If the facility is not encoded in *priority* using logical-or (`LOG_INFO | LOG_USER`), the value given in the `openlog()` call is used.

If `openlog()` has not been called prior to the call to `syslog()`, `openlog()` will be called with no arguments.

`syslog.openlog([ident[, logopt[, facility]])`

Logging options of subsequent `syslog()` calls can be set by calling `openlog()`. `syslog()` will call `openlog()` with no arguments if the log is not currently open.

The optional *ident* keyword argument is a string which is

prepended to every message, and defaults to `sys.argv[0]` with leading path components stripped. The optional *logopt* keyword argument (default is 0) is a bit field – see below for possible values to combine. The optional *facility* keyword argument (default is `LOG_USER`) sets the default facility for messages which do not have a facility explicitly encoded.

Changed in version 3.2: In previous versions, keyword arguments were not allowed, and *ident* was required. The default for *ident* was dependent on the system libraries, and often was `python` instead of the name of the python program file.

`syslog.closelog()`

Reset the syslog module values and call the system library `closelog()`.

This causes the module to behave as it does when initially imported. For example, `openlog()` will be called on the first `syslog()` call (if `openlog()` hasn't already been called), and *ident* and other `openlog()` parameters are reset to defaults.

`syslog.setlogmask(maskpri)`

Set the priority mask to *maskpri* and return the previous mask value. Calls to `syslog()` with a priority level not set in *maskpri* are ignored. The default is to log all priorities. The function `LOG_MASK(pri)` calculates the mask for the individual priority *pri*. The function `LOG_UPTO(pri)` calculates the mask for all priorities up to and including *pri*.

The module defines the following constants:

Priority levels (high to low):

`LOG_EMERG, LOG_ALERT, LOG_CRIT, LOG_ERR, LOG_WARNING, LOG_NOTICE, LOG_INFO, LOG_DEBUG.`

Facilities:

**LOG_KERN, LOG_USER, LOG_MAIL, LOG_DAEMON, LOG_AUTH, LOG_LPR,
LOG_NEWS, LOG_UUCP, LOG_CRON and LOG_LOCAL0 to LOG_LOCAL7.**

Log options:

LOG_PID, LOG_CONS, LOG_NDELAY, LOG_NOWAIT and LOG_PERROR if
defined in `<syslog.h>`.

33.13.1. Examples

33.13.1.1. Simple example

A simple set of examples:

```
import syslog

syslog.syslog('Processing started')
if error:
    syslog.syslog(syslog.LOG_ERR, 'Processing started')
```

An example of setting some log options, these would include the process ID in logged messages, and write the messages to the destination facility used for mail logging:

```
syslog.openlog(logopt=syslog.LOG_PID, facility=syslog.LOG_MAIL)
syslog.syslog('E-mail processing initiated...')
```

34. Undocumented Modules

Here's a quick listing of modules that are currently undocumented, but that should be documented. Feel free to contribute documentation for them! (Send via email to docs@python.org.)

The idea and original contents for this chapter were taken from a posting by Fredrik Lundh; the specific contents of this chapter have been substantially revised.

34.1. Platform specific modules

These modules are used to implement the `os.path` module, and are not documented beyond this mention. There's little need to document these.

`ntpath`

- Implementation of `os.path` on Win32, Win64, WinCE, and OS/2 platforms.

`posixpath`

- Implementation of `os.path` on POSIX.

1. Extending Python with C or C++

It is quite easy to add new built-in modules to Python, if you know how to program in C. Such *extension modules* can do two things that can't be done directly in Python: they can implement new built-in object types, and they can call C library functions and system calls.

To support extensions, the Python API (Application Programmers Interface) defines a set of functions, macros and variables that provide access to most aspects of the Python run-time system. The Python API is incorporated in a C source file by including the header `"Python.h"`.

The compilation of an extension module depends on its intended use as well as on your system setup; details are given in later chapters.

Do note that if your use case is calling C library functions or system calls, you should consider using the `ctypes` module rather than writing custom C code. Not only does `ctypes` let you write Python code to interface with C code, but it is more portable between implementations of Python than writing and compiling an extension module which typically ties you to CPython.

1.1. A Simple Example

Let's create an extension module called `spam` (the favorite food of Monty Python fans...) and let's say we want to create a Python interface to the C library function `system()`. [1] This function takes a null-terminated character string as argument and returns an integer. We want this function to be callable from Python as follows:

```
>>> import spam
>>> status = spam.system("ls -l")
```

Begin by creating a file `spammodule.c`. (Historically, if a module is called `spam`, the C file containing its implementation is called `spammodule.c`; if the module name is very long, like `spammify`, the module name can be just `spammify.c`.)

The first line of our file can be:

```
#include <Python.h>
```

which pulls in the Python API (you can add a comment describing the purpose of the module and a copyright notice if you like).

Note: Since Python may define some pre-processor definitions which affect the standard headers on some systems, you *must* include `Python.h` before any standard headers are included.

All user-visible symbols defined by `Python.h` have a prefix of `Py` or `PY`, except those defined in standard header files. For convenience, and since they are used extensively by the Python interpreter, "`Python.h`" includes a few standard header files: `<stdio.h>`, `<string.h>`, `<errno.h>`, and `<stdlib.h>`. If the latter header file does

not exist on your system, it declares the functions `malloc()`, `free()` and `realloc()` directly.

The next thing we add to our module file is the C function that will be called when the Python expression `spam.system(string)` is evaluated (we'll see shortly how it ends up being called):

```
static PyObject *
spam_system(PyObject *self, PyObject *args)
{
    const char *command;
    int sts;

    if (!PyArg_ParseTuple(args, "s", &command))
        return NULL;
    sts = system(command);
    return PyLong_FromLong(sts);
}
```

There is a straightforward translation from the argument list in Python (for example, the single expression `"ls -l"`) to the arguments passed to the C function. The C function always has two arguments, conventionally named *self* and *args*.

The *self* argument points to the module object for module-level functions; for a method it would point to the object instance.

The *args* argument will be a pointer to a Python tuple object containing the arguments. Each item of the tuple corresponds to an argument in the call's argument list. The arguments are Python objects — in order to do anything with them in our C function we have to convert them to C values. The function `PyArg_ParseTuple()` in the Python API checks the argument types and converts them to C values. It uses a template string to determine the required types of the arguments as well as the types of the C variables into which to store the converted values. More about this later.

`PyArg_ParseTuple()` returns true (nonzero) if all arguments have the right type and its components have been stored in the variables whose addresses are passed. It returns false (zero) if an invalid argument list was passed. In the latter case it also raises an appropriate exception so the calling function can return *NULL* immediately (as we saw in the example).

1.2. Intermezzo: Errors and Exceptions

An important convention throughout the Python interpreter is the following: when a function fails, it should set an exception condition and return an error value (usually a *NULL* pointer). Exceptions are stored in a static global variable inside the interpreter; if this variable is *NULL* no exception has occurred. A second global variable stores the “associated value” of the exception (the second argument to `raise`). A third variable contains the stack traceback in case the error originated in Python code. These three variables are the C equivalents of the result in Python of `sys.exc_info()` (see the section on module `sys` in the Python Library Reference). It is important to know about them to understand how errors are passed around.

The Python API defines a number of functions to set various types of exceptions.

The most common one is `PyErr_SetString()`. Its arguments are an exception object and a C string. The exception object is usually a predefined object like `PyExc_ZeroDivisionError`. The C string indicates the cause of the error and is converted to a Python string object and stored as the “associated value” of the exception.

Another useful function is `PyErr_SetFromErrno()`, which only takes an exception argument and constructs the associated value by inspection of the global variable `errno`. The most general function is `PyErr_SetObject()`, which takes two object arguments, the exception and its associated value. You don’t need to `Py_INCREF()` the objects passed to any of these functions.

You can test non-destructively whether an exception has been set with `PyErr_Occurred()`. This returns the current exception object, or

`NULL` if no exception has occurred. You normally don't need to call `PyErr_Occurred()` to see whether an error occurred in a function call, since you should be able to tell from the return value.

When a function *f* that calls another function *g* detects that the latter fails, *f* should itself return an error value (usually `NULL` or `-1`). It should *not* call one of the `PyErr_*`() functions — one has already been called by *g*. *f*'s caller is then supposed to also return an error indication to *its* caller, again *without* calling `PyErr_*`(), and so on — the most detailed cause of the error was already reported by the function that first detected it. Once the error reaches the Python interpreter's main loop, this aborts the currently executing Python code and tries to find an exception handler specified by the Python programmer.

(There are situations where a module can actually give a more detailed error message by calling another `PyErr_*`() function, and in such cases it is fine to do so. As a general rule, however, this is not necessary, and can cause information about the cause of the error to be lost: most operations can fail for a variety of reasons.)

To ignore an exception set by a function call that failed, the exception condition must be cleared explicitly by calling `PyErr_Clear()`. The only time C code should call `PyErr_Clear()` is if it doesn't want to pass the error on to the interpreter but wants to handle it completely by itself (possibly by trying something else, or pretending nothing went wrong).

Every failing `malloc()` call must be turned into an exception — the direct caller of `malloc()` (or `realloc()`) must call `PyErr_NoMemory()` and return a failure indicator itself. All the object-creating functions (for example, `PyLong_FromLong()`) already do this, so this note is only relevant to those who call `malloc()` directly.

Also note that, with the important exception of `PyArg_ParseTuple()` and friends, functions that return an integer status usually return a positive value or zero for success and `-1` for failure, like Unix system calls.

Finally, be careful to clean up garbage (by making `Py_XDECREF()` or `Py_DECREF()` calls for objects you have already created) when you return an error indicator!

The choice of which exception to raise is entirely yours. There are predeclared C objects corresponding to all built-in Python exceptions, such as `PyExc_ZeroDivisionError`, which you can use directly. Of course, you should choose exceptions wisely — don't use `PyExc_TypeError` to mean that a file couldn't be opened (that should probably be `PyExc_IOError`). If something's wrong with the argument list, the `PyArg_ParseTuple()` function usually raises `PyExc_TypeError`. If you have an argument whose value must be in a particular range or must satisfy other conditions, `PyExc_ValueError` is appropriate.

You can also define a new exception that is unique to your module. For this, you usually declare a static object variable at the beginning of your file:

```
static PyObject *SpamError;
```

and initialize it in your module's initialization function (`PyInit_spam()`) with an exception object (leaving out the error checking for now):

```
PyMODINIT_FUNC  
PyInit_spam(void)  
{  
    PyObject *m;  
  
    m = PyModule_Create(&spammodule);  
    if (m == NULL)
```

```

        return NULL;

    SpamError = PyErr_NewException("spam.error", NULL, NULL);
    Py_INCREF(SpamError);
    PyModule_AddObject(m, "error", SpamError);
    return m;
}

```

Note that the Python name for the exception object is `spam.error`. The `PyErr_NewException()` function may create a class with the base class being `Exception` (unless another class is passed in instead of `NULL`), described in *Built-in Exceptions*.

Note also that the `SpamError` variable retains a reference to the newly created exception class; this is intentional! Since the exception could be removed from the module by external code, an owned reference to the class is needed to ensure that it will not be discarded, causing `SpamError` to become a dangling pointer. Should it become a dangling pointer, C code which raises the exception could cause a core dump or other unintended side effects.

We discuss the use of `PyMODINIT_FUNC` as a function return type later in this sample.

The `spam.error` exception can be raised in your extension module using a call to `PyErr_SetString()` as shown below:

```

static PyObject *
spam_system(PyObject *self, PyObject *args)
{
    const char *command;
    int sts;

    if (!PyArg_ParseTuple(args, "s", &command))
        return NULL;
    sts = system(command);
    if (sts < 0) {
        PyErr_SetString(SpamError, "System command failed");
        return NULL;
    }
}

```

```
}  
    return PyLong_FromLong(sts);  
}
```

1.3. Back to the Example

Going back to our example function, you should now be able to understand this statement:

```
if (!PyArg_ParseTuple(args, "s", &command))
    return NULL;
```

It returns *NULL* (the error indicator for functions returning object pointers) if an error is detected in the argument list, relying on the exception set by `PyArg_ParseTuple()`. Otherwise the string value of the argument has been copied to the local variable `command`. This is a pointer assignment and you are not supposed to modify the string to which it points (so in Standard C, the variable `command` should properly be declared as `const char *command`).

The next statement is a call to the Unix function `system()`, passing it the string we just got from `PyArg_ParseTuple()`:

```
sts = system(command);
```

Our `spam.system()` function must return the value of `sts` as a Python object. This is done using the function `PyLong_FromLong()`.

```
return PyLong_FromLong(sts);
```

In this case, it will return an integer object. (Yes, even integers are objects on the heap in Python!)

If you have a C function that returns no useful argument (a function returning `void`), the corresponding Python function must return `None`. You need this idiom to do so (which is implemented by the `Py_RETURN_NONE` macro):

```
Py_INCREF(Py_None);  
return Py_None;
```

`Py_None` is the C name for the special Python object `None`. It is a genuine Python object rather than a *NULL* pointer, which means “error” in most contexts, as we have seen.

1.4. The Module's Method Table and Initialization Function

I promised to show how `spam_system()` is called from Python programs. First, we need to list its name and address in a “method table”:

```
static PyMethodDef SpamMethods[] = {
    ...
    {"system", spam_system, METH_VARARGS,
     "Execute a shell command."},
    ...
    {NULL, NULL, 0, NULL}          /* Sentinel */
};
```

Note the third entry (`METH_VARARGS`). This is a flag telling the interpreter the calling convention to be used for the C function. It should normally always be `METH_VARARGS` or `METH_VARARGS | METH_KEYWORDS`; a value of `0` means that an obsolete variant of `PyArg_ParseTuple()` is used.

When using only `METH_VARARGS`, the function should expect the Python-level parameters to be passed in as a tuple acceptable for parsing via `PyArg_ParseTuple()`; more information on this function is provided below.

The `METH_KEYWORDS` bit may be set in the third field if keyword arguments should be passed to the function. In this case, the C function should accept a third `PyObject *` parameter which will be a dictionary of keywords. Use `PyArg_ParseTupleAndKeywords()` to parse the arguments to such a function.

The method table must be referenced in the module definition structure:

```

static struct PyModuleDef spammodule = {
    PyModuleDef_HEAD_INIT,
    "spam", /* name of module */
    spam_doc, /* module documentation, may be NULL */
    -1, /* size of per-interpreter state of the module,
        or -1 if the module keeps state in global varia
    SpamMethods
};

```

This structure, in turn, must be passed to the interpreter in the module's initialization function. The initialization function must be named `PyInit_name()`, where *name* is the name of the module, and should be the only non-`static` item defined in the module file:

```

PyMODINIT_FUNC
PyInit_spam(void)
{
    return PyModule_Create(&spammodule);
}

```

Note that `PyMODINIT_FUNC` declares the function as `PyObject *` return type, declares any special linkage declarations required by the platform, and for C++ declares the function as `extern "C"`.

When the Python program imports module `spam` for the first time, `PyInit_spam()` is called. (See below for comments about embedding Python.) It calls `PyModule_Create()`, which returns a module object, and inserts built-in function objects into the newly created module based upon the table (an array of `PyMethodDef` structures) found in the module definition. `PyModule_Create()` returns a pointer to the module object that it creates. It may abort with a fatal error for certain errors, or return `NULL` if the module could not be initialized satisfactorily. The init function must return the module object to its caller, so that it then gets inserted into `sys.modules`.

When embedding Python, the `PyInit_spam()` function is not called

automatically unless there's an entry in the `PyImport_Inittab` table. To add the module to the initialization table, use `PyImport_AppendInittab()`, optionally followed by an import of the module:

```
int
main(int argc, char *argv[])
{
    /* Add a built-in module, before Py_Initialize */
    PyImport_AppendInittab("spam", PyInit_spam);

    /* Pass argv[0] to the Python interpreter */
    Py_SetProgramName(argv[0]);

    /* Initialize the Python interpreter.  Required. */
    Py_Initialize();

    /* Optionally import the module; alternatively,
       import can be deferred until the embedded script
       imports it. */
    PyImport_ImportModule("spam");
}
```

An example may be found in the file `Demo/embed/demo.c` in the Python source distribution.

Note: Removing entries from `sys.modules` or importing compiled modules into multiple interpreters within a process (or following a `fork()` without an intervening `exec()`) can create problems for some extension modules. Extension module authors should exercise caution when initializing internal data structures.

A more substantial example module is included in the Python source distribution as `Modules/xxmodule.c`. This file may be used as a template or simply read as an example.

1.5. Compilation and Linkage

There are two more things to do before you can use your new extension: compiling and linking it with the Python system. If you use dynamic loading, the details may depend on the style of dynamic loading your system uses; see the chapters about building extension modules (chapter *Building C and C++ Extensions with distutils*) and additional information that pertains only to building on Windows (chapter *Building C and C++ Extensions on Windows*) for more information about this.

If you can't use dynamic loading, or if you want to make your module a permanent part of the Python interpreter, you will have to change the configuration setup and rebuild the interpreter. Luckily, this is very simple on Unix: just place your file (`spammodule.c` for example) in the `Modules/` directory of an unpacked source distribution, add a line to the file `Modules/Setup.local` describing your file:

```
spam spammodule.o
```

and rebuild the interpreter by running **make** in the toplevel directory. You can also run **make** in the `Modules/` subdirectory, but then you must first rebuild `Makefile` there by running '**make** Makefile'. (This is necessary each time you change the `Setup` file.)

If your module requires additional libraries to link with, these can be listed on the line in the configuration file as well, for instance:

```
spam spammodule.o -lX11
```

1.6. Calling Python Functions from C

So far we have concentrated on making C functions callable from Python. The reverse is also useful: calling Python functions from C. This is especially the case for libraries that support so-called “callback” functions. If a C interface makes use of callbacks, the equivalent Python often needs to provide a callback mechanism to the Python programmer; the implementation will require calling the Python callback functions from a C callback. Other uses are also imaginable.

Fortunately, the Python interpreter is easily called recursively, and there is a standard interface to call a Python function. (I won't dwell on how to call the Python parser with a particular string as input — if you're interested, have a look at the implementation of the `-c` command line option in `Modules/main.c` from the Python source code.)

Calling a Python function is easy. First, the Python program must somehow pass you the Python function object. You should provide a function (or some other interface) to do this. When this function is called, save a pointer to the Python function object (be careful to `Py_INCREF()` it!) in a global variable — or wherever you see fit. For example, the following function might be part of a module definition:

```
static PyObject *my_callback = NULL;

static PyObject *
my_set_callback(PyObject *dummy, PyObject *args)
{
    PyObject *result = NULL;
    PyObject *temp;

    if (PyArg_ParseTuple(args, "O:set_callback", &temp)) {
        if (!PyCallable_Check(temp)) {
            PyErr_SetString(PyExc_TypeError, "parameter must be
```

```

        return NULL;
    }
    Py_XINCRREF(temp);          /* Add a reference to new cal
    Py_XDECREF(my_callback);   /* Dispose of previous callba
    my_callback = temp;        /* Remember new callback */
    /* Boilerplate to return "None" */
    Py_INCREF(Py_None);
    result = Py_None;
}
return result;
}

```

This function must be registered with the interpreter using the `METH_VARARGS` flag; this is described in section *The Module's Method Table and Initialization Function*. The `PyArg_ParseTuple()` function and its arguments are documented in section *Extracting Parameters in Extension Functions*.

The macros `Py_XINCRREF()` and `Py_XDECREF()` increment/decrement the reference count of an object and are safe in the presence of `NULL` pointers (but note that `temp` will not be `NULL` in this context). More info on them in section *Reference Counts*.

Later, when it is time to call the function, you call the C function `PyObject_CallObject()`. This function has two arguments, both pointers to arbitrary Python objects: the Python function, and the argument list. The argument list must always be a tuple object, whose length is the number of arguments. To call the Python function with no arguments, pass in `NULL`, or an empty tuple; to call it with one argument, pass a singleton tuple. `Py_BuildValue()` returns a tuple when its format string consists of zero or more format codes between parentheses. For example:

```

int arg;
PyObject *arglist;
PyObject *result;
...
arg = 123;

```

```
...
/* Time to call the callback */
arglist = Py_BuildValue("(i)", arg);
result = PyObject_CallObject(my_callback, arglist);
Py_DECREF(arglist);
```

`PyObject_CallObject()` returns a Python object pointer: this is the return value of the Python function. `PyObject_CallObject()` is “reference-count-neutral” with respect to its arguments. In the example a new tuple was created to serve as the argument list, which is `Py_DECREF()`-ed immediately after the call.

The return value of `PyObject_CallObject()` is “new”: either it is a brand new object, or it is an existing object whose reference count has been incremented. So, unless you want to save it in a global variable, you should somehow `Py_DECREF()` the result, even (especially!) if you are not interested in its value.

Before you do this, however, it is important to check that the return value isn't `NULL`. If it is, the Python function terminated by raising an exception. If the C code that called `PyObject_CallObject()` is called from Python, it should now return an error indication to its Python caller, so the interpreter can print a stack trace, or the calling Python code can handle the exception. If this is not possible or desirable, the exception should be cleared by calling `PyErr_Clear()`. For example:

```
if (result == NULL)
    return NULL; /* Pass error back */
...use result...
Py_DECREF(result);
```

Depending on the desired interface to the Python callback function, you may also have to provide an argument list to `PyObject_CallObject()`. In some cases the argument list is also provided by the Python program, through the same interface that

specified the callback function. It can then be saved and used in the same manner as the function object. In other cases, you may have to construct a new tuple to pass as the argument list. The simplest way to do this is to call `Py_BuildValue()`. For example, if you want to pass an integral event code, you might use the following code:

```
PyObject *arglist;
...
arglist = Py_BuildValue("(l)", eventcode);
result = PyObject_CallObject(my_callback, arglist);
Py_DECREF(arglist);
if (result == NULL)
    return NULL; /* Pass error back */
/* Here maybe use the result */
Py_DECREF(result);
```

Note the placement of `Py_DECREF(arglist)` immediately after the call, before the error check! Also note that strictly speaking this code is not complete: `Py_BuildValue()` may run out of memory, and this should be checked.

You may also call a function with keyword arguments by using `PyObject_Call()`, which supports arguments and keyword arguments. As in the above example, we use `Py_BuildValue()` to construct the dictionary.

```
PyObject *dict;
...
dict = Py_BuildValue("{s:i}", "name", val);
result = PyObject_Call(my_callback, NULL, dict);
Py_DECREF(dict);
if (result == NULL)
    return NULL; /* Pass error back */
/* Here maybe use the result */
Py_DECREF(result);
```

1.7. Extracting Parameters in Extension Functions

The `PyArg_ParseTuple()` function is declared as follows:

```
int PyArg_ParseTuple(PyObject *arg, char *format, ...);
```

The *arg* argument must be a tuple object containing an argument list passed from Python to a C function. The *format* argument must be a format string, whose syntax is explained in *Parsing arguments and building values* in the Python/C API Reference Manual. The remaining arguments must be addresses of variables whose type is determined by the format string.

Note that while `PyArg_ParseTuple()` checks that the Python arguments have the required types, it cannot check the validity of the addresses of C variables passed to the call: if you make mistakes there, your code will probably crash or at least overwrite random bits in memory. So be careful!

Note that any Python object references which are provided to the caller are *borrowed* references; do not decrement their reference count!

Some example calls:

```
#define PY_SSIZE_T_CLEAN /* Make "s#" use Py_ssize_t rather th  
#include <Python.h>
```

```
int ok;  
int i, j;  
long k, l;  
const char *s;  
Py_ssize_t size;
```

```
ok = PyArg_ParseTuple(args, ""); /* No arguments */
/* Python call: f() */
```

```
ok = PyArg_ParseTuple(args, "s", &s); /* A string */
/* Possible Python call: f('whoops!') */
```

```
ok = PyArg_ParseTuple(args, "lls", &k, &l, &s); /* Two longs and a string */
/* Possible Python call: f(1, 2, 'three') */
```

```
ok = PyArg_ParseTuple(args, "(ii)s#", &i, &j, &s, &size);
/* A pair of ints and a string, whose size is also returned */
/* Possible Python call: f((1, 2), 'three') */
```

```
{
    const char *file;
    const char *mode = "r";
    int bufsize = 0;
    ok = PyArg_ParseTuple(args, "s|si", &file, &mode, &bufsize);
    /* A string, and optionally another string and an integer */
    /* Possible Python calls:
       f('spam')
       f('spam', 'w')
       f('spam', 'wb', 100000) */
}
```

```
{
    int left, top, right, bottom, h, v;
    ok = PyArg_ParseTuple(args, "((ii)(ii))(ii)",
        &left, &top, &right, &bottom, &h, &v);
    /* A rectangle and a point */
    /* Possible Python call:
       f(((0, 0), (400, 300)), (10, 10)) */
}
```

```
{
    Py_complex c;
    ok = PyArg_ParseTuple(args, "D:myfunction", &c);
    /* a complex, also providing a function name for errors */
    /* Possible Python call: myfunction(1+2j) */
}
```

1.8. Keyword Parameters for Extension Functions

The `PyArg_ParseTupleAndKeywords()` function is declared as follows:

```
int PyArg_ParseTupleAndKeywords(PyObject *arg, PyObject *kwdict
                                char *format, char *kwlist[], .
```

The `arg` and `format` parameters are identical to those of the `PyArg_ParseTuple()` function. The `kwdict` parameter is the dictionary of keywords received as the third parameter from the Python runtime. The `kwlist` parameter is a `NULL`-terminated list of strings which identify the parameters; the names are matched with the type information from `format` from left to right. On success, `PyArg_ParseTupleAndKeywords()` returns true, otherwise it returns false and raises an appropriate exception.

Note: Nested tuples cannot be parsed when using keyword arguments! Keyword parameters passed in which are not present in the `kwlist` will cause `TypeError` to be raised.

Here is an example module which uses keywords, based on an example by Geoff Philbrick (philbrick@hks.com):

```
#include "Python.h"

static PyObject *
keywdarg_parrot(PyObject *self, PyObject *args, PyObject *keywd
{
    int voltage;
    char *state = "a stiff";
    char *action = "voom";
    char *type = "Norwegian Blue";

    static char *kwlist[] = {"voltage", "state", "action", "typ
```

```

    if (!PyArg_ParseTupleAndKeywords(args, keywds, "i|sss", kwl
                                     &voltage, &state, &action,
                                     return NULL;

    printf("-- This parrot wouldn't %s if you put %i Volts thro
           action, voltage);
    printf("-- Lovely plumage, the %s -- It's %s!\n", type, sta

    Py_INCREF(Py_None);

    return Py_None;
}

static PyMethodDef keywdarg_methods[] = {
    /* The cast of the function is necessary since PyCFunction
     * only take two PyObject* parameters, and keywdarg_parrot(
     * three.
     */
    {"parrot", (PyCFunction)keywdarg_parrot, METH_VARARGS | MET
     "Print a lovely skit to standard output."},
    {NULL, NULL, 0, NULL} /* sentinel */
};

```

```

void
initkeywdarg(void)
{
    /* Create the module and add the functions */
    Py_InitModule("keywdarg", keywdarg_methods);
}

```

1.9. Building Arbitrary Values

This function is the counterpart to `PyArg_ParseTuple()`. It is declared as follows:

```
PyObject *Py_BuildValue(char *format, ...);
```

It recognizes a set of format units similar to the ones recognized by `PyArg_ParseTuple()`, but the arguments (which are input to the function, not output) must not be pointers, just values. It returns a new Python object, suitable for returning from a C function called from Python.

One difference with `PyArg_ParseTuple()`: while the latter requires its first argument to be a tuple (since Python argument lists are always represented as tuples internally), `Py_BuildValue()` does not always build a tuple. It builds a tuple only if its format string contains two or more format units. If the format string is empty, it returns `None`; if it contains exactly one format unit, it returns whatever object is described by that format unit. To force it to return a tuple of size 0 or one, parenthesize the format string.

Examples (to the left the call, to the right the resulting Python value):

```
Py_BuildValue("")           None
Py_BuildValue("i", 123)     123
Py_BuildValue("iii", 123, 456, 789) (123, 456, 789)
Py_BuildValue("s", "hello") 'hello'
Py_BuildValue("y", "hello") b'hello'
Py_BuildValue("ss", "hello", "world") ('hello', 'world')
Py_BuildValue("s#", "hello", 4) 'hell'
Py_BuildValue("y#", "hello", 4) b'hell'
Py_BuildValue("()")        ()
Py_BuildValue("(i)", 123)  (123,)
Py_BuildValue("(ii)", 123, 456) (123, 456)
Py_BuildValue("(i,i)", 123, 456) (123, 456)
```

```
Py_BuildValue("[i,i]", 123, 456)      [123, 456]
Py_BuildValue("{s:i,s:i}",
               "abc", 123, "def", 456)  {'abc': 123, 'def': 45
Py_BuildValue("((ii)(ii)) (ii)",
               1, 2, 3, 4, 5, 6)      (((1, 2), (3, 4)), (5,
```

1.10. Reference Counts

In languages like C or C++, the programmer is responsible for dynamic allocation and deallocation of memory on the heap. In C, this is done using the functions `malloc()` and `free()`. In C++, the operators `new` and `delete` are used with essentially the same meaning and we'll restrict the following discussion to the C case.

Every block of memory allocated with `malloc()` should eventually be returned to the pool of available memory by exactly one call to `free()`. It is important to call `free()` at the right time. If a block's address is forgotten but `free()` is not called for it, the memory it occupies cannot be reused until the program terminates. This is called a *memory leak*. On the other hand, if a program calls `free()` for a block and then continues to use the block, it creates a conflict with re-use of the block through another `malloc()` call. This is called *using freed memory*. It has the same bad consequences as referencing uninitialized data — core dumps, wrong results, mysterious crashes.

Common causes of memory leaks are unusual paths through the code. For instance, a function may allocate a block of memory, do some calculation, and then free the block again. Now a change in the requirements for the function may add a test to the calculation that detects an error condition and can return prematurely from the function. It's easy to forget to free the allocated memory block when taking this premature exit, especially when it is added later to the code. Such leaks, once introduced, often go undetected for a long time: the error exit is taken only in a small fraction of all calls, and most modern machines have plenty of virtual memory, so the leak only becomes apparent in a long-running process that uses the leaking function frequently. Therefore, it's important to prevent leaks

from happening by having a coding convention or strategy that minimizes this kind of errors.

Since Python makes heavy use of `malloc()` and `free()`, it needs a strategy to avoid memory leaks as well as the use of freed memory. The chosen method is called *reference counting*. The principle is simple: every object contains a counter, which is incremented when a reference to the object is stored somewhere, and which is decremented when a reference to it is deleted. When the counter reaches zero, the last reference to the object has been deleted and the object is freed.

An alternative strategy is called *automatic garbage collection*. (Sometimes, reference counting is also referred to as a garbage collection strategy, hence my use of “automatic” to distinguish the two.) The big advantage of automatic garbage collection is that the user doesn’t need to call `free()` explicitly. (Another claimed advantage is an improvement in speed or memory usage — this is no hard fact however.) The disadvantage is that for C, there is no truly portable automatic garbage collector, while reference counting can be implemented portably (as long as the functions `malloc()` and `free()` are available — which the C Standard guarantees). Maybe some day a sufficiently portable automatic garbage collector will be available for C. Until then, we’ll have to live with reference counts.

While Python uses the traditional reference counting implementation, it also offers a cycle detector that works to detect reference cycles. This allows applications to not worry about creating direct or indirect circular references; these are the weakness of garbage collection implemented using only reference counting. Reference cycles consist of objects which contain (possibly indirect) references to themselves, so that each object in the cycle has a reference count which is non-zero. Typical reference counting implementations are not able to reclaim the memory belonging to any objects in a

reference cycle, or referenced from the objects in the cycle, even though there are no further references to the cycle itself.

The cycle detector is able to detect garbage cycles and can reclaim them so long as there are no finalizers implemented in Python (`__del__()` methods). When there are such finalizers, the detector exposes the cycles through the `gc` module (specifically, the `garbage` variable in that module). The `gc` module also exposes a way to run the detector (the `collect()` function), as well as configuration interfaces and the ability to disable the detector at runtime. The cycle detector is considered an optional component; though it is included by default, it can be disabled at build time using the `--without-cycle-gc` option to the `configure` script on Unix platforms (including Mac OS X). If the cycle detector is disabled in this way, the `gc` module will not be available.

1.10.1. Reference Counting in Python

There are two macros, `Py_INCREF(x)` and `Py_DECREF(x)`, which handle the incrementing and decrementing of the reference count. `Py_DECREF()` also frees the object when the count reaches zero. For flexibility, it doesn't call `free()` directly — rather, it makes a call through a function pointer in the object's *type object*. For this purpose (and others), every object also contains a pointer to its type object.

The big question now remains: when to use `Py_INCREF(x)` and `Py_DECREF(x)`? Let's first introduce some terms. Nobody "owns" an object; however, you can *own a reference* to an object. An object's reference count is now defined as the number of owned references to it. The owner of a reference is responsible for calling `Py_DECREF()` when the reference is no longer needed. Ownership of a reference can be transferred. There are three ways to dispose of an owned

reference: pass it on, store it, or call `Py_DECREF()`. Forgetting to dispose of an owned reference creates a memory leak.

It is also possible to *borrow* [2] a reference to an object. The borrower of a reference should not call `Py_DECREF()`. The borrower must not hold on to the object longer than the owner from which it was borrowed. Using a borrowed reference after the owner has disposed of it risks using freed memory and should be avoided completely. [3]

The advantage of borrowing over owning a reference is that you don't need to take care of disposing of the reference on all possible paths through the code — in other words, with a borrowed reference you don't run the risk of leaking when a premature exit is taken. The disadvantage of borrowing over owning is that there are some subtle situations where in seemingly correct code a borrowed reference can be used after the owner from which it was borrowed has in fact disposed of it.

A borrowed reference can be changed into an owned reference by calling `Py_INCREF()`. This does not affect the status of the owner from which the reference was borrowed — it creates a new owned reference, and gives full owner responsibilities (the new owner must dispose of the reference properly, as well as the previous owner).

1.10.2. Ownership Rules

Whenever an object reference is passed into or out of a function, it is part of the function's interface specification whether ownership is transferred with the reference or not.

Most functions that return a reference to an object pass on ownership with the reference. In particular, all functions whose function it is to create a new object, such as `PyLong_FromLong()` and

`Py_BuildValue()`, pass ownership to the receiver. Even if the object is not actually new, you still receive ownership of a new reference to that object. For instance, `PyLong_FromLong()` maintains a cache of popular values and can return a reference to a cached item.

Many functions that extract objects from other objects also transfer ownership with the reference, for instance `PyObject_GetAttrString()`. The picture is less clear, here, however, since a few common routines are exceptions: `PyTuple_GetItem()`, `PyList_GetItem()`, `PyDict_GetItem()`, and `PyDict_GetItemString()` all return references that you borrow from the tuple, list or dictionary.

The function `PyImport_AddModule()` also returns a borrowed reference, even though it may actually create the object it returns: this is possible because an owned reference to the object is stored in `sys.modules`.

When you pass an object reference into another function, in general, the function borrows the reference from you — if it needs to store it, it will use `Py_INCREF()` to become an independent owner. There are exactly two important exceptions to this rule: `PyTuple_SetItem()` and `PyList_SetItem()`. These functions take over ownership of the item passed to them — even if they fail! (Note that `PyDict_SetItem()` and friends don't take over ownership — they are “normal.”)

When a C function is called from Python, it borrows references to its arguments from the caller. The caller owns a reference to the object, so the borrowed reference's lifetime is guaranteed until the function returns. Only when such a borrowed reference must be stored or passed on, it must be turned into an owned reference by calling `Py_INCREF()`.

The object reference returned from a C function that is called from Python must be an owned reference — ownership is transferred

from the function to its caller.

1.10.3. Thin Ice

There are a few situations where seemingly harmless use of a borrowed reference can lead to problems. These all have to do with implicit invocations of the interpreter, which can cause the owner of a reference to dispose of it.

The first and most important case to know about is using `Py_DECREF()` on an unrelated object while borrowing a reference to a list item. For instance:

```
void
bug(PyObject *list)
{
    PyObject *item = PyList_GetItem(list, 0);

    PyList_SetItem(list, 1, PyLong_FromLong(0L));
    PyObject_Print(item, stdout, 0); /* BUG! */
}
```

This function first borrows a reference to `list[0]`, then replaces `list[1]` with the value `0`, and finally prints the borrowed reference. Looks harmless, right? But it's not!

Let's follow the control flow into `PyList_SetItem()`. The list owns references to all its items, so when item 1 is replaced, it has to dispose of the original item 1. Now let's suppose the original item 1 was an instance of a user-defined class, and let's further suppose that the class defined a `__del__()` method. If this class instance has a reference count of 1, disposing of it will call its `__del__()` method.

Since it is written in Python, the `__del__()` method can execute arbitrary Python code. Could it perhaps do something to invalidate the reference to `item` in `bug()`? You bet! Assuming that the list

passed into `bug()` is accessible to the `__del__()` method, it could execute a statement to the effect of `del list[0]`, and assuming this was the last reference to that object, it would free the memory associated with it, thereby invalidating `item`.

The solution, once you know the source of the problem, is easy: temporarily increment the reference count. The correct version of the function reads:

```
void
no_bug(PyObject *list)
{
    PyObject *item = PyList_GetItem(list, 0);

    Py_INCREF(item);
    PyList_SetItem(list, 1, PyLong_FromLong(0L));
    PyObject_Print(item, stdout, 0);
    Py_DECREF(item);
}
```

This is a true story. An older version of Python contained variants of this bug and someone spent a considerable amount of time in a C debugger to figure out why his `__del__()` methods would fail...

The second case of problems with a borrowed reference is a variant involving threads. Normally, multiple threads in the Python interpreter can't get in each other's way, because there is a global lock protecting Python's entire object space. However, it is possible to temporarily release this lock using the macro `Py_BEGIN_ALLOW_THREADS`, and to re-acquire it using `Py_END_ALLOW_THREADS`. This is common around blocking I/O calls, to let other threads use the processor while waiting for the I/O to complete. Obviously, the following function has the same problem as the previous one:

```
void
bug(PyObject *list)
```

```
{
    PyObject *item = PyList_GetItem(list, 0);
    Py_BEGIN_ALLOW_THREADS
    ...some blocking I/O call...
    Py_END_ALLOW_THREADS
    PyObject_Print(item, stdout, 0); /* BUG! */
}
```

1.10.4. NULL Pointers

In general, functions that take object references as arguments do not expect you to pass them *NULL* pointers, and will dump core (or cause later core dumps) if you do so. Functions that return object references generally return *NULL* only to indicate that an exception occurred. The reason for not testing for *NULL* arguments is that functions often pass the objects they receive on to other function — if each function were to test for *NULL*, there would be a lot of redundant tests and the code would run more slowly.

It is better to test for *NULL* only at the “source:” when a pointer that may be *NULL* is received, for example, from `malloc()` or from a function that may raise an exception.

The macros `Py_INCREF()` and `Py_DECREF()` do not check for *NULL* pointers — however, their variants `Py_XINCREF()` and `Py_XDECREF()` do.

The macros for checking for a particular object type (`Pytype_Check()`) don’t check for *NULL* pointers — again, there is much code that calls several of these in a row to test an object against various different expected types, and this would generate redundant tests. There are no variants with *NULL* checking.

The C function calling mechanism guarantees that the argument list passed to C functions (`args` in the examples) is never *NULL* — in fact it guarantees that it is always a tuple. [4]

It is a severe error to ever let a *NULL* pointer “escape” to the Python user.

1.11. Writing Extensions in C++

It is possible to write extension modules in C++. Some restrictions apply. If the main program (the Python interpreter) is compiled and linked by the C compiler, global or static objects with constructors cannot be used. This is not a problem if the main program is linked by the C++ compiler. Functions that will be called by the Python interpreter (in particular, module initialization functions) have to be declared using `extern "C"`. It is unnecessary to enclose the Python header files in `extern "C" {...}` — they use this form already if the symbol `__cplusplus` is defined (all recent C++ compilers define this symbol).

1.12. Providing a C API for an Extension Module

Many extension modules just provide new functions and types to be used from Python, but sometimes the code in an extension module can be useful for other extension modules. For example, an extension module could implement a type “collection” which works like lists without order. Just like the standard Python list type has a C API which permits extension modules to create and manipulate lists, this new collection type should have a set of C functions for direct manipulation from other extension modules.

At first sight this seems easy: just write the functions (without declaring them `static`, of course), provide an appropriate header file, and document the C API. And in fact this would work if all extension modules were always linked statically with the Python interpreter. When modules are used as shared libraries, however, the symbols defined in one module may not be visible to another module. The details of visibility depend on the operating system; some systems use one global namespace for the Python interpreter and all extension modules (Windows, for example), whereas others require an explicit list of imported symbols at module link time (AIX is one example), or offer a choice of different strategies (most Unices). And even if symbols are globally visible, the module whose functions one wishes to call might not have been loaded yet!

Portability therefore requires not to make any assumptions about symbol visibility. This means that all symbols in extension modules should be declared `static`, except for the module’s initialization function, in order to avoid name clashes with other extension modules (as discussed in section *The Module’s Method Table and Initialization Function*). And it means that symbols that *should* be accessible from other extension modules must be exported in a

different way.

Python provides a special mechanism to pass C-level information (pointers) from one extension module to another one: Capsules. A Capsule is a Python data type which stores a pointer (`void *`). Capsules can only be created and accessed via their C API, but they can be passed around like any other Python object. In particular, they can be assigned to a name in an extension module's namespace. Other extension modules can then import this module, retrieve the value of this name, and then retrieve the pointer from the Capsule.

There are many ways in which Capsules can be used to export the C API of an extension module. Each function could get its own Capsule, or all C API pointers could be stored in an array whose address is published in a Capsule. And the various tasks of storing and retrieving the pointers can be distributed in different ways between the module providing the code and the client modules.

Whichever method you choose, it's important to name your Capsules properly. The function `PyCapsule_New()` takes a name parameter (`const char *`); you're permitted to pass in a `NULL` name, but we strongly encourage you to specify a name. Properly named Capsules provide a degree of runtime type-safety; there is no feasible way to tell one unnamed Capsule from another.

In particular, Capsules used to expose C APIs should be given a name following this convention:

```
modulename.attributename
```

The convenience function `PyCapsule_Import()` makes it easy to load a C API provided via a Capsule, but only if the Capsule's name matches this convention. This behavior gives C API users a high degree of certainty that the Capsule they load contains the correct C

API.

The following example demonstrates an approach that puts most of the burden on the writer of the exporting module, which is appropriate for commonly used library modules. It stores all C API pointers (just one in the example!) in an array of `void` pointers which becomes the value of a Capsule. The header file corresponding to the module provides a macro that takes care of importing the module and retrieving its C API pointers; client modules only have to call this macro before accessing the C API.

The exporting module is a modification of the `spam` module from section *A Simple Example*. The function `spam.system()` does not call the C library function `system()` directly, but a function `PySpam_System()`, which would of course do something more complicated in reality (such as adding “spam” to every command). This function `PySpam_System()` is also exported to other extension modules.

The function `PySpam_System()` is a plain C function, declared `static` like everything else:

```
static int
PySpam_System(const char *command)
{
    return system(command);
}
```

The function `spam_system()` is modified in a trivial way:

```
static PyObject *
spam_system(PyObject *self, PyObject *args)
{
    const char *command;
    int sts;

    if (!PyArg_ParseTuple(args, "s", &command))
```

```
        return NULL;
    sts = PySpam_System(command);
    return PyLong_FromLong(sts);
}
```

In the beginning of the module, right after the line

```
#include "Python.h"
```

two more lines must be added:

```
#define SPAM_MODULE
#include "spammodule.h"
```

The `#define` is used to tell the header file that it is being included in the exporting module, not a client module. Finally, the module's initialization function must take care of initializing the C API pointer array:

```
PyMODINIT_FUNC
PyInit_spam(void)
{
    PyObject *m;
    static void *PySpam_API[PySpam_API_pointers];
    PyObject *c_api_object;

    m = PyModule_Create(&spammodule);
    if (m == NULL)
        return NULL;

    /* Initialize the C API pointer array */
    PySpam_API[PySpam_System_NUM] = (void *)PySpam_System;

    /* Create a Capsule containing the API pointer array's address */
    c_api_object = PyCapsule_New((void *)PySpam_API, "spam._C_API", NULL);

    if (c_api_object != NULL)
        PyModule_AddObject(m, "_C_API", c_api_object);
    return m;
}
```

Note that `PySpam_API` is declared `static`; otherwise the pointer array would disappear when `PyInit_spam()` terminates!

The bulk of the work is in the header file `spammodule.h`, which looks like this:

```
#ifndef Py_SPAMMODULE_H
#define Py_SPAMMODULE_H
#ifdef __cplusplus
extern "C" {
#endif

/* Header file for spammodule */

/* C API functions */
#define PySpam_System_NUM 0
#define PySpam_System_RETURN int
#define PySpam_System_PROTO (const char *command)

/* Total number of C API pointers */
#define PySpam_API_pointers 1

#ifdef SPAM_MODULE
/* This section is used when compiling spammodule.c */

static PySpam_System_RETURN PySpam_System PySpam_System_PROTO;

#else
/* This section is used in modules that use spammodule's API */

static void **PySpam_API;

#define PySpam_System \
    (*(PySpam_System_RETURN (*)(*)PySpam_System_PROTO) PySpam_API[PyS

/* Return -1 on error, 0 on success.
 * PyCapsule_Import will set an exception if there's an error.
 */
static int
import_spam(void)
{
    PySpam_API = (void **)PyCapsule_Import("spam._C_API", 0);
    return (PySpam_API != NULL) ? 0 : -1;
}
}
```

```

#endif

#ifdef __cplusplus
}
#endif

#endif /* !defined(Py_SPAMMODULE_H) */

```

All that a client module must do in order to have access to the function `PySpam_System()` is to call the function (or rather macro) `import_spam()` in its initialization function:

```

PyMODINIT_FUNC
PyInit_client(void)
{
    PyObject *m;

    m = PyModule_Create(&clientmodule);
    if (m == NULL)
        return NULL;
    if (import_spam() < 0)
        return NULL;
    /* additional initialization can happen here */
    return m;
}

```

The main disadvantage of this approach is that the file `spammodule.h` is rather complicated. However, the basic structure is the same for each function that is exported, so it has to be learned only once.

Finally it should be mentioned that Capsules offer additional functionality, which is especially useful for memory allocation and deallocation of the pointer stored in a Capsule. The details are described in the Python/C API Reference Manual in the section [Capsules](#) and in the implementation of Capsules (files `Include/pycapsule.h` and `objects/pycapsule.c` in the Python source code distribution).

Footnotes

- [1] An interface for this function already exists in the standard module `os` — it was chosen as a simple and straightforward example.
- [2] The metaphor of “borrowing” a reference is not completely correct: the owner still has a copy of the reference.
- [3] Checking that the reference count is at least 1 **does not work** — the reference count itself could be in freed memory and may thus be reused for another object!
- [4] These guarantees don’t hold when you use the “old” style calling convention — this is still found in much existing code.

2. Defining New Types

As mentioned in the last chapter, Python allows the writer of an extension module to define new types that can be manipulated from Python code, much like strings and lists in core Python.

This is not hard; the code for all extension types follows a pattern, but there are some details that you need to understand before you can get started.

2.1. The Basics

The Python runtime sees all Python objects as variables of type `PyObject*`. A `PyObject` is not a very magnificent object - it just contains the refcount and a pointer to the object's "type object". This is where the action is; the type object determines which (C) functions get called when, for instance, an attribute gets looked up on an object or it is multiplied by another object. These C functions are called "type methods" to distinguish them from things like `[].append` (which we call "object methods").

So, if you want to define a new object type, you need to create a new type object.

This sort of thing can only be explained by example, so here's a minimal, but complete, module that defines a new type:

```
#include <Python.h>

typedef struct {
    PyObject_HEAD
    /* Type-specific fields go here. */
} noddy_NoddyObject;

static PyTypeObject noddy_NoddyType = {
    PyVarObject_HEAD_INIT(NULL, 0)
    "noddy.Noddy",          /* tp_name */
    sizeof(noddy_NoddyObject), /* tp_basicsize */
    0,                      /* tp_itemsize */
    0,                      /* tp_dealloc */
    0,                      /* tp_print */
    0,                      /* tp_getattr */
    0,                      /* tp_setattr */
    0,                      /* tp_reserved */
    0,                      /* tp_repr */
    0,                      /* tp_as_number */
    0,                      /* tp_as_sequence */
    0,                      /* tp_as_mapping */
    0,                      /* tp_hash */
```

```

    0,                /* tp_call */
    0,                /* tp_str */
    0,                /* tp_getattro */
    0,                /* tp_setattro */
    0,                /* tp_as_buffer */
    Py_TPFLAGS_DEFAULT, /* tp_flags */
    "Noddy objects", /* tp_doc */
};

static PyModuleDef noddymodule = {
    PyModuleDef_HEAD_INIT,
    "noddy",
    "Example module that creates an extension type.",
    -1,
    NULL, NULL, NULL, NULL, NULL
};

PyMODINIT_FUNC
PyInit_noddy(void)
{
    PyObject* m;

    noddy_NoddyType.tp_new = PyType_GenericNew;
    if (PyType_Ready(&noddy_NoddyType) < 0)
        return NULL;

    m = PyModule_Create(&noddymodule);
    if (m == NULL)
        return NULL;

    Py_INCREF(&noddy_NoddyType);
    PyModule_AddObject(m, "Noddy", (PyObject *)&noddy_NoddyType
    return m;
}

```

Now that's quite a bit to take in at once, but hopefully bits will seem familiar from the last chapter.

The first bit that will be new is:

```

typedef struct {
    PyObject_HEAD
} noddy_NoddyObject;

```

This is what a Noddy object will contain—in this case, nothing more than every Python object contains, namely a refcount and a pointer to a type object. These are the fields the `PyObject_HEAD` macro brings in. The reason for the macro is to standardize the layout and to enable special debugging fields in debug builds. Note that there is no semicolon after the `PyObject_HEAD` macro; one is included in the macro definition. Be wary of adding one by accident; it's easy to do from habit, and your compiler might not complain, but someone else's probably will! (On Windows, MSVC is known to call this an error and refuse to compile the code.)

For contrast, let's take a look at the corresponding definition for standard Python floats:

```
typedef struct {
    PyObject_HEAD
    double ob_fval;
} PyFloatObject;
```

Moving on, we come to the crunch — the type object.

```
static PyTypeObject noddy_NoddyType = {
    PyVarObject_HEAD_INIT(NULL, 0)
    "noddy.Noddy",          /* tp_name */
    sizeof(noddy_NoddyObject), /* tp_basicsize */
    0,                      /* tp_itemsize */
    0,                      /* tp_dealloc */
    0,                      /* tp_print */
    0,                      /* tp_getattr */
    0,                      /* tp_setattr */
    0,                      /* tp_reserved */
    0,                      /* tp_repr */
    0,                      /* tp_as_number */
    0,                      /* tp_as_sequence */
    0,                      /* tp_as_mapping */
    0,                      /* tp_hash */
    0,                      /* tp_call */
    0,                      /* tp_str */
    0,                      /* tp_getattro */
    0,                      /* tp_setattro */
    0,                      /* tp_as_buffer */
```

```
Py_TPFLAGS_DEFAULT,          /* tp_flags */
"Noddy objects",             /* tp_doc */
};
```

Now if you go and look up the definition of `PyObject` in `object.h` you'll see that it has many more fields than the definition above. The remaining fields will be filled with zeros by the C compiler, and it's common practice to not specify them explicitly unless you need them.

This is so important that we're going to pick the top of it apart still further:

```
PyVarObject_HEAD_INIT(NULL, 0)
```

This line is a bit of a wart; what we'd like to write is:

```
PyVarObject_HEAD_INIT(&PyType_Type, 0)
```

as the type of a type object is "type", but this isn't strictly conforming C and some compilers complain. Fortunately, this member will be filled in for us by `PyType_Ready()`.

```
"noddy.Noddy",              /* tp_name */
```

The name of our type. This will appear in the default textual representation of our objects and in some error messages, for example:

```
>>> "" + noddy.new_noddy()
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
TypeError: cannot add type "noddy.Noddy" to string
```

Note that the name is a dotted name that includes both the module name and the name of the type within the module. The module in this case is `noddy` and the type is `Noddy`, so we set the type name to

`noddy.Noddy`.

```
sizeof(noddy_NoddyObject), /* tp_basicsize */
```

This is so that Python knows how much memory to allocate when you call `PyObject_New()`.

Note: If you want your type to be subclassable from Python, and your type has the same `tp_basicsize` as its base type, you may have problems with multiple inheritance. A Python subclass of your type will have to list your type first in its `__bases__`, or else it will not be able to call your type's `__new__()` method without getting an error. You can avoid this problem by ensuring that your type has a larger value for `tp_basicsize` than its base type does. Most of the time, this will be true anyway, because either your base type will be `object`, or else you will be adding data members to your base type, and therefore increasing its size.

```
0, /* tp_itemsize */
```

This has to do with variable length objects like lists and strings. Ignore this for now.

Skipping a number of type methods that we don't provide, we set the class flags to `Py_TPFLAGS_DEFAULT`.

```
Py_TPFLAGS_DEFAULT, /* tp_flags */
```

All types should include this constant in their flags. It enables all of the members defined by the current version of Python.

We provide a doc string for the type in `tp_doc`.

```
"Noddy objects", /* tp_doc */
```

Now we get into the type methods, the things that make your objects different from the others. We aren't going to implement any of these in this version of the module. We'll expand this example later to have more interesting behavior.

For now, all we want to be able to do is to create new **Noddy** objects. To enable object creation, we have to provide a `tp_new` implementation. In this case, we can just use the default implementation provided by the API function `PyType_GenericNew()`. We'd like to just assign this to the `tp_new` slot, but we can't, for portability sake. On some platforms or compilers, we can't statically initialize a structure member with a function defined in another C module, so, instead, we'll assign the `tp_new` slot in the module initialization function just before calling `PyType_Ready()`:

```
noddy_NoddyType.tp_new = PyType_GenericNew;  
if (PyType_Ready(&noddy_NoddyType) < 0)  
    return;
```

All the other type methods are `NULL`, so we'll go over them later — that's for a later section!

Everything else in the file should be familiar, except for some code in `PyInit_noddy()`:

```
if (PyType_Ready(&noddy_NoddyType) < 0)  
    return;
```

This initializes the **Noddy** type, filling in a number of members, including `ob_type` that we initially set to `NULL`.

```
PyModule_AddObject(m, "Noddy", (PyObject *)&noddy_NoddyType);
```

This adds the type to the module dictionary. This allows us to create **Noddy** instances by calling the **Noddy** class:

```
>>> import noddy
>>> mynoddy = noddy.Noddy()
```

That's it! All that remains is to build it; put the above code in a file called `noddy.c` and

```
from distutils.core import setup, Extension
setup(name="noddy", version="1.0",
      ext_modules=[Extension("noddy", ["noddy.c"])])
```

in a file called `setup.py`; then typing

```
$ python setup.py build
```

at a shell should produce a file `noddy.so` in a subdirectory; move to that directory and fire up Python — you should be able to `import noddy` and play around with Noddy objects.

That wasn't so hard, was it?

Of course, the current Noddy type is pretty uninteresting. It has no data and doesn't do anything. It can't even be subclassed.

2.1.1. Adding data and methods to the Basic example

Let's expand the basic example to add some data and methods. Let's also make the type usable as a base class. We'll create a new module, `noddy2` that adds these capabilities:

```
#include <Python.h>
#include "structmember.h"

typedef struct {
    PyObject_HEAD
    PyObject *first; /* first name */
    PyObject *last; /* last name */
```

```

        &self->number))

    return -1;

    if (first) {
        tmp = self->first;
        Py_INCREF(first);
        self->first = first;
        Py_XDECREF(tmp);
    }

    if (last) {
        tmp = self->last;
        Py_INCREF(last);
        self->last = last;
        Py_XDECREF(tmp);
    }

    return 0;
}

static PyMemberDef Noddy_members[] = {
    {"first", T_OBJECT_EX, offsetof(Noddy, first), 0,
     "first name"},
    {"last", T_OBJECT_EX, offsetof(Noddy, last), 0,
     "last name"},
    {"number", T_INT, offsetof(Noddy, number), 0,
     "noddy number"},
    {NULL} /* Sentinel */
};

static PyObject *
Noddy_name(Noddy* self)
{
    static PyObject *format = NULL;
    PyObject *args, *result;

    if (format == NULL) {
        format = PyUnicode_FromString("%s %s");
        if (format == NULL)
            return NULL;
    }

    if (self->first == NULL) {
        PyErr_SetString(PyExc_AttributeError, "first");
        return NULL;
    }
}

```

```

    if (self->last == NULL) {
        PyErr_SetString(PyExc_AttributeError, "last");
        return NULL;
    }

    args = Py_BuildValue("OO", self->first, self->last);
    if (args == NULL)
        return NULL;

    result = PyUnicode_Format(format, args);
    Py_DECREF(args);

    return result;
}

static PyMethodDef Noddy_methods[] = {
    {"name", (PyCFunction)Noddy_name, METH_NOARGS,
     "Return the name, combining the first and last name"},
    {NULL} /* Sentinel */
};

static PyObject NoddyType = {
    PyVarObject_HEAD_INIT(NULL, 0)
    "noddy.Noddy", /* tp_name */
    sizeof(Noddy), /* tp_basicsize */
    0, /* tp_itemsize */
    (destructor)Noddy_dealloc, /* tp_dealloc */
    0, /* tp_print */
    0, /* tp_getattr */
    0, /* tp_setattr */
    0, /* tp_reserved */
    0, /* tp_repr */
    0, /* tp_as_number */
    0, /* tp_as_sequence */
    0, /* tp_as_mapping */
    0, /* tp_hash */
    0, /* tp_call */
    0, /* tp_str */
    0, /* tp_getattro */
    0, /* tp_setattro */
    0, /* tp_as_buffer */
    Py_TPFLAGS_DEFAULT |
        Py_TPFLAGS_BASETYPE, /* tp_flags */
    "Noddy objects", /* tp_doc */
    0, /* tp_traverse */

```

```

0, /* tp_clear */
0, /* tp_richcompare */
0, /* tp_weaklistoffset */
0, /* tp_iter */
0, /* tp_iternext */
Noddy_methods, /* tp_methods */
Noddy_members, /* tp_members */
0, /* tp_getset */
0, /* tp_base */
0, /* tp_dict */
0, /* tp_descr_get */
0, /* tp_descr_set */
0, /* tp_dictoffset */
(initproc)Noddy_init, /* tp_init */
0, /* tp_alloc */
Noddy_new, /* tp_new */
};

static PyModuleDef noddy2module = {
    PyModuleDef_HEAD_INIT,
    "noddy2",
    "Example module that creates an extension type.",
    -1,
    NULL, NULL, NULL, NULL, NULL
};

PyMODINIT_FUNC
PyInit_noddy2(void)
{
    PyObject* m;

    if (PyType_Ready(&NoddyType) < 0)
        return NULL;

    m = PyModule_Create(&noddy2module);
    if (m == NULL)
        return NULL;

    Py_INCREF(&NoddyType);
    PyModule_AddObject(m, "Noddy", (PyObject *)&NoddyType);
    return m;
}

```

This version of the module has a number of changes.

We've added an extra include:

```
#include <structmember.h>
```

This include provides declarations that we use to handle attributes, as described a bit later.

The name of the **Noddy** object structure has been shortened to **Noddy**. The type object name has been shortened to **NoddyType**.

The **noddy** type now has three data attributes, *first*, *last*, and *number*. The *first* and *last* variables are Python strings containing first and last names. The *number* attribute is an integer.

The object structure is updated accordingly:

```
typedef struct {
    PyObject_HEAD
    PyObject *first;
    PyObject *last;
    int number;
} Noddy;
```

Because we now have data to manage, we have to be more careful about object allocation and deallocation. At a minimum, we need a deallocation method:

```
static void
Noddy_dealloc(Noddy* self)
{
    Py_XDECREF(self->first);
    Py_XDECREF(self->last);
    Py_TYPE(self)->tp_free((PyObject*)self);
}
```

which is assigned to the **tp_dealloc** member:

```
(destructor)Noddy_dealloc, /*tp_dealloc*/
```

This method decrements the reference counts of the two Python attributes. We use `Py_XDECREF()` here because the `first` and `last` members could be `NULL`. It then calls the `tp_free` member of the object's type to free the object's memory. Note that the object's type might not be `NoddyType`, because the object may be an instance of a subclass.

We want to make sure that the first and last names are initialized to empty strings, so we provide a new method:

```
static PyObject *
Noddy_new(PyTypeObject *type, PyObject *args, PyObject *kwds)
{
    Noddy *self;

    self = (Noddy *)type->tp_alloc(type, 0);
    if (self != NULL) {
        self->first = PyString_FromString("");
        if (self->first == NULL)
        {
            Py_DECREF(self);
            return NULL;
        }

        self->last = PyString_FromString("");
        if (self->last == NULL)
        {
            Py_DECREF(self);
            return NULL;
        }

        self->number = 0;
    }

    return (PyObject *)self;
}
```

and install it in the `tp_new` member:

```
Noddy_new, /* tp_new */
```

The `new` member is responsible for creating (as opposed to initializing) objects of the type. It is exposed in Python as the `__new__()` method. See the paper titled “Unifying types and classes in Python” for a detailed discussion of the `__new__()` method. One reason to implement a new method is to assure the initial values of instance variables. In this case, we use the new method to make sure that the initial values of the members `first` and `last` are not `NULL`. If we didn’t care whether the initial values were `NULL`, we could have used `PyType_GenericNew()` as our new method, as we did before. `PyType_GenericNew()` initializes all of the instance variable members to `NULL`.

The new method is a static method that is passed the type being instantiated and any arguments passed when the type was called, and that returns the new object created. New methods always accept positional and keyword arguments, but they often ignore the arguments, leaving the argument handling to initializer methods. Note that if the type supports subclassing, the type passed may not be the type being defined. The new method calls the `tp_alloc` slot to allocate memory. We don’t fill the `tp_alloc` slot ourselves. Rather `PyType_Ready()` fills it for us by inheriting it from our base class, which is `object` by default. Most types use the default allocation.

Note: If you are creating a co-operative `tp_new` (one that calls a base type’s `tp_new` or `__new__()`), you must *not* try to determine what method to call using method resolution order at runtime. Always statically determine what type you are going to call, and call its `tp_new` directly, or via `type->tp_base->tp_new`. If you do not do this, Python subclasses of your type that also inherit from other Python-defined classes may not work correctly. (Specifically, you may not be able to create instances of such subclasses without getting a `TypeError`.)

We provide an initialization function:

```
static int
Noddy_init(Noddy *self, PyObject *args, PyObject *kwds)
{
    PyObject *first=NULL, *last=NULL, *tmp;

    static char *kwlist[] = {"first", "last", "number", NULL};

    if (! PyArg_ParseTupleAndKeywords(args, kwds, "|00i", kwlist,
                                       &first, &last,
                                       &self->number))

        return -1;

    if (first) {
        tmp = self->first;
        Py_INCREF(first);
        self->first = first;
        Py_XDECREF(tmp);
    }

    if (last) {
        tmp = self->last;
        Py_INCREF(last);
        self->last = last;
        Py_XDECREF(tmp);
    }

    return 0;
}
```

by filling the `tp_init` slot.

```
(initproc)Noddy_init,      /* tp_init */
```

The `tp_init` slot is exposed in Python as the `__init__()` method. It is used to initialize an object after it's created. Unlike the `new` method, we can't guarantee that the initializer is called. The initializer isn't called when unpickling objects and it can be overridden. Our initializer accepts arguments to provide initial values for our instance. Initializers always accept positional and keyword arguments.

Initializers can be called multiple times. Anyone can call the `__init__()` method on our objects. For this reason, we have to be extra careful when assigning the new values. We might be tempted, for example to assign the `first` member like this:

```
if (first) {
    Py_XDECREF(self->first);
    Py_INCREF(first);
    self->first = first;
}
```

But this would be risky. Our type doesn't restrict the type of the `first` member, so it could be any kind of object. It could have a destructor that causes code to be executed that tries to access the `first` member. To be paranoid and protect ourselves against this possibility, we almost always reassign members before decrementing their reference counts. When don't we have to do this?

- when we absolutely know that the reference count is greater than 1
- when we know that deallocation of the object [1] will not cause any calls back into our type's code
- when decrementing a reference count in a `tp_dealloc` handler when garbage-collections is not supported [2]

We want to expose our instance variables as attributes. There are a number of ways to do that. The simplest way is to define member definitions:

```
static PyMemberDef Noddy_members[] = {
    {"first", T_OBJECT_EX, offsetof(Noddy, first), 0,
     "first name"},
    {"last", T_OBJECT_EX, offsetof(Noddy, last), 0,
     "last name"},
    {"number", T_INT, offsetof(Noddy, number), 0,
     "noddy number"},
    {NULL} /* Sentinel */
};
```

and put the definitions in the `tp_members` slot:

```
Noddy_members,          /* tp_members */
```

Each member definition has a member name, type, offset, access flags and documentation string. See the [Generic Attribute Management](#) section below for details.

A disadvantage of this approach is that it doesn't provide a way to restrict the types of objects that can be assigned to the Python attributes. We expect the first and last names to be strings, but any Python objects can be assigned. Further, the attributes can be deleted, setting the C pointers to *NULL*. Even though we can make sure the members are initialized to non-*NULL* values, the members can be set to *NULL* if the attributes are deleted.

We define a single method, `name()`, that outputs the objects name as the concatenation of the first and last names.

```
static PyObject *
Noddy_name(Noddy* self)
{
    static PyObject *format = NULL;
    PyObject *args, *result;

    if (format == NULL) {
        format = PyString_FromString("%s %s");
        if (format == NULL)
            return NULL;
    }

    if (self->first == NULL) {
        PyErr_SetString(PyExc_AttributeError, "first");
        return NULL;
    }

    if (self->last == NULL) {
        PyErr_SetString(PyExc_AttributeError, "last");
        return NULL;
    }
}
```

```

args = Py_BuildValue("OO", self->first, self->last);
if (args == NULL)
    return NULL;

result = PyString_Format(format, args);
Py_DECREF(args);

return result;
}

```

The method is implemented as a C function that takes a **Noddy** (or **Noddy** subclass) instance as the first argument. Methods always take an instance as the first argument. Methods often take positional and keyword arguments as well, but in this case we don't take any and don't need to accept a positional argument tuple or keyword argument dictionary. This method is equivalent to the Python method:

```

def name(self):
    return "%s %s" % (self.first, self.last)

```

Note that we have to check for the possibility that our **first** and **last** members are *NULL*. This is because they can be deleted, in which case they are set to *NULL*. It would be better to prevent deletion of these attributes and to restrict the attribute values to be strings. We'll see how to do that in the next section.

Now that we've defined the method, we need to create an array of method definitions:

```

static PyMethodDef Noddy_methods[] = {
    {"name", (PyCFunction)Noddy_name, METH_NOARGS,
     "Return the name, combining the first and last name"},
    },
    {NULL} /* Sentinel */
};

```

and assign them to the **tp_methods** slot:

```
Noddy_methods,          /* tp_methods */
```

Note that we used the `METH_NOARGS` flag to indicate that the method is passed no arguments.

Finally, we'll make our type usable as a base class. We've written our methods carefully so far so that they don't make any assumptions about the type of the object being created or used, so all we need to do is to add the `Py_TPFLAGS_BASETYPE` to our class flag definition:

```
Py_TPFLAGS_DEFAULT | Py_TPFLAGS_BASETYPE, /*tp_flags*/
```

We rename `PyInit_noddy()` to `PyInit_noddy2()` and update the module name in the `PyModuleDef` struct.

Finally, we update our `setup.py` file to build the new module:

```
from distutils.core import setup, Extension
setup(name="noddy", version="1.0",
      ext_modules=[
          Extension("noddy", ["noddy.c"]),
          Extension("noddy2", ["noddy2.c"]),
      ])
```

2.1.2. Providing finer control over data attributes

In this section, we'll provide finer control over how the `first` and `last` attributes are set in the `Noddy` example. In the previous version of our module, the instance variables `first` and `last` could be set to non-string values or even deleted. We want to make sure that these attributes always contain strings.

```
#include <Python.h>
#include "structmember.h"

typedef struct {
```

```

PyObject_HEAD
PyObject *first;
PyObject *last;
int number;
} Noddy;

static void
Noddy_dealloc(Noddy* self)
{
    Py_XDECREF(self->first);
    Py_XDECREF(self->last);
    Py_TYPE(self)->tp_free((PyObject*)self);
}

static PyObject *
Noddy_new(PyTypeObject *type, PyObject *args, PyObject *kwds)
{
    Noddy *self;

    self = (Noddy *)type->tp_alloc(type, 0);
    if (self != NULL) {
        self->first = PyUnicode_FromString("");
        if (self->first == NULL)
        {
            Py_DECREF(self);
            return NULL;
        }

        self->last = PyUnicode_FromString("");
        if (self->last == NULL)
        {
            Py_DECREF(self);
            return NULL;
        }

        self->number = 0;
    }

    return (PyObject *)self;
}

static int
Noddy_init(Noddy *self, PyObject *args, PyObject *kwds)
{
    PyObject *first=NULL, *last=NULL, *tmp;

    static char *kwlist[] = {"first", "last", "number", NULL};

```

```

    if (! PyArg_ParseTupleAndKeywords(args, kwds, "|SSi", kwlis
                                     &first, &last,
                                     &self->number))

        return -1;

    if (first) {
        tmp = self->first;
        Py_INCREF(first);
        self->first = first;
        Py_DECREF(tmp);
    }

    if (last) {
        tmp = self->last;
        Py_INCREF(last);
        self->last = last;
        Py_DECREF(tmp);
    }

    return 0;
}

static PyMemberDef Noddy_members[] = {
    {"number", T_INT, offsetof(Noddy, number), 0,
     "noddy number"},
    {NULL} /* Sentinel */
};

static PyObject *
Noddy_getfirst(Noddy *self, void *closure)
{
    Py_INCREF(self->first);
    return self->first;
}

static int

     (getter)Noddy_getfirst, (setter)Noddy_setfirst,
     "first name",
     NULL},
    {"last",
     (getter)Noddy_getlast, (setter)Noddy_setlast,
     "last name",
     NULL},
};

```

```

    {NULL} /* Sentinel */
};

static PyObject *
Noddy_name(Noddy* self)
{
    static PyObject *format = NULL;
    PyObject *args, *result;

    if (format == NULL) {
        format = PyUnicode_FromString("%s %s");
        if (format == NULL)
            return NULL;
    }

    args = Py_BuildValue("OO", self->first, self->last);
    if (args == NULL)
        return NULL;

    result = PyUnicode_Format(format, args);
    Py_DECREF(args);

    return result;
}

static PyMethodDef Noddy_methods[] = {
    {"name", (PyCFunction)Noddy_name, METH_NOARGS,
     "Return the name, combining the first and last name"},
    {NULL} /* Sentinel */
};

static PyTypeObject NoddyType = {
    PyVarObject_HEAD_INIT(NULL, 0)
    "noddy.Noddy", /* tp_name */
    sizeof(Noddy), /* tp_basicsize */
    0, /* tp_itemsize */
    (destructor)Noddy_dealloc, /* tp_dealloc */
    0, /* tp_print */
    0, /* tp_getattr */
    0, /* tp_setattr */
    0, /* tp_reserved */
    0, /* tp_repr */
    0, /* tp_as_number */
    0, /* tp_as_sequence */
    0, /* tp_as_mapping */
    0, /* tp_hash */
};

```

```

0, /* tp_call */
0, /* tp_str */
0, /* tp_getattro */
0, /* tp_setattro */
0, /* tp_as_buffer */
Py_TPFLAGS_DEFAULT |
    Py_TPFLAGS_BASETYPE, /* tp_flags */
"Noddy objects", /* tp_doc */
0, /* tp_traverse */
0, /* tp_clear */
0, /* tp_richcompare */
0, /* tp_weaklistoffset */
0, /* tp_iter */
0, /* tp_iternext */
Noddy_methods, /* tp_methods */

Noddy_getseters, /* tp_getset */
0, /* tp_base */
0, /* tp_dict */
0, /* tp_descr_get */
0, /* tp_descr_set */
0, /* tp_dictoffset */
(initproc)Noddy_init, /* tp_init */
0, /* tp_alloc */
Noddy_new, /* tp_new */
};

```

```

static PyModuleDef noddy3module = {
    PyModuleDef_HEAD_INIT,
    "noddy3",
    "Example module that creates an extension type.",
    -1,
    NULL, NULL, NULL, NULL, NULL
};

```

```

PyMODINIT_FUNC
PyInit_noddy3(void)
{
    PyObject* m;

    if (PyType_Ready(&NoddyType) < 0)
        return NULL;

    m = PyModule_Create(&noddy3module);
    if (m == NULL)
        return NULL;
}

```

```
Py_INCREF(&NoddyType);
PyModule_AddObject(m, "Noddy", (PyObject *)&NoddyType);
return m;
}
```

To provide greater control, over the `first` and `last` attributes, we'll use custom getter and setter functions. Here are the functions for getting and setting the `first` attribute:

```
Noddy_getfirst(Noddy *self, void *closure)
{
    Py_INCREF(self->first);
    return self->first;
}

static int
Noddy_setfirst(Noddy *self, PyObject *value, void *closure)
{
    if (value == NULL) {
        PyErr_SetString(PyExc_TypeError, "Cannot delete the first attribute");
        return -1;
    }

    if (!PyString_Check(value)) {
        PyErr_SetString(PyExc_TypeError,
            "The first attribute value must be a string");
        return -1;
    }

    Py_DECREF(self->first);
    Py_INCREF(value);
    self->first = value;

    return 0;
}
```

The getter function is passed a `Noddy` object and a “closure”, which is void pointer. In this case, the closure is ignored. (The closure supports an advanced usage in which definition data is passed to the getter and setter. This could, for example, be used to allow a single set of getter and setter functions that decide the attribute to get or

set based on data in the closure.)

The setter function is passed the `Noddy` object, the new value, and the closure. The new value may be `NULL`, in which case the attribute is being deleted. In our setter, we raise an error if the attribute is deleted or if the attribute value is not a string.

We create an array of `PyGetSetDef` structures:

```
static PyGetSetDef Noddy_getsetters[] = {
    {"first",
     (getter)Noddy_getfirst, (setter)Noddy_setfirst,
     "first name",
     NULL},
    {"last",
     (getter)Noddy_getlast, (setter)Noddy_setlast,
     "last name",
     NULL},
    {NULL} /* Sentinel */
};
```

and register it in the `tp_getset` slot:

```
Noddy_getsetters, /* tp_getset */
```

to register our attribute getters and setters.

The last item in a `PyGetSetDef` structure is the closure mentioned above. In this case, we aren't using the closure, so we just pass `NULL`.

We also remove the member definitions for these attributes:

```
static PyMemberDef Noddy_members[] = {
    {"number", T_INT, offsetof(Noddy, number), 0,
     "noddy number"},
    {NULL} /* Sentinel */
};
```

We also need to update the `tp_init` handler to only allow strings [3] to be passed:

```
static int
Noddy_init(Noddy *self, PyObject *args, PyObject *kwds)
{
    PyObject *first=NULL, *last=NULL, *tmp;

    static char *kwlist[] = {"first", "last", "number", NULL};

    if (! PyArg_ParseTupleAndKeywords(args, kwds, "|SSi", kwlist,
                                     &first, &last,
                                     &self->number))

        return -1;

    if (first) {
        tmp = self->first;
        Py_INCREF(first);
        self->first = first;
        Py_DECREF(tmp);
    }

    if (last) {
        tmp = self->last;
        Py_INCREF(last);
        self->last = last;
        Py_DECREF(tmp);
    }

    return 0;
}
```

With these changes, we can assure that the `first` and `last` members are never `NULL` so we can remove checks for `NULL` values in almost all cases. This means that most of the `Py_XDECREF()` calls can be converted to `Py_DECREF()` calls. The only place we can't change these calls is in the deallocator, where there is the possibility that the initialization of these members failed in the constructor.

We also rename the module initialization function and module name in the initialization function, as we did before, and we add an extra

definition to the `setup.py` file.

2.1.3. Supporting cyclic garbage collection

Python has a cyclic-garbage collector that can identify unneeded objects even when their reference counts are not zero. This can happen when objects are involved in cycles. For example, consider:

```
>>> l = []
>>> l.append(l)
>>> del l
```

In this example, we create a list that contains itself. When we delete it, it still has a reference from itself. Its reference count doesn't drop to zero. Fortunately, Python's cyclic-garbage collector will eventually figure out that the list is garbage and free it.

In the second version of the `Noddy` example, we allowed any kind of object to be stored in the `first` or `last` attributes. [4] This means that `Noddy` objects can participate in cycles:

```
>>> import noddy2
>>> n = noddy2.Noddy()
>>> l = [n]
>>> n.first = l
```

This is pretty silly, but it gives us an excuse to add support for the cyclic-garbage collector to the `Noddy` example. To support cyclic garbage collection, types need to fill two slots and set a class flag that enables these slots:

```
#include <Python.h>
#include "structmember.h"

typedef struct {
    PyObject_HEAD
    PyObject *first;
```

```

    PyObject *last;
    int number;
} Noddy;

static int
Noddy_traverse(Noddy *self, visitproc visit, void *arg)
{
    int vret;

    if (self->first) {
        vret = visit(self->first, arg);
        if (vret != 0)
            return vret;
    }
    if (self->last) {
        vret = visit(self->last, arg);
        if (vret != 0)
            return vret;
    }

    return 0;
}

static int
Noddy_clear(Noddy *self)
{
    PyObject *tmp;

    tmp = self->first;
    self->first = NULL;
    Py_XDECREF(tmp);

    tmp = self->last;
    self->last = NULL;
    Py_XDECREF(tmp);

    return 0;
}

static void
Noddy_dealloc(Noddy* self)
{
    Noddy_clear(self);
    Py_TYPE(self)->tp_free((PyObject*)self);
}

static PyObject *

```

```

Noddy_new(PyTypeObject *type, PyObject *args, PyObject *kwds)
{

```

```

    0,                                /* tp_descr_set */
    0,                                /* tp_dictoffset */
    (initproc)Noddy_init,             /* tp_init */
    0,                                /* tp_alloc */
    Noddy_new,                        /* tp_new */
};

static PyModuleDef noddy4module = {
    PyModuleDef_HEAD_INIT,
    "noddy4",
    "Example module that creates an extension type.",
    -1,
    NULL, NULL, NULL, NULL, NULL
};

PyMODINIT_FUNC
PyInit_noddy4(void)
{
    PyObject* m;

    if (PyType_Ready(&NoddyType) < 0)
        return NULL;

    m = PyModule_Create(&noddy4module);
    if (m == NULL)
        return NULL;

    Py_INCREF(&NoddyType);
    PyModule_AddObject(m, "Noddy", (PyObject *)&NoddyType);
    return m;
}

```

The traversal method provides access to subobjects that could participate in cycles:

```

static int
Noddy_traverse(Noddy *self, visitproc visit, void *arg)
{
    int vret;

    if (self->first) {
        vret = visit(self->first, arg);
        if (vret != 0)
            return vret;
    }
}

```

```

    if (self->last) {
        vret = visit(self->last, arg);
        if (vret != 0)
            return vret;
    }

    return 0;
}

```

For each subobject that can participate in cycles, we need to call the `visit()` function, which is passed to the traversal method. The `visit()` function takes as arguments the subobject and the extra argument `arg` passed to the traversal method. It returns an integer value that must be returned if it is non-zero.

Python provides a `Py_VISIT()` macro that automates calling visit functions. With `Py_VISIT()`, `Noddy_traverse()` can be simplified:

```

static int
Noddy_traverse(Noddy *self, visitproc visit, void *arg)
{
    Py_VISIT(self->first);
    Py_VISIT(self->last);
    return 0;
}

```

Note: Note that the `tp_traverse` implementation must name its arguments exactly `visit` and `arg` in order to use `Py_VISIT()`. This is to encourage uniformity across these boring implementations.

We also need to provide a method for clearing any subobjects that can participate in cycles. We implement the method and reimplement the deallocator to use it:

```

static int
Noddy_clear(Noddy *self)
{
    PyObject *tmp;
}

```

```

    tmp = self->first;
    self->first = NULL;
    Py_XDECREF(tmp);

    tmp = self->last;
    self->last = NULL;
    Py_XDECREF(tmp);

    return 0;
}

static void
Noddy_dealloc(Noddy* self)
{
    Noddy_clear(self);
    Py_TYPE(self)->tp_free((PyObject*)self);
}

```

Notice the use of a temporary variable in `Noddy_clear()`. We use the temporary variable so that we can set each member to *NULL* before decrementing its reference count. We do this because, as was discussed earlier, if the reference count drops to zero, we might cause code to run that calls back into the object. In addition, because we now support garbage collection, we also have to worry about code being run that triggers garbage collection. If garbage collection is run, our `tp_traverse` handler could get called. We can't take a chance of having `Noddy_traverse()` called when a member's reference count has dropped to zero and its value hasn't been set to *NULL*.

Python provides a `Py_CLEAR()` that automates the careful decrementing of reference counts. With `Py_CLEAR()`, the `Noddy_clear()` function can be simplified:

```

static int
Noddy_clear(Noddy *self)
{
    Py_CLEAR(self->first);
    Py_CLEAR(self->last);
    return 0;
}

```

```
}
```

Finally, we add the `Py_TPFLAGS_HAVE_GC` flag to the class flags:

```
Py_TPFLAGS_DEFAULT | Py_TPFLAGS_BASETYPE | Py_TPFLAGS_HAVE_GC,
```

That's pretty much it. If we had written custom `tp_alloc` or `tp_free` slots, we'd need to modify them for cyclic-garbage collection. Most extensions will use the versions automatically provided.

2.1.4. Subclassing other types

It is possible to create new extension types that are derived from existing types. It is easiest to inherit from the built in types, since an extension can easily use the `PyObject` it needs. It can be difficult to share these `PyObject` structures between extension modules.

In this example we will create a `shoddy` type that inherits from the built-in `list` type. The new type will be completely compatible with regular lists, but will have an additional `increment()` method that increases an internal counter.

```
>>> import shoddy
>>> s = shoddy.Shoddy(range(3))
>>> s.extend(s)
>>> print(len(s))
6
>>> print(s.increment())
1
>>> print(s.increment())
2
```

```
#include <Python.h>

typedef struct {
    PyListObject list;
    int state;
```

```

} Shoddy;

static PyObject *
Shoddy_increment(Shoddy *self, PyObject *unused)
{
    self->state++;
    return PyLong_FromLong(self->state);
}

static PyMethodDef Shoddy_methods[] = {
    {"increment", (PyCFunction)Shoddy_increment, METH_NOARGS,
     PyDoc_STR("increment state counter")},
    {NULL, NULL},
};

static int
Shoddy_init(Shoddy *self, PyObject *args, PyObject *kwds)
{
    if (PyList_Type.tp_init((PyObject *)self, args, kwds) < 0)
        return -1;
    self->state = 0;
    return 0;
}

static PyTypeObject ShoddyType = {
    PyObject_HEAD_INIT(NULL)
    "shoddy.Shoddy", /* tp_name */
    sizeof(Shoddy), /* tp_basicsize */
    0, /* tp_itemsize */
    0, /* tp_dealloc */
    0, /* tp_print */
    0, /* tp_getattr */
    0, /* tp_setattr */
    0, /* tp_reserved */
    0, /* tp_repr */
    0, /* tp_as_number */
    0, /* tp_as_sequence */
    0, /* tp_as_mapping */
    0, /* tp_hash */
    0, /* tp_call */
    0, /* tp_str */
    0, /* tp_getattro */
    0, /* tp_setattro */
    0, /* tp_as_buffer */

```

```

Py_TPFLAGS_DEFAULT |
    Py_TPFLAGS_BASETYPE, /* tp_flags */
    0, /* tp_doc */
    0, /* tp_traverse */
    0, /* tp_clear */
    0, /* tp_richcompare */
    0, /* tp_weaklistoffset */
    0, /* tp_iter */
    0, /* tp_iternext */
    Shoddy_methods, /* tp_methods */
    0, /* tp_members */
    0, /* tp_getset */
    0, /* tp_base */
    0, /* tp_dict */
    0, /* tp_descr_get */
    0, /* tp_descr_set */
    0, /* tp_dictoffset */
    (initproc)Shoddy_init, /* tp_init */
    0, /* tp_alloc */
    0, /* tp_new */
};

static PyModuleDef shoddymodule = {
    PyModuleDef_HEAD_INIT,
    "shoddy",
    "Shoddy module",
    -1,
    NULL, NULL, NULL, NULL, NULL
};

PyMODINIT_FUNC
PyInit_shoddy(void)
{
    PyObject *m;

    ShoddyType.tp_base = &PyList_Type;
    if (PyType_Ready(&ShoddyType) < 0)
        return NULL;

    m = PyModule_Create(&shoddymodule);
    if (m == NULL)
        return NULL;

    Py_INCREF(&ShoddyType);
    PyModule_AddObject(m, "Shoddy", (PyObject *) &ShoddyType);
    return m;
}

```

As you can see, the source code closely resembles the **Noddy** examples in previous sections. We will break down the main differences between them.

```
typedef struct {
    PyObject list;
    int state;
} Shoddy;
```

The primary difference for derived type objects is that the base type's object structure must be the first value. The base type will already include the `PyObject_HEAD()` at the beginning of its structure.

When a Python object is a **shoddy** instance, its *PyObject** pointer can be safely cast to both *PyListObject** and *Shoddy**.

```
static int
Shoddy_init(Shoddy *self, PyObject *args, PyObject *kwds)
{
    if (PyList_Type.tp_init((PyObject *)self, args, kwds) < 0)
        return -1;
    self->state = 0;
    return 0;
}
```

In the `__init__` method for our type, we can see how to call through to the `__init__` method of the base type.

This pattern is important when writing a type with custom `new` and `dealloc` methods. The `new` method should not actually create the memory for the object with `tp_alloc`, that will be handled by the base class when calling its `tp_new`.

When filling out the `PyTypeObject()` for the **shoddy** type, you see a slot for `tp_base()`. Due to cross platform compiler issues, you can't fill that field directly with the `PyList_Type()`; it can be done later in the module's `init()` function.

```

PyMODINIT_FUNC
PyInit_shoddy(void)
{
    PyObject *m;

    ShoddyType.tp_base = &PyList_Type;
    if (PyType_Ready(&ShoddyType) < 0)
        return NULL;

    m = PyModule_Create(&shoddyModule);
    if (m == NULL)
        return NULL;

    Py_INCREF(&ShoddyType);
    PyModule_AddObject(m, "Shoddy", (PyObject *) &ShoddyType);
    return m;
}

```

Before calling `PyType_Ready()`, the type structure must have the `tp_base` slot filled in. When we are deriving a new type, it is not necessary to fill out the `tp_alloc` slot with `PyType_GenericNew()` – the allocate function from the base type will be inherited.

After that, calling `PyType_Ready()` and adding the type object to the module is the same as with the basic `Noddy` examples.

2.2. Type Methods

This section aims to give a quick fly-by on the various type methods you can implement and what they do.

Here is the definition of `PyTypeObject`, with some fields only used in debug builds omitted:

```
typedef struct _typeobject {
    PyObject_VAR_HEAD
    char *tp_name; /* For printing, in format "<module>.<name>"
    int tp_basicsize, tp_itemsize; /* For allocation */

    /* Methods to implement standard operations */

    destructor tp_dealloc;
    printfunc tp_print;
    getattrfunc tp_getattr;
    setattrfunc tp_setattr;
    void *tp_reserved;
    reprfunc tp_repr;

    /* Method suites for standard classes */

    PyNumberMethods *tp_as_number;
    PySequenceMethods *tp_as_sequence;
    PyMappingMethods *tp_as_mapping;

    /* More standard operations (here for binary compatibility)

    hashfunc tp_hash;
    ternaryfunc tp_call;
    reprfunc tp_str;
    getattrofunc tp_getattro;
    setattrofunc tp_setattro;

    /* Functions to access object as input/output buffer */
    PyBufferProcs *tp_as_buffer;

    /* Flags to define presence of optional/expanded features */
    long tp_flags;
```

```

char *tp_doc; /* Documentation string */

/* call function for all accessible objects */
traverseproc tp_traverse;

/* delete references to contained objects */
inquiry tp_clear;

/* rich comparisons */
richcmpfunc tp_richcompare;

/* weak reference enabler */
long tp_weaklistoffset;

/* Iterators */
getiterfunc tp_iter;
iternextfunc tp_iternext;

/* Attribute descriptor and subclassing stuff */
struct PyMethodDef *tp_methods;
struct PyMemberDef *tp_members;
struct PyGetSetDef *tp_getset;
struct _typeobject *tp_base;
PyObject *tp_dict;
descrgetfunc tp_descr_get;
descrsetfunc tp_descr_set;
long tp_dictoffset;
initproc tp_init;
allocfunc tp_alloc;
newfunc tp_new;
freefunc tp_free; /* Low-level free-memory routine */
inquiry tp_is_gc; /* For PyObject_IS_GC */
PyObject *tp_bases;
PyObject *tp_mro; /* method resolution order */
PyObject *tp_cache;
PyObject *tp_subclasses;
PyObject *tp_weaklist;

} PyTypeObject;

```

Now that's a *lot* of methods. Don't worry too much though - if you have a type you want to define, the chances are very good that you will only implement a handful of these.

As you probably expect by now, we're going to go over this and give more information about the various handlers. We won't go in the order they are defined in the structure, because there is a lot of historical baggage that impacts the ordering of the fields; be sure your type initialization keeps the fields in the right order! It's often easiest to find an example that includes all the fields you need (even if they're initialized to 0) and then change the values to suit your new type.

```
char *tp_name; /* For printing */
```

The name of the type - as mentioned in the last section, this will appear in various places, almost entirely for diagnostic purposes. Try to choose something that will be helpful in such a situation!

```
int tp_basicsize, tp_itemsize; /* For allocation */
```

These fields tell the runtime how much memory to allocate when new objects of this type are created. Python has some built-in support for variable length structures (think: strings, lists) which is where the `tp_itemsize` field comes in. This will be dealt with later.

```
char *tp_doc;
```

Here you can put a string (or its address) that you want returned when the Python script references `obj.__doc__` to retrieve the doc string.

Now we come to the basic type methods—the ones most extension types will implement.

2.2.1. Finalization and De-allocation

```
destructor tp_dealloc;
```

This function is called when the reference count of the instance of your type is reduced to zero and the Python interpreter wants to reclaim it. If your type has memory to free or other clean-up to perform, put it here. The object itself needs to be freed here as well. Here is an example of this function:

```
static void
newdatatype_dealloc(newdatatypeobject * obj)
{
    free(obj->obj_UnderlyingDatatypePtr);
    Py_TYPE(obj)->tp_free(obj);
}
```

One important requirement of the deallocator function is that it leaves any pending exceptions alone. This is important since deallocators are frequently called as the interpreter unwinds the Python stack; when the stack is unwound due to an exception (rather than normal returns), nothing is done to protect the deallocators from seeing that an exception has already been set. Any actions which a deallocator performs which may cause additional Python code to be executed may detect that an exception has been set. This can lead to misleading errors from the interpreter. The proper way to protect against this is to save a pending exception before performing the unsafe action, and restoring it when done. This can be done using the `PyErr_Fetch()` and `PyErr_Restore()` functions:

```
static void
my_dealloc(PyObject *obj)
{
    MyObject *self = (MyObject *) obj;
    PyObject *cbresult;

    if (self->my_callback != NULL) {
        PyObject *err_type, *err_value, *err_traceback;
        int have_error = PyErr_Occurred() ? 1 : 0;

        if (have_error)
            PyErr_Fetch(&err_type, &err_value, &err_traceback);
    }
}
```

```

    cbresult = PyObject_CallObject(self->my_callback, NULL)
    if (cbresult == NULL)
        PyErr_WriteUnraisable(self->my_callback);
    else
        Py_DECREF(cbresult);

    if (have_error)
        PyErr_Restore(err_type, err_value, err_traceback);

    Py_DECREF(self->my_callback);
}
Py_TYPE(obj)->tp_free((PyObject*)self);
}

```

2.2.2. Object Presentation

In Python, there are two ways to generate a textual representation of an object: the `repr()` function, and the `str()` function. (The `print()` function just calls `str()`.) These handlers are both optional.

```

reprfunc tp_repr;
reprfunc tp_str;

```

The `tp_repr` handler should return a string object containing a representation of the instance for which it is called. Here is a simple example:

```

static PyObject *
newdatatype_repr(newdatatypeobject * obj)
{
    return PyString_FromFormat("Repr-ified_newdatatype{{size:%d}}",
                               obj->obj_UnderlyingDatatypePtr->

```

If no `tp_repr` handler is specified, the interpreter will supply a representation that uses the type's `tp_name` and a uniquely-identifying value for the object.

The `tp_str` handler is to `str()` what the `tp_repr` handler described above is to `repr()`; that is, it is called when Python code calls `str()` on an instance of your object. Its implementation is very similar to the `tp_repr` function, but the resulting string is intended for human consumption. If `tp_str` is not specified, the `tp_repr` handler is used instead.

Here is a simple example:

```
static PyObject *
newdatatype_str(newdatatypeobject * obj)
{
    return PyString_FromFormat("Stringified_newdatatype{{size:\
                                obj->obj_UnderlyingDatatypePtr->
```

2.2.3. Attribute Management

For every object which can support attributes, the corresponding type must provide the functions that control how the attributes are resolved. There needs to be a function which can retrieve attributes (if any are defined), and another to set attributes (if setting attributes is allowed). Removing an attribute is a special case, for which the new value passed to the handler is *NULL*.

Python supports two pairs of attribute handlers; a type that supports attributes only needs to implement the functions for one pair. The difference is that one pair takes the name of the attribute as a `char*`, while the other accepts a `PyObject*`. Each type can use whichever pair makes more sense for the implementation's convenience.

```
getattrfunc  tp_getattr;          /* char * version */
setattrfunc  tp_setattr;
/* ... */
getattrofunc tp_getattro;        /* PyObject * version */
setattrofunc tp_setattro;
```

If accessing attributes of an object is always a simple operation (this will be explained shortly), there are generic implementations which can be used to provide the `PyObject*` version of the attribute management functions. The actual need for type-specific attribute handlers almost completely disappeared starting with Python 2.2, though there are many examples which have not been updated to use some of the new generic mechanism that is available.

2.2.3.1. Generic Attribute Management

Most extension types only use *simple* attributes. So, what makes the attributes simple? There are only a couple of conditions that must be met:

1. The name of the attributes must be known when `PyType_Ready()` is called.
2. No special processing is needed to record that an attribute was looked up or set, nor do actions need to be taken based on the value.

Note that this list does not place any restrictions on the values of the attributes, when the values are computed, or how relevant data is stored.

When `PyType_Ready()` is called, it uses three tables referenced by the type object to create *descriptors* which are placed in the dictionary of the type object. Each descriptor controls access to one attribute of the instance object. Each of the tables is optional; if all three are `NULL`, instances of the type will only have attributes that are inherited from their base type, and should leave the `tp_getattro` and `tp_setattro` fields `NULL` as well, allowing the base type to handle attributes.

The tables are declared as three fields of the type object:

```
struct PyMethodDef *tp_methods;
struct PyMemberDef *tp_members;
struct PyGetSetDef *tp_getset;
```

If `tp_methods` is not `NULL`, it must refer to an array of `PyMethodDef` structures. Each entry in the table is an instance of this structure:

```
typedef struct PyMethodDef {
    char *m1_name; /* method name */
    PyCFunction m1_meth; /* implementation function */
    int m1_flags; /* flags */
    char *m1_doc; /* docstring */
} PyMethodDef;
```

One entry should be defined for each method provided by the type; no entries are needed for methods inherited from a base type. One additional entry is needed at the end; it is a sentinel that marks the end of the array. The `m1_name` field of the sentinel must be `NULL`.

XXX Need to refer to some unified discussion of the structure fields, shared with the next section.

The second table is used to define attributes which map directly to data stored in the instance. A variety of primitive C types are supported, and access may be read-only or read-write. The structures in the table are defined as:

```
typedef struct PyMemberDef {
    char *name;
    int type;
    int offset;
    int flags;
    char *doc;
} PyMemberDef;
```

For each entry in the table, a *descriptor* will be constructed and added to the type which will be able to extract a value from the instance structure. The `type` field should contain one of the type

codes defined in the `structmember.h` header; the value will be used to determine how to convert Python values to and from C values. The `flags` field is used to store flags which control how the attribute can be accessed.

XXX Need to move some of this to a shared section!

The following flag constants are defined in `structmember.h`; they may be combined using bitwise-OR.

Constant	Meaning
<code>READONLY</code>	Never writable.
<code>READ_RESTRICTED</code>	Not readable in restricted mode.
<code>WRITE_RESTRICTED</code>	Not writable in restricted mode.
<code>RESTRICTED</code>	Not readable or writable in restricted mode.

An interesting advantage of using the `tp_members` table to build descriptors that are used at runtime is that any attribute defined this way can have an associated doc string simply by providing the text in the table. An application can use the introspection API to retrieve the descriptor from the class object, and get the doc string using its `__doc__` attribute.

As with the `tp_methods` table, a sentinel entry with a `name` value of `NULL` is required.

2.2.3.2. Type-specific Attribute Management

For simplicity, only the `char*` version will be demonstrated here; the type of the `name` parameter is the only difference between the `char*` and `PyObject*` flavors of the interface. This example effectively does the same thing as the generic example above, but does not use the generic support added in Python 2.2. It explains how the handler

functions are called, so that if you do need to extend their functionality, you'll understand what needs to be done.

The `tp_getattr` handler is called when the object requires an attribute look-up. It is called in the same situations where the `__getattr__()` method of a class would be called.

Here is an example:

```
static PyObject *
newdatatype_getattr(newdatatypeobject *obj, char *name)
{
    if (strcmp(name, "data") == 0)
    {
        return PyInt_FromLong(obj->data);
    }

    PyErr_Format(PyExc_AttributeError,
                 "'%.50s' object has no attribute '%.400s'",
                 tp->tp_name, name);
    return NULL;
}
```

The `tp_setattr` handler is called when the `__setattr__()` or `__delattr__()` method of a class instance would be called. When an attribute should be deleted, the third parameter will be `NULL`. Here is an example that simply raises an exception; if this were really all you wanted, the `tp_setattr` handler should be set to `NULL`.

```
static int
newdatatype_setattr(newdatatypeobject *obj, char *name, PyObject *value)
{
    (void)PyErr_Format(PyExc_RuntimeError, "Read-only attribute");
    return -1;
}
```

2.2.4. Object Comparison

```
richcmpfunc tp_richcompare;
```

The `tp_richcompare` handler is called when comparisons are needed. It is analogous to the *rich comparison methods*, like `__lt__()`, and also called by `PyObject_RichCompare()` and `PyObject_RichCompareBool()`.

This function is called with two Python objects and the operator as arguments, where the operator is one of `Py_EQ`, `Py_NE`, `Py_LE`, `Py_GT`, `Py_LT` or `Py_GE`. It should compare the two objects with respect to the specified operator and return `Py_True` or `Py_False` if the comparison is successful, `Py_NotImplemented` to indicate that comparison is not implemented and the other object's comparison method should be tried, or `NULL` if an exception was set.

Here is a sample implementation, for a datatype that is considered equal if the size of an internal pointer is equal:

```
static int
newdatatype_richcmp(PyObject *obj1, PyObject *obj2, int op)
{
    PyObject *result;
    int c, size1, size2;

    /* code to make sure that both arguments are of type
       newdatatype omitted */

    size1 = obj1->obj_UnderlyingDatatypePtr->size;
    size2 = obj2->obj_UnderlyingDatatypePtr->size;

    switch (op) {
    case Py_LT: c = size1 < size2; break;
    case Py_LE: c = size1 <= size2; break;
    case Py_EQ: c = size1 == size2; break;
    case Py_NE: c = size1 != size2; break;
    case Py_GT: c = size1 > size2; break;
    case Py_GE: c = size1 >= size2; break;
    }
    result = c ? Py_True : Py_False;
    Py_INCREF(result);
}
```

```
    return result;
}
```

2.2.5. Abstract Protocol Support

Python supports a variety of *abstract* ‘protocols;’ the specific interfaces provided to use these interfaces are documented in *Abstract Objects Layer*.

A number of these abstract interfaces were defined early in the development of the Python implementation. In particular, the number, mapping, and sequence protocols have been part of Python since the beginning. Other protocols have been added over time. For protocols which depend on several handler routines from the type implementation, the older protocols have been defined as optional blocks of handlers referenced by the type object. For newer protocols there are additional slots in the main type object, with a flag bit being set to indicate that the slots are present and should be checked by the interpreter. (The flag bit does not indicate that the slot values are non-*NULL*. The flag may be set to indicate the presence of a slot, but a slot may still be unfilled.)

```
PyNumberMethods    tp_as_number;
PySequenceMethods  tp_as_sequence;
PyMappingMethods   tp_as_mapping;
```

If you wish your object to be able to act like a number, a sequence, or a mapping object, then you place the address of a structure that implements the C type **PyNumberMethods**, **PySequenceMethods**, or **PyMappingMethods**, respectively. It is up to you to fill in this structure with appropriate values. You can find examples of the use of each of these in the `objects` directory of the Python source distribution.

```
hashfunc tp_hash;
```

This function, if you choose to provide it, should return a hash number for an instance of your data type. Here is a moderately pointless example:

```
static long
newdatatype_hash(newdatatypeobject *obj)
{
    long result;
    result = obj->obj_UnderlyingDatatypePtr->size;
    result = result * 3;
    return result;
}
```

```
ternaryfunc tp_call;
```

This function is called when an instance of your data type is “called”, for example, if `obj1` is an instance of your data type and the Python script contains `obj1('hello')`, the `tp_call` handler is invoked.

This function takes three arguments:

1. `arg1` is the instance of the data type which is the subject of the call. If the call is `obj1('hello')`, then `arg1` is `obj1`.
2. `arg2` is a tuple containing the arguments to the call. You can use `PyArg_ParseTuple()` to extract the arguments.
3. `arg3` is a dictionary of keyword arguments that were passed. If this is non-`NULL` and you support keyword arguments, use `PyArg_ParseTupleAndKeywords()` to extract the arguments. If you do not want to support keyword arguments and this is non-`NULL`, raise a `TypeError` with a message saying that keyword arguments are not supported.

Here is a desultory example of the implementation of the call function.

```
/* Implement the call function.
 *   obj1 is the instance receiving the call.
```

```

*   obj2 is a tuple containing the arguments to the call, in
*   case 3 strings.
*/
static PyObject *
newdatatype_call(newdatatypeobject *obj, PyObject *args, PyObje
{
    PyObject *result;
    char *arg1;
    char *arg2;
    char *arg3;

    if (!PyArg_ParseTuple(args, "sss:call", &arg1, &arg2, &arg3
        return NULL;
    }
    result = PyString_FromFormat(
        "Returning -- value: [%d] arg1: [%s] arg2: [%s] arg3
        obj->obj_UnderlyingDatatypePtr->size,
        arg1, arg2, arg3);
    printf("\%s", PyString_AS_STRING(result));
    return result;
}

```

XXX some fields need to be added here...

```

/* Iterators */
getiterfunc tp_iter;
iternextfunc tp_iternext;

```

These functions provide support for the iterator protocol. Any object which wishes to support iteration over its contents (which may be generated during iteration) must implement the `tp_iter` handler. Objects which are returned by a `tp_iter` handler must implement both the `tp_iter` and `tp_iternext` handlers. Both handlers take exactly one parameter, the instance for which they are being called, and return a new reference. In the case of an error, they should set an exception and return `NULL`.

For an object which represents an iterable collection, the `tp_iter` handler must return an iterator object. The iterator object is responsible for maintaining the state of the iteration. For collections

which can support multiple iterators which do not interfere with each other (as lists and tuples do), a new iterator should be created and returned. Objects which can only be iterated over once (usually due to side effects of iteration) should implement this handler by returning a new reference to themselves, and should also implement the `tp_iternext` handler. File objects are an example of such an iterator.

Iterator objects should implement both handlers. The `tp_iter` handler should return a new reference to the iterator (this is the same as the `tp_iter` handler for objects which can only be iterated over destructively). The `tp_iternext` handler should return a new reference to the next object in the iteration if there is one. If the iteration has reached the end, it may return `NULL` without setting an exception or it may set `StopIteration`; avoiding the exception can yield slightly better performance. If an actual error occurs, it should set an exception and return `NULL`.

2.2.6. Weak Reference Support

One of the goals of Python's weak-reference implementation is to allow any type to participate in the weak reference mechanism without incurring the overhead on those objects which do not benefit by weak referencing (such as numbers).

For an object to be weakly referencable, the extension must include a `PyObject*` field in the instance structure for the use of the weak reference mechanism; it must be initialized to `NULL` by the object's constructor. It must also set the `tp_weaklistoffset` field of the corresponding type object to the offset of the field. For example, the instance type is defined with the following structure:

```
typedef struct {
    PyObject_HEAD
    PyObject *in_class;           /* The class object */
}
```

```

PyObject      *in_dict;          /* A dictionary */
PyObject      *in_weakreflist; /* List of weak references */
} PyInstanceObject;

```

The statically-declared type object for instances is defined this way:

```

PyTypeObject PyInstance_Type = {
    PyVarObject_HEAD_INIT(&PyType_Type, 0)
    0,
    "module.instance",

    /* Lots of stuff omitted for brevity... */

    Py_TPFLAGS_DEFAULT,          /* tp_flags */
    0,                            /* tp_doc */
    0,                            /* tp_traverse */
    0,                            /* tp_clear */
    0,                            /* tp_richcompa */
    0,                            /* tp_weaklisto */
    offsetof(PyInstanceObject, in_weakreflist), /* tp_weaklisto */
};

```

The type constructor is responsible for initializing the weak reference list to *NULL*:

```

static PyObject *
instance_new() {
    /* Other initialization stuff omitted for brevity */

    self->in_weakreflist = NULL;

    return (PyObject *) self;
}

```

The only further addition is that the destructor needs to call the weak reference manager to clear any weak references. This should be done before any other parts of the destruction have occurred, but is only required if the weak reference list is non-*NULL*:

```

static void
instance_dealloc(PyInstanceObject *inst)

```

```

{
    /* Allocate temporaries if needed, but do not begin
       destruction just yet.
       */

    if (inst->in_weakreflist != NULL)
        PyObject_ClearWeakRefs((PyObject *) inst);

    /* Proceed with object destruction normally. */
}

```

2.2.7. More Suggestions

Remember that you can omit most of these functions, in which case you provide `0` as a value. There are type definitions for each of the functions you must provide. They are in `object.h` in the Python include directory that comes with the source distribution of Python.

In order to learn how to implement any specific method for your new data type, do the following: Download and unpack the Python source distribution. Go to the `objects` directory, then search the C source files for `tp_` plus the function you want (for example, `tp_richcompare`). You will find examples of the function you want to implement.

When you need to verify that an object is an instance of the type you are implementing, use the `PyObject_TypeCheck()` function. A sample of its use might be something like the following:

```

if (! PyObject_TypeCheck(some_object, &MyType)) {
    PyErr_SetString(PyExc_TypeError, "arg #1 not a mything");
    return NULL;
}

```

Footnotes

This is true when we know that the object is a basic type, like a

[1] string or a float.

We relied on this in the `tp_dealloc` handler in this example, because our type doesn't support garbage collection. Even if a

[2] type supports garbage collection, there are calls that can be made to "untrack" the object from garbage collection, however, these calls are advanced and not covered here.

We now know that the first and last members are strings, so perhaps we could be less careful about decrementing their

[3] reference counts, however, we accept instances of string subclasses. Even though deallocating normal strings won't call back into our objects, we can't guarantee that deallocating an instance of a string subclass won't call back into our objects.

Even in the third version, we aren't guaranteed to avoid cycles.

[4] Instances of string subclasses are allowed and string subclasses could allow cycles even if normal strings don't.

3. Building C and C++ Extensions with distutils

Starting in Python 1.4, Python provides, on Unix, a special make file for building make files for building dynamically-linked extensions and custom interpreters. Starting with Python 2.0, this mechanism (known as related to Makefile.pre.in, and Setup files) is no longer supported. Building custom interpreters was rarely used, and extension modules can be built using distutils.

Building an extension module using distutils requires that distutils is installed on the build machine, which is included in Python 2.x and available separately for Python 1.5. Since distutils also supports creation of binary packages, users don't necessarily need a compiler and distutils to install the extension.

A distutils package contains a driver script, `setup.py`. This is a plain Python file, which, in the most simple case, could look like this:

```
from distutils.core import setup, Extension

module1 = Extension('demo',
                    sources = ['demo.c'])

setup (name = 'PackageName',
       version = '1.0',
       description = 'This is a demo package',
       ext_modules = [module1])
```

With this `setup.py`, and a file `demo.c`, running

```
python setup.py build
```

will compile `demo.c`, and produce an extension module named `demo` in the `build` directory. Depending on the system, the module file will

end up in a subdirectory `build/lib.system`, and may have a name like `demo.so` Or `demo.pyd`.

In the `setup.py`, all execution is performed by calling the `setup` function. This takes a variable number of keyword arguments, of which the example above uses only a subset. Specifically, the example specifies meta-information to build packages, and it specifies the contents of the package. Normally, a package will contain of addition modules, like Python source modules, documentation, subpackages, etc. Please refer to the `distutils` documentation in *Distributing Python Modules* to learn more about the features of `distutils`; this section explains building extension modules only.

It is common to pre-compute arguments to `setup()`, to better structure the driver script. In the example above, the `ext_modules` argument to `setup()` is a list of extension modules, each of which is an instance of the `Extension`. In the example, the instance defines an extension named `demo` which is build by compiling a single source file, `demo.c`.

In many cases, building an extension is more complex, since additional preprocessor defines and libraries may be needed. This is demonstrated in the example below.

```
from distutils.core import setup, Extension

module1 = Extension('demo',
                    define_macros = [('MAJOR_VERSION', '1'),
                                     ('MINOR_VERSION', '0')],
                    include_dirs = ['/usr/local/include'],
                    libraries = ['tcl83'],
                    library_dirs = ['/usr/local/lib'],
                    sources = ['demo.c'])

setup (name = 'PackageName',
       version = '1.0',
```

```
description = 'This is a demo package',
author = 'Martin v. Loewis',
author_email = 'martin@v.loewis.de',
url = 'http://docs.python.org/extending/building',
long_description = '''
This is really just a demo package.
'''
    ext_modules = [module1])
```

In this example, `setup()` is called with additional meta-information, which is recommended when distribution packages have to be built. For the extension itself, it specifies preprocessor defines, include directories, library directories, and libraries. Depending on the compiler, distutils passes this information in different ways to the compiler. For example, on Unix, this may result in the compilation commands

```
gcc -DNDEBUG -g -O3 -Wall -Wstrict-prototypes -fPIC -DMAJOR_VER
gcc -shared build/temp.linux-i686-2.2/demo.o -L/usr/local/lib -
```

These lines are for demonstration purposes only; distutils users should trust that distutils gets the invocations right.

3.1. Distributing your extension modules

When an extension has been successfully build, there are three ways to use it.

End-users will typically want to install the module, they do so by running

```
python setup.py install
```

Module maintainers should produce source packages; to do so, they run

```
python setup.py sdist
```

In some cases, additional files need to be included in a source distribution; this is done through a `MANIFEST.in` file; see the `distutils` documentation for details.

If the source distribution has been build successfully, maintainers can also create binary distributions. Depending on the platform, one of the following commands can be used to do so.

```
python setup.py bdist_wininst  
python setup.py bdist_rpm  
python setup.py bdist_dumb
```

4. Building C and C++ Extensions on Windows

This chapter briefly explains how to create a Windows extension module for Python using Microsoft Visual C++, and follows with more detailed background information on how it works. The explanatory material is useful for both the Windows programmer learning to build Python extensions and the Unix programmer interested in producing software which can be successfully built on both Unix and Windows.

Module authors are encouraged to use the distutils approach for building extension modules, instead of the one described in this section. You will still need the C compiler that was used to build Python; typically Microsoft Visual C++.

Note: This chapter mentions a number of filenames that include an encoded Python version number. These filenames are represented with the version number shown as `xY`; in practice, 'x' will be the major version number and 'Y' will be the minor version number of the Python release you're working with. For example, if you are using Python 2.2.1, `xY` will actually be `22`.

4.1. A Cookbook Approach

There are two approaches to building extension modules on Windows, just as there are on Unix: use the `distutils` package to control the build process, or do things manually. The `distutils` approach works well for most extensions; documentation on using `distutils` to build and package extension modules is available in *Distributing Python Modules*. This section describes the manual approach to building Python extensions written in C or C++.

To build extensions using these instructions, you need to have a copy of the Python sources of the same version as your installed Python. You will need Microsoft Visual C++ “Developer Studio”; project files are supplied for VC++ version 7.1, but you can use older versions of VC++. Notice that you should use the same version of VC++ that was used to build Python itself. The example files described here are distributed with the Python sources in the `PC\example_nt\` directory.

1. **Copy the example files** — The `example_nt` directory is a subdirectory of the `PC` directory, in order to keep all the PC-specific files under the same directory in the source distribution. However, the `example_nt` directory can’t actually be used from this location. You first need to copy or move it up one level, so that `example_nt` is a sibling of the `PC` and `Include` directories. Do all your work from within this new location.
2. **Open the project** — From VC++, use the *File* ▶ *Open Solution* dialog (not *File* ▶ *Open!*). Navigate to and select the file `example.sln`, in the *copy* of the `example_nt` directory you made above. Click Open.
3. **Build the example DLL** — In order to check that everything is

set up right, try building:

4. Select a configuration. This step is optional. Choose *Build* ▶ *Configuration Manager* ▶ *Active Solution Configuration* and select either *Release* or *Debug*. If you skip this step, VC++ will use the Debug configuration by default.
5. Build the DLL. Choose *Build* ▶ *Build Solution*. This creates all intermediate and result files in a subdirectory called either `Debug` or `Release`, depending on which configuration you selected in the preceding step.
6. **Testing the debug-mode DLL** — Once the Debug build has succeeded, bring up a DOS box, and change to the `example_nt\Debug` directory. You should now be able to repeat the following session (`c>` is the DOS prompt, `>>>` is the Python prompt; note that build information and various debug output from Python may not match this screen dump exactly):

```
C>..\..\PCbuild\python_d
Adding parser accelerators ...
Done.
Python 2.2 (#28, Dec 19 2001, 23:26:37) [MSC 32 bit (Intel)]
Type "copyright", "credits" or "license" for more informati
>>> import example
[4897 refs]
>>> example.foo()
Hello, world
[4903 refs]
>>>
```

Congratulations! You've successfully built your first Python extension module.

7. **Creating your own project** — Choose a name and create a directory for it. Copy your C sources into it. Note that the module source file name does not necessarily have to match the module

name, but the name of the initialization function should match the module name — you can only import a module `spam` if its initialization function is called `initspam()`, and it should call `Py_InitModule()` with the string `"spam"` as its first argument (use the minimal `example.c` in this directory as a guide). By convention, it lives in a file called `spam.c` or `spammodule.c`. The output file should be called `spam.pyd` (in Release mode) or `spam_d.pyd` (in Debug mode). The extension `.pyd` was chosen to avoid confusion with a system library `spam.dll` to which your module could be a Python interface.

Now your options are:

8. Copy `example.sln` and `example.vcproj`, rename them to `spam.*`, and edit them by hand, or
9. Create a brand new project; instructions are below.

In either case, copy `example_nt\example.def` to `spam\spam.def`, and edit the new `spam.def` so its second line contains the string `'initspam'`. If you created a new project yourself, add the file `spam.def` to the project now. (This is an annoying little file with only two lines. An alternative approach is to forget about the `.def` file, and add the option `/export:initspam` somewhere to the Link settings, by manually editing the setting in Project Properties dialog).

10. **Creating a brand new project** — Use the *File* ▶ *New* ▶ *Project* dialog to create a new Project Workspace. Select *Visual C++ Projects/Win32/ Win32 Project*, enter the name (`spam`), and make sure the Location is set to parent of the `spam` directory you have created (which should be a direct subdirectory of the Python build tree, a sibling of `Include` and `PC`). Select Win32 as

the platform (in my version, this is the only choice). Make sure the Create new workspace radio button is selected. Click OK.

You should now create the file `spam.def` as instructed in the previous section. Add the source files to the project, using *Project* ▶ *Add Existing Item*. Set the pattern to `*.*` and select both `spam.c` and `spam.def` and click OK. (Inserting them one by one is fine too.)

Now open the *Project* ▶ *spam properties* dialog. You only need to change a few settings. Make sure *All Configurations* is selected from the *Settings for:* dropdown list. Select the C/C++ tab. Choose the General category in the popup menu at the top. Type the following text in the entry box labeled *Additional Include Directories*:

```
..\Include,..\PC
```

Then, choose the General category in the Linker tab, and enter

```
..\PCbuild
```

in the text box labelled *Additional library Directories*.

Now you need to add some mode-specific settings:

Select *Release* in the *Configuration* dropdown list. Choose the *Link* tab, choose the *Input* category, and append `pythonXY.lib` to the list in the *Additional Dependencies* box.

Select *Debug* in the *Configuration* dropdown list, and append `pythonXY_d.lib` to the list in the *Additional Dependencies* box. Then click the C/C++ tab, select *Code Generation*, and select *Multi-threaded Debug DLL* from the *Runtime library* dropdown list.

Select *Release* again from the *Configuration* dropdown list. Select *Multi-threaded DLL* from the *Runtime library* dropdown list.

If your module creates a new type, you may have trouble with this line:

```
PyVarObject_HEAD_INIT(&PyType_Type, 0)
```

Static type object initializers in extension modules may cause compiles to fail with an error message like “initializer not a constant”. This shows up when building DLL under MSVC. Change it to:

```
PyVarObject_HEAD_INIT(NULL, 0)
```

and add the following to the module initialization function:

```
if (PyType_Ready(&MyObject_Type) < 0)  
    return NULL;
```

4.2. Differences Between Unix and Windows

Unix and Windows use completely different paradigms for run-time loading of code. Before you try to build a module that can be dynamically loaded, be aware of how your system works.

In Unix, a shared object (`.so`) file contains code to be used by the program, and also the names of functions and data that it expects to find in the program. When the file is joined to the program, all references to those functions and data in the file's code are changed to point to the actual locations in the program where the functions and data are placed in memory. This is basically a link operation.

In Windows, a dynamic-link library (`.dll`) file has no dangling references. Instead, an access to functions or data goes through a lookup table. So the DLL code does not have to be fixed up at runtime to refer to the program's memory; instead, the code already uses the DLL's lookup table, and the lookup table is modified at runtime to point to the functions and data.

In Unix, there is only one type of library file (`.a`) which contains code from several object files (`.o`). During the link step to create a shared object file (`.so`), the linker may find that it doesn't know where an identifier is defined. The linker will look for it in the object files in the libraries; if it finds it, it will include all the code from that object file.

In Windows, there are two types of library, a static library and an import library (both called `.lib`). A static library is like a Unix `.a` file; it contains code to be included as necessary. An import library is basically used only to reassure the linker that a certain identifier is legal, and will be present in the program when the DLL is loaded. So the linker uses the information from the import library to build the

lookup table for using identifiers that are not included in the DLL. When an application or a DLL is linked, an import library may be generated, which will need to be used for all future DLLs that depend on the symbols in the application or DLL.

Suppose you are building two dynamic-load modules, B and C, which should share another block of code A. On Unix, you would *not* pass `A.a` to the linker for `B.so` and `C.so`; that would cause it to be included twice, so that B and C would each have their own copy. In Windows, building `A.dll` will also build `A.lib`. You *do* pass `A.lib` to the linker for B and C. `A.lib` does not contain code; it just contains information which will be used at runtime to access A's code.

In Windows, using an import library is sort of like using `import spam`; it gives you access to spam's names, but does not create a separate copy. On Unix, linking with a library is more like `from spam import *`; it does create a separate copy.

4.3. Using DLLs in Practice

Windows Python is built in Microsoft Visual C++; using other compilers may or may not work (though Borland seems to). The rest of this section is MSVC++ specific.

When creating DLLs in Windows, you must pass `pythonXY.lib` to the linker. To build two DLLs, `spam` and `ni` (which uses C functions found in `spam`), you could use these commands:

```
cl /LD /I/python/include spam.c ../libs/pythonXY.lib
cl /LD /I/python/include ni.c spam.lib ../libs/pythonXY.lib
```

The first command created three files: `spam.obj`, `spam.dll` and `spam.lib`. `spam.dll` does not contain any Python functions (such as `PyArg_ParseTuple()`), but it does know how to find the Python code thanks to `pythonXY.lib`.

The second command created `ni.dll` (and `.obj` and `.lib`), which knows how to find the necessary functions from `spam`, and also from the Python executable.

Not every identifier is exported to the lookup table. If you want any other modules (including Python) to be able to see your identifiers, you have to say `_declspec(dllexport)`, as in `void _declspec(dllexport) initspam(void)` or `PyObject _declspec(dllexport) *NiGetSpamData(void)`.

Developer Studio will throw in a lot of import libraries that you do not really need, adding about 100K to your executable. To get rid of them, use the Project Settings dialog, Link tab, to specify *ignore default libraries*. Add the correct `msvcrtxx.lib` to the list of libraries.

5. Embedding Python in Another Application

The previous chapters discussed how to extend Python, that is, how to extend the functionality of Python by attaching a library of C functions to it. It is also possible to do it the other way around: enrich your C/C++ application by embedding Python in it. Embedding provides your application with the ability to implement some of the functionality of your application in Python rather than C or C++. This can be used for many purposes; one example would be to allow users to tailor the application to their needs by writing some scripts in Python. You can also use it yourself if some of the functionality can be written in Python more easily.

Embedding Python is similar to extending it, but not quite. The difference is that when you extend Python, the main program of the application is still the Python interpreter, while if you embed Python, the main program may have nothing to do with Python — instead, some parts of the application occasionally call the Python interpreter to run some Python code.

So if you are embedding Python, you are providing your own main program. One of the things this main program has to do is initialize the Python interpreter. At the very least, you have to call the function `Py_Initialize()`. There are optional calls to pass command line arguments to Python. Then later you can call the interpreter from any part of the application.

There are several different ways to call the interpreter: you can pass a string containing Python statements to `PyRun_SimpleString()`, or you can pass a stdio file pointer and a file name (for identification in error messages only) to `PyRun_SimpleFile()`. You can also call the lower-level operations described in the previous chapters to

construct and use Python objects.

See also:

Python/C API Reference Manual

The details of Python's C interface are given in this manual. A great deal of necessary information can be found here.

5.1. Very High Level Embedding

The simplest form of embedding Python is the use of the very high level interface. This interface is intended to execute a Python script without needing to interact with the application directly. This can for example be used to perform some operation on a file.

```
#include <Python.h>

int
main(int argc, char *argv[])
{
    Py_Initialize();
    PyRun_SimpleString("from time import time,ctime\n"
                      "print('Today is', ctime(time))\n");
    Py_Finalize();
    return 0;
}
```

The above code first initializes the Python interpreter with `Py_Initialize()`, followed by the execution of a hard-coded Python script that print the date and time. Afterwards, the `Py_Finalize()` call shuts the interpreter down, followed by the end of the program. In a real program, you may want to get the Python script from another source, perhaps a text-editor routine, a file, or a database. Getting the Python code from a file can better be done by using the `PyRun_SimpleFile()` function, which saves you the trouble of allocating memory space and loading the file contents.

5.2. Beyond Very High Level Embedding: An overview

The high level interface gives you the ability to execute arbitrary pieces of Python code from your application, but exchanging data values is quite cumbersome to say the least. If you want that, you should use lower level calls. At the cost of having to write more C code, you can achieve almost anything.

It should be noted that extending Python and embedding Python is quite the same activity, despite the different intent. Most topics discussed in the previous chapters are still valid. To show this, consider what the extension code from Python to C really does:

1. Convert data values from Python to C,
2. Perform a function call to a C routine using the converted values, and
3. Convert the data values from the call from C to Python.

When embedding Python, the interface code does:

1. Convert data values from C to Python,
2. Perform a function call to a Python interface routine using the converted values, and
3. Convert the data values from the call from Python to C.

As you can see, the data conversion steps are simply swapped to accommodate the different direction of the cross-language transfer. The only difference is the routine that you call between both data conversions. When extending, you call a C routine, when embedding, you call a Python routine.

This chapter will not discuss how to convert data from Python to C and vice versa. Also, proper use of references and dealing with

errors is assumed to be understood. Since these aspects do not differ from extending the interpreter, you can refer to earlier chapters for the required information.

5.3. Pure Embedding

The first program aims to execute a function in a Python script. Like in the section about the very high level interface, the Python interpreter does not directly interact with the application (but that will change in the next section).

The code to run a function defined in a Python script is:

```
#include <Python.h>

int
main(int argc, char *argv[])
{
    PyObject *pName, *pModule, *pDict, *pFunc;
    PyObject *pArgs, *pValue;
    int i;

    if (argc < 3) {
        fprintf(stderr, "Usage: call pythonfile funcname [args]\n");
        return 1;
    }

    Py_Initialize();
    pName = PyUnicode_FromString(argv[1]);
    /* Error checking of pName left out */

    pModule = PyImport_Import(pName);
    Py_DECREF(pName);

    if (pModule != NULL) {
        pFunc = PyObject_GetAttrString(pModule, argv[2]);
        /* pFunc is a new reference */

        if (pFunc && PyCallable_Check(pFunc)) {
            pArgs = PyTuple_New(argc - 3);
            for (i = 0; i < argc - 3; ++i) {
                pValue = PyLong_FromLong(atoi(argv[i + 3]));
                if (!pValue) {
                    Py_DECREF(pArgs);
                    Py_DECREF(pModule);
                    fprintf(stderr, "Cannot convert argument\n");
                }
            }
        }
    }
}
```

```

        return 1;
    }
    /* pValue reference stolen here: */
    PyTuple_SetItem(pArgs, i, pValue);
}
pValue = PyObject_CallObject(pFunc, pArgs);
Py_DECREF(pArgs);
if (pValue != NULL) {
    printf("Result of call: %ld\n", PyLong_AsLong(pValue));
    Py_DECREF(pValue);
}
else {
    Py_DECREF(pFunc);
    Py_DECREF(pModule);
    PyErr_Print();
    fprintf(stderr, "Call failed\n");
    return 1;
}
}
else {
    if (PyErr_Occurred())
        PyErr_Print();
    fprintf(stderr, "Cannot find function \"%s\"\n", argv[1]);
}
Py_XDECREF(pFunc);
Py_DECREF(pModule);
}
else {
    PyErr_Print();
    fprintf(stderr, "Failed to load \"%s\"\n", argv[1]);
    return 1;
}
Py_Finalize();
return 0;
}

```

This code loads a Python script using `argv[1]`, and calls the function named in `argv[2]`. Its integer arguments are the other values of the `argv` array. If you compile and link this program (let's call the finished executable **call**), and use it to execute a Python script, such as:

```

def multiply(a,b):
    print("Will compute", a, "times", b)

```

```
c = 0
for i in range(0, a):
    c = c + b
return c
```

then the result should be:

```
$ call multiply multiply 3 2
Will compute 3 times 2
Result of call: 6
```

Although the program is quite large for its functionality, most of the code is for data conversion between Python and C, and for error reporting. The interesting part with respect to embedding Python starts with

```
Py_Initialize();
pName = PyString_FromString(argv[1]);
/* Error checking of pName left out */
pModule = PyImport_Import(pName);
```

After initializing the interpreter, the script is loaded using `PyImport_Import()`. This routine needs a Python string as its argument, which is constructed using the `PyString_FromString()` data conversion routine.

```
pFunc = PyObject_GetAttrString(pModule, argv[2]);
/* pFunc is a new reference */

if (pFunc && PyCallable_Check(pFunc)) {
    ...
}
Py_XDECREF(pFunc);
```

Once the script is loaded, the name we're looking for is retrieved using `PyObject_GetAttrString()`. If the name exists, and the object returned is callable, you can safely assume that it is a function. The program then proceeds by constructing a tuple of arguments as normal. The call to the Python function is then made with:

```
pValue = PyObject_CallObject(pFunc, pArgs);
```

Upon return of the function, `pValue` is either *NULL* or it contains a reference to the return value of the function. Be sure to release the reference after examining the value.

5.4. Extending Embedded Python

Until now, the embedded Python interpreter had no access to functionality from the application itself. The Python API allows this by extending the embedded interpreter. That is, the embedded interpreter gets extended with routines provided by the application. While it sounds complex, it is not so bad. Simply forget for a while that the application starts the Python interpreter. Instead, consider the application to be a set of subroutines, and write some glue code that gives Python access to those routines, just like you would write a normal Python extension. For example:

```
static int numargs=0;

/* Return the number of arguments of the application command line
static PyObject*
emb_numargs(PyObject *self, PyObject *args)
{
    if(!PyArg_ParseTuple(args, ":numargs"))
        return NULL;
    return PyLong_FromLong(numargs);
}

static PyMethodDef EmbMethods[] = {
    {"numargs", emb_numargs, METH_VARARGS,
     "Return the number of arguments received by the process."}
    {NULL, NULL, 0, NULL}
};

static PyModuleDef EmbModule = {
    PyModuleDef_HEAD_INIT, "emb", NULL, -1, EmbMethods,
    NULL, NULL, NULL, NULL
};

static PyObject*
PyInit_emb(void)
{
    return PyModule_Create(&EmbModule);
}
```

Insert the above code just above the `main()` function. Also, insert the following two statements before the call to `Py_Initialize()`:

```
numargs = argc;  
PyImport_AppendInittab("emb", &PyInit_emb);
```

These two lines initialize the `numargs` variable, and make the `emb.numargs()` function accessible to the embedded Python interpreter. With these extensions, the Python script can do things like

```
import emb  
print("Number of arguments", emb.numargs())
```

In a real application, the methods will expose an API of the application to Python.

5.5. Embedding Python in C++

It is also possible to embed Python in a C++ program; precisely how this is done will depend on the details of the C++ system used; in general you will need to write the main program in C++, and use the C++ compiler to compile and link your program. There is no need to recompile Python itself using C++.

5.6. Linking Requirements

While the **configure** script shipped with the Python sources will correctly build Python to export the symbols needed by dynamically linked extensions, this is not automatically inherited by applications which embed the Python library statically, at least on Unix. This is an issue when the application is linked to the static runtime library (`libpython.a`) and needs to load dynamic extensions (implemented as `.so` files).

The problem is that some entry points are defined by the Python runtime solely for extension modules to use. If the embedding application does not use any of these entry points, some linkers will not include those entries in the symbol table of the finished executable. Some additional options are needed to inform the linker not to remove these symbols.

Determining the right options to use for any given platform can be quite difficult, but fortunately the Python configuration already has those values. To retrieve them from an installed Python interpreter, start an interactive interpreter and have a short session like this:

```
>>> import distutils.sysconfig
>>> distutils.sysconfig.get_config_var('LINKFORSHARED')
'-Xlinker -export-dynamic'
```

The contents of the string presented will be the options that should be used. If the string is empty, there's no need to add any additional options. The **LINKFORSHARED** definition corresponds to the variable of the same name in Python's top-level `Makefile`.

Introduction

The Application Programmer's Interface to Python gives C and C++ programmers access to the Python interpreter at a variety of levels. The API is equally usable from C++, but for brevity it is generally referred to as the Python/C API. There are two fundamentally different reasons for using the Python/C API. The first reason is to write *extension modules* for specific purposes; these are C modules that extend the Python interpreter. This is probably the most common use. The second reason is to use Python as a component in a larger application; this technique is generally referred to as *embedding Python* in an application.

Writing an extension module is a relatively well-understood process, where a “cookbook” approach works well. There are several tools that automate the process to some extent. While people have embedded Python in other applications since its early existence, the process of embedding Python is less straightforward than writing an extension.

Many API functions are useful independent of whether you're embedding or extending Python; moreover, most applications that embed Python will need to provide a custom extension as well, so it's probably a good idea to become familiar with writing an extension before attempting to embed Python in a real application.

Include Files

All function, type and macro definitions needed to use the Python/C API are included in your code by the following line:

```
#include "Python.h"
```

This implies inclusion of the following standard headers: `<stdio.h>`, `<string.h>`, `<errno.h>`, `<limits.h>`, `<assert.h>` and `<stdlib.h>` (if available).

Note: Since Python may define some pre-processor definitions which affect the standard headers on some systems, you *must* include `Python.h` before any standard headers are included.

All user visible names defined by `Python.h` (except those defined by the included standard headers) have one of the prefixes `Py` or `_Py`. Names beginning with `_Py` are for internal use by the Python implementation and should not be used by extension writers. Structure member names do not have a reserved prefix.

Important: user code should never define names that begin with `Py` or `_Py`. This confuses the reader, and jeopardizes the portability of the user code to future Python versions, which may define additional names beginning with one of these prefixes.

The header files are typically installed with Python. On Unix, these are located in the directories `prefix/include/pythonversion/` and `exec_prefix/include/pythonversion/`, where `prefix` and `exec_prefix` are defined by the corresponding parameters to Python's **configure** script and `version` is `sys.version[:3]`. On Windows, the headers are installed in `prefix/include`, where `prefix`

is the installation directory specified to the installer.

To include the headers, place both directories (if different) on your compiler's search path for includes. Do *not* place the parent directories on the search path and then use `#include <pythonX.Y/Python.h>`; this will break on multi-platform builds since the platform independent headers under `prefix` include the platform specific headers from `exec_prefix`.

C++ users should note that though the API is defined entirely using C, the header files do properly declare the entry points to be `extern "c"`, so there is no need to do anything special to use the API from C++.

Objects, Types and Reference Counts

Most Python/C API functions have one or more arguments as well as a return value of type `PyObject*`. This type is a pointer to an opaque data type representing an arbitrary Python object. Since all Python object types are treated the same way by the Python language in most situations (e.g., assignments, scope rules, and argument passing), it is only fitting that they should be represented by a single C type. Almost all Python objects live on the heap: you never declare an automatic or static variable of type `PyObject`, only pointer variables of type `PyObject*` can be declared. The sole exception are the type objects; since these must never be deallocated, they are typically static `PyTypeObject` objects.

All Python objects (even Python integers) have a *type* and a *reference count*. An object's type determines what kind of object it is (e.g., an integer, a list, or a user-defined function; there are many more as explained in *The standard type hierarchy*). For each of the well-known types there is a macro to check whether an object is of that type; for instance, `PyList_Check(a)` is true if (and only if) the object pointed to by `a` is a Python list.

Reference Counts

The reference count is important because today's computers have a finite (and often severely limited) memory size; it counts how many different places there are that have a reference to an object. Such a place could be another object, or a global (or static) C variable, or a local variable in some C function. When an object's reference count becomes zero, the object is deallocated. If it contains references to other objects, their reference count is decremented. Those other objects may be deallocated in turn, if this decrement makes their

reference count become zero, and so on. (There's an obvious problem with objects that reference each other here; for now, the solution is "don't do that.")

Reference counts are always manipulated explicitly. The normal way is to use the macro `Py_INCREF()` to increment an object's reference count by one, and `Py_DECREF()` to decrement it by one. The `Py_DECREF()` macro is considerably more complex than the `Py_INCREF()` one, since it must check whether the reference count becomes zero and then cause the object's deallocator to be called. The deallocator is a function pointer contained in the object's type structure. The type-specific deallocator takes care of decrementing the reference counts for other objects contained in the object if this is a compound object type, such as a list, as well as performing any additional finalization that's needed. There's no chance that the reference count can overflow; at least as many bits are used to hold the reference count as there are distinct memory locations in virtual memory (assuming `sizeof(Py_ssize_t) >= sizeof(void*)`). Thus, the reference count increment is a simple operation.

It is not necessary to increment an object's reference count for every local variable that contains a pointer to an object. In theory, the object's reference count goes up by one when the variable is made to point to it and it goes down by one when the variable goes out of scope. However, these two cancel each other out, so at the end the reference count hasn't changed. The only real reason to use the reference count is to prevent the object from being deallocated as long as our variable is pointing to it. If we know that there is at least one other reference to the object that lives at least as long as our variable, there is no need to increment the reference count temporarily. An important situation where this arises is in objects that are passed as arguments to C functions in an extension module that are called from Python; the call mechanism guarantees to hold a reference to every argument for the duration of the call.

However, a common pitfall is to extract an object from a list and hold on to it for a while without incrementing its reference count. Some other operation might conceivably remove the object from the list, decrementing its reference count and possibly deallocating it. The real danger is that innocent-looking operations may invoke arbitrary Python code which could do this; there is a code path which allows control to flow back to the user from a `Py_DECREF()`, so almost any operation is potentially dangerous.

A safe approach is to always use the generic operations (functions whose name begins with `PyObject_`, `PyNumber_`, `PySequence_` or `PyMapping_`). These operations always increment the reference count of the object they return. This leaves the caller with the responsibility to call `Py_DECREF()` when they are done with the result; this soon becomes second nature.

Reference Count Details

The reference count behavior of functions in the Python/C API is best explained in terms of *ownership of references*. Ownership pertains to references, never to objects (objects are not owned: they are always shared). “Owning a reference” means being responsible for calling `Py_DECREF` on it when the reference is no longer needed. Ownership can also be transferred, meaning that the code that receives ownership of the reference then becomes responsible for eventually decref’ing it by calling `Py_DECREF()` or `Py_XDECREF()` when it’s no longer needed—or passing on this responsibility (usually to its caller). When a function passes ownership of a reference on to its caller, the caller is said to receive a *new* reference. When no ownership is transferred, the caller is said to *borrow* the reference. Nothing needs to be done for a borrowed reference.

Conversely, when a calling function passes in a reference to an

object, there are two possibilities: the function *steals* a reference to the object, or it does not. *Stealing a reference* means that when you pass a reference to a function, that function assumes that it now owns that reference, and you are not responsible for it any longer.

Few functions steal references; the two notable exceptions are `PyList_SetItem()` and `PyTuple_SetItem()`, which steal a reference to the item (but not to the tuple or list into which the item is put!). These functions were designed to steal a reference because of a common idiom for populating a tuple or list with newly created objects; for example, the code to create the tuple `(1, 2, "three")` could look like this (forgetting about error handling for the moment; a better way to code this is shown below):

```
PyObject *t;  
  
t = PyTuple_New(3);  
PyTuple_SetItem(t, 0, PyLong_FromLong(1L));  
PyTuple_SetItem(t, 1, PyLong_FromLong(2L));  
PyTuple_SetItem(t, 2, PyString_FromString("three"));
```

Here, `PyLong_FromLong()` returns a new reference which is immediately stolen by `PyTuple_SetItem()`. When you want to keep using an object although the reference to it will be stolen, use `Py_INCREF()` to grab another reference before calling the reference-stealing function.

Incidentally, `PyTuple_SetItem()` is the *only* way to set tuple items; `PySequence_SetItem()` and `PyObject_SetItem()` refuse to do this since tuples are an immutable data type. You should only use `PyTuple_SetItem()` for tuples that you are creating yourself.

Equivalent code for populating a list can be written using `PyList_New()` and `PyList_SetItem()`.

However, in practice, you will rarely use these ways of creating and

populating a tuple or list. There's a generic function, `Py_BuildValue()`, that can create most common objects from C values, directed by a *format string*. For example, the above two blocks of code could be replaced by the following (which also takes care of the error checking):

```
PyObject *tuple, *list;

tuple = Py_BuildValue("(iis)", 1, 2, "three");
list = Py_BuildValue("[iis]", 1, 2, "three");
```

It is much more common to use `PyObject_SetItem()` and friends with items whose references you are only borrowing, like arguments that were passed in to the function you are writing. In that case, their behaviour regarding reference counts is much saner, since you don't have to increment a reference count so you can give a reference away ("have it be stolen"). For example, this function sets all items of a list (actually, any mutable sequence) to a given item:

```
int
set_all(PyObject *target, PyObject *item)
{
    int i, n;

    n = PyObject_Length(target);
    if (n < 0)
        return -1;
    for (i = 0; i < n; i++) {
        PyObject *index = PyLong_FromLong(i);
        if (!index)
            return -1;
        if (PyObject_SetItem(target, index, item) < 0)
            return -1;
        Py_DECREF(index);
    }
    return 0;
}
```

The situation is slightly different for function return values. While passing a reference to most functions does not change your

ownership responsibilities for that reference, many functions that return a reference to an object give you ownership of the reference. The reason is simple: in many cases, the returned object is created on the fly, and the reference you get is the only reference to the object. Therefore, the generic functions that return object references, like `PyObject_GetItem()` and `PySequence_GetItem()`, always return a new reference (the caller becomes the owner of the reference).

It is important to realize that whether you own a reference returned by a function depends on which function you call only — *the plumage* (the type of the object passed as an argument to the function) *doesn't enter into it!* Thus, if you extract an item from a list using `PyList_GetItem()`, you don't own the reference — but if you obtain the same item from the same list using `PySequence_GetItem()` (which happens to take exactly the same arguments), you do own a reference to the returned object.

Here is an example of how you could write a function that computes the sum of the items in a list of integers; once using `PyList_GetItem()`, and once using `PySequence_GetItem()`.

```
long
sum_list(PyObject *list)
{
    int i, n;
    long total = 0;
    PyObject *item;

    n = PyList_Size(list);
    if (n < 0)
        return -1; /* Not a list */
    for (i = 0; i < n; i++) {
        item = PyList_GetItem(list, i); /* Can't fail */
        if (!PyLong_Check(item)) continue; /* Skip non-integers */
        total += PyLong_AsLong(item);
    }
    return total;
}
```

```

long
sum_sequence(PyObject *sequence)
{
    int i, n;
    long total = 0;
    PyObject *item;
    n = PySequence_Length(sequence);
    if (n < 0)
        return -1; /* Has no length */
    for (i = 0; i < n; i++) {
        item = PySequence_GetItem(sequence, i);
        if (item == NULL)
            return -1; /* Not a sequence, or other failure */
        if (PyLong_Check(item))
            total += PyLong_AsLong(item);
        Py_DECREF(item); /* Discard reference ownership */
    }
    return total;
}

```

Types

There are few other data types that play a significant role in the Python/C API; most are simple C types such as `int`, `long`, `double` and `char*`. A few structure types are used to describe static tables used to list the functions exported by a module or the data attributes of a new object type, and another is used to describe the value of a complex number. These will be discussed together with the functions that use them.

Exceptions

The Python programmer only needs to deal with exceptions if specific error handling is required; unhandled exceptions are automatically propagated to the caller, then to the caller's caller, and so on, until they reach the top-level interpreter, where they are reported to the user accompanied by a stack traceback.

For C programmers, however, error checking always has to be explicit. All functions in the Python/C API can raise exceptions, unless an explicit claim is made otherwise in a function's documentation. In general, when a function encounters an error, it sets an exception, discards any object references that it owns, and returns an error indicator. If not documented otherwise, this indicator is either *NULL* or `-1`, depending on the function's return type. A few functions return a Boolean true/false result, with false indicating an error. Very few functions return no explicit error indicator or have an ambiguous return value, and require explicit testing for errors with `PyErr_Occurred()`. These exceptions are always explicitly documented.

Exception state is maintained in per-thread storage (this is equivalent to using global storage in an unthreaded application). A thread can be in one of two states: an exception has occurred, or not. The function `PyErr_Occurred()` can be used to check for this: it returns a borrowed reference to the exception type object when an exception has occurred, and *NULL* otherwise. There are a number of functions to set the exception state: `PyErr_SetString()` is the most common (though not the most general) function to set the exception state, and `PyErr_Clear()` clears the exception state.

The full exception state consists of three objects (all of which can be *NULL*): the exception type, the corresponding exception value, and

the traceback. These have the same meanings as the Python result of `sys.exc_info()`; however, they are not the same: the Python objects represent the last exception being handled by a Python `try ... except` statement, while the C level exception state only exists while an exception is being passed on between C functions until it reaches the Python bytecode interpreter's main loop, which takes care of transferring it to `sys.exc_info()` and friends.

Note that starting with Python 1.5, the preferred, thread-safe way to access the exception state from Python code is to call the function `sys.exc_info()`, which returns the per-thread exception state for Python code. Also, the semantics of both ways to access the exception state have changed so that a function which catches an exception will save and restore its thread's exception state so as to preserve the exception state of its caller. This prevents common bugs in exception handling code caused by an innocent-looking function overwriting the exception being handled; it also reduces the often unwanted lifetime extension for objects that are referenced by the stack frames in the traceback.

As a general principle, a function that calls another function to perform some task should check whether the called function raised an exception, and if so, pass the exception state on to its caller. It should discard any object references that it owns, and return an error indicator, but it should *not* set another exception — that would overwrite the exception that was just raised, and lose important information about the exact cause of the error.

A simple example of detecting exceptions and passing them on is shown in the `sum_sequence()` example above. It so happens that that example doesn't need to clean up any owned references when it detects an error. The following example function shows some error cleanup. First, to remind you why you like Python, we show the equivalent Python code:

```

def incr_item(dict, key):
    try:
        item = dict[key]
    except KeyError:
        item = 0
    dict[key] = item + 1

```

Here is the corresponding C code, in all its glory:

```

int
incr_item(PyObject *dict, PyObject *key)
{
    /* Objects all initialized to NULL for Py_XDECREF */
    PyObject *item = NULL, *const_one = NULL, *incremented_item
    int rv = -1; /* Return value initialized to -1 (failure) */

    item = PyObject_GetItem(dict, key);
    if (item == NULL) {
        /* Handle KeyError only: */
        if (!PyErr_ExceptionMatches(PyExc_KeyError))
            goto error;

        /* Clear the error and use zero: */
        PyErr_Clear();
        item = PyLong_FromLong(0L);
        if (item == NULL)
            goto error;
    }
    const_one = PyLong_FromLong(1L);
    if (const_one == NULL)
        goto error;

    incremented_item = PyNumber_Add(item, const_one);
    if (incremented_item == NULL)
        goto error;

    if (PyObject_SetItem(dict, key, incremented_item) < 0)
        goto error;
    rv = 0; /* Success */
    /* Continue with cleanup code */

error:
    /* Cleanup code, shared by success and failure path */

    /* Use Py_XDECREF() to ignore NULL references */

```

```
Py_XDECREF(item);
Py_XDECREF(const_one);
Py_XDECREF(incremented_item);

return rv; /* -1 for error, 0 for success */
}
```

This example represents an endorsed use of the `goto` statement in C! It illustrates the use of `PyErr_ExceptionMatches()` and `PyErr_Clear()` to handle specific exceptions, and the use of `Py_XDECREF()` to dispose of owned references that may be `NULL` (note the 'x' in the name; `Py_DECREF()` would crash when confronted with a `NULL` reference). It is important that the variables used to hold owned references are initialized to `NULL` for this to work; likewise, the proposed return value is initialized to `-1` (failure) and only set to success after the final call made is successful.

Embedding Python

The one important task that only embedders (as opposed to extension writers) of the Python interpreter have to worry about is the initialization, and possibly the finalization, of the Python interpreter. Most functionality of the interpreter can only be used after the interpreter has been initialized.

The basic initialization function is `Py_Initialize()`. This initializes the table of loaded modules, and creates the fundamental modules `builtins`, `__main__`, `sys`, and `exceptions`. It also initializes the module search path (`sys.path`).

`Py_Initialize()` does not set the “script argument list” (`sys.argv`). If this variable is needed by Python code that will be executed later, it must be set explicitly with a call to `PySys_SetArgvEx(argc, argv, updatepath)` after the call to `Py_Initialize()`.

On most systems (in particular, on Unix and Windows, although the details are slightly different), `Py_Initialize()` calculates the module search path based upon its best guess for the location of the standard Python interpreter executable, assuming that the Python library is found in a fixed location relative to the Python interpreter executable. In particular, it looks for a directory named `lib/pythonX.Y` relative to the parent directory where the executable named `python` is found on the shell command search path (the environment variable `PATH`).

For instance, if the Python executable is found in `/usr/local/bin/python`, it will assume that the libraries are in `/usr/local/lib/pythonX.Y`. (In fact, this particular path is also the “fallback” location, used when no executable file named `python` is

found along `PATH`.) The user can override this behavior by setting the environment variable `PYTHONHOME`, or insert additional directories in front of the standard path by setting `PYTHONPATH`.

The embedding application can steer the search by calling `Py_SetProgramName(file)` *before* calling `Py_Initialize()`. Note that `PYTHONHOME` still overrides this and `PYTHONPATH` is still inserted in front of the standard path. An application that requires total control has to provide its own implementation of `Py_GetPath()`, `Py_GetPrefix()`, `Py_GetExecPrefix()`, and `Py_GetProgramFullPath()` (all defined in `Modules/getpath.c`).

Sometimes, it is desirable to “uninitialize” Python. For instance, the application may want to start over (make another call to `Py_Initialize()`) or the application is simply done with its use of Python and wants to free memory allocated by Python. This can be accomplished by calling `Py_Finalize()`. The function `Py_IsInitialized()` returns true if Python is currently in the initialized state. More information about these functions is given in a later chapter. Notice that `Py_Finalize()` does *not* free all memory allocated by the Python interpreter, e.g. memory allocated by extension modules currently cannot be released.

Debugging Builds

Python can be built with several macros to enable extra checks of the interpreter and extension modules. These checks tend to add a large amount of overhead to the runtime so they are not enabled by default.

A full list of the various types of debugging builds is in the file `Misc/SpecialBuilds.txt` in the Python source distribution. Builds are available that support tracing of reference counts, debugging the memory allocator, or low-level profiling of the main interpreter loop. Only the most frequently-used builds will be described in the remainder of this section.

Compiling the interpreter with the `Py_DEBUG` macro defined produces what is generally meant by “a debug build” of Python. `Py_DEBUG` is enabled in the Unix build by adding `--with-pydebug` to the `configure` command. It is also implied by the presence of the not-Python-specific `_DEBUG` macro. When `Py_DEBUG` is enabled in the Unix build, compiler optimization is disabled.

In addition to the reference count debugging described below, the following extra checks are performed:

- Extra checks are added to the object allocator.
- Extra checks are added to the parser and compiler.
- Downcasts from wide types to narrow types are checked for loss of information.
- A number of assertions are added to the dictionary and set implementations. In addition, the set object acquires a `test_c_api()` method.
- Sanity checks of the input arguments are added to frame creation.

- The storage for ints is initialized with a known invalid pattern to catch reference to uninitialized digits.
- Low-level tracing and extra exception checking are added to the runtime virtual machine.
- Extra checks are added to the memory arena implementation.
- Extra debugging is added to the thread module.

There may be additional checks not mentioned here.

Defining `Py_TRACE_REFS` enables reference tracing. When defined, a circular doubly linked list of active objects is maintained by adding two extra fields to every `PyObject`. Total allocations are tracked as well. Upon exit, all existing references are printed. (In interactive mode this happens after every statement run by the interpreter.) Implied by `Py_DEBUG`.

Please refer to `Misc/SpecialBuilds.txt` in the Python source distribution for more detailed information.

The Very High Level Layer

The functions in this chapter will let you execute Python source code given in a file or a buffer, but they will not let you interact in a more detailed way with the interpreter.

Several of these functions accept a start symbol from the grammar as a parameter. The available start symbols are `Py_eval_input`, `Py_file_input`, and `Py_single_input`. These are described following the functions which accept them as parameters.

Note also that several of these functions take `FILE*` parameters. One particular issue which needs to be handled carefully is that the `FILE` structure for different C libraries can be different and incompatible. Under Windows (at least), it is possible for dynamically linked extensions to actually use different libraries, so care should be taken that `FILE*` parameters are only passed to these functions if it is certain that they were created by the same library that the Python runtime is using.

`int Py_Main(int argc, wchar_t **argv)`

The main program for the standard interpreter. This is made available for programs which embed Python. The `argc` and `argv` parameters should be prepared exactly as those which are passed to a C program's `main()` function (converted to `wchar_t` according to the user's locale). It is important to note that the argument list may be modified (but the contents of the strings pointed to by the argument list are not). The return value will be the integer passed to the `sys.exit()` function, `1` if the interpreter exits due to an exception, or `2` if the parameter list does not represent a valid Python command line.

Note that if an otherwise unhandled `SystemError` is raised, this

function will not return 1, but exit the process, as long as `Py_InspectFlag` is not set.

`int PyRun_AnyFile(FILE *fp, const char *filename)`

This is a simplified interface to `PyRun_AnyFileExFlags()` below, leaving `closeit` set to 0 and `flags` set to `NULL`.

`int PyRun_AnyFileFlags(FILE *fp, const char *filename, PyCompilerFlags *flags)`

This is a simplified interface to `PyRun_AnyFileExFlags()` below, leaving the `closeit` argument set to 0.

`int PyRun_AnyFileEx(FILE *fp, const char *filename, int closeit)`

This is a simplified interface to `PyRun_AnyFileExFlags()` below, leaving the `flags` argument set to `NULL`.

`int PyRun_AnyFileExFlags(FILE *fp, const char *filename, int closeit, PyCompilerFlags *flags)`

If `fp` refers to a file associated with an interactive device (console or terminal input or Unix pseudo-terminal), return the value of `PyRun_InteractiveLoop()`, otherwise return the result of `PyRun_SimpleFile()`. `filename` is decoded from the filesystem encoding (`sys.getfilesystemencoding()`). If `filename` is `NULL`, this function uses "???" as the filename.

`int PyRun_SimpleString(const char *command)`

This is a simplified interface to `PyRun_SimpleStringFlags()` below, leaving the `PyCompilerFlags*` argument set to `NULL`.

`int PyRun_SimpleStringFlags(const char *command, PyCompilerFlags *flags)`

Executes the Python source code from `command` in the `__main__` module according to the `flags` argument. If `__main__` does not

already exist, it is created. Returns `0` on success or `-1` if an exception was raised. If there was an error, there is no way to get the exception information. For the meaning of *flags*, see below.

Note that if an otherwise unhandled `SystemError` is raised, this function will not return `-1`, but exit the process, as long as `Py_InspectFlag` is not set.

`int PyRun_SimpleFile(FILE *fp, const char *filename)`

This is a simplified interface to `PyRun_SimpleFileExFlags()` below, leaving *closeit* set to `0` and *flags* set to `NULL`.

`int PyRun_SimpleFileFlags(FILE *fp, const char *filename, PyCompilerFlags *flags)`

This is a simplified interface to `PyRun_SimpleFileExFlags()` below, leaving *closeit* set to `0`.

`int PyRun_SimpleFileEx(FILE *fp, const char *filename, int closeit)`

This is a simplified interface to `PyRun_SimpleFileExFlags()` below, leaving *flags* set to `NULL`.

`int PyRun_SimpleFileExFlags(FILE *fp, const char *filename, int closeit, PyCompilerFlags *flags)`

Similar to `PyRun_SimpleStringFlags()`, but the Python source code is read from *fp* instead of an in-memory string. *filename* should be the name of the file, it is decoded from the filesystem encoding (`sys.getfilesystemencoding()`). If *closeit* is true, the file is closed before `PyRun_SimpleFileExFlags` returns.

`int PyRun_InteractiveOne(FILE *fp, const char *filename)`

This is a simplified interface to `PyRun_InteractiveOneFlags()` below, leaving *flags* set to `NULL`.

int PyRun_InteractiveOneFlags(FILE *fp, const char *filename, PyCompilerFlags *flags)

Read and execute a single statement from a file associated with an interactive device according to the *flags* argument. The user will be prompted using `sys.ps1` and `sys.ps2`. *filename* is decoded from the filesystem encoding (`sys.getfilesystemencoding()`).

Returns `0` when the input was executed successfully, `-1` if there was an exception, or an error code from the `errcode.h` include file distributed as part of Python if there was a parse error. (Note that `errcode.h` is not included by `Python.h`, so must be included specifically if needed.)

int PyRun_InteractiveLoop(FILE *fp, const char *filename)

This is a simplified interface to `PyRun_InteractiveLoopFlags()` below, leaving *flags* set to `NULL`.

int PyRun_InteractiveLoopFlags(FILE *fp, const char *filename, PyCompilerFlags *flags)

Read and execute statements from a file associated with an interactive device until EOF is reached. The user will be prompted using `sys.ps1` and `sys.ps2`. *filename* is decoded from the filesystem encoding (`sys.getfilesystemencoding()`). Returns `0` at EOF.

struct _node* PyParser_SimpleParseString(const char *str, int start)

This is a simplified interface to `PyParser_SimpleParseStringFlagsFilename()` below, leaving *filename* set to `NULL` and *flags* set to `0`.

struct _node* PyParser_SimpleParseStringFlags(const char *str, int start, int flags)

This is a simplified interface to `PyParser_SimpleParseStringFlagsFilename()` below, leaving `filename` set to `NULL`.

```
struct _node* PyParser_SimpleParseStringFlagsFilename(const char *str, const char *filename, int start, int flags)
```

Parse Python source code from `str` using the start token `start` according to the `flags` argument. The result can be used to create a code object which can be evaluated efficiently. This is useful if a code fragment must be evaluated many times. `filename` is decoded from the filesystem encoding (`sys.getfilesystemencoding()`).

```
struct _node* PyParser_SimpleParseFile(FILE *fp, const char *filename, int start)
```

This is a simplified interface to `PyParser_SimpleParseFileFlags()` below, leaving `flags` set to 0

```
struct _node* PyParser_SimpleParseFileFlags(FILE *fp, const char *filename, int start, int flags)
```

Similar to `PyParser_SimpleParseStringFlagsFilename()`, but the Python source code is read from `fp` instead of an in-memory string.

```
PyObject* PyRun_String(const char *str, int start, PyObject *globals, PyObject *locals)
```

Return value: New reference.

This is a simplified interface to `PyRun_StringFlags()` below, leaving `flags` set to `NULL`.

```
PyObject* PyRun_StringFlags(const char *str, int start, PyObject *globals, PyObject *locals, PyCompilerFlags *flags)
```

Return value: New reference.

Execute Python source code from `str` in the context specified by

the dictionaries *globals* and *locals* with the compiler flags specified by *flags*. The parameter *start* specifies the start token that should be used to parse the source code.

Returns the result of executing the code as a Python object, or *NULL* if an exception was raised.

```
PyObject* PyRun_File(FILE *fp, const char *filename, int start,  
PyObject *globals, PyObject *locals)
```

Return value: New reference.

This is a simplified interface to `PyRun_FileExFlags()` below, leaving *closeit* set to 0 and *flags* set to *NULL*.

```
PyObject* PyRun_FileEx(FILE *fp, const char *filename, int start,  
PyObject *globals, PyObject *locals, int closeit)
```

Return value: New reference.

This is a simplified interface to `PyRun_FileExFlags()` below, leaving *flags* set to *NULL*.

```
PyObject* PyRun_FileFlags(FILE *fp, const char *filename, int  
start, PyObject *globals, PyObject *locals, PyCompilerFlags *flags)
```

Return value: New reference.

This is a simplified interface to `PyRun_FileExFlags()` below, leaving *closeit* set to 0.

```
PyObject* PyRun_FileExFlags(FILE *fp, const char *filename, int  
start, PyObject *globals, PyObject *locals, int closeit,  
PyCompilerFlags *flags)
```

Return value: New reference.

Similar to `PyRun_StringFlags()`, but the Python source code is read from *fp* instead of an in-memory string. *filename* should be the name of the file, it is decoded from the filesystem encoding (`sys.getfilesystemencoding()`). If *closeit* is true, the file is closed before `PyRun_FileExFlags()` returns.

`PyObject*` **Py_CompileString**(const char **str*, const char **filename*, int *start*)

Return value: New reference.

This is a simplified interface to `Py_CompileStringFlags()` below, leaving *flags* set to `NULL`.

`PyObject*` **Py_CompileStringFlags**(const char **str*, const char **filename*, int *start*, `PyCompilerFlags` **flags*)

Return value: New reference.

This is a simplified interface to `Py_CompileStringExFlags()` below, with *optimize* set to `-1`.

`PyObject*` **Py_CompileStringExFlags**(const char **str*, const char **filename*, int *start*, `PyCompilerFlags` **flags*, int *optimize*)

Parse and compile the Python source code in *str*, returning the resulting code object. The start token is given by *start*; this can be used to constrain the code which can be compiled and should be `Py_eval_input`, `Py_file_input`, or `Py_single_input`. The filename specified by *filename* is used to construct the code object and may appear in tracebacks or `SyntaxError` exception messages, it is decoded from the filesystem encoding (`sys.getfilesystemencoding()`). This returns `NULL` if the code cannot be parsed or compiled.

The integer *optimize* specifies the optimization level of the compiler; a value of `-1` selects the optimization level of the interpreter as given by `-O` options. Explicit levels are `0` (no optimization; `__debug__` is true), `1` (asserts are removed, `__debug__` is false) or `2` (docstrings are removed too).

New in version 3.2.

`PyObject*` **PyEval_EvalCode**(`PyObject` **co*, `PyObject` **globals*,

PyObject *locals)

Return value: New reference.

This is a simplified interface to `PyEval_EvalCodeEx()`, with just the code object, and the dictionaries of global and local variables. The other arguments are set to `NULL`.

PyObject* **PyEval_EvalCodeEx**(PyObject *co, PyObject *globals, PyObject *locals, PyObject **args, int argcount, PyObject **kws, int kwcount, PyObject **defs, int defcount, PyObject *closure)

Evaluate a precompiled code object, given a particular environment for its evaluation. This environment consists of dictionaries of global and local variables, arrays of arguments, keywords and defaults, and a closure tuple of cells.

PyObject* **PyEval_EvalFrame**(PyFrameObject *f)

Evaluate an execution frame. This is a simplified interface to `PyEval_EvalFrameEx`, for backward compatibility.

PyObject* **PyEval_EvalFrameEx**(PyFrameObject *f, int *throwflag*)

This is the main, unvarnished function of Python interpretation. It is literally 2000 lines long. The code object associated with the execution frame *f* is executed, interpreting bytecode and executing calls as needed. The additional *throwflag* parameter can mostly be ignored - if true, then it causes an exception to immediately be thrown; this is used for the `throw()` methods of generator objects.

int **PyEval_MergeCompilerFlags**(PyCompilerFlags *cf)

This function changes the flags of the current evaluation frame, and returns true on success, false on failure.

int **Py_eval_input**

The start symbol from the Python grammar for isolated expressions; for use with `Py_CompileString()`.

int **Py_file_input**

The start symbol from the Python grammar for sequences of statements as read from a file or other source; for use with `Py_CompileString()`. This is the symbol to use when compiling arbitrarily long Python source code.

int **Py_single_input**

The start symbol from the Python grammar for a single statement; for use with `Py_CompileString()`. This is the symbol used for the interactive interpreter loop.

struct **PyCompilerFlags**

This is the structure used to hold compiler flags. In cases where code is only being compiled, it is passed as `int flags`, and in cases where code is being executed, it is passed as `PyCompilerFlags *flags`. In this case, `from __future__ import` can modify *flags*.

Whenever `PyCompilerFlags *flags` is *NULL*, `cf_flags` is treated as equal to 0, and any modification due to `from __future__ import` is discarded.

```
struct PyCompilerFlags {
    int cf_flags;
}
```

int **CO_FUTURE_DIVISION**

This bit can be set in *flags* to cause division operator `/` to be interpreted as “true division” according to [PEP 238](#).

Reference Counting

The macros in this section are used for managing reference counts of Python objects.

void **Py_INCREF**(PyObject *o)

Increment the reference count for object *o*. The object must not be *NULL*; if you aren't sure that it isn't *NULL*, use **Py_XINCREF()**.

void **Py_XINCREF**(PyObject *o)

Increment the reference count for object *o*. The object may be *NULL*, in which case the macro has no effect.

void **Py_DECREF**(PyObject *o)

Decrement the reference count for object *o*. The object must not be *NULL*; if you aren't sure that it isn't *NULL*, use **Py_XDECREF()**. If the reference count reaches zero, the object's type's deallocation function (which must not be *NULL*) is invoked.

Warning: The deallocation function can cause arbitrary Python code to be invoked (e.g. when a class instance with a `__del__()` method is deallocated). While exceptions in such code are not propagated, the executed code has free access to all Python global variables. This means that any object that is reachable from a global variable should be in a consistent state before **Py_DECREF()** is invoked. For example, code to delete an object from a list should copy a reference to the deleted object in a temporary variable, update the list data structure, and then call **Py_DECREF()** for the temporary variable.

void **Py_XDECREF**(PyObject *o)

Decrement the reference count for object *o*. The object may be *NULL*, in which case the macro has no effect; otherwise the

effect is the same as for `Py_DECREF()`, and the same warning applies.

`void Py_CLEAR(PyObject *o)`

Decrement the reference count for object *o*. The object may be *NULL*, in which case the macro has no effect; otherwise the effect is the same as for `Py_DECREF()`, except that the argument is also set to *NULL*. The warning for `Py_DECREF()` does not apply with respect to the object passed because the macro carefully uses a temporary variable and sets the argument to *NULL* before decrementing its reference count.

It is a good idea to use this macro whenever decrementing the value of a variable that might be traversed during garbage collection.

The following functions are for runtime dynamic embedding of Python: `Py_IncRef(PyObject *o)`, `Py_DecRef(PyObject *o)`. They are simply exported function versions of `Py_XINCREF()` and `Py_XDECREF()`, respectively.

The following functions or macros are only for use within the interpreter core: `_Py_Dealloc()`, `_Py_ForgetReference()`, `_Py_NewReference()`, as well as the global variable `_Py_RefTotal`.

Exception Handling

The functions described in this chapter will let you handle and raise Python exceptions. It is important to understand some of the basics of Python exception handling. It works somewhat like the Unix `errno` variable: there is a global indicator (per thread) of the last error that occurred. Most functions don't clear this on success, but will set it to indicate the cause of the error on failure. Most functions also return an error indicator, usually `NULL` if they are supposed to return a pointer, or `-1` if they return an integer (exception: the `PyArg_*` functions return `1` for success and `0` for failure).

When a function must fail because some function it called failed, it generally doesn't set the error indicator; the function it called already set it. It is responsible for either handling the error and clearing the exception or returning after cleaning up any resources it holds (such as object references or memory allocations); it should *not* continue normally if it is not prepared to handle the error. If returning due to an error, it is important to indicate to the caller that an error has been set. If the error is not handled or carefully propagated, additional calls into the Python/C API may not behave as intended and may fail in mysterious ways.

The error indicator consists of three Python objects corresponding to the result of `sys.exc_info()`. API functions exist to interact with the error indicator in various ways. There is a separate error indicator for each thread.

`void PyErr_PrintEx(int set_sys_last_vars)`

Print a standard traceback to `sys.stderr` and clear the error indicator. Call this function only when the error indicator is set. (Otherwise it will cause a fatal error!)

If `set_sys_last_vars` is nonzero, the variables `sys.last_type`, `sys.last_value` and `sys.last_traceback` will be set to the type, value and traceback of the printed exception, respectively.

void `PyErr_Print()`

Alias for `PyErr_PrintEx(1)`.

`PyObject*` `PyErr_Occurred()`

Return value: Borrowed reference.

Test whether the error indicator is set. If set, return the exception type (the first argument to the last call to one of the `PyErr_Set*()` functions or to `PyErr_Restore()`). If not set, return `NULL`. You do not own a reference to the return value, so you do not need to `Py_DECREF()` it.

Note: Do not compare the return value to a specific exception; use `PyErr_ExceptionMatches()` instead, shown below. (The comparison could easily fail since the exception may be an instance instead of a class, in the case of a class exception, or it may be a subclass of the expected exception.)

int `PyErr_ExceptionMatches(PyObject *exc)`

Equivalent to `PyErr_GivenExceptionMatches(PyErr_Occurred(), exc)`. This should only be called when an exception is actually set; a memory access violation will occur if no exception has been raised.

int `PyErr_GivenExceptionMatches(PyObject *given, PyObject *exc)`

Return true if the *given* exception matches the exception in *exc*. If *exc* is a class object, this also returns true when *given* is an instance of a subclass. If *exc* is a tuple, all exceptions in the tuple (and recursively in subtuples) are searched for a match.

```
void PyErr_NormalizeException(PyObject**exc, PyObject**val,
PyObject**tb)
```

Under certain circumstances, the values returned by `PyErr_Fetch()` below can be “unnormalized”, meaning that `*exc` is a class object but `*val` is not an instance of the same class. This function can be used to instantiate the class in that case. If the values are already normalized, nothing happens. The delayed normalization is implemented to improve performance.

```
void PyErr_Clear()
```

Clear the error indicator. If the error indicator is not set, there is no effect.

```
void PyErr_Fetch(PyObject **ptype, PyObject **pvalue, PyObject
**ptraceback)
```

Retrieve the error indicator into three variables whose addresses are passed. If the error indicator is not set, set all three variables to `NULL`. If it is set, it will be cleared and you own a reference to each object retrieved. The value and traceback object may be `NULL` even when the type object is not.

Note: This function is normally only used by code that needs to handle exceptions or by code that needs to save and restore the error indicator temporarily.

```
void PyErr_Restore(PyObject *type, PyObject *value, PyObject
*traceback)
```

Set the error indicator from the three objects. If the error indicator is already set, it is cleared first. If the objects are `NULL`, the error indicator is cleared. Do not pass a `NULL` type and non-`NULL` value or traceback. The exception type should be a class. Do not pass an invalid exception type or value. (Violating these rules will cause subtle problems later.) This call takes away a reference to

each object: you must own a reference to each object before the call and after the call you no longer own these references. (If you don't understand this, don't use this function. I warned you.)

Note: This function is normally only used by code that needs to save and restore the error indicator temporarily; use `PyErr_Fetch()` to save the current exception state.

`void PyErr_SetString(PyObject *type, const char *message)`

This is the most common way to set the error indicator. The first argument specifies the exception type; it is normally one of the standard exceptions, e.g. `PyExc_RuntimeError`. You need not increment its reference count. The second argument is an error message; it is decoded from `'utf-8'`.

`void PyErr_SetObject(PyObject *type, PyObject *value)`

This function is similar to `PyErr_SetString()` but lets you specify an arbitrary Python object for the “value” of the exception.

`PyObject* PyErr_Format(PyObject *exception, const char *format, ...)`

Return value: Always NULL.

This function sets the error indicator and returns `NULL`. `exception` should be a Python exception class. The `format` and subsequent parameters help format the error message; they have the same meaning and values as in `PyUnicode_FromFormat()`. `format` is an ASCII-encoded string.

`void PyErr_SetNone(PyObject *type)`

This is a shorthand for `PyErr_SetObject(type, Py_None)`.

`int PyErr_BadArgument()`

This is a shorthand for `PyErr_SetString(PyExc_TypeError,`

`message`), where *message* indicates that a built-in operation was invoked with an illegal argument. It is mostly for internal use.

PyObject* **PyErr_NoMemory()**

Return value: Always NULL.

This is a shorthand for `PyErr_SetNone(PyExc_MemoryError)`; it returns `NULL` so an object allocation function can write `return PyErr_NoMemory()`; when it runs out of memory.

PyObject* **PyErr_SetFromErrno(PyObject *type)**

Return value: Always NULL.

This is a convenience function to raise an exception when a C library function has returned an error and set the C variable `errno`. It constructs a tuple object whose first item is the integer `errno` value and whose second item is the corresponding error message (gotten from `strerror()`), and then calls `PyErr_SetObject(type, object)`. On Unix, when the `errno` value is `EINTR`, indicating an interrupted system call, this calls `PyErr_CheckSignals()`, and if that set the error indicator, leaves it set to that. The function always returns `NULL`, so a wrapper function around a system call can write `return PyErr_SetFromErrno(type)`; when the system call returns an error.

PyObject* **PyErr_SetFromErrnoWithFilename(PyObject *type, const char *filename)**

Return value: Always NULL.

Similar to `PyErr_SetFromErrno()`, with the additional behavior that if *filename* is not `NULL`, it is passed to the constructor of *type* as a third parameter. In the case of exceptions such as `IOError` and `OSError`, this is used to define the `filename` attribute of the exception instance. *filename* is decoded from the filesystem encoding (`sys.getfilesystemencoding()`).

PyObject* **PyErr_SetFromWindowsErr**(int *ierr*)

Return value: Always NULL.

This is a convenience function to raise `WindowsError`. If called with *ierr* of 0, the error code returned by a call to `GetLastError()` is used instead. It calls the Win32 function `FormatMessage()` to retrieve the Windows description of error code given by *ierr* or `GetLastError()`, then it constructs a tuple object whose first item is the *ierr* value and whose second item is the corresponding error message (gotten from `FormatMessage()`), and then calls `PyErr_SetObject(PyExc_WindowsError, object)`. This function always returns `NULL`. Availability: Windows.

PyObject* **PyErr_SetExcFromWindowsErr**(PyObject **type*, int *ierr*)

Return value: Always NULL.

Similar to `PyErr_SetFromWindowsErr()`, with an additional parameter specifying the exception type to be raised. Availability: Windows.

PyObject* **PyErr_SetFromWindowsErrWithFilename**(int *ierr*, const char **filename*)

Return value: Always NULL.

Similar to `PyErr_SetFromWindowsErr()`, with the additional behavior that if *filename* is not `NULL`, it is passed to the constructor of `WindowsError` as a third parameter. *filename* is decoded from the filesystem encoding (`sys.getfilesystemencoding()`). Availability: Windows.

PyObject* **PyErr_SetExcFromWindowsErrWithFilename**(PyObject **type*, int *ierr*, char **filename*)

Return value: Always NULL.

Similar to `PyErr_SetFromWindowsErrWithFilename()`, with an additional parameter specifying the exception type to be raised. Availability: Windows.

`void PyErr_SyntaxLocationEx(char *filename, int lineno, int col_offset)`

Set file, line, and offset information for the current exception. If the current exception is not a `SyntaxError`, then it sets additional attributes, which make the exception printing subsystem think the exception is a `SyntaxError`. *filename* is decoded from the filesystem encoding (`sys.getfilesystemencoding()`).

New in version 3.2.

`void PyErr_SyntaxLocation(char *filename, int lineno)`

Like `PyErr_SyntaxLocationEx()`, but the `col_offset` parameter is omitted.

`void PyErr_BadInternalCall()`

This is a shorthand for `PyErr_SetString(PyExc_SystemError, message)`, where *message* indicates that an internal operation (e.g. a Python/C API function) was invoked with an illegal argument. It is mostly for internal use.

`int PyErr_WarnEx(PyObject *category, char *message, int stack_level)`

Issue a warning message. The *category* argument is a warning category (see below) or `NULL`; the *message* argument is an UTF-8 encoded string. *stack_level* is a positive number giving a number of stack frames; the warning will be issued from the currently executing line of code in that stack frame. A *stack_level* of 1 is the function calling `PyErr_WarnEx()`, 2 is the function above that, and so forth.

This function normally prints a warning message to `sys.stderr`; however, it is also possible that the user has specified that warnings are to be turned into errors, and in that case this will raise an exception. It is also possible that the function raises an

exception because of a problem with the warning machinery (the implementation imports the `warnings` module to do the heavy lifting). The return value is `0` if no exception is raised, or `-1` if an exception is raised. (It is not possible to determine whether a warning message is actually printed, nor what the reason is for the exception; this is intentional.) If an exception is raised, the caller should do its normal exception handling (for example, `Py_DECREF()` owned references and return an error value).

Warning categories must be subclasses of `warning`; the default warning category is `RuntimeWarning`. The standard Python warning categories are available as global variables whose names are `PyExc_` followed by the Python exception name. These have the type `PyObject*`; they are all class objects. Their names are `PyExc_Warning`, `PyExc_UserWarning`, `PyExc_UnicodeWarning`, `PyExc_DeprecationWarning`, `PyExc_SyntaxWarning`, `PyExc_RuntimeWarning`, and `PyExc_FutureWarning`. `PyExc_Warning` is a subclass of `PyExc_Exception`; the other warning categories are subclasses of `PyExc_Warning`.

For information about warning control, see the documentation for the `warnings` module and the `-W` option in the command line documentation. There is no C API for warning control.

```
int PyErr_WarnExplicit(PyObject *category, const char *message,
const char *filename, int lineno, const char *module, PyObject
*registry)
```

Issue a warning message with explicit control over all warning attributes. This is a straightforward wrapper around the Python function `warnings.warn_explicit()`, see there for more information. The `module` and `registry` arguments may be set to `NULL` to get the default effect described there. `message` and `module` are UTF-8 encoded strings, `filename` is decoded from the

filesystem encoding (`sys.getfilesystemencoding()`).

`int PyErr_WarnFormat(PyObject *category, Py_ssize_t stack_level, const char *format, ...)`

Function similar to `PyErr_WarnEx()`, but use `PyUnicode_FromFormat()` to format the warning message. `format` is an ASCII-encoded string.

New in version 3.2.

`int PyErr_CheckSignals()`

This function interacts with Python's signal handling. It checks whether a signal has been sent to the processes and if so, invokes the corresponding signal handler. If the `signal` module is supported, this can invoke a signal handler written in Python. In all cases, the default effect for `SIGINT` is to raise the `KeyboardInterrupt` exception. If an exception is raised the error indicator is set and the function returns `-1`; otherwise the function returns `0`. The error indicator may or may not be cleared if it was previously set.

`void PyErr_SetInterrupt()`

This function simulates the effect of a `SIGINT` signal arriving — the next time `PyErr_CheckSignals()` is called, `KeyboardInterrupt` will be raised. It may be called without holding the interpreter lock.

`int PySignal_SetWakeupFd(int fd)`

This utility function specifies a file descriptor to which a `'\0'` byte will be written whenever a signal is received. It returns the previous such file descriptor. The value `-1` disables the feature; this is the initial state. This is equivalent to `signal.set_wakeup_fd()` in Python, but without any error

checking. *fd* should be a valid file descriptor. The function should only be called from the main thread.

`PyObject*` `PyErr_NewException`(`char *name`, `PyObject *base`,
`PyObject *dict`)

Return value: *New reference.*

This utility function creates and returns a new exception object. The *name* argument must be the name of the new exception, a C string of the form `module.class`. The *base* and *dict* arguments are normally `NULL`. This creates a class object derived from `Exception` (accessible in C as `PyExc_Exception`).

The `__module__` attribute of the new class is set to the first part (up to the last dot) of the *name* argument, and the class name is set to the last part (after the last dot). The *base* argument can be used to specify alternate base classes; it can either be only one class or a tuple of classes. The *dict* argument can be used to specify a dictionary of class variables and methods.

`PyObject*` `PyErr_NewExceptionWithDoc`(`char *name`, `char *doc`,
`PyObject *base`, `PyObject *dict`)

Return value: *New reference.*

Same as `PyErr_NewException()`, except that the new exception class can easily be given a docstring: If *doc* is non-`NULL`, it will be used as the docstring for the exception class.

New in version 3.2.

`void` `PyErr_WriteUnraisable`(`PyObject *obj`)

This utility function prints a warning message to `sys.stderr` when an exception has been set but it is impossible for the interpreter to actually raise the exception. It is used, for example, when an exception occurs in an `__del__()` method.

The function is called with a single argument *obj* that identifies the context in which the unraisable exception occurred. The repr of *obj* will be printed in the warning message.

Exception Objects

PyObject* **PyException_GetTraceback**(PyObject *ex)

Return the traceback associated with the exception as a new reference, as accessible from Python through `__traceback__`. If there is no traceback associated, this returns *NULL*.

int **PyException_SetTraceback**(PyObject *ex, PyObject *tb)

Set the traceback associated with the exception to *tb*. Use `Py_None` to clear it.

PyObject* **PyException_GetContext**(PyObject *ex)

Return the context (another exception instance during whose handling *ex* was raised) associated with the exception as a new reference, as accessible from Python through `__context__`. If there is no context associated, this returns *NULL*.

void **PyException_SetContext**(PyObject *ex, PyObject *ctx)

Set the context associated with the exception to *ctx*. Use *NULL* to clear it. There is no type check to make sure that *ctx* is an exception instance. This steals a reference to *ctx*.

PyObject* **PyException_GetCause**(PyObject *ex)

Return the cause (another exception instance set by `raise ... from ...`) associated with the exception as a new reference, as accessible from Python through `__cause__`. If there is no cause associated, this returns *NULL*.

void **PyException_SetCause**(PyObject *ex, PyObject *ctx)

Set the cause associated with the exception to *ctx*. Use *NULL* to clear it. There is no type check to make sure that *ctx* is an exception instance. This steals a reference to *ctx*.

Unicode Exception Objects

The following functions are used to create and modify Unicode exceptions from C.

PyObject* **PyUnicodeDecodeError_Create**(const char **encoding*, const char **object*, Py_ssize_t *length*, Py_ssize_t *start*, Py_ssize_t *end*, const char **reason*)

Create a **UnicodeDecodeError** object with the attributes *encoding*, *object*, *length*, *start*, *end* and *reason*. *encoding* and *reason* are UTF-8 encoded strings.

PyObject* **PyUnicodeEncodeError_Create**(const char **encoding*, const Py_UNICODE **object*, Py_ssize_t *length*, Py_ssize_t *start*, Py_ssize_t *end*, const char **reason*)

Create a **UnicodeEncodeError** object with the attributes *encoding*, *object*, *length*, *start*, *end* and *reason*. *encoding* and *reason* are UTF-8 encoded strings.

PyObject* **PyUnicodeTranslateError_Create**(const Py_UNICODE **object*, Py_ssize_t *length*, Py_ssize_t *start*, Py_ssize_t *end*, const char **reason*)

Create a **UnicodeTranslateError** object with the attributes *object*, *length*, *start*, *end* and *reason*. *reason* is an UTF-8 encoded string.

PyObject* **PyUnicodeDecodeError_GetEncoding**(PyObject **exc*)

PyObject* **PyUnicodeEncodeError_GetEncoding**(PyObject **exc*)

Return the *encoding* attribute of the given exception object.

PyObject* **PyUnicodeDecodeError_GetObject**(PyObject **exc*)

PyObject* **PyUnicodeEncodeError_GetObject**(PyObject **exc*)

PyObject* **PyUnicodeTranslateError_GetObject**(PyObject **exc*)

Return the *object* attribute of the given exception object.

int PyUnicodeDecodeError_GetStart(PyObject *exc, Py_ssize_t *start)

int PyUnicodeEncodeError_GetStart(PyObject *exc, Py_ssize_t *start)

int PyUnicodeTranslateError_GetStart(PyObject *exc, Py_ssize_t *start)

Get the *start* attribute of the given exception object and place it into *start. *start* must not be *NULL*. Return 0 on success, -1 on failure.

int PyUnicodeDecodeError_SetStart(PyObject *exc, Py_ssize_t start)

int PyUnicodeEncodeError_SetStart(PyObject *exc, Py_ssize_t start)

int PyUnicodeTranslateError_SetStart(PyObject *exc, Py_ssize_t start)

Set the *start* attribute of the given exception object to *start*. Return 0 on success, -1 on failure.

int PyUnicodeDecodeError_GetEnd(PyObject *exc, Py_ssize_t *end)

int PyUnicodeEncodeError_GetEnd(PyObject *exc, Py_ssize_t *end)

int PyUnicodeTranslateError_GetEnd(PyObject *exc, Py_ssize_t *end)

Get the *end* attribute of the given exception object and place it into *end. *end* must not be *NULL*. Return 0 on success, -1 on failure.

int PyUnicodeDecodeError_SetEnd(PyObject *exc, Py_ssize_t end)

int PyUnicodeEncodeError_SetEnd(PyObject *exc, Py_ssize_t end)

int PyUnicodeTranslateError_SetEnd(PyObject *exc, Py_ssize_t end)

Set the *end* attribute of the given exception object to *end*. Return 0 on success, -1 on failure.

`PyObject*` `PyUnicodeDecodeError_GetReason(PyObject *exc)`

`PyObject*` `PyUnicodeEncodeError_GetReason(PyObject *exc)`

`PyObject*` `PyUnicodeTranslateError_GetReason(PyObject *exc)`

Return the *reason* attribute of the given exception object.

`int` `PyUnicodeDecodeError_SetReason(PyObject *exc, const char *reason)`

`int` `PyUnicodeEncodeError_SetReason(PyObject *exc, const char *reason)`

`int` `PyUnicodeTranslateError_SetReason(PyObject *exc, const char *reason)`

Set the *reason* attribute of the given exception object to *reason*. Return 0 on success, -1 on failure.

Recursion Control

These two functions provide a way to perform safe recursive calls at the C level, both in the core and in extension modules. They are needed if the recursive code does not necessarily invoke Python code (which tracks its recursion depth automatically).

int `Py_EnterRecursiveCall`(char **where*)

Marks a point where a recursive C-level call is about to be performed.

If `USE_STACKCHECK` is defined, this function checks if the the OS stack overflowed using `PyOS_CheckStack()`. In this is the case, it sets a `MemoryError` and returns a nonzero value.

The function then checks if the recursion limit is reached. If this is the case, a `RuntimeError` is set and a nonzero value is returned. Otherwise, zero is returned.

where should be a string such as " in instance check" to be concatenated to the `RuntimeError` message caused by the recursion depth limit.

void `Py_LeaveRecursiveCall`()

Ends a `Py_EnterRecursiveCall()`. Must be called once for each *successful* invocation of `Py_EnterRecursiveCall()`.

Properly implementing `tp_repr` for container types requires special recursion handling. In addition to protecting the stack, `tp_repr` also needs to track objects to prevent cycles. The following two functions facilitate this functionality. Effectively, these are the C equivalent to `reprlib.recursive_repr()`.

`int Py_ReprEnter(PyObject *object)`

Called at the beginning of the `tp_repr` implementation to detect cycles.

If the object has already been processed, the function returns a positive integer. In that case the `tp_repr` implementation should return a string object indicating a cycle. As examples, `dict` objects return `{...}` and `list` objects return `[...]`.

The function will return a negative integer if the recursion limit is reached. In that case the `tp_repr` implementation should typically return `NULL`.

Otherwise, the function returns zero and the `tp_repr` implementation can continue normally.

`void Py_ReprLeave(PyObject *object)`

Ends a `Py_ReprEnter()`. Must be called once for each invocation of `Py_ReprEnter()` that returns zero.

Standard Exceptions

All standard Python exceptions are available as global variables whose names are `PyExc_` followed by the Python exception name. These have the type `PyObject*`; they are all class objects. For completeness, here are all the variables:

C Name	Python Name	Notes
<code>PyExc_BaseException</code>	<code>BaseException</code>	(1)
<code>PyExc_Exception</code>	<code>Exception</code>	(1)
<code>PyExc_ArithmeticError</code>	<code>ArithmeticError</code>	(1)
<code>PyExc_LookupError</code>	<code>LookupError</code>	(1)
<code>PyExc_AssertionError</code>	<code>AssertionError</code>	
<code>PyExc_AttributeError</code>	<code>AttributeError</code>	
<code>PyExc_EOFError</code>	<code>EOFError</code>	
<code>PyExc_EnvironmentError</code>	<code>EnvironmentError</code>	(1)
<code>PyExc_FloatingPointError</code>	<code>FloatingPointError</code>	
<code>PyExc_IOError</code>	<code>IOError</code>	
<code>PyExc_ImportError</code>	<code>ImportError</code>	
<code>PyExc_IndexError</code>	<code>IndexError</code>	
<code>PyExc_KeyError</code>	<code>KeyError</code>	
<code>PyExc_KeyboardInterrupt</code>	<code>KeyboardInterrupt</code>	
<code>PyExc_MemoryError</code>	<code>MemoryError</code>	
<code>PyExc_NameError</code>	<code>NameError</code>	
<code>PyExc_NotImplementedError</code>	<code>NotImplementedError</code>	
<code>PyExc_OSError</code>	<code>OSError</code>	
<code>PyExc_OverflowError</code>	<code>OverflowError</code>	
<code>PyExc_ReferenceError</code>	<code>ReferenceError</code>	(2)
<code>PyExc_RuntimeError</code>	<code>RuntimeError</code>	
<code>PyExc_SyntaxError</code>	<code>SyntaxError</code>	
<code>PyExc_SystemError</code>	<code>SystemError</code>	

<code>PyExc_SystemExit</code>	<code>SystemExit</code>	
<code>PyExc_TypeError</code>	<code>TypeError</code>	
<code>PyExc_ValueError</code>	<code>ValueError</code>	
<code>PyExc_WindowsError</code>	<code>WindowsError</code>	(3)
<code>PyExc_ZeroDivisionError</code>	<code>ZeroDivisionError</code>	

Notes:

1. This is a base class for other standard exceptions.
2. This is the same as `weakref.ReferenceError`.
3. Only defined on Windows; protect code that uses this by testing that the preprocessor macro `MS_WINDOWS` is defined.

Utilities

The functions in this chapter perform various utility tasks, ranging from helping C code be more portable across platforms, using Python modules from C, and parsing function arguments and constructing Python values from C values.

[Manual](#) » [Utilities](#) »

Operating System Utilities

int Py_FdIsInteractive(FILE *fp, const char *filename)

Return true (nonzero) if the standard I/O file *fp* with name *filename* is deemed interactive. This is the case for files for which `isatty(fileno(fp))` is true. If the global flag `Py_InteractiveFlag` is true, this function also returns true if the *filename* pointer is `NULL` or if the name is equal to one of the strings `'<stdin>'` or `'???'`.

void PyOS_AfterFork()

Function to update some internal state after a process fork; this should be called in the new process if the Python interpreter will continue to be used. If a new executable is loaded into the new process, this function does not need to be called.

int PyOS_CheckStack()

Return true when the interpreter runs out of stack space. This is a reliable check, but is only available when `USE_STACKCHECK` is defined (currently on Windows using the Microsoft Visual C++ compiler). `USE_STACKCHECK` will be defined automatically; you should never change the definition in your own code.

PyOS_sighandler_t PyOS_getsig(int i)

Return the current signal handler for signal *i*. This is a thin wrapper around either `sigaction()` or `signal()`. Do not call those functions directly! `PyOS_sighandler_t` is a typedef alias for `void (*)(int)`.

PyOS_sighandler_t PyOS_setsig(int i, PyOS_sighandler_t h)

Set the signal handler for signal *i* to be *h*; return the old signal handler. This is a thin wrapper around either `sigaction()` or

`signal()`. Do not call those functions directly! `PyOS_sighandler_t` is a typedef alias for `void (*)(int)`.

System Functions

These are utility functions that make functionality from the `sys` module accessible to C code. They all work with the current interpreter thread's `sys` module's dict, which is contained in the internal thread state structure.

`PyObject *PySys_GetObject(char *name)`

Return value: Borrowed reference.

Return the object *name* from the `sys` module or `NULL` if it does not exist, without setting an exception.

`FILE *PySys_GetFile(char *name, FILE *def)`

Return the `FILE*` associated with the object *name* in the `sys` module, or *def* if *name* is not in the module or is not associated with a `FILE*`.

`int PySys_SetObject(char *name, PyObject *v)`

Set *name* in the `sys` module to *v* unless *v* is `NULL`, in which case *name* is deleted from the `sys` module. Returns `0` on success, `-1` on error.

`void PySys_ResetWarnOptions()`

Reset `sys.warnoptions` to an empty list.

`void PySys_AddWarnOption(wchar_t *s)`

Append *s* to `sys.warnoptions`.

`void PySys_AddWarnOptionUnicode(PyObject *unicode)`

Append *unicode* to `sys.warnoptions`.

`void PySys_SetPath(wchar_t *path)`

Set `sys.path` to a list object of paths found in *path* which should

be a list of paths separated with the platform's search path delimiter (: on Unix, ; on Windows).

void PySys_WriteStdout(const char **format*, ...)

Write the output string described by *format* to `sys.stdout`. No exceptions are raised, even if truncation occurs (see below).

format should limit the total size of the formatted output string to 1000 bytes or less – after 1000 bytes, the output string is truncated. In particular, this means that no unrestricted “%s” formats should occur; these should be limited using “%.<N>s” where <N> is a decimal number calculated so that <N> plus the maximum size of other formatted text does not exceed 1000 bytes. Also watch out for “%f”, which can print hundreds of digits for very large numbers.

If a problem occurs, or `sys.stdout` is unset, the formatted message is written to the real (C level) *stdout*.

void PySys_WriteStderr(const char **format*, ...)

As `PySys_WriteStdout()`, but write to `sys.stderr` or *stderr* instead.

void PySys_FormatStdout(const char **format*, ...)

Function similar to `PySys_WriteStdout()` but format the message using `PyUnicode_FromFormatV()` and don't truncate the message to an arbitrary length.

New in version 3.2.

void PySys_FormatStderr(const char **format*, ...)

As `PySys_FormatStdout()`, but write to `sys.stderr` or *stderr* instead.

New in version 3.2.

`void PySys_AddXOption(const wchar_t *s)`

Parse `s` as a set of `-X` options and add them to the current options mapping as returned by `PySys_GetXOptions()`.

New in version 3.2.

`PyObject *PySys_GetXOptions()`

Return value: Borrowed reference.

Return the current dictionary of `-X` options, similarly to `sys._xoptions`. On error, `NULL` is returned and an exception is set.

New in version 3.2.

Process Control

`void Py_FatalError(const char *message)`

Print a fatal error message and kill the process. No cleanup is performed. This function should only be invoked when a condition is detected that would make it dangerous to continue using the Python interpreter; e.g., when the object administration appears to be corrupted. On Unix, the standard C library function `abort()` is called which will attempt to produce a `core` file.

`void Py_Exit(int status)`

Exit the current process. This calls `Py_Finalize()` and then calls the standard C library function `exit(status)`.

`int Py_AtExit(void (*func) ())`

Register a cleanup function to be called by `Py_Finalize()`. The cleanup function will be called with no arguments and should return no value. At most 32 cleanup functions can be registered. When the registration is successful, `Py_AtExit()` returns `0`; on failure, it returns `-1`. The cleanup function registered last is called first. Each cleanup function will be called at most once. Since Python's internal finalization will have completed before the cleanup function, no Python APIs should be called by *func*.

[Manual](#) » [Utilities](#) »

Importing Modules

PyObject* **PyImport_ImportModule**(const char *name)

Return value: New reference.

This is a simplified interface to **PyImport_ImportModuleEx()** below, leaving the *globals* and *locals* arguments set to *NULL* and *level* set to 0. When the *name* argument contains a dot (when it specifies a submodule of a package), the *fromlist* argument is set to the list `['*']` so that the return value is the named module rather than the top-level package containing it as would otherwise be the case. (Unfortunately, this has an additional side effect when *name* in fact specifies a subpackage instead of a submodule: the submodules specified in the package's `__all__` variable are loaded.) Return a new reference to the imported module, or *NULL* with an exception set on failure. A failing import of a module doesn't leave the module in `sys.modules`.

This function always uses absolute imports.

PyObject* **PyImport_ImportModuleNoBlock**(const char *name)

This version of **PyImport_ImportModule()** does not block. It's intended to be used in C functions that import other modules to execute a function. The import may block if another thread holds the import lock. The function **PyImport_ImportModuleNoBlock()** never blocks. It first tries to fetch the module from `sys.modules` and falls back to **PyImport_ImportModule()** unless the lock is held, in which case the function will raise an **ImportError**.

PyObject* **PyImport_ImportModuleEx**(char *name, PyObject *globals, PyObject *locals, PyObject *fromlist)

Return value: New reference.

Import a module. This is best described by referring to the built-in

Python function `__import__()`, as the standard `__import__()` function calls this function directly.

The return value is a new reference to the imported module or top-level package, or `NULL` with an exception set on failure. Like for `__import__()`, the return value when a submodule of a package was requested is normally the top-level package, unless a non-empty *fromlist* was given.

Failing imports remove incomplete module objects, like with `PyImport_ImportModule()`.

`PyObject*` **`PyImport_ImportModuleLevel`**(char *name, PyObject *globals, PyObject *locals, PyObject *fromlist, int level)

Return value: New reference.

Import a module. This is best described by referring to the built-in Python function `__import__()`, as the standard `__import__()` function calls this function directly.

The return value is a new reference to the imported module or top-level package, or `NULL` with an exception set on failure. Like for `__import__()`, the return value when a submodule of a package was requested is normally the top-level package, unless a non-empty *fromlist* was given.

`PyObject*` **`PyImport_Import`**(PyObject *name)

Return value: New reference.

This is a higher-level interface that calls the current “import hook function” (with an explicit *level* of 0, meaning absolute import). It invokes the `__import__()` function from the `__builtins__` of the current globals. This means that the import is done using whatever import hooks are installed in the current environment.

This function always uses absolute imports.

`PyObject*` `PyImport_ReloadModule(PyObject *m)`

Return value: New reference.

Reload a module. Return a new reference to the reloaded module, or `NULL` with an exception set on failure (the module still exists in this case).

`PyObject*` `PyImport_AddModule(const char *name)`

Return value: Borrowed reference.

Return the module object corresponding to a module name. The `name` argument may be of the form `package.module`. First check the modules dictionary if there's one there, and if not, create a new one and insert it in the modules dictionary. Return `NULL` with an exception set on failure.

Note: This function does not load or import the module; if the module wasn't already loaded, you will get an empty module object. Use `PyImport_ImportModule()` or one of its variants to import a module. Package structures implied by a dotted name for `name` are not created if not already present.

`PyObject*` `PyImport_ExecCodeModule(char *name, PyObject *co)`

Return value: New reference.

Given a module name (possibly of the form `package.module`) and a code object read from a Python bytecode file or obtained from the built-in function `compile()`, load the module. Return a new reference to the module object, or `NULL` with an exception set if an error occurred. `name` is removed from `sys.modules` in error cases, even if `name` was already in `sys.modules` on entry to `PyImport_ExecCodeModule()`. Leaving incompletely initialized modules in `sys.modules` is dangerous, as imports of such modules have no way to know that the module object is an unknown (and probably damaged with respect to the module author's intents) state.

The module's `__file__` attribute will be set to the code object's `co_filename`.

This function will reload the module if it was already imported. See `PyImport_ReloadModule()` for the intended way to reload a module.

If *name* points to a dotted name of the form `package.module`, any package structures not already created will still not be created.

See also `PyImport_ExecCodeModuleEx()` and `PyImport_ExecCodeModuleWithPathnames()`.

`PyObject*` `PyImport_ExecCodeModuleEx(char *name, PyObject *co, char *pathname)`

Return value: *New reference.*

Like `PyImport_ExecCodeModule()`, but the `__file__` attribute of the module object is set to *pathname* if it is non-NULL.

See also `PyImport_ExecCodeModuleWithPathnames()`.

`PyObject*` `PyImport_ExecCodeModuleWithPathnames(char *name, PyObject *co, char *pathname, char *cpathname)`

Like `PyImport_ExecCodeModuleEx()`, but the `__cached__` attribute of the module object is set to *cpathname* if it is non-NULL. Of the three functions, this is the preferred one to use.

New in version 3.2.

`long` `PyImport_GetMagicNumber()`

Return the magic number for Python bytecode files (a.k.a. `.pyc` and `.pyo` files). The magic number should be present in the first four bytes of the bytecode file, in little-endian byte order.

`const char * PyImport_GetMagicTag()`

Return the magic tag string for **PEP 3147** format Python bytecode file names.

New in version 3.2.

`PyObject* PyImport_GetModuleDict()`

Return value: Borrowed reference.

Return the dictionary used for the module administration (a.k.a. `sys.modules`). Note that this is a per-interpreter variable.

`PyObject* PyImport_GetImporter(PyObject *path)`

Return an importer object for a `sys.path/pkg.__path__` item *path*, possibly by fetching it from the `sys.path_importer_cache` dict. If it wasn't yet cached, traverse `sys.path_hooks` until a hook is found that can handle the path item. Return `None` if no hook could; this tells our caller it should fall back to the built-in import mechanism. Cache the result in `sys.path_importer_cache`. Return a new reference to the importer object.

`void _PyImport_Init()`

Initialize the import mechanism. For internal use only.

`void PyImport_Cleanup()`

Empty the module table. For internal use only.

`void _PyImport_Fini()`

Finalize the import mechanism. For internal use only.

`PyObject* _PyImport_FindExtension(char *, char *)`

For internal use only.

`PyObject* _PyImport_FixupExtension(char *, char *)`

For internal use only.

int PyImport_ImportFrozenModule(char *name)

Load a frozen module named *name*. Return `1` for success, `0` if the module is not found, and `-1` with an exception set if the initialization failed. To access the imported module on a successful load, use `PyImport_ImportModule()`. (Note the misnomer — this function would reload the module if it was already imported.)

struct _frozen

This is the structure type definition for frozen module descriptors, as generated by the `freeze` utility (see `Tools/freeze/` in the Python source distribution). Its definition, found in `Include/import.h`, is:

```
struct _frozen {
    char *name;
    unsigned char *code;
    int size;
};
```

struct _frozen* PyImport_FrozenModules

This pointer is initialized to point to an array of `struct _frozen` records, terminated by one whose members are all `NULL` or zero. When a frozen module is imported, it is searched in this table. Third-party code could play tricks with this to provide a dynamically created collection of frozen modules.

int PyImport_AppendInittab(const char *name, PyObject* (*initfunc)(void))

Add a single module to the existing table of built-in modules. This is a convenience wrapper around `PyImport_ExtendInittab()`, returning `-1` if the table could not be extended. The new module can be imported by the name *name*, and uses the function *initfunc* as the initialization function called on the first attempted

import. This should be called before `Py_Initialize()`.

struct `_inittab`

Structure describing a single entry in the list of built-in modules. Each of these structures gives the name and initialization function for a module built into the interpreter. Programs which embed Python may use an array of these structures in conjunction with `PyImport_ExtendInittab()` to provide additional built-in modules. The structure is defined in `Include/import.h` as:

```
struct _inittab {
    char *name;
    PyObject* (*initfunc)(void);
};
```

int `PyImport_ExtendInittab(struct _inittab *newtab)`

Add a collection of modules to the table of built-in modules. The *newtab* array must end with a sentinel entry which contains `NULL` for the `name` field; failure to provide the sentinel value can result in a memory fault. Returns `0` on success or `-1` if insufficient memory could be allocated to extend the internal table. In the event of failure, no modules are added to the internal table. This should be called before `Py_Initialize()`.

Data marshalling support

These routines allow C code to work with serialized objects using the same data format as the `marshal` module. There are functions to write data into the serialization format, and additional functions that can be used to read the data back. Files used to store marshalled data must be opened in binary mode.

Numeric values are stored with the least significant byte first.

The module supports two versions of the data format: version 0 is the historical version, version 1 shares interned strings in the file, and upon unmarshalling. Version 2 uses a binary format for floating point numbers. `Py_MARSHAL_VERSION` indicates the current file format (currently 2).

`void PyMarshal_WriteLongToFile(long value, FILE *file, int version)`

Marshal a `long` integer, *value*, to *file*. This will only write the least-significant 32 bits of *value*; regardless of the size of the native `long` type. *version* indicates the file format.

`void PyMarshal_WriteObjectToFile(PyObject *value, FILE *file, int version)`

Marshal a Python object, *value*, to *file*. *version* indicates the file format.

`PyObject* PyMarshal_WriteObjectToString(PyObject *value, int version)`

Return value: *New reference.*

Return a string object containing the marshalled representation of *value*. *version* indicates the file format.

The following functions allow marshalled values to be read back in.

XXX What about error detection? It appears that reading past the end of the file will always result in a negative numeric value (where that's relevant), but it's not clear that negative values won't be handled properly when there's no error. What's the right way to tell? Should only non-negative values be written using these routines?

long PyMarshal_ReadLongFromFile(FILE *file)

Return a C `long` from the data stream in a `FILE*` opened for reading. Only a 32-bit value can be read in using this function, regardless of the native size of `long`.

int PyMarshal_ReadShortFromFile(FILE *file)

Return a C `short` from the data stream in a `FILE*` opened for reading. Only a 16-bit value can be read in using this function, regardless of the native size of `short`.

PyObject* PyMarshal_ReadObjectFromFile(FILE *file)

Return value: New reference.

Return a Python object from the data stream in a `FILE*` opened for reading. On error, sets the appropriate exception (`EOFError` or `TypeError`) and returns `NULL`.

PyObject* PyMarshal_ReadLastObjectFromFile(FILE *file)

Return value: New reference.

Return a Python object from the data stream in a `FILE*` opened for reading. Unlike `PyMarshal_ReadObjectFromFile()`, this function assumes that no further objects will be read from the file, allowing it to aggressively load file data into memory so that the deserialization can operate from data in memory rather than reading a byte at a time from the file. Only use these variant if you are certain that you won't be reading anything else from the file. On error, sets the appropriate exception (`EOFError` or `TypeError`) and returns `NULL`.

`PyObject*` `PyMarshal_ReadObjectFromString`(`char *string`,
`Py_ssize_t len`)

Return value: New reference.

Return a Python object from the data stream in a character buffer containing *len* bytes pointed to by *string*. On error, sets the appropriate exception (`EOFError` or `TypeError`) and returns `NULL`.

Parsing arguments and building values

These functions are useful when creating your own extensions functions and methods. Additional information and examples are available in *Extending and Embedding the Python Interpreter*.

The first three of these functions described, `PyArg_ParseTuple()`, `PyArg_ParseTupleAndKeywords()`, and `PyArg_Parse()`, all use *format strings* which are used to tell the function about the expected arguments. The format strings use the same syntax for each of these functions.

Parsing arguments

A format string consists of zero or more “format units.” A format unit describes one Python object; it is usually a single character or a parenthesized sequence of format units. With a few exceptions, a format unit that is not a parenthesized sequence normally corresponds to a single address argument to these functions. In the following description, the quoted form is the format unit; the entry in (round) parentheses is the Python object type that matches the format unit; and the entry in [square] brackets is the type of the C variable(s) whose address should be passed.

Strings and buffers

These formats allow to access an object as a contiguous chunk of memory. You don't have to provide raw storage for the returned unicode or bytes area. Also, you won't have to release any memory yourself, except with the `es`, `es#`, `et` and `et#` formats.

However, when a `Py_buffer` structure gets filled, the underlying buffer is locked so that the caller can subsequently use the buffer even inside a `Py_BEGIN_ALLOW_THREADS` block without the risk of mutable data being resized or destroyed. As a result, **you have to call `PyBuffer_Release()`** after you have finished processing the data (or in any early abort case).

Unless otherwise stated, buffers are not NUL-terminated.

Note: For all # variants of formats (`s#`, `y#`, etc.), the type of the length argument (int or `Py_ssize_t`) is controlled by defining the macro `PY_SSIZE_T_CLEAN` before including `Python.h`. If the macro was defined, length is a `Py_ssize_t` rather than an `int`. This

behavior will change in a future Python version to only support `Py_ssize_t` and drop `int` support. It is best to always define `PY_SSIZE_T_CLEAN`.

`s` (`str`) [`const char *`]

Convert a Unicode object to a C pointer to a character string. A pointer to an existing string is stored in the character pointer variable whose address you pass. The C string is NUL-terminated. The Python string must not contain embedded NUL bytes; if it does, a `TypeError` exception is raised. Unicode objects are converted to C strings using `'utf-8'` encoding. If this conversion fails, a `UnicodeError` is raised.

Note: This format does not accept bytes-like objects. If you want to accept filesystem paths and convert them to C character strings, it is preferable to use the `o&` format with `PyUnicode_FSConverter()` as *converter*.

`s*` (`str`, `bytes`, `bytearray` or buffer compatible object) [`Py_buffer`]

This format accepts Unicode objects as well as objects supporting the buffer protocol. It fills a `Py_buffer` structure provided by the caller. In this case the resulting C string may contain embedded NUL bytes. Unicode objects are converted to C strings using `'utf-8'` encoding.

`s#` (`str`, `bytes` or read-only buffer compatible object) [`const char *`, `int` or `Py_ssize_t`]

Like `s*`, except that it doesn't accept mutable buffer-like objects such as `bytearray`. The result is stored into two C variables, the first one a pointer to a C string, the second one its length. The string may contain embedded null bytes. Unicode objects are converted to C strings using `'utf-8'` encoding.

`z` (`str` or `None`) [`const char *`]

Like `s`, but the Python object may also be `None`, in which case the C pointer is set to `NULL`.

`z*` (`str`, `bytes`, `bytearray`, buffer compatible object or `None`)
[`Py_buffer`]

Like `s*`, but the Python object may also be `None`, in which case the `buf` member of the `Py_buffer` structure is set to `NULL`.

`z#` (`str`, `bytes`, read-only buffer compatible object or `None`) [`const char *`, `int`]

Like `s#`, but the Python object may also be `None`, in which case the C pointer is set to `NULL`.

`y` (`bytes`) [`const char *`]

This format converts a bytes-like object to a C pointer to a character string; it does not accept Unicode objects. The bytes buffer must not contain embedded NUL bytes; if it does, a `TypeError` exception is raised.

`y*` (`bytes`, `bytearray` or buffer compatible object) [`Py_buffer`]

This variant on `s*` doesn't accept Unicode objects, only objects supporting the buffer protocol. **This is the recommended way to accept binary data.**

`y#` (`bytes`) [`const char *`, `int`]

This variant on `s#` doesn't accept Unicode objects, only bytes-like objects.

`s` (`bytes`) [`PyBytesObject *`]

Requires that the Python object is a `bytes` object, without attempting any conversion. Raises `TypeError` if the object is not a bytes object. The C variable may also be declared as `PyObject*`.

`Y` (`bytearray`) [`PyByteArrayObject *`]

Requires that the Python object is a `bytearray` object, without attempting any conversion. Raises `TypeError` if the object is not a `bytearray` object. The C variable may also be declared as

PyObject*.

u (**str**) [Py_UNICODE*]

Convert a Python Unicode object to a C pointer to a NUL-terminated buffer of Unicode characters. You must pass the address of a **Py_UNICODE** pointer variable, which will be filled with the pointer to an existing Unicode buffer. Please note that the width of a **Py_UNICODE** character depends on compilation options (it is either 16 or 32 bits). The Python string must not contain embedded NUL characters; if it does, a **TypeError** exception is raised.

Note: Since **u** doesn't give you back the length of the string, and it may contain embedded NUL characters, it is recommended to use **u#** or **u** instead.

u# (**str**) [Py_UNICODE*, int]

This variant on **u** stores into two C variables, the first one a pointer to a Unicode data buffer, the second one its length.

z (**str** or **None**) [Py_UNICODE*]

Like **u**, but the Python object may also be **None**, in which case the **Py_UNICODE** pointer is set to **NULL**.

Z# (**str** or **None**) [Py_UNICODE*, int]

Like **u#**, but the Python object may also be **None**, in which case the **Py_UNICODE** pointer is set to **NULL**.

u (**str**) [PyUnicodeObject*]

Requires that the Python object is a Unicode object, without attempting any conversion. Raises **TypeError** if the object is not a Unicode object. The C variable may also be declared as **PyObject***.

w* (**bytearray** or read-write byte-oriented buffer) [Py_buffer]

This format accepts any object which implements the read-write

buffer interface. It fills a `Py_buffer` structure provided by the caller. The buffer may contain embedded null bytes. The caller have to call `PyBuffer_Release()` when it is done with the buffer.

`es (str)` [`const char *encoding, char **buffer`]

This variant on `s` is used for encoding Unicode into a character buffer. It only works for encoded data without embedded NUL bytes.

This format requires two arguments. The first is only used as input, and must be a `const char*` which points to the name of an encoding as a NUL-terminated string, or `NULL`, in which case `'utf-8'` encoding is used. An exception is raised if the named encoding is not known to Python. The second argument must be a `char**`; the value of the pointer it references will be set to a buffer with the contents of the argument text. The text will be encoded in the encoding specified by the first argument.

`PyArg_ParseTuple()` will allocate a buffer of the needed size, copy the encoded data into this buffer and adjust `*buffer` to reference the newly allocated storage. The caller is responsible for calling `PyMem_Free()` to free the allocated buffer after use.

`et (str, bytes or bytearray)` [`const char *encoding, char **buffer`]

Same as `es` except that byte string objects are passed through without recoding them. Instead, the implementation assumes that the byte string object uses the encoding passed in as parameter.

`es# (str)` [`const char *encoding, char **buffer, int *buffer_length`]

This variant on `s#` is used for encoding Unicode into a character buffer. Unlike the `es` format, this variant allows input data which contains NUL characters.

It requires three arguments. The first is only used as input, and must be a `const char*` which points to the name of an encoding

as a NUL-terminated string, or *NULL*, in which case `'utf-8'` encoding is used. An exception is raised if the named encoding is not known to Python. The second argument must be a `char**`; the value of the pointer it references will be set to a buffer with the contents of the argument text. The text will be encoded in the encoding specified by the first argument. The third argument must be a pointer to an integer; the referenced integer will be set to the number of bytes in the output buffer.

There are two modes of operation:

If **buffer* points a *NULL* pointer, the function will allocate a buffer of the needed size, copy the encoded data into this buffer and set **buffer* to reference the newly allocated storage. The caller is responsible for calling `PyMem_Free()` to free the allocated buffer after usage.

If **buffer* points to a non-*NULL* pointer (an already allocated buffer), `PyArg_ParseTuple()` will use this location as the buffer and interpret the initial value of **buffer_length* as the buffer size. It will then copy the encoded data into the buffer and NUL-terminate it. If the buffer is not large enough, a `ValueError` will be set.

In both cases, **buffer_length* is set to the length of the encoded data without the trailing NUL byte.

et# (`str`, `bytes` or `bytearray`) [`const char *encoding`, `char **buffer`, `int *buffer_length`]

Same as `es#` except that byte string objects are passed through without recoding them. Instead, the implementation assumes that the byte string object uses the encoding passed in as parameter.

Numbers

b (`int`) [unsigned char]

Convert a nonnegative Python integer to an unsigned tiny int, stored in a C `unsigned char`.

B (`int`) [unsigned char]

Convert a Python integer to a tiny int without overflow checking, stored in a C `unsigned char`.

h (`int`) [short int]

Convert a Python integer to a C `short int`.

H (`int`) [unsigned short int]

Convert a Python integer to a C `unsigned short int`, without overflow checking.

i (`int`) [int]

Convert a Python integer to a plain C `int`.

I (`int`) [unsigned int]

Convert a Python integer to a C `unsigned int`, without overflow checking.

l (`int`) [long int]

Convert a Python integer to a C `long int`.

k (`int`) [unsigned long]

Convert a Python integer to a C `unsigned long` without overflow checking.

L (`int`) [PY_LONG_LONG]

Convert a Python integer to a C `long long`. This format is only available on platforms that support `long long` (or `_int64` on Windows).

K (`int`) [unsigned PY_LONG_LONG]

Convert a Python integer to a C `unsigned long long` without overflow checking. This format is only available on platforms that support `unsigned long long` (or `unsigned _int64` on Windows).

- n (**int**) [Py_ssize_t]
Convert a Python integer to a C **Py_ssize_t**.
- c (**bytes** of length 1) [char]
Convert a Python byte, represented as a **bytes** object of length 1, to a C **char**.
- c (**str** of length 1) [int]
Convert a Python character, represented as a **str** object of length 1, to a C **int**.
- f (**float**) [float]
Convert a Python floating point number to a C **float**.
- d (**float**) [double]
Convert a Python floating point number to a C **double**.
- D (**complex**) [Py_complex]
Convert a Python complex number to a C **Py_complex** structure.

Other objects

- o (object) [PyObject*]
Store a Python object (without any conversion) in a C object pointer. The C program thus receives the actual object that was passed. The object's reference count is not increased. The pointer stored is not *NULL*.
- o! (object) [PyObject*, PyObject*]
Store a Python object in a C object pointer. This is similar to `o`, but takes two C arguments: the first is the address of a Python type object, the second is the address of the C variable (of type **PyObject***) into which the object pointer is stored. If the Python object does not have the required type, **TypeError** is raised.
- o& (object) [converter, anything]
Convert a Python object to a C variable through a *converter*

function. This takes two arguments: the first is a function, the second is the address of a C variable (of arbitrary type), converted to `void *`. The *converter* function in turn is called as follows:

```
status = converter(object, address);
```

where *object* is the Python object to be converted and *address* is the `void*` argument that was passed to the `PyArg_Parse*`(`)` function. The returned *status* should be `1` for a successful conversion and `0` if the conversion has failed. When the conversion fails, the *converter* function should raise an exception and leave the content of *address* unmodified.

If the *converter* returns `Py_CLEANUP_SUPPORTED`, it may get called a second time if the argument parsing eventually fails, giving the converter a chance to release any memory that it had already allocated. In this second call, the *object* parameter will be `NULL`; *address* will have the same value as in the original call.

Changed in version 3.1: `Py_CLEANUP_SUPPORTED` was added.

`(items)` (`tuple`) [*matching-items*]

The object must be a Python sequence whose length is the number of format units in *items*. The C arguments must correspond to the individual format units in *items*. Format units for sequences may be nested.

It is possible to pass “long” integers (integers whose value exceeds the platform’s `LONG_MAX`) however no proper range checking is done — the most significant bits are silently truncated when the receiving field is too small to receive the value (actually, the semantics are inherited from downcasts in C — your mileage may vary).

A few other characters have a meaning in a format string. These

may not occur inside nested parentheses. They are:

|

Indicates that the remaining arguments in the Python argument list are optional. The C variables corresponding to optional arguments should be initialized to their default value — when an optional argument is not specified, `PyArg_ParseTuple()` does not touch the contents of the corresponding C variable(s).

:

The list of format units ends here; the string after the colon is used as the function name in error messages (the “associated value” of the exception that `PyArg_ParseTuple()` raises).

;

The list of format units ends here; the string after the semicolon is used as the error message *instead* of the default error message.

: and ; mutually exclude each other.

Note that any Python object references which are provided to the caller are *borrowed* references; do not decrement their reference count!

Additional arguments passed to these functions must be addresses of variables whose type is determined by the format string; these are used to store values from the input tuple. There are a few cases, as described in the list of format units above, where these parameters are used as input values; they should match what is specified for the corresponding format unit in that case.

For the conversion to succeed, the *arg* object must match the format and the format must be exhausted. On success, the `PyArg_Parse*()` functions return true, otherwise they return false and raise an appropriate exception. When the `PyArg_Parse*()` functions fail due to conversion failure in one of the format units, the variables at the addresses corresponding to that and the following format units are

left untouched.

API Functions

int **PyArg_ParseTuple**(PyObject *args, const char *format, ...)

Parse the parameters of a function that takes only positional parameters into local variables. Returns true on success; on failure, it returns false and raises the appropriate exception.

int **PyArg_VaParse**(PyObject *args, const char *format, va_list vargs)

Identical to **PyArg_ParseTuple()**, except that it accepts a va_list rather than a variable number of arguments.

int **PyArg_ParseTupleAndKeywords**(PyObject *args, PyObject *kw, const char *format, char *keywords[], ...)

Parse the parameters of a function that takes both positional and keyword parameters into local variables. Returns true on success; on failure, it returns false and raises the appropriate exception.

int **PyArg_VaParseTupleAndKeywords**(PyObject *args, PyObject *kw, const char *format, char *keywords[], va_list vargs)

Identical to **PyArg_ParseTupleAndKeywords()**, except that it accepts a va_list rather than a variable number of arguments.

int **PyArg_ValidateKeywordArguments**(PyObject *)

Ensure that the keys in the keywords argument dictionary are strings. This is only needed if **PyArg_ParseTupleAndKeywords()** is not used, since the latter already does this check.

New in version 3.2.

int **PyArg_Parse**(PyObject *args, const char *format, ...)

Function used to deconstruct the argument lists of “old-style” functions — these are functions which use the `METH_OLDARGS` parameter parsing method. This is not recommended for use in parameter parsing in new code, and most code in the standard interpreter has been modified to no longer use this for that purpose. It does remain a convenient way to decompose other tuples, however, and may continue to be used for that purpose.

```
int PyArg_UnpackTuple(PyObject *args, const char *name,
Py_ssize_t min, Py_ssize_t max, ...)
```

A simpler form of parameter retrieval which does not use a format string to specify the types of the arguments. Functions which use this method to retrieve their parameters should be declared as `METH_VARARGS` in function or method tables. The tuple containing the actual parameters should be passed as *args*; it must actually be a tuple. The length of the tuple must be at least *min* and no more than *max*; *min* and *max* may be equal. Additional arguments must be passed to the function, each of which should be a pointer to a `PyObject*` variable; these will be filled in with the values from *args*; they will contain borrowed references. The variables which correspond to optional parameters not given by *args* will not be filled in; these should be initialized by the caller. This function returns true on success and false if *args* is not a tuple or contains the wrong number of elements; an exception will be set if there was a failure.

This is an example of the use of this function, taken from the sources for the `_weakref` helper module for weak references:

```
static PyObject *
weakref_ref(PyObject *self, PyObject *args)
{
    PyObject *object;
    PyObject *callback = NULL;
    PyObject *result = NULL;
```

```
    if (PyArg_UnpackTuple(args, "ref", 1, 2, &object, &callb
        result = PyWeakref_NewRef(object, callback);
    }
    return result;
}
```

The call to `PyArg_UnpackTuple()` in this example is entirely equivalent to this call to `PyArg_ParseTuple()`:

```
PyArg_ParseTuple(args, "O|O:ref", &object, &callback)
```

Building values

`PyObject*` **Py_BuildValue**(const char **format*, ...)

Return value: New reference.

Create a new value based on a format string similar to those accepted by the `PyArg_Parse*`() family of functions and a sequence of values. Returns the value or `NULL` in the case of an error; an exception will be raised if `NULL` is returned.

`Py_BuildValue()` does not always build a tuple. It builds a tuple only if its format string contains two or more format units. If the format string is empty, it returns `None`; if it contains exactly one format unit, it returns whatever object is described by that format unit. To force it to return a tuple of size 0 or one, parenthesize the format string.

When memory buffers are passed as parameters to supply data to build objects, as for the `s` and `s#` formats, the required data is copied. Buffers provided by the caller are never referenced by the objects created by `Py_BuildValue()`. In other words, if your code invokes `malloc()` and passes the allocated memory to `Py_BuildValue()`, your code is responsible for calling `free()` for that memory once `Py_BuildValue()` returns.

In the following description, the quoted form is the format unit; the entry in (round) parentheses is the Python object type that the format unit will return; and the entry in [square] brackets is the type of the C value(s) to be passed.

The characters space, tab, colon and comma are ignored in format strings (but not within format units such as `s#`). This can be used to make long format strings a tad more readable.

s (**str** or **None**) [char *]

Convert a null-terminated C string to a Python **str** object using 'utf-8' encoding. If the C string pointer is *NULL*, **None** is used.

s# (**str** or **None**) [char *, int]

Convert a C string and its length to a Python **str** object using 'utf-8' encoding. If the C string pointer is *NULL*, the length is ignored and **None** is returned.

y (**bytes**) [char *]

This converts a C string to a Python **bytes()** object. If the C string pointer is *NULL*, **None** is returned.

y# (**bytes**) [char *, int]

This converts a C string and its lengths to a Python object. If the C string pointer is *NULL*, **None** is returned.

z (**str** or **None**) [char *]

Same as **s**.

z# (**str** or **None**) [char *, int]

Same as **s#**.

u (**str**) [Py_UNICODE *]

Convert a null-terminated buffer of Unicode (UCS-2 or UCS-4) data to a Python Unicode object. If the Unicode buffer pointer is *NULL*, **None** is returned.

u# (**str**) [Py_UNICODE *, int]

Convert a Unicode (UCS-2 or UCS-4) data buffer and its length to a Python Unicode object. If the Unicode buffer pointer is *NULL*, the length is ignored and **None** is returned.

U (**str** or **None**) [char *]

Same as `s`.

`U# (str or None) [char *, int]`

Same as `s#`.

`i (int) [int]`

Convert a plain C `int` to a Python integer object.

`b (int) [char]`

Convert a plain C `char` to a Python integer object.

`h (int) [short int]`

Convert a plain C `short int` to a Python integer object.

`l (int) [long int]`

Convert a C `long int` to a Python integer object.

`B (int) [unsigned char]`

Convert a C `unsigned char` to a Python integer object.

`H (int) [unsigned short int]`

Convert a C `unsigned short int` to a Python integer object.

`I (int) [unsigned int]`

Convert a C `unsigned int` to a Python integer object.

`k (int) [unsigned long]`

Convert a C `unsigned long` to a Python integer object.

`L (int) [PY_LONG_LONG]`

Convert a C `long long` to a Python integer object. Only available on platforms that support `long long` (or `_int64` on Windows).

`κ (int) [unsigned PY_LONG_LONG]`

Convert a C `unsigned long long` to a Python integer object. Only available on platforms that support `unsigned long long`

(Or `unsigned _int64` on Windows).

n (`int`) [`Py_ssize_t`]

Convert a C `Py_ssize_t` to a Python integer.

c (`bytes` of length 1) [`char`]

Convert a C `int` representing a byte to a Python `bytes` object of length 1.

c (`str` of length 1) [`int`]

Convert a C `int` representing a character to Python `str` object of length 1.

d (`float`) [`double`]

Convert a C `double` to a Python floating point number.

f (`float`) [`float`]

Convert a C `float` to a Python floating point number.

D (`complex`) [`Py_complex *`]

Convert a C `Py_complex` structure to a Python complex number.

o (`object`) [`PyObject *`]

Pass a Python object untouched (except for its reference count, which is incremented by one). If the object passed in is a `NULL` pointer, it is assumed that this was caused because the call producing the argument found an error and set an exception. Therefore, `Py_BuildValue()` will return `NULL` but won't raise an exception. If no exception has been raised yet, `SystemError` is set.

s (`object`) [`PyObject *`]

Same as **o**.

N (`object`) [`PyObject *`]

Same as `o`, except it doesn't increment the reference count on the object. Useful when the object is created by a call to an object constructor in the argument list.

`o&` (object) [*converter, anything*]

Convert *anything* to a Python object through a *converter* function. The function is called with *anything* (which should be compatible with `void *`) as its argument and should return a "new" Python object, or `NULL` if an error occurred.

`(items)` (**tuple**) [*matching-items*]

Convert a sequence of C values to a Python tuple with the same number of items.

`[items]` (**list**) [*matching-items*]

Convert a sequence of C values to a Python list with the same number of items.

`{items}` (**dict**) [*matching-items*]

Convert a sequence of C values to a Python dictionary. Each pair of consecutive C values adds one item to the dictionary, serving as key and value, respectively.

If there is an error in the format string, the `SystemError` exception is set and `NULL` returned.

`PyObject*` **Py_VaBuildValue**(const char **format*, va_list *vargs*)

Identical to `Py_BuildValue()`, except that it accepts a `va_list` rather than a variable number of arguments.

String conversion and formatting

Functions for number conversion and formatted string output.

int **PyOS_snprintf**(char **str*, size_t *size*, const char **format*, ...)

Output not more than *size* bytes to *str* according to the format string *format* and the extra arguments. See the Unix man page *snprintf(2)*.

int **PyOS_vsnprintf**(char **str*, size_t *size*, const char **format*, va_list *va*)

Output not more than *size* bytes to *str* according to the format string *format* and the variable argument list *va*. Unix man page *vsnprintf(2)*.

PyOS_snprintf() and **PyOS_vsnprintf()** wrap the Standard C library functions `snprintf()` and `vsnprintf()`. Their purpose is to guarantee consistent behavior in corner cases, which the Standard C functions do not.

The wrappers ensure that `str[*size-1]` is always `'\0'` upon return. They never write more than *size* bytes (including the trailing `'\0'`) into *str*. Both functions require that `str != NULL`, `size > 0` and `format != NULL`.

If the platform doesn't have `vsnprintf()` and the buffer size needed to avoid truncation exceeds *size* by more than 512 bytes, Python aborts with a `Py_FatalError`.

The return value (*rv*) for these functions should be interpreted as follows:

- When `0 <= rv < size`, the output conversion was successful

and `rv` characters were written to `str` (excluding the trailing `'\0'` byte at `str[*rv]`).

- When `rv >= size`, the output conversion was truncated and a buffer with `rv + 1` bytes would have been needed to succeed. `str[*size-1]` is `'\0'` in this case.
- When `rv < 0`, “something bad happened.” `str[*size-1]` is `'\0'` in this case too, but the rest of `str` is undefined. The exact cause of the error depends on the underlying platform.

The following functions provide locale-independent string to number conversions.

```
double PyOS_string_to_double(const char *s, char **endptr,  
PyObject *overflow_exception)
```

Convert a string `s` to a `double`, raising a Python exception on failure. The set of accepted strings corresponds to the set of strings accepted by Python’s `float()` constructor, except that `s` must not have leading or trailing whitespace. The conversion is independent of the current locale.

If `endptr` is `NULL`, convert the whole string. Raise `ValueError` and return `-1.0` if the string is not a valid representation of a floating-point number.

If `endptr` is not `NULL`, convert as much of the string as possible and set `*endptr` to point to the first unconverted character. If no initial segment of the string is the valid representation of a floating-point number, set `*endptr` to point to the beginning of the string, raise `ValueError`, and return `-1.0`.

If `s` represents a value that is too large to store in a float (for example, `"1e500"` is such a string on many platforms) then if `overflow_exception` is `NULL` return `Py_HUGE_VAL` (with an

appropriate sign) and don't set any exception. Otherwise, `overflow_exception` must point to a Python exception object; raise that exception and return `-1.0`. In both cases, set `*endptr` to point to the first character after the converted value.

If any other error occurs during the conversion (for example an out-of-memory error), set the appropriate Python exception and return `-1.0`.

New in version 3.1.

`char* PyOS_double_to_string(double val, char format_code, int precision, int flags, int *ptype)`

Convert a `double val` to a string using supplied `format_code`, `precision`, and `flags`.

`format_code` must be one of `'e'`, `'E'`, `'f'`, `'F'`, `'g'`, `'G'` or `'r'`. For `'r'`, the supplied `precision` must be 0 and is ignored. The `'r'` format code specifies the standard `repr()` format.

`flags` can be zero or more of the values `Py_DTST_SIGN`, `Py_DTST_ADD_DOT_0`, or `Py_DTST_ALT`, or-ed together:

- `Py_DTST_SIGN` means to always precede the returned string with a sign character, even if `val` is non-negative.
- `Py_DTST_ADD_DOT_0` means to ensure that the returned string will not look like an integer.
- `Py_DTST_ALT` means to apply “alternate” formatting rules. See the documentation for the `PyOS_snprintf()` `'#'` specifier for details.

If `ptype` is non-NULL, then the value it points to will be set to one of `Py_DTST_FINITE`, `Py_DTST_INFINITE`, or `Py_DTST_NAN`, signifying that `val` is a finite number, an infinite number, or not a number, respectively.

The return value is a pointer to *buffer* with the converted string or *NULL* if the conversion failed. The caller is responsible for freeing the returned string by calling `PyMem_Free()`.

New in version 3.1.

`char* PyOS_stricmp(char *s1, char *s2)`

Case insensitive comparison of strings. The function works almost identically to `strcmp()` except that it ignores the case.

`char* PyOS_strnicmp(char *s1, char *s2, Py_ssize_t size)`

Case insensitive comparison of strings. The function works almost identically to `strncmp()` except that it ignores the case.

Reflection

PyObject* **PyEval_GetBuiltins()**

Return value: Borrowed reference.

Return a dictionary of the builtins in the current execution frame, or the interpreter of the thread state if no frame is currently executing.

PyObject* **PyEval_GetLocals()**

Return value: Borrowed reference.

Return a dictionary of the local variables in the current execution frame, or *NULL* if no frame is currently executing.

PyObject* **PyEval_GetGlobals()**

Return value: Borrowed reference.

Return a dictionary of the global variables in the current execution frame, or *NULL* if no frame is currently executing.

PyFrameObject* **PyEval_GetFrame()**

Return value: Borrowed reference.

Return the current thread state's frame, which is *NULL* if no frame is currently executing.

int **PyFrame_GetLineNumber(PyFrameObject *frame)**

Return the line number that *frame* is currently executing.

const char* **PyEval_GetFuncName(PyObject *func)**

Return the name of *func* if it is a function, class or instance object, else the name of *func*'s type.

const char* **PyEval_GetFuncDesc(PyObject *func)**

Return a description string, depending on the type of *func*. Return values include “()” for functions and methods, ” constructor”, ” instance”, and ” object”. Concatenated with the result of

`PyEval_GetFuncName()`, the result will be a description of *func*.

Manual » Utilities »

Codec registry and support functions

`int PyCodec_Register(PyObject *search_function)`

Register a new codec search function.

As side effect, this tries to load the `encodings` package, if not yet done, to make sure that it is always first in the list of search functions.

`int PyCodec_KnownEncoding(const char *encoding)`

Return `1` or `0` depending on whether there is a registered codec for the given *encoding*.

`PyObject* PyCodec_Encode(PyObject *object, const char *encoding, const char *errors)`

Generic codec based encoding API.

object is passed through the encoder function found for the given *encoding* using the error handling method defined by *errors*. *errors* may be `NULL` to use the default method defined for the codec. Raises a `LookupError` if no encoder can be found.

`PyObject* PyCodec_Decode(PyObject *object, const char *encoding, const char *errors)`

Generic codec based decoding API.

object is passed through the decoder function found for the given *encoding* using the error handling method defined by *errors*. *errors* may be `NULL` to use the default method defined for the codec. Raises a `LookupError` if no encoder can be found.

Codec lookup API

In the following functions, the *encoding* string is looked up converted to all lower-case characters, which makes encodings looked up through this mechanism effectively case-insensitive. If no codec is found, a **KeyError** is set and *NULL* returned.

PyObject* **PyCodec_Encoder**(const char **encoding*)

Get an encoder function for the given *encoding*.

PyObject* **PyCodec_Decoder**(const char **encoding*)

Get a decoder function for the given *encoding*.

PyObject* **PyCodec_IncrementalEncoder**(const char **encoding*,
const char **errors*)

Get an **IncrementalEncoder** object for the given *encoding*.

PyObject* **PyCodec_IncrementalDecoder**(const char **encoding*,
const char **errors*)

Get an **IncrementalDecoder** object for the given *encoding*.

PyObject* **PyCodec_StreamReader**(const char **encoding*, **PyObject**
**stream*, const char **errors*)

Get a **StreamReader** factory function for the given *encoding*.

PyObject* **PyCodec_StreamWriter**(const char **encoding*, **PyObject**
**stream*, const char **errors*)

Get a **StreamWriter** factory function for the given *encoding*.

Registry API for Unicode encoding error handlers

`int PyCodec_RegisterError(const char *name, PyObject *error)`

Register the error handling callback function *error* under the given *name*. This callback function will be called by a codec when it encounters unencodable characters/undecodable bytes and *name* is specified as the error parameter in the call to the encode/decode function.

The callback gets a single argument, an instance of `UnicodeEncodeError`, `UnicodeDecodeError` or `UnicodeTranslateError` that holds information about the problematic sequence of characters or bytes and their offset in the original string (see *Unicode Exception Objects* for functions to extract this information). The callback must either raise the given exception, or return a two-item tuple containing the replacement for the problematic sequence, and an integer giving the offset in the original string at which encoding/decoding should be resumed.

Return `0` on success, `-1` on error.

`PyObject* PyCodec_LookupError(const char *name)`

Lookup the error handling callback function registered under *name*. As a special case `NULL` can be passed, in which case the error handling callback for “strict” will be returned.

`PyObject* PyCodec_StrictErrors(PyObject *exc)`

Raise *exc* as an exception.

`PyObject* PyCodec_IgnoreErrors(PyObject *exc)`

Ignore the unicode error, skipping the faulty input.

PyObject* **PyCodec_ReplaceErrors(PyObject *exc)**

Replace the unicode encode error with `?` or `U+FFFD`.

PyObject* **PyCodec_XMLCharRefReplaceErrors(PyObject *exc)**

Replace the unicode encode error with XML character references.

PyObject* **PyCodec_BackslashReplaceErrors(PyObject *exc)**

Replace the unicode encode error with backslash escapes (`\x`, `\u` and `\U`).

Abstract Objects Layer

The functions in this chapter interact with Python objects regardless of their type, or with wide classes of object types (e.g. all numerical types, or all sequence types). When used on object types for which they do not apply, they will raise a Python exception.

It is not possible to use these functions on objects that are not properly initialized, such as a list object that has been created by `PyList_New()`, but whose items have not been set to some non-NULL value yet.

Python v3.2 documentation » Python/C API Reference

[previous](#) | [next](#) | [modules](#) | [index](#)

[Manual](#) » [Abstract Objects Layer](#) »

Object Protocol

`int PyObject_Print(PyObject *o, FILE *fp, int flags)`

Print an object `o`, on file `fp`. Returns `-1` on error. The flags argument is used to enable certain printing options. The only option currently supported is `Py_PRINT_RAW`; if given, the `str()` of the object is written instead of the `repr()`.

`int PyObject_HasAttr(PyObject *o, PyObject *attr_name)`

Returns `1` if `o` has the attribute `attr_name`, and `0` otherwise. This is equivalent to the Python expression `hasattr(o, attr_name)`. This function always succeeds.

`int PyObject_HasAttrString(PyObject *o, const char *attr_name)`

Returns `1` if `o` has the attribute `attr_name`, and `0` otherwise. This is equivalent to the Python expression `hasattr(o, attr_name)`. This function always succeeds.

`PyObject* PyObject_GetAttr(PyObject *o, PyObject *attr_name)`

Return value: New reference.

Retrieve an attribute named `attr_name` from object `o`. Returns the attribute value on success, or `NULL` on failure. This is the equivalent of the Python expression `o.attr_name`.

`PyObject* PyObject_GetAttrString(PyObject *o, const char *attr_name)`

Return value: New reference.

Retrieve an attribute named `attr_name` from object `o`. Returns the attribute value on success, or `NULL` on failure. This is the equivalent of the Python expression `o.attr_name`.

`PyObject* PyObject_GenericGetAttr(PyObject *o, PyObject`

**name*)

Generic attribute getter function that is meant to be put into a type object's `tp_getattro` slot. It looks for a descriptor in the dictionary of classes in the object's MRO as well as an attribute in the object's `__dict__` (if present). As outlined in *Implementing Descriptors*, data descriptors take preference over instance attributes, while non-data descriptors don't. Otherwise, an `AttributeError` is raised.

`int PyObject_SetAttr(PyObject *o, PyObject *attr_name, PyObject *v)`

Set the value of the attribute named `attr_name`, for object `o`, to the value `v`. Returns `-1` on failure. This is the equivalent of the Python statement `o.attr_name = v`.

`int PyObject_SetAttrString(PyObject *o, const char *attr_name, PyObject *v)`

Set the value of the attribute named `attr_name`, for object `o`, to the value `v`. Returns `-1` on failure. This is the equivalent of the Python statement `o.attr_name = v`.

`int PyObject_GenericSetAttr(PyObject *o, PyObject *name, PyObject *value)`

Generic attribute setter function that is meant to be put into a type object's `tp_setattro` slot. It looks for a data descriptor in the dictionary of classes in the object's MRO, and if found it takes preference over setting the attribute in the instance dictionary. Otherwise, the attribute is set in the object's `__dict__` (if present). Otherwise, an `AttributeError` is raised and `-1` is returned.

`int PyObject_De1Attr(PyObject *o, PyObject *attr_name)`

Delete attribute named `attr_name`, for object `o`. Returns `-1` on failure. This is the equivalent of the Python statement `de1`

`o.attr_name`.

`int PyObject_De1AttrString(PyObject *o, const char *attr_name)`

Delete attribute named `attr_name`, for object `o`. Returns `-1` on failure. This is the equivalent of the Python statement `del o.attr_name`.

`PyObject* PyObject_RichCompare(PyObject *o1, PyObject *o2, int opid)`

Return value: New reference.

Compare the values of `o1` and `o2` using the operation specified by `opid`, which must be one of `Py_LT`, `Py_LE`, `Py_EQ`, `Py_NE`, `Py_GT`, or `Py_GE`, corresponding to `<`, `<=`, `==`, `!=`, `>`, or `>=` respectively. This is the equivalent of the Python expression `o1 op o2`, where `op` is the operator corresponding to `opid`. Returns the value of the comparison on success, or `NULL` on failure.

`int PyObject_RichCompareBool(PyObject *o1, PyObject *o2, int opid)`

Compare the values of `o1` and `o2` using the operation specified by `opid`, which must be one of `Py_LT`, `Py_LE`, `Py_EQ`, `Py_NE`, `Py_GT`, or `Py_GE`, corresponding to `<`, `<=`, `==`, `!=`, `>`, or `>=` respectively. Returns `-1` on error, `0` if the result is false, `1` otherwise. This is the equivalent of the Python expression `o1 op o2`, where `op` is the operator corresponding to `opid`.

Note: If `o1` and `o2` are the same object, `PyObject_RichCompareBool()` will always return `1` for `Py_EQ` and `0` for `Py_NE`.

`PyObject* PyObject_Repr(PyObject *o)`

Return value: New reference.

Compute a string representation of object *o*. Returns the string representation on success, *NULL* on failure. This is the equivalent of the Python expression `repr(o)`. Called by the `repr()` built-in function.

PyObject* **PyObject_ASCII(PyObject *o)**

As `PyObject_Repr()`, compute a string representation of object *o*, but escape the non-ASCII characters in the string returned by `PyObject_Repr()` with `\x`, `\u` or `\U` escapes. This generates a string similar to that returned by `PyObject_Repr()` in Python 2. Called by the `ascii()` built-in function.

PyObject* **PyObject_Str(PyObject *o)**

Return value: New reference.

Compute a string representation of object *o*. Returns the string representation on success, *NULL* on failure. This is the equivalent of the Python expression `str(o)`. Called by the `str()` built-in function and, therefore, by the `print()` function.

PyObject* **PyObject_Bytes(PyObject *o)**

Compute a bytes representation of object *o*. *NULL* is returned on failure and a bytes object on success. This is equivalent to the Python expression `bytes(o)`, when *o* is not an integer. Unlike `bytes(o)`, a `TypeError` is raised when *o* is an integer instead of a zero-initialized bytes object.

int **PyObject_IsInstance(PyObject *inst, PyObject *cls)**

Returns `1` if *inst* is an instance of the class *cls* or a subclass of *cls*, or `0` if not. On error, returns `-1` and sets an exception. If *cls* is a type object rather than a class object, `PyObject_IsInstance()` returns `1` if *inst* is of type *cls*. If *cls* is a tuple, the check will be done against every entry in *cls*. The result will be `1` when at least one of the checks returns `1`, otherwise it will be `0`. If *inst* is not a

class instance and *cls* is neither a type object, nor a class object, nor a tuple, *inst* must have a `__class__` attribute — the class relationship of the value of that attribute with *cls* will be used to determine the result of this function.

Subclass determination is done in a fairly straightforward way, but includes a wrinkle that implementors of extensions to the class system may want to be aware of. If **A** and **B** are class objects, **B** is a subclass of **A** if it inherits from **A** either directly or indirectly. If either is not a class object, a more general mechanism is used to determine the class relationship of the two objects. When testing if *B* is a subclass of *A*, if *A* is *B*, `PyObject_IsSubclass()` returns true. If *A* and *B* are different objects, *B*'s `__bases__` attribute is searched in a depth-first fashion for *A* — the presence of the `__bases__` attribute is considered sufficient for this determination.

`int PyObject_IsSubclass(PyObject *derived, PyObject *cls)`

Returns `1` if the class *derived* is identical to or derived from the class *cls*, otherwise returns `0`. In case of an error, returns `-1`. If *cls* is a tuple, the check will be done against every entry in *cls*. The result will be `1` when at least one of the checks returns `1`, otherwise it will be `0`. If either *derived* or *cls* is not an actual class object (or tuple), this function uses the generic algorithm described above.

`int PyCallable_Check(PyObject *o)`

Determine if the object *o* is callable. Return `1` if the object is callable and `0` otherwise. This function always succeeds.

`PyObject* PyObject_Call(PyObject *callable_object, PyObject *args, PyObject *kw)`

Return value: *New reference.*

Call a callable Python object *callable_object*, with arguments

given by the tuple *args*, and named arguments given by the dictionary *kw*. If no named arguments are needed, *kw* may be *NULL*. *args* must not be *NULL*, use an empty tuple if no arguments are needed. Returns the result of the call on success, or *NULL* on failure. This is the equivalent of the Python expression `callable_object(*args, **kw)`.

PyObject* **PyObject_CallObject**(PyObject *callable_object,
PyObject *args)

Return value: New reference.

Call a callable Python object *callable_object*, with arguments given by the tuple *args*. If no arguments are needed, then *args* may be *NULL*. Returns the result of the call on success, or *NULL* on failure. This is the equivalent of the Python expression `callable_object(*args)`.

PyObject* **PyObject_CallFunction**(PyObject *callable, char
*format, ...)

Return value: New reference.

Call a callable Python object *callable*, with a variable number of C arguments. The C arguments are described using a `Py_BuildValue()` style format string. The format may be *NULL*, indicating that no arguments are provided. Returns the result of the call on success, or *NULL* on failure. This is the equivalent of the Python expression `callable(*args)`. Note that if you only pass `PyObject * args`, `PyObject_CallFunctionObjArgs()` is a faster alternative.

PyObject* **PyObject_CallMethod**(PyObject *o, char *method, char
*format, ...)

Return value: New reference.

Call the method named *method* of object *o* with a variable number of C arguments. The C arguments are described by a `Py_BuildValue()` format string that should produce a tuple. The

format may be *NULL*, indicating that no arguments are provided. Returns the result of the call on success, or *NULL* on failure. This is the equivalent of the Python expression `o.method(args)`. Note that if you only pass `PyObject * args`, `PyObject_CallMethodObjArgs()` is a faster alternative.

`PyObject*` `PyObject_CallFunctionObjArgs(PyObject *callable, ..., NULL)`

Return value: New reference.

Call a callable Python object *callable*, with a variable number of `PyObject*` arguments. The arguments are provided as a variable number of parameters followed by *NULL*. Returns the result of the call on success, or *NULL* on failure.

`PyObject*` `PyObject_CallMethodObjArgs(PyObject *o, PyObject *name, ..., NULL)`

Return value: New reference.

Calls a method of the object *o*, where the name of the method is given as a Python string object in *name*. It is called with a variable number of `PyObject*` arguments. The arguments are provided as a variable number of parameters followed by *NULL*. Returns the result of the call on success, or *NULL* on failure.

`Py_hash_t` `PyObject_Hash(PyObject *o)`

Compute and return the hash value of an object *o*. On failure, return `-1`. This is the equivalent of the Python expression `hash(o)`.

Changed in version 3.2.

`Py_hash_t` `PyObject_HashNotImplemented(PyObject *o)`

Set a `TypeError` indicating that `type(o)` is not hashable and return `-1`. This function receives special treatment when stored in

a `tp_hash` slot, allowing a type to explicitly indicate to the interpreter that it is not hashable.

`int PyObject_IsTrue(PyObject *o)`

Returns `1` if the object `o` is considered to be true, and `0` otherwise. This is equivalent to the Python expression `not not o`. On failure, return `-1`.

`int PyObject_Not(PyObject *o)`

Returns `0` if the object `o` is considered to be true, and `1` otherwise. This is equivalent to the Python expression `not o`. On failure, return `-1`.

`PyObject* PyObject_Type(PyObject *o)`

Return value: New reference.

When `o` is non-`NULL`, returns a type object corresponding to the object type of object `o`. On failure, raises `SystemError` and returns `NULL`. This is equivalent to the Python expression `type(o)`. This function increments the reference count of the return value. There's really no reason to use this function instead of the common expression `o->ob_type`, which returns a pointer of type `PyTypeObject*`, except when the incremented reference count is needed.

`int PyObject_TypeCheck(PyObject *o, PyTypeObject *type)`

Return true if the object `o` is of type `type` or a subtype of `type`. Both parameters must be non-`NULL`.

`Py_ssize_t PyObject_Length(PyObject *o)`

`Py_ssize_t PyObject_Size(PyObject *o)`

Return the length of object `o`. If the object `o` provides either the sequence and mapping protocols, the sequence length is returned. On error, `-1` is returned. This is the equivalent to the

Python expression `len(o)`.

PyObject* **PyObject_GetItem**(PyObject *o, PyObject *key)

Return value: New reference.

Return element of `o` corresponding to the object `key` or `NULL` on failure. This is the equivalent of the Python expression `o[key]`.

int **PyObject_SetItem**(PyObject *o, PyObject *key, PyObject *v)

Map the object `key` to the value `v`. Returns `-1` on failure. This is the equivalent of the Python statement `o[key] = v`.

int **PyObject_DelItem**(PyObject *o, PyObject *key)

Delete the mapping for `key` from `o`. Returns `-1` on failure. This is the equivalent of the Python statement `del o[key]`.

PyObject* **PyObject_Dir**(PyObject *o)

Return value: New reference.

This is equivalent to the Python expression `dir(o)`, returning a (possibly empty) list of strings appropriate for the object argument, or `NULL` if there was an error. If the argument is `NULL`, this is like the Python `dir()`, returning the names of the current locals; in this case, if no execution frame is active then `NULL` is returned but `PyErr_Occurred()` will return false.

PyObject* **PyObject_GetIter**(PyObject *o)

Return value: New reference.

This is equivalent to the Python expression `iter(o)`. It returns a new iterator for the object argument, or the object itself if the object is already an iterator. Raises `TypeError` and returns `NULL` if the object cannot be iterated.

[previous](#) | [next](#) | [modules](#) | [index](#)

[Manual](#) » [Abstract Objects Layer](#) »

Number Protocol

`int PyNumber_Check(PyObject *o)`

Returns `1` if the object `o` provides numeric protocols, and false otherwise. This function always succeeds.

`PyObject* PyNumber_Add(PyObject *o1, PyObject *o2)`

Return value: New reference.

Returns the result of adding `o1` and `o2`, or `NULL` on failure. This is the equivalent of the Python expression `o1 + o2`.

`PyObject* PyNumber_Subtract(PyObject *o1, PyObject *o2)`

Return value: New reference.

Returns the result of subtracting `o2` from `o1`, or `NULL` on failure. This is the equivalent of the Python expression `o1 - o2`.

`PyObject* PyNumber_Multiply(PyObject *o1, PyObject *o2)`

Return value: New reference.

Returns the result of multiplying `o1` and `o2`, or `NULL` on failure. This is the equivalent of the Python expression `o1 * o2`.

`PyObject* PyNumber_FloorDivide(PyObject *o1, PyObject *o2)`

Return value: New reference.

Return the floor of `o1` divided by `o2`, or `NULL` on failure. This is equivalent to the “classic” division of integers.

`PyObject* PyNumber_TrueDivide(PyObject *o1, PyObject *o2)`

Return value: New reference.

Return a reasonable approximation for the mathematical value of `o1` divided by `o2`, or `NULL` on failure. The return value is “approximate” because binary floating point numbers are approximate; it is not possible to represent all real numbers in base two. This function can return a floating point value when

passed two integers.

PyObject* **PyNumber_Remainder**(PyObject *o1, PyObject *o2)

Return value: New reference.

Returns the remainder of dividing *o1* by *o2*, or *NULL* on failure. This is the equivalent of the Python expression `o1 % o2`.

PyObject* **PyNumber_Divmod**(PyObject *o1, PyObject *o2)

Return value: New reference.

See the built-in function `divmod()`. Returns *NULL* on failure. This is the equivalent of the Python expression `divmod(o1, o2)`.

PyObject* **PyNumber_Power**(PyObject *o1, PyObject *o2, PyObject *o3)

Return value: New reference.

See the built-in function `pow()`. Returns *NULL* on failure. This is the equivalent of the Python expression `pow(o1, o2, o3)`, where *o3* is optional. If *o3* is to be ignored, pass `Py_None` in its place (passing *NULL* for *o3* would cause an illegal memory access).

PyObject* **PyNumber_Negative**(PyObject *o)

Return value: New reference.

Returns the negation of *o* on success, or *NULL* on failure. This is the equivalent of the Python expression `-o`.

PyObject* **PyNumber_Positive**(PyObject *o)

Return value: New reference.

Returns *o* on success, or *NULL* on failure. This is the equivalent of the Python expression `+o`.

PyObject* **PyNumber_Absolute**(PyObject *o)

Return value: New reference.

Returns the absolute value of *o*, or *NULL* on failure. This is the equivalent of the Python expression `abs(o)`.

PyObject* **PyNumber_Invert**(PyObject *o)

Return value: New reference.

Returns the bitwise negation of *o* on success, or *NULL* on failure. This is the equivalent of the Python expression `~o`.

PyObject* **PyNumber_Lshift**(PyObject *o1, PyObject *o2)

Return value: New reference.

Returns the result of left shifting *o1* by *o2* on success, or *NULL* on failure. This is the equivalent of the Python expression `o1 << o2`.

PyObject* **PyNumber_Rshift**(PyObject *o1, PyObject *o2)

Return value: New reference.

Returns the result of right shifting *o1* by *o2* on success, or *NULL* on failure. This is the equivalent of the Python expression `o1 >> o2`.

PyObject* **PyNumber_And**(PyObject *o1, PyObject *o2)

Return value: New reference.

Returns the “bitwise and” of *o1* and *o2* on success and *NULL* on failure. This is the equivalent of the Python expression `o1 & o2`.

PyObject* **PyNumber_Xor**(PyObject *o1, PyObject *o2)

Return value: New reference.

Returns the “bitwise exclusive or” of *o1* by *o2* on success, or *NULL* on failure. This is the equivalent of the Python expression `o1 ^ o2`.

PyObject* **PyNumber_Or**(PyObject *o1, PyObject *o2)

Return value: New reference.

Returns the “bitwise or” of *o1* and *o2* on success, or *NULL* on failure. This is the equivalent of the Python expression `o1 | o2`.

`PyObject*` `PyNumber_InPlaceAdd(PyObject *o1, PyObject *o2)`

Return value: New reference.

Returns the result of adding `o1` and `o2`, or `NULL` on failure. The operation is done *in-place* when `o1` supports it. This is the equivalent of the Python statement `o1 += o2`.

`PyObject*` `PyNumber_InPlaceSubtract(PyObject *o1, PyObject *o2)`

Return value: New reference.

Returns the result of subtracting `o2` from `o1`, or `NULL` on failure. The operation is done *in-place* when `o1` supports it. This is the equivalent of the Python statement `o1 -= o2`.

`PyObject*` `PyNumber_InPlaceMultiply(PyObject *o1, PyObject *o2)`

Return value: New reference.

Returns the result of multiplying `o1` and `o2`, or `NULL` on failure. The operation is done *in-place* when `o1` supports it. This is the equivalent of the Python statement `o1 *= o2`.

`PyObject*` `PyNumber_InPlaceFloorDivide(PyObject *o1, PyObject *o2)`

Return value: New reference.

Returns the mathematical floor of dividing `o1` by `o2`, or `NULL` on failure. The operation is done *in-place* when `o1` supports it. This is the equivalent of the Python statement `o1 //= o2`.

`PyObject*` `PyNumber_InPlaceTrueDivide(PyObject *o1, PyObject *o2)`

Return value: New reference.

Return a reasonable approximation for the mathematical value of `o1` divided by `o2`, or `NULL` on failure. The return value is “approximate” because binary floating point numbers are approximate; it is not possible to represent all real numbers in

base two. This function can return a floating point value when passed two integers. The operation is done *in-place* when *o1* supports it.

`PyObject*` `PyNumber_InPlaceRemainder(PyObject *o1, PyObject *o2)`

Return value: New reference.

Returns the remainder of dividing *o1* by *o2*, or *NULL* on failure. The operation is done *in-place* when *o1* supports it. This is the equivalent of the Python statement `o1 %= o2`.

`PyObject*` `PyNumber_InPlacePower(PyObject *o1, PyObject *o2, PyObject *o3)`

Return value: New reference.

See the built-in function `pow()`. Returns *NULL* on failure. The operation is done *in-place* when *o1* supports it. This is the equivalent of the Python statement `o1 **= o2` when *o3* is `Py_None`, or an in-place variant of `pow(o1, o2, o3)` otherwise. If *o3* is to be ignored, pass `Py_None` in its place (passing *NULL* for *o3* would cause an illegal memory access).

`PyObject*` `PyNumber_InPlaceLshift(PyObject *o1, PyObject *o2)`

Return value: New reference.

Returns the result of left shifting *o1* by *o2* on success, or *NULL* on failure. The operation is done *in-place* when *o1* supports it. This is the equivalent of the Python statement `o1 <<= o2`.

`PyObject*` `PyNumber_InPlaceRshift(PyObject *o1, PyObject *o2)`

Return value: New reference.

Returns the result of right shifting *o1* by *o2* on success, or *NULL* on failure. The operation is done *in-place* when *o1* supports it. This is the equivalent of the Python statement `o1 >>= o2`.

`PyObject*` `PyNumber_InPlaceAnd(PyObject *o1, PyObject *o2)`

Return value: New reference.

Returns the “bitwise and” of *o1* and *o2* on success and *NULL* on failure. The operation is done *in-place* when *o1* supports it. This is the equivalent of the Python statement `o1 &= o2`.

PyObject* **PyNumber_InPlaceXor**(PyObject **o1*, PyObject **o2*)

Return value: New reference.

Returns the “bitwise exclusive or” of *o1* by *o2* on success, or *NULL* on failure. The operation is done *in-place* when *o1* supports it. This is the equivalent of the Python statement `o1 ^= o2`.

PyObject* **PyNumber_InPlaceOr**(PyObject **o1*, PyObject **o2*)

Return value: New reference.

Returns the “bitwise or” of *o1* and *o2* on success, or *NULL* on failure. The operation is done *in-place* when *o1* supports it. This is the equivalent of the Python statement `o1 |= o2`.

PyObject* **PyNumber_Long**(PyObject **o*)

Return value: New reference.

Returns the *o* converted to an integer object on success, or *NULL* on failure. This is the equivalent of the Python expression `int(o)`.

PyObject* **PyNumber_Float**(PyObject **o*)

Return value: New reference.

Returns the *o* converted to a float object on success, or *NULL* on failure. This is the equivalent of the Python expression `float(o)`.

PyObject* **PyNumber_Index**(PyObject **o*)

Returns the *o* converted to a Python int on success or *NULL* with a **TypeError** exception raised on failure.

PyObject* **PyNumber_ToBase**(PyObject **n*, int *base*)

Returns the integer *n* converted to *base* as a string with a base

marker of `'0b'`, `'0o'`, or `'0x'` if applicable. When *base* is not 2, 8, 10, or 16, the format is `'x#num'` where *x* is the base. If *n* is not an int object, it is converted with `PyNumber_Index()` first.

`Py_ssize_t PyNumber_AsSsize_t(PyObject *o, PyObject *exc)`

Returns *o* converted to a `Py_ssize_t` value if *o* can be interpreted as an integer. If *o* can be converted to a Python int but the attempt to convert to a `Py_ssize_t` value would raise an `OverflowError`, then the *exc* argument is the type of exception that will be raised (usually `IndexError` or `OverflowError`). If *exc* is `NULL`, then the exception is cleared and the value is clipped to `PY_SSIZE_T_MIN` for a negative integer or `PY_SSIZE_T_MAX` for a positive integer.

`int PyIndex_Check(PyObject *o)`

Returns True if *o* is an index integer (has the `nb_index` slot of the `tp_as_number` structure filled in).

[Manual](#) » [Abstract Objects Layer](#) »

Sequence Protocol

`int PySequence_Check(PyObject *o)`

Return `1` if the object provides sequence protocol, and `0` otherwise. This function always succeeds.

`Py_ssize_t PySequence_Size(PyObject *o)`

`Py_ssize_t PySequence_Length(PyObject *o)`

Returns the number of objects in sequence `o` on success, and `-1` on failure. For objects that do not provide sequence protocol, this is equivalent to the Python expression `len(o)`.

`PyObject* PySequence_Concat(PyObject *o1, PyObject *o2)`

Return value: New reference.

Return the concatenation of `o1` and `o2` on success, and `NULL` on failure. This is the equivalent of the Python expression `o1 + o2`.

`PyObject* PySequence_Repeat(PyObject *o, Py_ssize_t count)`

Return value: New reference.

Return the result of repeating sequence object `o` `count` times, or `NULL` on failure. This is the equivalent of the Python expression `o * count`.

`PyObject* PySequence_InPlaceConcat(PyObject *o1, PyObject *o2)`

Return value: New reference.

Return the concatenation of `o1` and `o2` on success, and `NULL` on failure. The operation is done *in-place* when `o1` supports it. This is the equivalent of the Python expression `o1 += o2`.

`PyObject* PySequence_InPlaceRepeat(PyObject *o, Py_ssize_t count)`

Return value: New reference.

Return the result of repeating sequence object *o* *count* times, or *NULL* on failure. The operation is done *in-place* when *o* supports it. This is the equivalent of the Python expression `o *= count`.

`PyObject*` **PySequence_GetItem**(`PyObject *o`, `Py_ssize_t i`)

Return value: New reference.

Return the *i*th element of *o*, or *NULL* on failure. This is the equivalent of the Python expression `o[i]`.

`PyObject*` **PySequence_GetSlice**(`PyObject *o`, `Py_ssize_t i1`,
`Py_ssize_t i2`)

Return value: New reference.

Return the slice of sequence object *o* between *i1* and *i2*, or *NULL* on failure. This is the equivalent of the Python expression `o[i1:i2]`.

`int` **PySequence_SetItem**(`PyObject *o`, `Py_ssize_t i`, `PyObject *v`)

Assign object *v* to the *i*th element of *o*. Returns `-1` on failure. This is the equivalent of the Python statement `o[i] = v`. This function *does not* steal a reference to *v*.

`int` **PySequence_DeItem**(`PyObject *o`, `Py_ssize_t i`)

Delete the *i*th element of object *o*. Returns `-1` on failure. This is the equivalent of the Python statement `del o[i]`.

`int` **PySequence_SetSlice**(`PyObject *o`, `Py_ssize_t i1`, `Py_ssize_t i2`,
`PyObject *v`)

Assign the sequence object *v* to the slice in sequence object *o* from *i1* to *i2*. This is the equivalent of the Python statement `o[i1:i2] = v`.

`int` **PySequence_DeSlice**(`PyObject *o`, `Py_ssize_t i1`, `Py_ssize_t i2`)

Delete the slice in sequence object *o* from *i1* to *i2*. Returns `-1` on failure. This is the equivalent of the Python statement `del o[i1:i2]`.

`Py_ssize_t PySequence_Count(PyObject *o, PyObject *value)`

Return the number of occurrences of *value* in *o*, that is, return the number of keys for which `o[key] == value`. On failure, return `-1`. This is equivalent to the Python expression `o.count(value)`.

`int PySequence_Contains(PyObject *o, PyObject *value)`

Determine if *o* contains *value*. If an item in *o* is equal to *value*, return `1`, otherwise return `0`. On error, return `-1`. This is equivalent to the Python expression `value in o`.

`Py_ssize_t PySequence_Index(PyObject *o, PyObject *value)`

Return the first index *i* for which `o[i] == value`. On error, return `-1`. This is equivalent to the Python expression `o.index(value)`.

`PyObject* PySequence_List(PyObject *o)`

Return value: New reference.

Return a list object with the same contents as the arbitrary sequence *o*. The returned list is guaranteed to be new.

`PyObject* PySequence_Tuple(PyObject *o)`

Return value: New reference.

Return a tuple object with the same contents as the arbitrary sequence *o* or `NULL` on failure. If *o* is a tuple, a new reference will be returned, otherwise a tuple will be constructed with the appropriate contents. This is equivalent to the Python expression `tuple(o)`.

`PyObject* PySequence_Fast(PyObject *o, const char *m)`

Return value: New reference.

Returns the sequence *o* as a tuple, unless it is already a tuple or list, in which case *o* is returned. Use `PySequence_Fast_GET_ITEM()` to access the members of the result. Returns *NULL* on failure. If the object is not a sequence, raises `TypeError` with *m* as the message text.

`PyObject*` `PySequence_Fast_GET_ITEM(PyObject *o, Py_ssize_t i)`

Return value: Borrowed reference.

Return the *i*th element of *o*, assuming that *o* was returned by `PySequence_Fast()`, *o* is not *NULL*, and that *i* is within bounds.

`PyObject**` `PySequence_Fast_ITEMS(PyObject *o)`

Return the underlying array of PyObject pointers. Assumes that *o* was returned by `PySequence_Fast()` and *o* is not *NULL*.

Note, if a list gets resized, the reallocation may relocate the items array. So, only use the underlying array pointer in contexts where the sequence cannot change.

`PyObject*` `PySequence_ITEM(PyObject *o, Py_ssize_t i)`

Return value: New reference.

Return the *i*th element of *o* or *NULL* on failure. Macro form of `PySequence_GetItem()` but without checking that `PySequence_Check(o)()` is true and without adjustment for negative indices.

`Py_ssize_t` `PySequence_Fast_GET_SIZE(PyObject *o)`

Returns the length of *o*, assuming that *o* was returned by `PySequence_Fast()` and that *o* is not *NULL*. The size can also be gotten by calling `PySequence_Size()` on *o*, but `PySequence_Fast_GET_SIZE()` is faster because it can assume *o* is a list or tuple.

Mapping Protocol

`int PyMapping_Check(PyObject *o)`

Return `1` if the object provides mapping protocol, and `0` otherwise. This function always succeeds.

`Py_ssize_t PyMapping_Size(PyObject *o)`

`Py_ssize_t PyMapping_Length(PyObject *o)`

Returns the number of keys in object `o` on success, and `-1` on failure. For objects that do not provide mapping protocol, this is equivalent to the Python expression `len(o)`.

`int PyMapping_DeItemString(PyObject *o, char *key)`

Remove the mapping for object `key` from the object `o`. Return `-1` on failure. This is equivalent to the Python statement `del o[key]`.

`int PyMapping_DeItem(PyObject *o, PyObject *key)`

Remove the mapping for object `key` from the object `o`. Return `-1` on failure. This is equivalent to the Python statement `del o[key]`.

`int PyMapping_HasKeyString(PyObject *o, char *key)`

On success, return `1` if the mapping object has the key `key` and `0` otherwise. This is equivalent to the Python expression `key in o`. This function always succeeds.

`int PyMapping_HasKey(PyObject *o, PyObject *key)`

Return `1` if the mapping object has the key `key` and `0` otherwise. This is equivalent to the Python expression `key in o`. This function always succeeds.

`PyObject* PyMapping_Keys(PyObject *o)`

Return value: New reference.

On success, return a list of the keys in object *o*. On failure, return *NULL*. This is equivalent to the Python expression `list(o.keys())`.

PyObject* **PyMapping_Values**(PyObject **o*)

Return value: New reference.

On success, return a list of the values in object *o*. On failure, return *NULL*. This is equivalent to the Python expression `list(o.values())`.

PyObject* **PyMapping_Items**(PyObject **o*)

Return value: New reference.

On success, return a list of the items in object *o*, where each item is a tuple containing a key-value pair. On failure, return *NULL*. This is equivalent to the Python expression `list(o.items())`.

PyObject* **PyMapping_GetItemString**(PyObject **o*, char **key*)

Return value: New reference.

Return element of *o* corresponding to the object *key* or *NULL* on failure. This is the equivalent of the Python expression `o[key]`.

int **PyMapping_SetItemString**(PyObject **o*, char **key*, PyObject **v*)

Map the object *key* to the value *v* in object *o*. Returns `-1` on failure. This is the equivalent of the Python statement `o[key] = v`.

Iterator Protocol

There are only a couple of functions specifically for working with iterators.

`int PyIter_Check(PyObject *o)`

Return true if the object `o` supports the iterator protocol.

`PyObject* PyIter_Next(PyObject *o)`

Return value: New reference.

Return the next value from the iteration `o`. If the object is an iterator, this retrieves the next value from the iteration, and returns `NULL` with no exception set if there are no remaining items. If the object is not an iterator, `TypeError` is raised, or if there is an error in retrieving the item, returns `NULL` and passes along the exception.

To write a loop which iterates over an iterator, the C code should look something like this:

```
PyObject *iterator = PyObject_GetIter(obj);
PyObject *item;

if (iterator == NULL) {
    /* propagate error */
}

while (item = PyIter_Next(iterator)) {
    /* do something with item */
    ...
    /* release reference when done */
    Py_DECREF(item);
}

Py_DECREF(iterator);

if (PyErr_Occurred()) {
    /* propagate error */
}
```

```
else {  
    /* continue doing useful work */  
}
```

Buffer Protocol

Certain objects available in Python wrap access to an underlying memory array or *buffer*. Such objects include the built-in `bytes` and `bytearray`, and some extension types like `array.array`. Third-party libraries may define their own types for special purposes, such as image processing or numeric analysis.

While each of these types have their own semantics, they share the common characteristic of being backed by a possibly large memory buffer. It is then desirable, in some situations, to access that buffer directly and without intermediate copying.

Python provides such a facility at the C level in the form of the *buffer protocol*. This protocol has two sides:

- on the producer side, a type can export a “buffer interface” which allows objects of that type to expose information about their underlying buffer. This interface is described in the section *Buffer Object Structures*;
- on the consumer side, several means are available to obtain a pointer to the raw underlying data of an object (for example a method parameter).

Simple objects such as `bytes` and `bytearray` expose their underlying buffer in byte-oriented form. Other forms are possible; for example, the elements exposed by a `array.array` can be multi-byte values.

An example consumer of the buffer interface is the `write()` method of file objects: any object that can export a series of bytes through the buffer interface can be written to a file. While `write()` only needs read-only access to the internal contents of the object passed to it, other methods such as `readinto()` need write access to the contents of their argument. The buffer interface allows objects to selectively

allow or reject exporting of read-write and read-only buffers.

There are two ways for a consumer of the buffer interface to acquire a buffer over a target object:

- call `PyObject_GetBuffer()` with the right parameters;
- call `PyArg_ParseTuple()` (or one of its siblings) with one of the `y*`, `w*` or `s*` *format codes*.

In both cases, `PyBuffer_Release()` must be called when the buffer isn't needed anymore. Failure to do so could lead to various issues such as resource leaks.

The buffer structure

Buffer structures (or simply “buffers”) are useful as a way to expose the binary data from another object to the Python programmer. They can also be used as a zero-copy slicing mechanism. Using their ability to reference a block of memory, it is possible to expose any data to the Python programmer quite easily. The memory could be a large, constant array in a C extension, it could be a raw block of memory for manipulation before passing to an operating system library, or it could be used to pass around structured data in its native, in-memory format.

Contrary to most data types exposed by the Python interpreter, buffers are not `PyObject` pointers but rather simple C structures. This allows them to be created and copied very simply. When a generic wrapper around a buffer is needed, a `memoryview` object can be created.

`Py_buffer`

`void *buf`

A pointer to the start of the memory for the object.

`Py_ssize_t len`

The total length of the memory in bytes.

`int readonly`

An indicator of whether the buffer is read only.

`const char *format`

A `NULL` terminated string in `struct` module style syntax giving the contents of the elements available through the buffer. If this is `NULL`, `"B"` (unsigned bytes) is assumed.

int ndim

The number of dimensions the memory represents as a multi-dimensional array. If it is 0, **strides** and **suboffsets** must be *NULL*.

Py_ssize_t *shape

An array of **Py_ssize_t**s the length of **ndim** giving the shape of the memory as a multi-dimensional array. Note that `(*shape)[0] * ... * (*shape)[ndims-1] * itemsize` should be equal to **len**.

Py_ssize_t *strides

An array of **Py_ssize_t**s the length of **ndim** giving the number of bytes to skip to get to a new element in each dimension.

Py_ssize_t *suboffsets

An array of **Py_ssize_t**s the length of **ndim**. If these suboffset numbers are greater than or equal to 0, then the value stored along the indicated dimension is a pointer and the suboffset value dictates how many bytes to add to the pointer after de-referencing. A suboffset value that is negative indicates that no de-referencing should occur (striding in a contiguous memory block).

Here is a function that returns a pointer to the element in an N-D array pointed to by an N-dimensional index when there are both non-NULL strides and suboffsets:

```
void *get_item_pointer(int ndim, void *buf, Py_ssize_t *s
    Py_ssize_t *suboffsets, Py_ssize_t *indices) {
    char *pointer = (char*)buf;
    int i;
    for (i = 0; i < ndim; i++) {
        pointer += strides[i] * indices[i];
        if (suboffsets[i] >= 0) {
            pointer = *((char**)pointer) + suboffsets[i];
        }
    }
}
```

```
    }  
  }  
  return (void*)pointer;  
}
```

Py_ssize_t `itemsize`

This is a storage for the `itemsize` (in bytes) of each element of the shared memory. It is technically un-necessary as it can be obtained using `PyBuffer_SizeFromFormat()`, however an exporter may know this information without parsing the format string and it is necessary to know the `itemsize` for proper interpretation of striding. Therefore, storing it is more convenient and faster.

void *`internal`

This is for use internally by the exporting object. For example, this might be re-cast as an integer by the exporter and used to store flags about whether or not the shape, strides, and suboffsets arrays must be freed when the buffer is released. The consumer should never alter this value.

Buffer-related functions

`int PyObject_CheckBuffer(PyObject *obj)`

Return 1 if *obj* supports the buffer interface otherwise 0. When 1 is returned, it doesn't guarantee that `PyObject_GetBuffer()` will succeed.

`int PyObject_GetBuffer(PyObject *obj, Py_buffer *view, int flags)`

Export a view over some internal data from the target object *obj*. *obj* must not be NULL, and *view* must point to an existing `Py_buffer` structure allocated by the caller (most uses of this function will simply declare a local variable of type `Py_buffer`). The *flags* argument is a bit field indicating what kind of buffer is requested. The buffer interface allows for complicated memory layout possibilities; however, some callers won't want to handle all the complexity and instead request a simple view of the target object (using `PyBUF_SIMPLE` for a read-only view and `PyBUF_WRITABLE` for a read-write view).

Some exporters may not be able to share memory in every possible way and may need to raise errors to signal to some consumers that something is just not possible. These errors should be a `BufferError` unless there is another error that is actually causing the problem. The exporter can use flags information to simplify how much of the `Py_buffer` structure is filled in with non-default values and/or raise an error if the object can't support a simpler view of its memory.

On success, 0 is returned and the *view* structure is filled with useful values. On error, -1 is returned and an exception is raised; the *view* is left in an undefined state.

The following are the possible values to the *flags* arguments.

PyBUF_SIMPLE

This is the default flag. The returned buffer exposes a read-only memory area. The format of data is assumed to be raw unsigned bytes, without any particular structure. This is a “stand-alone” flag constant. It never needs to be ‘|’d to the others. The exporter will raise an error if it cannot provide such a contiguous buffer of bytes.

PyBUF_WRITABLE

Like [PyBUF_SIMPLE](#), but the returned buffer is writable. If the exporter doesn’t support writable buffers, an error is raised.

PyBUF_STRIDES

This implies [PyBUF_ND](#). The returned buffer must provide strides information (i.e. the strides cannot be NULL). This would be used when the consumer can handle strided, discontinuous arrays. Handling strides automatically assumes you can handle shape. The exporter can raise an error if a strided representation of the data is not possible (i.e. without the suboffsets).

PyBUF_ND

The returned buffer must provide shape information. The memory will be assumed C-style contiguous (last dimension varies the fastest). The exporter may raise an error if it cannot provide this kind of contiguous buffer. If this is not given then shape will be *NULL*.

PyBUF_C_CONTIGUOUS

PyBUF_F_CONTIGUOUS

PyBUF_ANY_CONTIGUOUS

These flags indicate that the contiguity returned buffer must be respectively, C-contiguous (last dimension varies the fastest), Fortran contiguous (first dimension varies the fastest) or either one. All of these flags imply [PyBUF_STRIDES](#) and

guarantee that the strides buffer info structure will be filled in correctly.

PyBUF_INDIRECT

This flag indicates the returned buffer must have suboffsets information (which can be NULL if no suboffsets are needed). This can be used when the consumer can handle indirect array referencing implied by these suboffsets. This implies **PyBUF_STRIDES**.

PyBUF_FORMAT

The returned buffer must have true format information if this flag is provided. This would be used when the consumer is going to be checking for what 'kind' of data is actually stored. An exporter should always be able to provide this information if requested. If format is not explicitly requested then the format must be returned as *NULL* (which means 'B', or unsigned bytes).

PyBUF_STRIDED

This is equivalent to `(PyBUF_STRIDES | PyBUF_WRITABLE)`.

PyBUF_STRIDED_RO

This is equivalent to `(PyBUF_STRIDES)`.

PyBUF_RECORDS

This is equivalent to `(PyBUF_STRIDES | PyBUF_FORMAT | PyBUF_WRITABLE)`.

PyBUF_RECORDS_RO

This is equivalent to `(PyBUF_STRIDES | PyBUF_FORMAT)`.

PyBUF_FULL

This is equivalent to `(PyBUF_INDIRECT | PyBUF_FORMAT | PyBUF_WRITABLE)`.

PyBUF_FULL_RO

This is equivalent to `(PyBUF_INDIRECT | PyBUF_FORMAT)`.

PyBUF_CONTIG

This is equivalent to `(PyBUF_ND | PyBUF_WRITABLE)`.

PyBUF_CONTIG_RO

This is equivalent to `(PyBUF_ND)`.

`void PyBuffer_Release(Py_buffer *view)`

Release the buffer *view*. This should be called when the buffer is no longer being used as it may free memory from it.

`Py_ssize_t PyBuffer_SizeFromFormat(const char *)`

Return the implied `~Py_buffer.itemsize` from the struct-type `~Py_buffer.format`.

`int PyObject_CopyToObject(PyObject *obj, void *buf, Py_ssize_t len, char fortran)`

Copy *len* bytes of data pointed to by the contiguous chunk of memory pointed to by *buf* into the buffer exported by *obj*. The buffer must of course be writable. Return 0 on success and return -1 and raise an error on failure. If the object does not have a writable buffer, then an error is raised. If *fortran* is `'F'`, then if the object is multi-dimensional, then the data will be copied into the array in Fortran-style (first dimension varies the fastest). If *fortran* is `'C'`, then the data will be copied into the array in C-style (last dimension varies the fastest). If *fortran* is `'A'`, then it does not matter and the copy will be made in whatever way is more efficient.

`int PyBuffer_IsContiguous(Py_buffer *view, char fortran)`

Return 1 if the memory defined by the *view* is C-style (*fortran* is `'C'`) or Fortran-style (*fortran* is `'F'`) contiguous or either one

(*fortran* is 'A'). Return 0 otherwise.

```
void PyBuffer_FillContiguousStrides(int ndim, Py_ssize_t  
*shape, Py_ssize_t *strides, Py_ssize_t itemsize, char fortran)
```

Fill the *strides* array with byte-strides of a contiguous (C-style if *fortran* is 'C' or Fortran-style if *fortran* is 'F') array of the given shape with the given number of bytes per element.

```
int PyBuffer_FillInfo(Py_buffer *view, PyObject *obj, void *buf,  
Py_ssize_t len, int readonly, int infoflags)
```

Fill in a buffer-info structure, *view*, correctly for an exporter that can only share a contiguous chunk of memory of “unsigned bytes” of the given length. Return 0 on success and -1 (with raising an error) on error.

Old Buffer Protocol

Deprecated since version 3.0.

These functions were part of the “old buffer protocol” API in Python 2. In Python 3, this protocol doesn’t exist anymore but the functions are still exposed to ease porting 2.x code. They act as a compatibility wrapper around the *new buffer protocol*, but they don’t give you control over the lifetime of the resources acquired when a buffer is exported.

Therefore, it is recommended that you call `PyObject_GetBuffer()` (or the `y*` or `w*` *format codes* with the `PyArg_ParseTuple()` family of functions) to get a buffer view over an object, and `PyBuffer_Release()` when the buffer view can be released.

```
int PyObject_AsCharBuffer(PyObject *obj, const char **buffer,  
Py_ssize_t *buffer_len)
```

Returns a pointer to a read-only memory location usable as character-based input. The `obj` argument must support the single-segment character buffer interface. On success, returns `0`, sets `buffer` to the memory location and `buffer_len` to the buffer length. Returns `-1` and sets a `TypeError` on error.

```
int PyObject_AsReadBuffer(PyObject *obj, const void **buffer,  
Py_ssize_t *buffer_len)
```

Returns a pointer to a read-only memory location containing arbitrary data. The `obj` argument must support the single-segment readable buffer interface. On success, returns `0`, sets `buffer` to the memory location and `buffer_len` to the buffer length. Returns `-1` and sets a `TypeError` on error.

```
int PyObject_CheckReadBuffer(PyObject *o)
```

Returns `1` if `o` supports the single-segment readable buffer interface. Otherwise returns `0`.

```
int PyObject_AsWriteBuffer(PyObject *obj, void **buffer,  
Py_ssize_t *buffer_len)
```

Returns a pointer to a writable memory location. The `obj` argument must support the single-segment, character buffer interface. On success, returns `0`, sets `buffer` to the memory location and `buffer_len` to the buffer length. Returns `-1` and sets a **`TypeError`** on error.

Concrete Objects Layer

The functions in this chapter are specific to certain Python object types. Passing them an object of the wrong type is not a good idea; if you receive an object from a Python program and you are not sure that it has the right type, you must perform a type check first; for example, to check that an object is a dictionary, use `PyDict_Check()`. The chapter is structured like the “family tree” of Python object types.

Warning: While the functions described in this chapter carefully check the type of the objects which are passed in, many of them do not check for *NULL* being passed instead of a valid object. Allowing *NULL* to be passed in can cause memory access violations and immediate termination of the interpreter.

Fundamental Objects

This section describes Python type objects and the singleton object **None**.

- Type Objects
- The None Object

Numeric Objects

- Integer Objects
- Boolean Objects
- Floating Point Objects
- Complex Number Objects
 - Complex Numbers as C Structures
 - Complex Numbers as Python Objects

Sequence Objects

Generic operations on sequence objects were discussed in the previous chapter; this section deals with the specific kinds of sequence objects that are intrinsic to the Python language.

- Bytes Objects
- Byte Array Objects
 - Type check macros
 - Direct API functions
 - Macros
- Unicode Objects and Codecs
 - Unicode Objects
 - Unicode Type
 - Unicode Character Properties
 - Plain Py_UNICODE
 - File System Encoding
 - wchar_t Support
 - Built-in Codecs
 - Generic Codecs
 - UTF-8 Codecs
 - UTF-32 Codecs
 - UTF-16 Codecs
 - UTF-7 Codecs
 - Unicode-Escape Codecs
 - Raw-Unicode-Escape Codecs
 - Latin-1 Codecs
 - ASCII Codecs
 - Character Map Codecs
 - MBCS codecs for Windows
 - Methods & Slots
 - Methods and Slot Functions
- Tuple Objects

- List Objects

Mapping Objects

- Dictionary Objects

Other Objects

- Set Objects
- Function Objects
- Instance Method Objects
- Method Objects
- File Objects
- Module Objects
 - Initializing C modules
- Iterator Objects
- Descriptor Objects
- Slice Objects
- MemoryView objects
- Weak Reference Objects
- Capsules
- Cell Objects
- Generator Objects
- DateTime Objects
- Code Objects

Manual » Concrete Objects Layer »

Type Objects

PyTypeObject

The C structure of the objects used to describe built-in types.

PyObject* **PyType_Type**

This is the type object for type objects; it is the same object as **type** in the Python layer.

int **PyType_Check**(PyObject *o)

Return true if the object *o* is a type object, including instances of types derived from the standard type object. Return false in all other cases.

int **PyType_CheckExact**(PyObject *o)

Return true if the object *o* is a type object, but not a subtype of the standard type object. Return false in all other cases.

unsigned int **PyType_ClearCache**()

Clear the internal lookup cache. Return the current version tag.

long **PyType_GetFlags**(PyTypeObject* type)

Return the `tp_flags` member of *type*. This function is primarily meant for use with *Py_LIMITED_API*; the individual flag bits are guaranteed to be stable across Python releases, but access to `tp_flags` itself is not part of the limited API.

New in version 3.2.

void **PyType_Modified**(PyTypeObject *type)

Invalidate the internal lookup cache for the type and all of its subtypes. This function must be called after any manual modification of the attributes or base classes of the type.

`int PyType_HasFeature(PyObject *o, int feature)`

Return true if the type object *o* sets the feature *feature*. Type features are denoted by single bit flags.

`int PyType_IS_GC(PyObject *o)`

Return true if the type object includes support for the cycle detector; this tests the type flag `Py_TPFLAGS_HAVE_GC`.

`int PyType_IsSubtype(PyTypeObject *a, PyTypeObject *b)`

Return true if *a* is a subtype of *b*.

`PyObject* PyType_GenericAlloc(PyTypeObject *type, Py_ssize_t nitems)`

Return value: New reference.

XXX: Document.

`PyObject* PyType_GenericNew(PyTypeObject *type, PyObject *args, PyObject *kwargs)`

Return value: New reference.

XXX: Document.

`int PyType_Ready(PyTypeObject *type)`

Finalize a type object. This should be called on all type objects to finish their initialization. This function is responsible for adding inherited slots from a type's base class. Return `0` on success, or return `-1` and sets an exception on error.

Python v3.2 documentation » Python/C API Reference

[previous](#) | [next](#) | [modules](#) | [index](#)

[Manual](#) » [Concrete Objects Layer](#) »

The None Object

Note that the `PyTypeObject` for `None` is not directly exposed in the Python/C API. Since `None` is a singleton, testing for object identity (using `==` in C) is sufficient. There is no `PyNone_Check()` function for the same reason.

`PyObject*` `Py_None`

The Python `None` object, denoting lack of value. This object has no methods. It needs to be treated just like any other object with respect to reference counts.

`Py_RETURN_NONE`

Properly handle returning `Py_None` from within a C function (that is, increment the reference count of `None` and return it.)

Python v3.2 documentation » Python/C API Reference

[previous](#) | [next](#) | [modules](#) | [index](#)

[Manual](#) » [Concrete Objects Layer](#) »

Integer Objects

All integers are implemented as “long” integer objects of arbitrary size.

PyLongObject

This subtype of **PyObject** represents a Python integer object.

PyTypeObject PyLong_Type

This instance of **PyTypeObject** represents the Python integer type. This is the same object as **int** in the Python layer.

int PyLong_Check(PyObject *p)

Return true if its argument is a **PyLongObject** or a subtype of **PyLongObject**.

int PyLong_CheckExact(PyObject *p)

Return true if its argument is a **PyLongObject**, but not a subtype of **PyLongObject**.

PyObject* PyLong_FromLong(long v)

Return value: New reference.

Return a new **PyLongObject** object from *v*, or *NULL* on failure.

The current implementation keeps an array of integer objects for all integers between `-5` and `256`, when you create an `int` in that range you actually just get back a reference to the existing object. So it should be possible to change the value of `1`. I suspect the behaviour of Python in this case is undefined. :-)

PyObject* PyLong_FromUnsignedLong(unsigned long v)

Return value: New reference.

Return a new **PyLongObject** object from a C `unsigned long`, or

NULL on failure.

PyObject* **PyLong_FromSsize_t**(Py_ssize_t *v*)

Return a new **PyLongObject** object from a C **Py_ssize_t**, or *NULL* on failure.

PyObject* **PyLong_FromSize_t**(size_t *v*)

Return a new **PyLongObject** object from a C **size_t**, or *NULL* on failure.

PyObject* **PyLong_FromLongLong**(PY_LONG_LONG *v*)

Return value: New reference.

Return a new **PyLongObject** object from a C **long long**, or *NULL* on failure.

PyObject* **PyLong_FromUnsignedLongLong**(unsigned PY_LONG_LONG *v*)

Return value: New reference.

Return a new **PyLongObject** object from a C **unsigned long long**, or *NULL* on failure.

PyObject* **PyLong_FromDouble**(double *v*)

Return value: New reference.

Return a new **PyLongObject** object from the integer part of *v*, or *NULL* on failure.

PyObject* **PyLong_FromString**(char **str*, char ***pend*, int *base*)

Return value: New reference.

Return a new **PyLongObject** based on the string value in *str*, which is interpreted according to the radix in *base*. If *pend* is non-*NULL*, **pend* will point to the first character in *str* which follows the representation of the number. If *base* is 0, the radix will be determined based on the leading characters of *str*: if *str* starts with '0x' or '0X', radix 16 will be used; if *str* starts with '0o' or

'00', radix 8 will be used; if *str* starts with '0b' or '0B', radix 2 will be used; otherwise radix 10 will be used. If *base* is not 0, it must be between 2 and 36, inclusive. Leading spaces are ignored. If there are no digits, `ValueError` will be raised.

`PyObject*` `PyLong_FromUnicode(Py_UNICODE *u, Py_ssize_t length, int base)`

Return value: *New reference.*

Convert a sequence of Unicode digits to a Python integer value. The Unicode string is first encoded to a byte string using `PyUnicode_EncodeDecimal()` and then converted using `PyLong_FromString()`.

`PyObject*` `PyLong_FromVoidPtr(void *p)`

Return value: *New reference.*

Create a Python integer from the pointer *p*. The pointer value can be retrieved from the resulting value using `PyLong_AsVoidPtr()`.

`long` `PyLong_AsLong(PyObject *pylong)`

Return a C `long` representation of the contents of *pylong*. If *pylong* is greater than `LONG_MAX`, raise an `OverflowError`, and return -1. Convert non-long objects automatically to long first, and return -1 if that raises exceptions.

`long` `PyLong_AsLongAndOverflow(PyObject *pylong, int *overflow)`

Return a C `long` representation of the contents of *pylong*. If *pylong* is greater than `LONG_MAX` or less than `LONG_MIN`, set **overflow* to 1 or -1, respectively, and return -1; otherwise, set **overflow* to 0. If any other exception occurs (for example a `TypeError` or `MemoryError`), then -1 will be returned and **overflow* will be 0.

`PY_LONG_LONG` `PyLong_AsLongLongAndOverflow(PyObject`

**pylong*, int **overflow*)

Return a C `long long` representation of the contents of *pylong*. If *pylong* is greater than `PY_LLONG_MAX` or less than `PY_LLONG_MIN`, set **overflow* to `1` or `-1`, respectively, and return `-1`; otherwise, set **overflow* to `0`. If any other exception occurs (for example a `TypeError` or `MemoryError`), then `-1` will be returned and **overflow* will be `0`.

New in version 3.2.

`Py_ssize_t PyLong_AsSsize_t(PyObject *pylong)`

Return a C `Py_ssize_t` representation of the contents of *pylong*. If *pylong* is greater than `PY_SSIZE_T_MAX`, an `OverflowError` is raised and `-1` will be returned.

`unsigned long PyLong_AsUnsignedLong(PyObject *pylong)`

Return a C `unsigned long` representation of the contents of *pylong*. If *pylong* is greater than `ULONG_MAX`, an `OverflowError` is raised.

`size_t PyLong_AsSize_t(PyObject *pylong)`

Return a `size_t` representation of the contents of *pylong*. If *pylong* is greater than the maximum value for a `size_t`, an `OverflowError` is raised.

`PY_LONG_LONG PyLong_AsLongLong(PyObject *pylong)`

Return a C `long long` from a Python integer. If *pylong* cannot be represented as a `long long`, an `OverflowError` is raised and `-1` is returned.

`unsigned PY_LONG_LONG`

`PyLong_AsUnsignedLongLong(PyObject *pylong)`

Return a C `unsigned long long` from a Python integer. If *pylong*

cannot be represented as an `unsigned long long`, an `OverflowError` is raised and `(unsigned long long)-1` is returned.

Changed in version 3.1: A negative `pylong` now raises `OverflowError`, not `TypeError`.

`unsigned long PyLong_AsUnsignedLongMask(PyObject *io)`

Return a C `unsigned long` from a Python integer, without checking for overflow.

`unsigned PY_LONG_LONG`

`PyLong_AsUnsignedLongLongMask(PyObject *io)`

Return a C `unsigned long long` from a Python integer, without checking for overflow.

`double PyLong_AsDouble(PyObject *pylong)`

Return a C `double` representation of the contents of `pylong`. If `pylong` cannot be approximately represented as a `double`, an `OverflowError` exception is raised and `-1.0` will be returned.

`void* PyLong_AsVoidPtr(PyObject *pylong)`

Convert a Python integer `pylong` to a C `void` pointer. If `pylong` cannot be converted, an `OverflowError` will be raised. This is only assured to produce a usable `void` pointer for values created with `PyLong_FromVoidPtr()`.

Boolean Objects

Booleans in Python are implemented as a subclass of integers. There are only two booleans, `Py_False` and `Py_True`. As such, the normal creation and deletion functions don't apply to booleans. The following macros are available, however.

`int PyBool_Check(PyObject *o)`

Return true if `o` is of type `PyBool_Type`.

`PyObject* Py_False`

The Python `False` object. This object has no methods. It needs to be treated just like any other object with respect to reference counts.

`PyObject* Py_True`

The Python `True` object. This object has no methods. It needs to be treated just like any other object with respect to reference counts.

`Py_RETURN_FALSE`

Return `Py_False` from a function, properly incrementing its reference count.

`Py_RETURN_TRUE`

Return `Py_True` from a function, properly incrementing its reference count.

`PyObject* PyBool_FromLong(long v)`

Return value: New reference.

Return a new reference to `Py_True` or `Py_False` depending on the truth value of `v`.

Floating Point Objects

PyFloatObject

This subtype of `PyObject` represents a Python floating point object.

PyTypeObject PyFloat_Type

This instance of `PyTypeObject` represents the Python floating point type. This is the same object as `float` in the Python layer.

int PyFloat_Check(PyObject *p)

Return true if its argument is a `PyFloatObject` or a subtype of `PyFloatObject`.

int PyFloat_CheckExact(PyObject *p)

Return true if its argument is a `PyFloatObject`, but not a subtype of `PyFloatObject`.

PyObject* PyFloat_FromString(PyObject *str)

Return value: New reference.

Create a `PyFloatObject` object based on the string value in `str`, or `NULL` on failure.

PyObject* PyFloat_FromDouble(double v)

Return value: New reference.

Create a `PyFloatObject` object from `v`, or `NULL` on failure.

double PyFloat_AsDouble(PyObject *pyfloat)

Return a C `double` representation of the contents of `pyfloat`. If `pyfloat` is not a Python floating point object but has a `__float__()` method, this method will first be called to convert `pyfloat` into a float.

`double PyFloat_AS_DOUBLE(PyObject *pyfloat)`

Return a C `double` representation of the contents of *pyfloat*, but without error checking.

`PyObject* PyFloat_GetInfo(void)`

Return a structseq instance which contains information about the precision, minimum and maximum values of a float. It's a thin wrapper around the header file `float.h`.

`double PyFloat_GetMax()`

Return the maximum representable finite float *DBL_MAX* as C `double`.

`double PyFloat_GetMin()`

Return the minimum normalized positive float *DBL_MIN* as C `double`.

`int PyFloat_ClearFreeList()`

Clear the float free list. Return the number of items that could not be freed.

Manual » Concrete Objects Layer »

Complex Number Objects

Python's complex number objects are implemented as two distinct types when viewed from the C API: one is the Python object exposed to Python programs, and the other is a C structure which represents the actual complex number value. The API provides functions for working with both.

Complex Numbers as C Structures

Note that the functions which accept these structures as parameters and return them as results do so *by value* rather than dereferencing them through pointers. This is consistent throughout the API.

Py_complex

The C structure which corresponds to the value portion of a Python complex number object. Most of the functions for dealing with complex number objects use structures of this type as input or output values, as appropriate. It is defined as:

```
typedef struct {  
    double real;  
    double imag;  
} Py_complex;
```

Py_complex _Py_c_sum(Py_complex left, Py_complex right)

Return the sum of two complex numbers, using the C **Py_complex** representation.

Py_complex _Py_c_diff(Py_complex left, Py_complex right)

Return the difference between two complex numbers, using the C **Py_complex** representation.

Py_complex _Py_c_neg(Py_complex complex)

Return the negation of the complex number *complex*, using the C **Py_complex** representation.

Py_complex _Py_c_prod(Py_complex left, Py_complex right)

Return the product of two complex numbers, using the C **Py_complex** representation.

Py_complex _Py_c_quot(Py_complex dividend, Py_complex

divisor)

Return the quotient of two complex numbers, using the C `Py_complex` representation.

`Py_complex _Py_c_pow(Py_complex num, Py_complex exp)`

Return the exponentiation of *num* by *exp*, using the C `Py_complex` representation.

Complex Numbers as Python Objects

PyComplexObject

This subtype of **PyObject** represents a Python complex number object.

PyTypeObject PyComplex_Type

This instance of **PyTypeObject** represents the Python complex number type. It is the same object as **complex** in the Python layer.

int PyComplex_Check(PyObject *p)

Return true if its argument is a **PyComplexObject** or a subtype of **PyComplexObject**.

int PyComplex_CheckExact(PyObject *p)

Return true if its argument is a **PyComplexObject**, but not a subtype of **PyComplexObject**.

PyObject* PyComplex_FromCComplex(Py_complex v)

Return value: New reference.

Create a new Python complex number object from a C **Py_complex** value.

PyObject* PyComplex_FromDoubles(double real, double imag)

Return value: New reference.

Return a new **PyComplexObject** object from *real* and *imag*.

double PyComplex_RealAsDouble(PyObject *op)

Return the real part of *op* as a C **double**.

double PyComplex_ImagAsDouble(PyObject *op)

Return the imaginary part of *op* as a C **double**.

`Py_complex PyComplex_AsCComplex(PyObject *op)`

Return the `Py_complex` value of the complex number *op*.

If *op* is not a Python complex number object but has a `__complex__()` method, this method will first be called to convert *op* to a Python complex number object.

Python v3.2 documentation » Python/C API Reference

[previous](#) | [next](#) | [modules](#) | [index](#)

[Manual](#) » [Concrete Objects Layer](#) »

Bytes Objects

These functions raise `TypeError` when expecting a bytes parameter and are called with a non-bytes parameter.

`PyBytesObject`

This subtype of `PyObject` represents a Python bytes object.

`PyTypeObject PyBytes_Type`

This instance of `PyTypeObject` represents the Python bytes type; it is the same object as `bytes` in the Python layer.

`int PyBytes_Check(PyObject *o)`

Return true if the object `o` is a bytes object or an instance of a subtype of the bytes type.

`int PyBytes_CheckExact(PyObject *o)`

Return true if the object `o` is a bytes object, but not an instance of a subtype of the bytes type.

`PyObject* PyBytes_FromString(const char *v)`

Return a new bytes object with a copy of the string `v` as value on success, and `NULL` on failure. The parameter `v` must not be `NULL`; it will not be checked.

`PyObject* PyBytes_FromStringAndSize(const char *v, Py_ssize_t len)`

Return a new bytes object with a copy of the string `v` as value and length `len` on success, and `NULL` on failure. If `v` is `NULL`, the contents of the bytes object are uninitialized.

`PyObject* PyBytes_FromFormat(const char *format, ...)`

Take a C `printf()`-style `format` string and a variable number of arguments, calculate the size of the resulting Python bytes object

and return a bytes object with the values formatted into it. The variable arguments must be C types and must correspond exactly to the format characters in the *format* string. The following format characters are allowed:

Format Characters	Type	Comment
<code>%%</code>	<i>n/a</i>	The literal % character.
<code>%c</code>	int	A single character, represented as an C int.
<code>%d</code>	int	Exactly equivalent to <code>printf("%d")</code> .
<code>%u</code>	unsigned int	Exactly equivalent to <code>printf("%u")</code> .
<code>%ld</code>	long	Exactly equivalent to <code>printf("%ld")</code> .
<code>%lu</code>	unsigned long	Exactly equivalent to <code>printf("%lu")</code> .
<code>%zd</code>	Py_ssize_t	Exactly equivalent to <code>printf("%zd")</code> .
<code>%zu</code>	size_t	Exactly equivalent to <code>printf("%zu")</code> .
<code>%i</code>	int	Exactly equivalent to <code>printf("%i")</code> .
<code>%x</code>	int	Exactly equivalent to <code>printf("%x")</code> .
<code>%s</code>	char*	A null-terminated C character array.
<code>%p</code>	void*	The hex representation of a C pointer. Mostly equivalent to <code>printf("%p")</code> except that it is guaranteed to start with the literal <code>0x</code> regardless of what the platform's <code>printf</code> yields.

An unrecognized format character causes all the rest of the

format string to be copied as-is to the result string, and any extra arguments discarded.

PyObject* **PyBytes_FromFormatV**(const char **format*, va_list *vargs*)

Identical to **PyBytes_FromFormat()** except that it takes exactly two arguments.

PyObject* **PyBytes_FromObject**(PyObject **o*)

Return the bytes representation of object *o* that implements the buffer protocol.

Py_ssize_t **PyBytes_Size**(PyObject **o*)

Return the length of the bytes in bytes object *o*.

Py_ssize_t **PyBytes_GET_SIZE**(PyObject **o*)

Macro form of **PyBytes_Size()** but without error checking.

char* **PyBytes_AsString**(PyObject **o*)

Return a NUL-terminated representation of the contents of *o*. The pointer refers to the internal buffer of *o*, not a copy. The data must not be modified in any way, unless the string was just created using **PyBytes_FromStringAndSize(NULL, size)**. It must not be deallocated. If *o* is not a string object at all, **PyBytes_AsString()** returns *NULL* and raises **TypeError**.

char* **PyBytes_AS_STRING**(PyObject **string*)

Macro form of **PyBytes_AsString()** but without error checking.

int **PyBytes_AsStringAndSize**(PyObject **obj*, char ***buffer*, Py_ssize_t **length*)

Return a NUL-terminated representation of the contents of the object *obj* through the output variables *buffer* and *length*.

If *length* is *NULL*, the resulting buffer may not contain NUL

characters; if it does, the function returns `-1` and a `TypeError` is raised.

The buffer refers to an internal string buffer of *obj*, not a copy. The data must not be modified in any way, unless the string was just created using `PyBytes_FromStringAndSize(NULL, size)`. It must not be deallocated. If *string* is not a string object at all, `PyBytes_AsStringAndSize()` returns `-1` and raises `TypeError`.

`void PyBytes_Concat(PyObject **bytes, PyObject *newpart)`

Create a new bytes object in **bytes* containing the contents of *newpart* appended to *bytes*; the caller will own the new reference. The reference to the old value of *bytes* will be stolen. If the new string cannot be created, the old reference to *bytes* will still be discarded and the value of **bytes* will be set to `NULL`; the appropriate exception will be set.

`void PyBytes_ConcatAndDel(PyObject **bytes, PyObject *newpart)`

Create a new string object in **bytes* containing the contents of *newpart* appended to *bytes*. This version decrements the reference count of *newpart*.

`int _PyBytes_Resize(PyObject **bytes, Py_ssize_t newsize)`

A way to resize a bytes object even though it is “immutable”. Only use this to build up a brand new bytes object; don’t use this if the bytes may already be known in other parts of the code. It is an error to call this function if the refcount on the input bytes object is not one. Pass the address of an existing bytes object as an lvalue (it may be written into), and the new size desired. On success, **bytes* holds the resized bytes object and `0` is returned; the address in **bytes* may differ from its input value. If the reallocation fails, the original bytes object at **bytes* is deallocated, **bytes* is set to `NULL`, a memory exception is set, and `-1` is returned.

Byte Array Objects

PyByteArrayObject

This subtype of `PyObject` represents a Python bytearray object.

PyTypeObject PyByteArray_Type

This instance of `PyTypeObject` represents the Python bytearray type; it is the same object as `bytearray` in the Python layer.

Type check macros

`int PyByteArray_Check(PyObject *o)`

Return true if the object `o` is a bytearray object or an instance of a subtype of the bytearray type.

`int PyByteArray_CheckExact(PyObject *o)`

Return true if the object `o` is a bytearray object, but not an instance of a subtype of the bytearray type.

Direct API functions

PyObject* **PyByteArray_FromObject**(PyObject *o)

Return a new bytearray object from any object, *o*, that implements the buffer protocol.

PyObject* **PyByteArray_FromStringAndSize**(const char *string, Py_ssize_t len)

Create a new bytearray object from *string* and its length, *len*. On failure, *NULL* is returned.

PyObject* **PyByteArray_Concat**(PyObject *a, PyObject *b)

Concat bytearrays *a* and *b* and return a new bytearray with the result.

Py_ssize_t **PyByteArray_Size**(PyObject *bytearray)

Return the size of *bytearray* after checking for a *NULL* pointer.

char* **PyByteArray_AsString**(PyObject *bytearray)

Return the contents of *bytearray* as a char array after checking for a *NULL* pointer.

int **PyByteArray_Resize**(PyObject *bytearray, Py_ssize_t len)

Resize the internal buffer of *bytearray* to *len*.

Macros

These macros trade safety for speed and they don't check pointers.

`char* PyByteArray_AS_STRING(PyObject *bytearray)`

Macro version of `PyByteArray_AsString()`.

`Py_ssize_t PyByteArray_GET_SIZE(PyObject *bytearray)`

Macro version of `PyByteArray_Size()`.

Unicode Objects and Codecs

Unicode Objects

Unicode Type

These are the basic Unicode object types used for the Unicode implementation in Python:

Py_UNICODE

This type represents the storage type which is used by Python internally as basis for holding Unicode ordinals. Python's default builds use a 16-bit type for `Py_UNICODE` and store Unicode values internally as UCS2. It is also possible to build a UCS4 version of Python (most recent Linux distributions come with UCS4 builds of Python). These builds then use a 32-bit type for `Py_UNICODE` and store Unicode data internally as UCS4. On platforms where `wchar_t` is available and compatible with the chosen Python Unicode build variant, `Py_UNICODE` is a typedef alias for `wchar_t` to enhance native platform compatibility. On all other platforms, `Py_UNICODE` is a typedef alias for either `unsigned short` (UCS2) or `unsigned long` (UCS4).

Note that UCS2 and UCS4 Python builds are not binary compatible. Please keep this in mind when writing extensions or interfaces.

PyUnicodeObject

This subtype of `PyObject` represents a Python Unicode object.

`PyTypeObject` **PyUnicode_Type**

This instance of `PyTypeObject` represents the Python Unicode type. It is exposed to Python code as `str`.

The following APIs are really C macros and can be used to do fast checks and to access internal read-only data of Unicode objects:

int PyUnicode_Check(PyObject *o)

Return true if the object *o* is a Unicode object or an instance of a Unicode subtype.

int PyUnicode_CheckExact(PyObject *o)

Return true if the object *o* is a Unicode object, but not an instance of a subtype.

Py_ssize_t PyUnicode_GET_SIZE(PyObject *o)

Return the size of the object. *o* has to be a **PyUnicodeObject** (not checked).

Py_ssize_t PyUnicode_GET_DATA_SIZE(PyObject *o)

Return the size of the object's internal buffer in bytes. *o* has to be a **PyUnicodeObject** (not checked).

Py_UNICODE* PyUnicode_AS_UNICODE(PyObject *o)

Return a pointer to the internal **Py_UNICODE** buffer of the object. *o* has to be a **PyUnicodeObject** (not checked).

const char* PyUnicode_AS_DATA(PyObject *o)

Return a pointer to the internal buffer of the object. *o* has to be a **PyUnicodeObject** (not checked).

int PyUnicode_ClearFreeList()

Clear the free list. Return the total number of freed items.

Unicode Character Properties

Unicode provides many different character properties. The most often needed ones are available through these macros which are mapped to C functions depending on the Python configuration.

int Py_UNICODE_ISSPACE(Py_UNICODE ch)

Return 1 or 0 depending on whether *ch* is a whitespace character.

int **Py_UNICODE_ISLOWER**(Py_UNICODE *ch*)

Return 1 or 0 depending on whether *ch* is a lowercase character.

int **Py_UNICODE_ISUPPER**(Py_UNICODE *ch*)

Return 1 or 0 depending on whether *ch* is an uppercase character.

int **Py_UNICODE_ISTITLE**(Py_UNICODE *ch*)

Return 1 or 0 depending on whether *ch* is a titlecase character.

int **Py_UNICODE_ISLINEBREAK**(Py_UNICODE *ch*)

Return 1 or 0 depending on whether *ch* is a linebreak character.

int **Py_UNICODE_ISDECIMAL**(Py_UNICODE *ch*)

Return 1 or 0 depending on whether *ch* is a decimal character.

int **Py_UNICODE_ISDIGIT**(Py_UNICODE *ch*)

Return 1 or 0 depending on whether *ch* is a digit character.

int **Py_UNICODE_ISNUMERIC**(Py_UNICODE *ch*)

Return 1 or 0 depending on whether *ch* is a numeric character.

int **Py_UNICODE_ISALPHA**(Py_UNICODE *ch*)

Return 1 or 0 depending on whether *ch* is an alphabetic character.

int **Py_UNICODE_ISALNUM**(Py_UNICODE *ch*)

Return 1 or 0 depending on whether *ch* is an alphanumeric character.

int **Py_UNICODE_ISPRINTABLE**(Py_UNICODE *ch*)

Return 1 or 0 depending on whether *ch* is a printable character.

Nonprintable characters are those characters defined in the Unicode character database as “Other” or “Separator”, excepting the ASCII space (0x20) which is considered printable. (Note that printable characters in this context are those which should not be escaped when `repr()` is invoked on a string. It has no bearing on the handling of strings written to `sys.stdout` or `sys.stderr`.)

These APIs can be used for fast direct character conversions:

`Py_UNICODE Py_UNICODE_TOLOWER(Py_UNICODE ch)`

Return the character *ch* converted to lower case.

`Py_UNICODE Py_UNICODE_TOUPPER(Py_UNICODE ch)`

Return the character *ch* converted to upper case.

`Py_UNICODE Py_UNICODE_TOTITLE(Py_UNICODE ch)`

Return the character *ch* converted to title case.

`int Py_UNICODE_TODECIMAL(Py_UNICODE ch)`

Return the character *ch* converted to a decimal positive integer. Return `-1` if this is not possible. This macro does not raise exceptions.

`int Py_UNICODE_TODIGIT(Py_UNICODE ch)`

Return the character *ch* converted to a single digit integer. Return `-1` if this is not possible. This macro does not raise exceptions.

`double Py_UNICODE_TONUMERIC(Py_UNICODE ch)`

Return the character *ch* converted to a double. Return `-1.0` if this is not possible. This macro does not raise exceptions.

Plain `Py_UNICODE`

To create Unicode objects and access their basic sequence

properties, use these APIs:

PyObject* **PyUnicode_FromUnicode**(const Py_UNICODE **u*,
Py_ssize_t *size*)

Return value: New reference.

Create a Unicode object from the Py_UNICODE buffer *u* of the given size. *u* may be *NULL* which causes the contents to be undefined. It is the user's responsibility to fill in the needed data. The buffer is copied into the new object. If the buffer is not *NULL*, the return value might be a shared object. Therefore, modification of the resulting Unicode object is only allowed when *u* is *NULL*.

PyObject* **PyUnicode_FromStringAndSize**(const char **u*,
Py_ssize_t *size*)

Create a Unicode object from the char buffer *u*. The bytes will be interpreted as being UTF-8 encoded. *u* may also be *NULL* which causes the contents to be undefined. It is the user's responsibility to fill in the needed data. The buffer is copied into the new object. If the buffer is not *NULL*, the return value might be a shared object. Therefore, modification of the resulting Unicode object is only allowed when *u* is *NULL*.

PyObject ***PyUnicode_FromString**(const char **u*)

Create a Unicode object from an UTF-8 encoded null-terminated char buffer *u*.

PyObject* **PyUnicode_FromFormat**(const char **format*, ...)

Take a C `printf()`-style *format* string and a variable number of arguments, calculate the size of the resulting Python unicode string and return a string with the values formatted into it. The variable arguments must be C types and must correspond exactly to the format characters in the *format* ASCII-encoded string. The following format characters are allowed:

Format Characters	Type	Comment
<code>%%</code>	<i>n/a</i>	The literal % character.
<code>%c</code>	int	A single character, represented as an C int.
<code>%d</code>	int	Exactly equivalent to <code>printf("%d")</code> .
<code>%u</code>	unsigned int	Exactly equivalent to <code>printf("%u")</code> .
<code>%ld</code>	long	Exactly equivalent to <code>printf("%ld")</code> .
<code>%lu</code>	unsigned long	Exactly equivalent to <code>printf("%lu")</code> .
<code>%lld</code>	long long	Exactly equivalent to <code>printf("%lld")</code> .
<code>%llu</code>	unsigned long long	Exactly equivalent to <code>printf("%llu")</code> .
<code>%zd</code>	Py_ssize_t	Exactly equivalent to <code>printf("%zd")</code> .
<code>%zu</code>	size_t	Exactly equivalent to <code>printf("%zu")</code> .
<code>%i</code>	int	Exactly equivalent to <code>printf("%i")</code> .
<code>%x</code>	int	Exactly equivalent to <code>printf("%x")</code> .
<code>%s</code>	char*	A null-terminated C character array.
<code>%p</code>	void*	The hex representation of a C pointer. Mostly equivalent to <code>printf("%p")</code> except that it is guaranteed to start with the literal <code>0x</code> regardless of what the platform's <code>printf</code> yields.
<code>%A</code>	PyObject*	The result of calling <code>ascii()</code> .

%U	PyObject*	A unicode object.
%V	PyObject*, char *	A unicode object (which may be <i>NULL</i>) and a null-terminated C character array as a second parameter (which will be used, if the first parameter is <i>NULL</i>).
%S	PyObject*	The result of calling <code>PyObject_Str()</code> .
%R	PyObject*	The result of calling <code>PyObject_Repr()</code> .

An unrecognized format character causes all the rest of the format string to be copied as-is to the result string, and any extra arguments discarded.

Note: The “%lld” and “%llu” format specifiers are only available when `HAVE_LONG_LONG` is defined.

Changed in version 3.2: Support for “%lld” and “%llu” added.

PyObject* `PyUnicode_FromFormatV`(const char **format*, va_list *vargs*)

Identical to `PyUnicode_FromFormat()` except that it takes exactly two arguments.

PyObject* `PyUnicode_TransformDecimalToASCII`(Py_UNICODE **s*, Py_ssize_t *size*)

Create a Unicode object by replacing all decimal digits in `Py_UNICODE` buffer of the given size by ASCII digits 0–9 according to their decimal value. Return *NULL* if an exception occurs.

Py_UNICODE* `PyUnicode_AsUnicode`(PyObject **unicode*)

Return a read-only pointer to the Unicode object’s internal

`Py_UNICODE` buffer, `NULL` if `unicode` is not a Unicode object.

`Py_UNICODE*` `PyUnicode_AsUnicodeCopy(PyObject *unicode)`

Create a copy of a unicode string ending with a nul character. Return `NULL` and raise a `MemoryError` exception on memory allocation failure, otherwise return a new allocated buffer (use `PyMem_Free()` to free the buffer).

New in version 3.2.

`Py_ssize_t` `PyUnicode_GetSize(PyObject *unicode)`

Return the length of the Unicode object.

`PyObject*` `PyUnicode_FromEncodedObject(PyObject *obj, const char *encoding, const char *errors)`

Return value: New reference.

Coerce an encoded object `obj` to an Unicode object and return a reference with incremented refcount.

`bytes`, `bytearray` and other char buffer compatible objects are decoded according to the given encoding and using the error handling defined by `errors`. Both can be `NULL` to have the interface use the default values (see the next section for details).

All other objects, including Unicode objects, cause a `TypeError` to be set.

The API returns `NULL` if there was an error. The caller is responsible for decref'ing the returned objects.

`PyObject*` `PyUnicode_FromObject(PyObject *obj)`

Return value: New reference.

Shortcut for `PyUnicode_FromEncodedObject(obj, NULL, "strict")` which is used throughout the interpreter whenever coercion to Unicode is needed.

If the platform supports `wchar_t` and provides a header file `wchar.h`, Python can interface directly to this type using the following functions. Support is optimized if Python's own `Py_UNICODE` type is identical to the system's `wchar_t`.

File System Encoding

To encode and decode file names and other environment strings, `Py_FileSystemEncoding` should be used as the encoding, and `"surrogateescape"` should be used as the error handler ([PEP 383](#)). To encode file names during argument parsing, the `"o&"` converter should be used, passing `PyUnicode_FSConverter()` as the conversion function:

`int PyUnicode_FSConverter(PyObject* obj, void* result)`

ParseTuple converter: encode `str` objects to `bytes` using `PyUnicode_EncodeFSDefault()`; `bytes` objects are output as-is. `result` must be a `PyBytesObject*` which must be released when it is no longer used.

New in version 3.1.

To decode file names during argument parsing, the `"o&"` converter should be used, passing `PyUnicode_FSDecoder()` as the conversion function:

`int PyUnicode_FSDecoder(PyObject* obj, void* result)`

ParseTuple converter: decode `bytes` objects to `str` using `PyUnicode_DecodeFSDefaultAndSize()`; `str` objects are output as-is. `result` must be a `PyUnicodeObject*` which must be released when it is no longer used.

New in version 3.2.

PyObject* **PyUnicode_DecodeFSDefaultAndSize**(const char *s,
Py_ssize_t size)

Decode a string using **Py_FileSystemDefaultEncoding** and the **'surrogateescape'** error handler, or **'strict'** on Windows.

If **Py_FileSystemDefaultEncoding** is not set, fall back to the locale encoding.

Changed in version 3.2: Use **'strict'** error handler on Windows.

PyObject* **PyUnicode_DecodeFSDefault**(const char *s)

Decode a null-terminated string using **Py_FileSystemDefaultEncoding** and the **'surrogateescape'** error handler, or **'strict'** on Windows.

If **Py_FileSystemDefaultEncoding** is not set, fall back to the locale encoding.

Use **PyUnicode_DecodeFSDefaultAndSize()** if you know the string length.

Changed in version 3.2: Use **'strict'** error handler on Windows.

PyObject* **PyUnicode_EncodeFSDefault**(PyObject *unicode)

Encode a Unicode object to **Py_FileSystemDefaultEncoding** with the **'surrogateescape'** error handler, or **'strict'** on Windows, and return **bytes**.

If **Py_FileSystemDefaultEncoding** is not set, fall back to the locale encoding.

New in version 3.2.

wchar_t Support

wchar_t support for platforms which support it:

`PyObject*` **PyUnicode_FromWideChar**(const wchar_t *w, Py_ssize_t size)

Return value: New reference.

Create a Unicode object from the wchar_t buffer w of the given size. Passing -1 as the size indicates that the function must itself compute the length, using wcslen. Return *NULL* on failure.

Py_ssize_t **PyUnicode_AsWideChar**(PyUnicodeObject *unicode, wchar_t *w, Py_ssize_t size)

Copy the Unicode object contents into the wchar_t buffer w. At most size wchar_t characters are copied (excluding a possibly trailing 0-termination character). Return the number of wchar_t characters copied or -1 in case of an error. Note that the resulting wchar_t string may or may not be 0-terminated. It is the responsibility of the caller to make sure that the wchar_t string is 0-terminated in case this is required by the application.

wchar_t* **PyUnicode_AsWideCharString**(PyObject *unicode, Py_ssize_t *size)

Convert the Unicode object to a wide character string. The output string always ends with a nul character. If size is not *NULL*, write the number of wide characters (excluding the trailing 0-termination character) into *size.

Returns a buffer allocated by `PyMem_Alloc()` (use `PyMem_Free()` to free it) on success. On error, returns *NULL*, *size is undefined and raises a `MemoryError`.

New in version 3.2.

Built-in Codecs

Python provides a set of built-in codecs which are written in C for speed. All of these codecs are directly usable via the following functions.

Many of the following APIs take two arguments encoding and errors. These parameters encoding and errors have the same semantics as the ones of the built-in `str()` string object constructor.

Setting encoding to `NULL` causes the default encoding to be used which is ASCII. The file system calls should use `PyUnicode_FSConverter()` for encoding file names. This uses the variable `Py_FileSystemDefaultEncoding` internally. This variable should be treated as read-only: On some systems, it will be a pointer to a static string, on others, it will change at run-time (such as when the application invokes `setlocale`).

Error handling is set by errors which may also be set to `NULL` meaning to use the default handling defined for the codec. Default error handling for all built-in codecs is “strict” (`ValueError` is raised).

The codecs all use a similar interface. Only deviation from the following generic ones are documented for simplicity.

Generic Codecs

These are the generic codec APIs:

`PyObject*` `PyUnicode_Decode`(const char *s, Py_ssize_t size, const char *encoding, const char *errors)

Return value: *New reference.*

Create a Unicode object by decoding *size* bytes of the encoded

string *s*. *encoding* and *errors* have the same meaning as the parameters of the same name in the `unicode()` built-in function. The codec to be used is looked up using the Python codec registry. Return *NULL* if an exception was raised by the codec.

`PyObject*` **PyUnicode_Encode**(const `Py_UNICODE` *s, `Py_ssize_t` size, const char *encoding, const char *errors)

Return value: New reference.

Encode the `Py_UNICODE` buffer of the given size and return a Python bytes object. *encoding* and *errors* have the same meaning as the parameters of the same name in the Unicode `encode()` method. The codec to be used is looked up using the Python codec registry. Return *NULL* if an exception was raised by the codec.

`PyObject*` **PyUnicode_AsEncodedString**(`PyObject` *unicode, const char *encoding, const char *errors)

Return value: New reference.

Encode a Unicode object and return the result as Python bytes object. *encoding* and *errors* have the same meaning as the parameters of the same name in the Unicode `encode()` method. The codec to be used is looked up using the Python codec registry. Return *NULL* if an exception was raised by the codec.

UTF-8 Codecs

These are the UTF-8 codec APIs:

`PyObject*` **PyUnicode_DecodeUTF8**(const char *s, `Py_ssize_t` size, const char *errors)

Return value: New reference.

Create a Unicode object by decoding *size* bytes of the UTF-8 encoded string *s*. Return *NULL* if an exception was raised by the codec.

`PyObject*` `PyUnicode_DecodeUTF8Stateful`(const char *s,
Py_ssize_t size, const char *errors, Py_ssize_t *consumed)

Return value: New reference.

If *consumed* is `NULL`, behave like `PyUnicode_DecodeUTF8()`. If *consumed* is not `NULL`, trailing incomplete UTF-8 byte sequences will not be treated as an error. Those bytes will not be decoded and the number of bytes that have been decoded will be stored in *consumed*.

`PyObject*` `PyUnicode_EncodeUTF8`(const Py_UNICODE *s,
Py_ssize_t size, const char *errors)

Return value: New reference.

Encode the `Py_UNICODE` buffer of the given size using UTF-8 and return a Python bytes object. Return `NULL` if an exception was raised by the codec.

`PyObject*` `PyUnicode_AsUTF8String`(PyObject *unicode)

Return value: New reference.

Encode a Unicode object using UTF-8 and return the result as Python bytes object. Error handling is “strict”. Return `NULL` if an exception was raised by the codec.

UTF-32 Codecs

These are the UTF-32 codec APIs:

`PyObject*` `PyUnicode_DecodeUTF32`(const char *s, Py_ssize_t size,
const char *errors, int *byteorder)

Decode *length* bytes from a UTF-32 encoded buffer string and return the corresponding Unicode object. *errors* (if non-`NULL`) defines the error handling. It defaults to “strict”.

If *byteorder* is non-`NULL`, the decoder starts decoding using the given byte order:

```
*byteorder == -1: little endian
*byteorder == 0: native order
*byteorder == 1: big endian
```

If `*byteorder` is zero, and the first four bytes of the input data are a byte order mark (BOM), the decoder switches to this byte order and the BOM is not copied into the resulting Unicode string. If `*byteorder` is `-1` or `1`, any byte order mark is copied to the output.

After completion, `*byteorder` is set to the current byte order at the end of input data.

In a narrow build codepoints outside the BMP will be decoded as surrogate pairs.

If `byteorder` is `NULL`, the codec starts in native order mode.

Return `NULL` if an exception was raised by the codec.

PyObject* **PyUnicode_DecodeUTF32Stateful**(const char *s, Py_ssize_t size, const char *errors, int *byteorder, Py_ssize_t *consumed)

If `consumed` is `NULL`, behave like **PyUnicode_DecodeUTF32()**. If `consumed` is not `NULL`, **PyUnicode_DecodeUTF32Stateful()** will not treat trailing incomplete UTF-32 byte sequences (such as a number of bytes not divisible by four) as an error. Those bytes will not be decoded and the number of bytes that have been decoded will be stored in `consumed`.

PyObject* **PyUnicode_EncodeUTF32**(const Py_UNICODE *s, Py_ssize_t size, const char *errors, int byteorder)

Return a Python bytes object holding the UTF-32 encoded value of the Unicode data in `s`. Output is written according to the following byte order:

```
byteorder == -1: little endian
byteorder == 0:  native byte order (writes a BOM mark)
byteorder == 1:  big endian
```

If `byteorder` is `0`, the output string will always start with the Unicode BOM mark (U+FEFF). In the other two modes, no BOM mark is prepended.

If `Py_UNICODE_WIDE` is not defined, surrogate pairs will be output as a single codepoint.

Return `NULL` if an exception was raised by the codec.

PyObject* **PyUnicode_AsUTF32String**(PyObject **unicode*)

Return a Python byte string using the UTF-32 encoding in native byte order. The string always starts with a BOM mark. Error handling is “strict”. Return `NULL` if an exception was raised by the codec.

UTF-16 Codecs

These are the UTF-16 codec APIs:

PyObject* **PyUnicode_DecodeUTF16**(const char **s*, Py_ssize_t *size*, const char **errors*, int **byteorder*)

Return value: *New reference.*

Decode *length* bytes from a UTF-16 encoded buffer string and return the corresponding Unicode object. *errors* (if non-`NULL`) defines the error handling. It defaults to “strict”.

If *byteorder* is non-`NULL`, the decoder starts decoding using the given byte order:

```
*byteorder == -1: little endian
*byteorder == 0:  native order
*byteorder == 1:  big endian
```

If `*byteorder` is zero, and the first two bytes of the input data are a byte order mark (BOM), the decoder switches to this byte order and the BOM is not copied into the resulting Unicode string. If `*byteorder` is `-1` or `1`, any byte order mark is copied to the output (where it will result in either a `\ufeff` or a `\ufffe` character).

After completion, `*byteorder` is set to the current byte order at the end of input data.

If `byteorder` is `NULL`, the codec starts in native order mode.

Return `NULL` if an exception was raised by the codec.

PyObject* **PyUnicode_DecodeUTF16Stateful**(const char *s, Py_ssize_t size, const char *errors, int *byteorder, Py_ssize_t *consumed)

Return value: New reference.

If `consumed` is `NULL`, behave like `PyUnicode_DecodeUTF16()`. If `consumed` is not `NULL`, `PyUnicode_DecodeUTF16Stateful()` will not treat trailing incomplete UTF-16 byte sequences (such as an odd number of bytes or a split surrogate pair) as an error. Those bytes will not be decoded and the number of bytes that have been decoded will be stored in `consumed`.

PyObject* **PyUnicode_EncodeUTF16**(const Py_UNICODE *s, Py_ssize_t size, const char *errors, int byteorder)

Return value: New reference.

Return a Python bytes object holding the UTF-16 encoded value of the Unicode data in `s`. Output is written according to the following byte order:

```
byteorder == -1: little endian
byteorder == 0: native byte order (writes a BOM mark)
byteorder == 1: big endian
```

If `byteorder` is `0`, the output string will always start with the Unicode BOM mark (U+FEFF). In the other two modes, no BOM mark is prepended.

If `Py_UNICODE_WIDE` is defined, a single `Py_UNICODE` value may get represented as a surrogate pair. If it is not defined, each `Py_UNICODE` value is interpreted as an UCS-2 character.

Return `NULL` if an exception was raised by the codec.

`PyObject*` `PyUnicode_AsUTF16String(PyObject *unicode)`

Return value: New reference.

Return a Python byte string using the UTF-16 encoding in native byte order. The string always starts with a BOM mark. Error handling is “strict”. Return `NULL` if an exception was raised by the codec.

UTF-7 Codecs

These are the UTF-7 codec APIs:

`PyObject*` `PyUnicode_DecodeUTF7(const char *s, Py_ssize_t size, const char *errors)`

Create a Unicode object by decoding `size` bytes of the UTF-7 encoded string `s`. Return `NULL` if an exception was raised by the codec.

`PyObject*` `PyUnicode_DecodeUTF7Stateful(const char *s, Py_ssize_t size, const char *errors, Py_ssize_t *consumed)`

If `consumed` is `NULL`, behave like `PyUnicode_DecodeUTF7()`. If `consumed` is not `NULL`, trailing incomplete UTF-7 base-64 sections will not be treated as an error. Those bytes will not be decoded and the number of bytes that have been decoded will be stored in `consumed`.

PyObject* **PyUnicode_EncodeUTF7**(const **Py_UNICODE** *s, **Py_ssize_t** size, int *base64SetO*, int *base64WhiteSpace*, const char *errors)

Encode the **Py_UNICODE** buffer of the given size using UTF-7 and return a Python bytes object. Return *NULL* if an exception was raised by the codec.

If *base64SetO* is nonzero, “Set O” (punctuation that has no otherwise special meaning) will be encoded in base-64. If *base64WhiteSpace* is nonzero, whitespace will be encoded in base-64. Both are set to zero for the Python “utf-7” codec.

Unicode-Escape Codecs

These are the “Unicode Escape” codec APIs:

PyObject* **PyUnicode_DecodeUnicodeEscape**(const char *s, **Py_ssize_t** size, const char *errors)

Return value: New reference.

Create a Unicode object by decoding *size* bytes of the Unicode-Escape encoded string *s*. Return *NULL* if an exception was raised by the codec.

PyObject* **PyUnicode_EncodeUnicodeEscape**(const **Py_UNICODE** *s, **Py_ssize_t** size)

Return value: New reference.

Encode the **Py_UNICODE** buffer of the given size using Unicode-Escape and return a Python string object. Return *NULL* if an exception was raised by the codec.

PyObject* **PyUnicode_AsUnicodeEscapeString**(**PyObject** *unicode)

Return value: New reference.

Encode a Unicode object using Unicode-Escape and return the

result as Python string object. Error handling is “strict”. Return *NULL* if an exception was raised by the codec.

Raw-Unicode-Escape Codecs

These are the “Raw Unicode Escape” codec APIs:

`PyObject*` **PyUnicode_DecodeRawUnicodeEscape**(const char *s,
Py_ssize_t size, const char *errors)

Return value: New reference.

Create a Unicode object by decoding *size* bytes of the Raw-Unicode-Escape encoded string *s*. Return *NULL* if an exception was raised by the codec.

`PyObject*` **PyUnicode_EncodeRawUnicodeEscape**(const
Py_UNICODE *s, Py_ssize_t size, const char *errors)

Return value: New reference.

Encode the `Py_UNICODE` buffer of the given size using Raw-Unicode-Escape and return a Python string object. Return *NULL* if an exception was raised by the codec.

`PyObject*` **PyUnicode_AsRawUnicodeEscapeString**(PyObject
*unicode)

Return value: New reference.

Encode a Unicode object using Raw-Unicode-Escape and return the result as Python string object. Error handling is “strict”. Return *NULL* if an exception was raised by the codec.

Latin-1 Codecs

These are the Latin-1 codec APIs: Latin-1 corresponds to the first 256 Unicode ordinals and only these are accepted by the codecs during encoding.

PyObject* **PyUnicode_DecodeLatin1**(const char *s, Py_ssize_t size, const char *errors)

Return value: New reference.

Create a Unicode object by decoding *size* bytes of the Latin-1 encoded string *s*. Return *NULL* if an exception was raised by the codec.

PyObject* **PyUnicode_EncodeLatin1**(const Py_UNICODE *s, Py_ssize_t size, const char *errors)

Return value: New reference.

Encode the **Py_UNICODE** buffer of the given size using Latin-1 and return a Python bytes object. Return *NULL* if an exception was raised by the codec.

PyObject* **PyUnicode_AsLatin1String**(PyObject *unicode)

Return value: New reference.

Encode a Unicode object using Latin-1 and return the result as Python bytes object. Error handling is “strict”. Return *NULL* if an exception was raised by the codec.

ASCII Codecs

These are the ASCII codec APIs. Only 7-bit ASCII data is accepted. All other codes generate errors.

PyObject* **PyUnicode_DecodeASCII**(const char *s, Py_ssize_t size, const char *errors)

Return value: New reference.

Create a Unicode object by decoding *size* bytes of the ASCII encoded string *s*. Return *NULL* if an exception was raised by the codec.

PyObject* **PyUnicode_EncodeASCII**(const Py_UNICODE *s, Py_ssize_t size, const char *errors)

Return value: New reference.

Encode the `Py_UNICODE` buffer of the given size using ASCII and return a Python bytes object. Return `NULL` if an exception was raised by the codec.

`PyObject*` `PyUnicode_AsASCIIString(PyObject *unicode)`

Return value: New reference.

Encode a Unicode object using ASCII and return the result as Python bytes object. Error handling is “strict”. Return `NULL` if an exception was raised by the codec.

Character Map Codecs

These are the mapping codec APIs:

This codec is special in that it can be used to implement many different codecs (and this is in fact what was done to obtain most of the standard codecs included in the `encodings` package). The codec uses mapping to encode and decode characters.

Decoding mappings must map single string characters to single Unicode characters, integers (which are then interpreted as Unicode ordinals) or `None` (meaning “undefined mapping” and causing an error).

Encoding mappings must map single Unicode characters to single string characters, integers (which are then interpreted as Latin-1 ordinals) or `None` (meaning “undefined mapping” and causing an error).

The mapping objects provided must only support the `__getitem__` mapping interface.

If a character lookup fails with a `LookupError`, the character is copied as-is meaning that its ordinal value will be interpreted as Unicode or

Latin-1 ordinal resp. Because of this, mappings only need to contain those mappings which map characters to different code points.

`PyObject*` **PyUnicode_DecodeCharmap**(const char *s, Py_ssize_t size, `PyObject` *mapping, const char *errors)

Return value: New reference.

Create a Unicode object by decoding *size* bytes of the encoded string *s* using the given *mapping* object. Return *NULL* if an exception was raised by the codec. If *mapping* is *NULL* latin-1 decoding will be done. Else it can be a dictionary mapping byte or a unicode string, which is treated as a lookup table. Byte values greater than the length of the string and U+FFFE “characters” are treated as “undefined mapping”.

`PyObject*` **PyUnicode_EncodeCharmap**(const `Py_UNICODE` *s, Py_ssize_t size, `PyObject` *mapping, const char *errors)

Return value: New reference.

Encode the `Py_UNICODE` buffer of the given size using the given *mapping* object and return a Python string object. Return *NULL* if an exception was raised by the codec.

`PyObject*` **PyUnicode_AsCharmapString**(`PyObject` *unicode, `PyObject` *mapping)

Return value: New reference.

Encode a Unicode object using the given *mapping* object and return the result as Python string object. Error handling is “strict”. Return *NULL* if an exception was raised by the codec.

The following codec API is special in that maps Unicode to Unicode.

`PyObject*` **PyUnicode_TranslateCharmap**(const `Py_UNICODE` *s, Py_ssize_t size, `PyObject` *table, const char *errors)

Return value: New reference.

Translate a `Py_UNICODE` buffer of the given length by applying a

character mapping *table* to it and return the resulting Unicode object. Return *NULL* when an exception was raised by the codec.

The *mapping* table must map Unicode ordinal integers to Unicode ordinal integers or *None* (causing deletion of the character).

Mapping tables need only provide the `__getitem__()` interface; dictionaries and sequences work well. Unmapped character ordinals (ones which cause a `LookupError`) are left untouched and are copied as-is.

These are the MBCS codec APIs. They are currently only available on Windows and use the Win32 MBCS converters to implement the conversions. Note that MBCS (or DBCS) is a class of encodings, not just one. The target encoding is defined by the user settings on the machine running the codec.

MBCS codecs for Windows

`PyObject*` `PyUnicode_DecodeMBCS`(const char *s, Py_ssize_t size, const char *errors)

Return value: New reference.

Create a Unicode object by decoding *size* bytes of the MBCS encoded string *s*. Return *NULL* if an exception was raised by the codec.

`PyObject*` `PyUnicode_DecodeMBCSStateful`(const char *s, int size, const char *errors, int *consumed)

If *consumed* is *NULL*, behave like `PyUnicode_DecodeMBCS()`. If *consumed* is not *NULL*, `PyUnicode_DecodeMBCSStateful()` will not decode trailing lead byte and the number of bytes that have been decoded will be stored in *consumed*.

`PyObject*` **PyUnicode_EncodeMBCS**(const `Py_UNICODE` *s,
`Py_ssize_t` size, const char *errors)

Return value: New reference.

Encode the `Py_UNICODE` buffer of the given size using MBCS and return a Python bytes object. Return *NULL* if an exception was raised by the codec.

`PyObject*` **PyUnicode_AsMBCSString**(`PyObject` *unicode)

Return value: New reference.

Encode a Unicode object using MBCS and return the result as Python bytes object. Error handling is “strict”. Return *NULL* if an exception was raised by the codec.

Methods & Slots

Methods and Slot Functions

The following APIs are capable of handling Unicode objects and strings on input (we refer to them as strings in the descriptions) and return Unicode objects or integers as appropriate.

They all return `NULL` or `-1` if an exception occurs.

`PyObject*` **PyUnicode_Concat**(`PyObject *left`, `PyObject *right`)

Return value: New reference.

Concat two strings giving a new Unicode string.

`PyObject*` **PyUnicode_Split**(`PyObject *s`, `PyObject *sep`,
`Py_ssize_t maxsplit`)

Return value: New reference.

Split a string giving a list of Unicode strings. If `sep` is `NULL`, splitting will be done at all whitespace substrings. Otherwise, splits occur at the given separator. At most `maxsplit` splits will be done. If negative, no limit is set. Separators are not included in the resulting list.

`PyObject*` **PyUnicode_Splitlines**(`PyObject *s`, `int keepend`)

Return value: New reference.

Split a Unicode string at line breaks, returning a list of Unicode strings. CRLF is considered to be one line break. If `keepend` is 0, the Line break characters are not included in the resulting strings.

`PyObject*` **PyUnicode_Translate**(`PyObject *str`, `PyObject *table`,
`const char *errors`)

Return value: New reference.

Translate a string by applying a character mapping table to it and return the resulting Unicode object.

The mapping table must map Unicode ordinal integers to Unicode ordinal integers or None (causing deletion of the character).

Mapping tables need only provide the `__getitem__()` interface; dictionaries and sequences work well. Unmapped character ordinals (ones which cause a `LookupError`) are left untouched and are copied as-is.

`errors` has the usual meaning for codecs. It may be `NULL` which indicates to use the default error handling.

`PyObject*` **PyUnicode_Join**(`PyObject` *separator, `PyObject` *seq)

Return value: New reference.

Join a sequence of strings using the given separator and return the resulting Unicode string.

`int` **PyUnicode_Tailmatch**(`PyObject` *str, `PyObject` *substr, `Py_ssize_t` start, `Py_ssize_t` end, `int` direction)

Return 1 if `substr` matches `str`*[`*start:end`] at the given tail end (`direction == -1` means to do a prefix match, `direction == 1` a suffix match), 0 otherwise. Return `-1` if an error occurred.

`Py_ssize_t` **PyUnicode_Find**(`PyObject` *str, `PyObject` *substr, `Py_ssize_t` start, `Py_ssize_t` end, `int` direction)

Return the first position of `substr` in `str`*[`*start:end`] using the given `direction` (`direction == 1` means to do a forward search, `direction == -1` a backward search). The return value is the index of the first match; a value of `-1` indicates that no match was found, and `-2` indicates that an error occurred and an exception has been set.

`Py_ssize_t` **PyUnicode_Count**(`PyObject` *str, `PyObject` *substr, `Py_ssize_t` start, `Py_ssize_t` end)

Return the number of non-overlapping occurrences of *substr* in `str[start:end]`. Return `-1` if an error occurred.

`PyObject*` **PyUnicode_Replace**(`PyObject` **str*, `PyObject` **substr*,
`PyObject` **replstr*, `Py_ssize_t` *maxcount*)

Return value: New reference.

Replace at most *maxcount* occurrences of *substr* in *str* with *replstr* and return the resulting Unicode object. *maxcount* == `-1` means replace all occurrences.

`int` **PyUnicode_Compare**(`PyObject` **left*, `PyObject` **right*)

Compare two strings and return `-1`, `0`, `1` for less than, equal, and greater than, respectively.

`int` **PyUnicode_CompareWithASCIIString**(`PyObject` **uni*, `char`
**string*)

Compare a unicode object, *uni*, with *string* and return `-1`, `0`, `1` for less than, equal, and greater than, respectively. It is best to pass only ASCII-encoded strings, but the function interprets the input string as ISO-8859-1 if it contains non-ASCII characters”.

`int` **PyUnicode_RichCompare**(`PyObject` **left*, `PyObject` **right*, `int` *op*)

Rich compare two unicode strings and return one of the following:

- `NULL` in case an exception was raised
- `Py_True` or `Py_False` for successful comparisons
- `Py_NotImplemented` in case the type combination is unknown

Note that `Py_EQ` and `Py_NE` comparisons can cause a `UnicodeWarning` in case the conversion of the arguments to Unicode fails with a `UnicodeDecodeError`.

Possible values for *op* are `Py_GT`, `Py_GE`, `Py_EQ`, `Py_NE`, `Py_LT`, and `Py_LE`.

PyObject* **PyUnicode_Format**(PyObject **format*, PyObject **args*)

Return value: New reference.

Return a new string object from *format* and *args*; this is analogous to `format % args`. The *args* argument must be a tuple.

int **PyUnicode_Contains**(PyObject **container*, PyObject **element*)

Check whether *element* is contained in *container* and return true or false accordingly.

element has to coerce to a one element Unicode string. `-1` is returned if there was an error.

void **PyUnicode_InternInPlace**(PyObject ***string*)

Intern the argument **string* in place. The argument must be the address of a pointer variable pointing to a Python unicode string object. If there is an existing interned string that is the same as **string*, it sets **string* to it (decrementing the reference count of the old string object and incrementing the reference count of the interned string object), otherwise it leaves **string* alone and interns it (incrementing its reference count). (Clarification: even though there is a lot of talk about reference counts, think of this function as reference-count-neutral; you own the object after the call if and only if you owned it before the call.)

PyObject* **PyUnicode_InternFromString**(const char **v*)

A combination of **PyUnicode_FromString()** and **PyUnicode_InternInPlace()**, returning either a new unicode string object that has been interned, or a new (“owned”) reference to an earlier interned string object with the same value.

Tuple Objects

PyTupleObject

This subtype of `PyObject` represents a Python tuple object.

PyTypeObject PyTuple_Type

This instance of `PyTypeObject` represents the Python tuple type; it is the same object as `tuple` in the Python layer.

int PyTuple_Check(PyObject *p)

Return true if `p` is a tuple object or an instance of a subtype of the tuple type.

int PyTuple_CheckExact(PyObject *p)

Return true if `p` is a tuple object, but not an instance of a subtype of the tuple type.

PyObject* PyTuple_New(Py_ssize_t len)

Return value: New reference.

Return a new tuple object of size `len`, or `NULL` on failure.

PyObject* PyTuple_Pack(Py_ssize_t n, ...)

Return value: New reference.

Return a new tuple object of size `n`, or `NULL` on failure. The tuple values are initialized to the subsequent `n` C arguments pointing to Python objects. `PyTuple_Pack(2, a, b)` is equivalent to `Py_BuildValue("(00)", a, b)`.

Py_ssize_t PyTuple_Size(PyObject *p)

Take a pointer to a tuple object, and return the size of that tuple.

Py_ssize_t PyTuple_GET_SIZE(PyObject *p)

Return the size of the tuple `p`, which must be non-`NULL` and point

to a tuple; no error checking is performed.

`PyObject*` `PyTuple_GetItem(PyObject *p, Py_ssize_t pos)`

Return value: Borrowed reference.

Return the object at position `pos` in the tuple pointed to by `p`. If `pos` is out of bounds, return `NULL` and sets an `IndexError` exception.

`PyObject*` `PyTuple_GET_ITEM(PyObject *p, Py_ssize_t pos)`

Return value: Borrowed reference.

Like `PyTuple_GetItem()`, but does no checking of its arguments.

`PyObject*` `PyTuple_GetSlice(PyObject *p, Py_ssize_t low, Py_ssize_t high)`

Return value: New reference.

Take a slice of the tuple pointed to by `p` from `low` to `high` and return it as a new tuple.

`int` `PyTuple_SetItem(PyObject *p, Py_ssize_t pos, PyObject *o)`

Insert a reference to object `o` at position `pos` of the tuple pointed to by `p`. Return `0` on success.

Note: This function “steals” a reference to `o`.

`void` `PyTuple_SET_ITEM(PyObject *p, Py_ssize_t pos, PyObject *o)`

Like `PyTuple_SetItem()`, but does no error checking, and should *only* be used to fill in brand new tuples.

Note: This function “steals” a reference to `o`.

`int` `_PyTuple_Resize(PyObject **p, Py_ssize_t newsize)`

Can be used to resize a tuple. `newsize` will be the new length of the tuple. Because tuples are *supposed* to be immutable, this

should only be used if there is only one reference to the object. Do *not* use this if the tuple may already be known to some other part of the code. The tuple will always grow or shrink at the end. Think of this as destroying the old tuple and creating a new one, only more efficiently. Returns `0` on success. Client code should never assume that the resulting value of `*p` will be the same as before calling this function. If the object referenced by `*p` is replaced, the original `*p` is destroyed. On failure, returns `-1` and sets `*p` to `NULL`, and raises `MemoryError` or `SystemError`.

int PyTuple_ClearFreeList()

Clear the free list. Return the total number of freed items.

Python v3.2 documentation » Python/C API Reference

[previous](#) | [next](#) | [modules](#) | [index](#)

[Manual](#) » [Concrete Objects Layer](#) »

List Objects

PyListObject

This subtype of `PyObject` represents a Python list object.

PyObject PyList_Type

This instance of `PyObject` represents the Python list type.

This is the same object as `list` in the Python layer.

int PyList_Check(PyObject *p)

Return true if `p` is a list object or an instance of a subtype of the list type.

int PyList_CheckExact(PyObject *p)

Return true if `p` is a list object, but not an instance of a subtype of the list type.

PyObject* PyList_New(Py_ssize_t len)

Return value: New reference.

Return a new list of length `len` on success, or `NULL` on failure.

Note: If `len` is greater than zero, the returned list object's items are set to `NULL`. Thus you cannot use abstract API functions such as `PySequence_SetItem()` or expose the object to Python code before setting all items to a real object with `PyList_SetItem()`.

Py_ssize_t PyList_Size(PyObject *list)

Return the length of the list object in `list`; this is equivalent to `len(list)` on a list object.

Py_ssize_t PyList_GET_SIZE(PyObject *list)

Macro form of `PyList_Size()` without error checking.

`PyObject*` `PyList_GetItem(PyObject *list, Py_ssize_t index)`

Return value: Borrowed reference.

Return the object at position *index* in the list pointed to by *list*. The position must be positive, indexing from the end of the list is not supported. If *index* is out of bounds, return `NULL` and set an `IndexError` exception.

`PyObject*` `PyList_GET_ITEM(PyObject *list, Py_ssize_t i)`

Return value: Borrowed reference.

Macro form of `PyList_GetItem()` without error checking.

`int` `PyList_SetItem(PyObject *list, Py_ssize_t index, PyObject *item)`

Set the item at index *index* in list to *item*. Return `0` on success or `-1` on failure.

Note: This function “steals” a reference to *item* and discards a reference to an item already in the list at the affected position.

`void` `PyList_SET_ITEM(PyObject *list, Py_ssize_t i, PyObject *o)`

Macro form of `PyList_SetItem()` without error checking. This is normally only used to fill in new lists where there is no previous content.

Note: This macro “steals” a reference to *item*, and, unlike `PyList_SetItem()`, does *not* discard a reference to any item that is being replaced; any reference in *list* at position *i* will be leaked.

`int` `PyList_Insert(PyObject *list, Py_ssize_t index, PyObject *item)`

Insert the item *item* into list *list* in front of index *index*. Return `0` if successful; return `-1` and set an exception if unsuccessful.

Analogous to `list.insert(index, item)`.

`int PyList_Append(PyObject *list, PyObject *item)`

Append the object *item* at the end of list *list*. Return `0` if successful; return `-1` and set an exception if unsuccessful. Analogous to `list.append(item)`.

`PyObject* PyList_GetSlice(PyObject *list, Py_ssize_t low, Py_ssize_t high)`

Return value: New reference.

Return a list of the objects in *list* containing the objects *between low and high*. Return `NULL` and set an exception if unsuccessful. Analogous to `list[low:high]`. Negative indices, as when slicing from Python, are not supported.

`int PyList_SetSlice(PyObject *list, Py_ssize_t low, Py_ssize_t high, PyObject *itemlist)`

Set the slice of *list* between *low* and *high* to the contents of *itemlist*. Analogous to `list[low:high] = itemlist`. The *itemlist* may be `NULL`, indicating the assignment of an empty list (slice deletion). Return `0` on success, `-1` on failure. Negative indices, as when slicing from Python, are not supported.

`int PyList_Sort(PyObject *list)`

Sort the items of *list* in place. Return `0` on success, `-1` on failure. This is equivalent to `list.sort()`.

`int PyList_Reverse(PyObject *list)`

Reverse the items of *list* in place. Return `0` on success, `-1` on failure. This is the equivalent of `list.reverse()`.

`PyObject* PyList_AsTuple(PyObject *list)`

Return value: New reference.

Return a new tuple object containing the contents of *list*; equivalent to `tuple(list)`.

Dictionary Objects

PyDictObject

This subtype of **PyObject** represents a Python dictionary object.

PyObject PyDict_Type

This instance of **PyObject** represents the Python dictionary type. This is the same object as **dict** in the Python layer.

int PyDict_Check(PyObject *p)

Return true if *p* is a dict object or an instance of a subtype of the dict type.

int PyDict_CheckExact(PyObject *p)

Return true if *p* is a dict object, but not an instance of a subtype of the dict type.

PyObject* PyDict_New()

Return value: New reference.

Return a new empty dictionary, or *NULL* on failure.

PyObject* PyDictProxy_New(PyObject *dict)

Return value: New reference.

Return a proxy object for a mapping which enforces read-only behavior. This is normally used to create a proxy to prevent modification of the dictionary for non-dynamic class types.

void PyDict_Clear(PyObject *p)

Empty an existing dictionary of all key-value pairs.

int PyDict_Contains(PyObject *p, PyObject *key)

Determine if dictionary *p* contains *key*. If an item in *p* matches *key*, return **1**, otherwise return **0**. On error, return **-1**. This is

equivalent to the Python expression `key in p`.

PyObject* **PyDict_Copy**(PyObject *p)

Return value: New reference.

Return a new dictionary that contains the same key-value pairs as *p*.

int **PyDict_SetItem**(PyObject *p, PyObject *key, PyObject *val)

Insert *value* into the dictionary *p* with a key of *key*. *key* must be *hashable*; if it isn't, **TypeError** will be raised. Return `0` on success or `-1` on failure.

int **PyDict_SetItemString**(PyObject *p, const char *key, PyObject *val)

Insert *value* into the dictionary *p* using *key* as a key. *key* should be a `char*`. The key object is created using `PyUnicode_FromString(key)`. Return `0` on success or `-1` on failure.

int **PyDict_DeItem**(PyObject *p, PyObject *key)

Remove the entry in dictionary *p* with key *key*. *key* must be hashable; if it isn't, **TypeError** is raised. Return `0` on success or `-1` on failure.

int **PyDict_DeItemString**(PyObject *p, char *key)

Remove the entry in dictionary *p* which has a key specified by the string *key*. Return `0` on success or `-1` on failure.

PyObject* **PyDict_GetItem**(PyObject *p, PyObject *key)

Return value: Borrowed reference.

Return the object from dictionary *p* which has a key *key*. Return `NULL` if the key *key* is not present, but *without* setting an exception.

PyObject* **PyDict_GetItemWithError**(PyObject *p, PyObject *key)

Variant of `PyDict_GetItem()` that does not suppress exceptions. Return `NULL` **with** an exception set if an exception occurred. Return `NULL` **without** an exception set if the key wasn't present.

`PyObject*` `PyDict_GetItemString(PyObject *p, const char *key)`

Return value: Borrowed reference.

This is the same as `PyDict_GetItem()`, but `key` is specified as a `char*`, rather than a `PyObject*`.

`PyObject*` `PyDict_Items(PyObject *p)`

Return value: New reference.

Return a `PyListObject` containing all the items from the dictionary.

`PyObject*` `PyDict_Keys(PyObject *p)`

Return value: New reference.

Return a `PyListObject` containing all the keys from the dictionary.

`PyObject*` `PyDict_Values(PyObject *p)`

Return value: New reference.

Return a `PyListObject` containing all the values from the dictionary `p`.

`Py_ssize_t` `PyDict_Size(PyObject *p)`

Return the number of items in the dictionary. This is equivalent to `len(p)` on a dictionary.

`int` `PyDict_Next(PyObject *p, Py_ssize_t *ppos, PyObject **pkey, PyObject **pvalue)`

Iterate over all key-value pairs in the dictionary `p`. The `Py_ssize_t` referred to by `ppos` must be initialized to `0` prior to the first call to this function to start the iteration; the function returns true for each pair in the dictionary, and false once all pairs have been reported. The parameters `pkey` and `pvalue` should either point to

`PyObject*` variables that will be filled in with each key and value, respectively, or may be `NULL`. Any references returned through them are borrowed. `p`pos should not be altered during iteration. Its value represents offsets within the internal dictionary structure, and since the structure is sparse, the offsets are not consecutive.

For example:

```
PyObject *key, *value;
Py_ssize_t pos = 0;

while (PyDict_Next(self->dict, &pos, &key, &value)) {
    /* do something interesting with the values... */
    ...
}
```

The dictionary `p` should not be mutated during iteration. It is safe to modify the values of the keys as you iterate over the dictionary, but only so long as the set of keys does not change. For example:

```
PyObject *key, *value;
Py_ssize_t pos = 0;

while (PyDict_Next(self->dict, &pos, &key, &value)) {
    long i = PyLong_AsLong(value);
    if (i == -1 && PyErr_Occurred()) {
        return -1;
    }
    PyObject *o = PyLong_FromLong(i + 1);
    if (o == NULL)
        return -1;
    if (PyDict_SetItem(self->dict, key, o) < 0) {
        Py_DECREF(o);
        return -1;
    }
    Py_DECREF(o);
}
```

`int PyDict_Merge(PyObject *a, PyObject *b, int override)`

Iterate over mapping object `b` adding key-value pairs to dictionary

a. *b* may be a dictionary, or any object supporting `PyMapping_Keys()` and `PyObject_GetItem()`. If *override* is true, existing pairs in *a* will be replaced if a matching key is found in *b*, otherwise pairs will only be added if there is not a matching key in *a*. Return 0 on success or -1 if an exception was raised.

int **PyDict_Update**(PyObject *a, PyObject *b)

This is the same as `PyDict_Merge(a, b, 1)` in C, or `a.update(b)` in Python. Return 0 on success or -1 if an exception was raised.

int **PyDict_MergeFromSeq2**(PyObject *a, PyObject *seq2, int *override*)

Update or merge into dictionary *a*, from the key-value pairs in *seq2*. *seq2* must be an iterable object producing iterable objects of length 2, viewed as key-value pairs. In case of duplicate keys, the last wins if *override* is true, else the first wins. Return 0 on success or -1 if an exception was raised. Equivalent Python (except for the return value):

```
def PyDict_MergeFromSeq2(a, seq2, override):
    for key, value in seq2:
        if override or key not in a:
            a[key] = value
```

Python v3.2 documentation » Python/C API Reference

Manual » Concrete Objects Layer »

Set Objects

This section details the public API for `set` and `frozenset` objects. Any functionality not listed below is best accessed using either the abstract object protocol (including `PyObject_CallMethod()`, `PyObject_RichCompareBool()`, `PyObject_Hash()`, `PyObject_Repr()`, `PyObject_IsTrue()`, `PyObject_Print()`, and `PyObject_GetIter()`) or the abstract number protocol (including `PyNumber_And()`, `PyNumber_Subtract()`, `PyNumber_Or()`, `PyNumber_Xor()`, `PyNumber_InPlaceAnd()`, `PyNumber_InPlaceSubtract()`, `PyNumber_InPlaceOr()`, and `PyNumber_InPlaceXor()`).

PySetObject

This subtype of `PyObject` is used to hold the internal data for both `set` and `frozenset` objects. It is like a `PyDictObject` in that it is a fixed size for small sets (much like tuple storage) and will point to a separate, variable sized block of memory for medium and large sized sets (much like list storage). None of the fields of this structure should be considered public and are subject to change. All access should be done through the documented API rather than by manipulating the values in the structure.

PyTypeObject PySet_Type

This is an instance of `PyTypeObject` representing the Python `set` type.

PyTypeObject PyFrozenSet_Type

This is an instance of `PyTypeObject` representing the Python `frozenset` type.

The following type check macros work on pointers to any Python object. Likewise, the constructor functions work with any iterable Python object.

`int PySet_Check(PyObject *p)`

Return true if *p* is a `set` object or an instance of a subtype.

`int PyFrozenSet_Check(PyObject *p)`

Return true if *p* is a `frozenset` object or an instance of a subtype.

`int PyAnySet_Check(PyObject *p)`

Return true if *p* is a `set` object, a `frozenset` object, or an instance of a subtype.

`int PyAnySet_CheckExact(PyObject *p)`

Return true if *p* is a `set` object or a `frozenset` object but not an instance of a subtype.

`int PyFrozenSet_CheckExact(PyObject *p)`

Return true if *p* is a `frozenset` object but not an instance of a subtype.

`PyObject* PySet_New(PyObject *iterable)`

Return value: New reference.

Return a new `set` containing objects returned by the *iterable*. The *iterable* may be `NULL` to create a new empty set. Return the new set on success or `NULL` on failure. Raise `TypeError` if *iterable* is not actually iterable. The constructor is also useful for copying a set (`c=set(s)`).

`PyObject* PyFrozenSet_New(PyObject *iterable)`

Return value: New reference.

Return a new `frozenset` containing objects returned by the *iterable*. The *iterable* may be `NULL` to create a new empty frozenset. Return the new set on success or `NULL` on failure. Raise `TypeError` if *iterable* is not actually iterable.

The following functions and macros are available for instances of `set` or `frozenset` or instances of their subtypes.

`Py_ssize_t PySet_Size(PyObject *anyset)`

Return the length of a `set` or `frozenset` object. Equivalent to `len(anyset)`. Raises a `PyExc_SystemError` if `anyset` is not a `set`, `frozenset`, or an instance of a subtype.

`Py_ssize_t PySet_GET_SIZE(PyObject *anyset)`

Macro form of `PySet_Size()` without error checking.

`int PySet_Contains(PyObject *anyset, PyObject *key)`

Return 1 if found, 0 if not found, and -1 if an error is encountered. Unlike the Python `__contains__()` method, this function does not automatically convert unhashable sets into temporary frozensets. Raise a `TypeError` if the `key` is unhashable. Raise `PyExc_SystemError` if `anyset` is not a `set`, `frozenset`, or an instance of a subtype.

`int PySet_Add(PyObject *set, PyObject *key)`

Add `key` to a `set` instance. Also works with `frozenset` instances (like `PyTuple_SetItem()` it can be used to fill-in the values of brand new frozensets before they are exposed to other code). Return 0 on success or -1 on failure. Raise a `TypeError` if the `key` is unhashable. Raise a `MemoryError` if there is no room to grow. Raise a `SystemError` if `set` is not an instance of `set` or its subtype.

The following functions are available for instances of `set` or its subtypes but not for instances of `frozenset` or its subtypes.

`int PySet_Discard(PyObject *set, PyObject *key)`

Return 1 if found and removed, 0 if not found (no action taken),

and -1 if an error is encountered. Does not raise `KeyError` for missing keys. Raise a `TypeError` if the `key` is unhashable. Unlike the Python `discard()` method, this function does not automatically convert unhashable sets into temporary frozensets. Raise `PyExc_SystemError` if `set` is not an instance of `set` or its subtype.

`PyObject*` **PySet_Pop**(`PyObject *set`)

Return value: New reference.

Return a new reference to an arbitrary object in the `set`, and removes the object from the `set`. Return `NULL` on failure. Raise `KeyError` if the set is empty. Raise a `SystemError` if `set` is not an instance of `set` or its subtype.

`int` **PySet_Clear**(`PyObject *set`)

Empty an existing set of all elements.

[Manual](#) » [Concrete Objects Layer](#) »

Function Objects

There are a few functions specific to Python functions.

PyFunctionObject

The C structure used for functions.

PyObject PyFunction_Type

This is an instance of **PyObject** and represents the Python function type. It is exposed to Python programmers as `types.FunctionType`.

int PyFunction_Check(PyObject *o)

Return true if `o` is a function object (has type **PyFunction_Type**). The parameter must not be `NULL`.

PyObject* PyFunction_New(PyObject *code, PyObject *globals)

Return value: New reference.

Return a new function object associated with the code object `code`. `globals` must be a dictionary with the global variables accessible to the function.

The function's docstring, name and `__module__` are retrieved from the code object, the argument defaults and closure are set to `NULL`.

PyObject* PyFunction_GetCode(PyObject *op)

Return value: Borrowed reference.

Return the code object associated with the function object `op`.

PyObject* PyFunction_GetGlobals(PyObject *op)

Return value: Borrowed reference.

Return the globals dictionary associated with the function object `op`.

`PyObject*` **PyFunction_GetModule**(`PyObject *op`)

Return value: Borrowed reference.

Return the `__module__` attribute of the function object `op`. This is normally a string containing the module name, but can be set to any other object by Python code.

`PyObject*` **PyFunction_GetDefaults**(`PyObject *op`)

Return value: Borrowed reference.

Return the argument default values of the function object `op`. This can be a tuple of arguments or `NULL`.

`int` **PyFunction_SetDefaults**(`PyObject *op`, `PyObject *defaults`)

Set the argument default values for the function object `op`. `defaults` must be `Py_None` or a tuple.

Raises `SystemError` and returns `-1` on failure.

`PyObject*` **PyFunction_GetClosure**(`PyObject *op`)

Return value: Borrowed reference.

Return the closure associated with the function object `op`. This can be `NULL` or a tuple of cell objects.

`int` **PyFunction_SetClosure**(`PyObject *op`, `PyObject *closure`)

Set the closure associated with the function object `op`. `closure` must be `Py_None` or a tuple of cell objects.

Raises `SystemError` and returns `-1` on failure.

`PyObject *`**PyFunction_GetAnnotations**(`PyObject *op`)

Return the annotations of the function object `op`. This can be a mutable dictionary or `NULL`.

`int` **PyFunction_SetAnnotations**(`PyObject *op`, `PyObject *annotations`)

Set the annotations for the function object `op`. `annotations` must

be a dictionary or *Py_None*.

Raises **SystemError** and returns `-1` on failure.

Instance Method Objects

An instance method is a wrapper for a `PyCFunction` and the new way to bind a `PyCFunction` to a class object. It replaces the former call `PyMethod_New(func, NULL, class)`.

`PyObject PyInstanceMethod_Type`

This instance of `PyObject` represents the Python instance method type. It is not exposed to Python programs.

`int PyInstanceMethod_Check(PyObject *o)`

Return true if `o` is an instance method object (has type `PyInstanceMethod_Type`). The parameter must not be `NULL`.

`PyObject* PyInstanceMethod_New(PyObject *func)`

Return a new instance method object, with `func` being any callable object `func` is the function that will be called when the instance method is called.

`PyObject* PyInstanceMethod_Function(PyObject *im)`

Return the function object associated with the instance method `im`.

`PyObject* PyInstanceMethod_GET_FUNCTION(PyObject *im)`

Macro version of `PyInstanceMethod_Function()` which avoids error checking.

Method Objects

Methods are bound function objects. Methods are always bound to an instance of an user-defined class. Unbound methods (methods bound to a class object) are no longer available.

`PyObject PyMethod_Type`

This instance of `PyObject` represents the Python method type. This is exposed to Python programs as `types.MethodType`.

`int PyMethod_Check(PyObject *o)`

Return true if `o` is a method object (has type `PyMethod_Type`). The parameter must not be `NULL`.

`PyObject* PyMethod_New(PyObject *func, PyObject *self)`

Return value: New reference.

Return a new method object, with `func` being any callable object and `self` the instance the method should be bound. `func` is the function that will be called when the method is called. `self` must not be `NULL`.

`PyObject* PyMethod_Function(PyObject *meth)`

Return value: Borrowed reference.

Return the function object associated with the method `meth`.

`PyObject* PyMethod_GET_FUNCTION(PyObject *meth)`

Return value: Borrowed reference.

Macro version of `PyMethod_Function()` which avoids error checking.

`PyObject* PyMethod_Self(PyObject *meth)`

Return value: Borrowed reference.

Return the instance associated with the method `meth`.

`PyObject*` **PyMethod_GET_SELF**(`PyObject` *meth)

Return value: Borrowed reference.

Macro version of `PyMethod_self()` which avoids error checking.

`int` **PyMethod_ClearFreeList**()

Clear the free list. Return the total number of freed items.

Python v3.2 documentation » Python/C API Reference

[previous](#) | [next](#) | [modules](#) | [index](#)

Manual » Concrete Objects Layer »

File Objects

These APIs are a minimal emulation of the Python 2 C API for built-in file objects, which used to rely on the buffered I/O (`FILE*`) support from the C standard library. In Python 3, files and streams use the new `io` module, which defines several layers over the low-level unbuffered I/O of the operating system. The functions described below are convenience C wrappers over these new APIs, and meant mostly for internal error reporting in the interpreter; third-party code is advised to access the `io` APIs instead.

PyFile_FromFd(int *fd*, char **name*, char **mode*, int *buffering*, char **encoding*, char **errors*, char **newline*, int *closefd*)

Create a Python file object from the file descriptor of an already opened file *fd*. The arguments *name*, *encoding*, *errors* and *newline* can be `NULL` to use the defaults; *buffering* can be `-1` to use the default. *name* is ignored and kept for backward compatibility. Return `NULL` on failure. For a more comprehensive description of the arguments, please refer to the `io.open()` function documentation.

Warning: Since Python streams have their own buffering layer, mixing them with OS-level file descriptors can produce various issues (such as unexpected ordering of data).

Changed in version 3.2: Ignore *name* attribute.

int **PyObject_AsFileDescriptor**(PyObject **p*)

Return the file descriptor associated with *p* as an `int`. If the object is an integer, its value is returned. If not, the object's `fileno()` method is called if it exists; the method must return an integer, which is returned as the file descriptor value. Sets an exception and returns `-1` on failure.

`PyObject*` **PyFile_GetLine**(`PyObject *`*p*, `int` *n*)

Return value: *New reference.*

Equivalent to `p.readline([n])`, this function reads one line from the object *p*. *p* may be a file object or any object with a `readline()` method. If *n* is `0`, exactly one line is read, regardless of the length of the line. If *n* is greater than `0`, no more than *n* bytes will be read from the file; a partial line can be returned. In both cases, an empty string is returned if the end of the file is reached immediately. If *n* is less than `0`, however, one line is read regardless of length, but `EOFError` is raised if the end of the file is reached immediately.

`int` **PyFile_WriteObject**(`PyObject *`*obj*, `PyObject *`*p*, `int` *flags*)

Write object *obj* to file object *p*. The only supported flag for *flags* is `Py_PRINT_RAW`; if given, the `str()` of the object is written instead of the `repr()`. Return `0` on success or `-1` on failure; the appropriate exception will be set.

`int` **PyFile_WriteString**(`const char *`*s*, `PyObject *`*p*)

Write string *s* to file object *p*. Return `0` on success or `-1` on failure; the appropriate exception will be set.

Module Objects

There are only a few functions special to module objects.

`PyObject` `PyModule_Type`

This instance of `PyObject` represents the Python module type. This is exposed to Python programs as `types.ModuleType`.

`int` `PyModule_Check(PyObject *p)`

Return true if `p` is a module object, or a subtype of a module object.

`int` `PyModule_CheckExact(PyObject *p)`

Return true if `p` is a module object, but not a subtype of `PyModule_Type`.

`PyObject*` `PyModule_New(const char *name)`

Return value: New reference.

Return a new module object with the `__name__` attribute set to `name`. Only the module's `__doc__` and `__name__` attributes are filled in; the caller is responsible for providing a `__file__` attribute.

`PyObject*` `PyModule_GetDict(PyObject *module)`

Return value: Borrowed reference.

Return the dictionary object that implements `module`'s namespace; this object is the same as the `__dict__` attribute of the module object. This function never fails. It is recommended extensions use other `PyModule_*`() and `PyObject_*`() functions rather than directly manipulate a module's `__dict__`.

`char*` `PyModule_GetName(PyObject *module)`

Return `module`'s `__name__` value. If the module does not provide

one, or if it is not a string, `SystemError` is raised and `NULL` is returned.

`char* PyModule_GetFilename(PyObject *module)`

Similar to `PyModule_GetFilenameObject()` but return the filename encoded to 'utf-8'.

Deprecated since version 3.2: `PyModule_GetFilename()` raises `UnicodeEncodeError` on unencodable filenames, use `PyModule_GetFilenameObject()` instead.

`PyObject* PyModule_GetFilenameObject(PyObject *module)`

Return the name of the file from which `module` was loaded using `module`'s `__file__` attribute. If this is not defined, or if it is not a unicode string, raise `SystemError` and return `NULL`; otherwise return a reference to a `PyUnicodeObject`.

New in version 3.2.

`void* PyModule_GetState(PyObject *module)`

Return the "state" of the module, that is, a pointer to the block of memory allocated at module creation time, or `NULL`. See `PyModuleDef.m_size`.

`PyModuleDef* PyModule_GetDef(PyObject *module)`

Return a pointer to the `PyModuleDef` struct from which the module was created, or `NULL` if the module wasn't created with `PyModule_Create()`.

Initializing C modules

These functions are usually used in the module initialization function.

PyObject* **PyModule_Create**(PyModuleDef **module*)

Create a new module object, given the definition in *module*. This behaves like **PyModule_Create2()** with *module_api_version* set to **PYTHON_API_VERSION**.

PyObject* **PyModule_Create2**(PyModuleDef **module*, int *module_api_version*)

Create a new module object, given the definition in *module*, assuming the API version *module_api_version*. If that version does not match the version of the running interpreter, a **RuntimeWarning** is emitted.

Note: Most uses of this function should be using **PyModule_Create()** instead; only use this if you are sure you need it.

PyModuleDef

This struct holds all information that is needed to create a module object. There is usually only one static variable of that type for each module, which is statically initialized and then passed to **PyModule_Create()** in the module initialization function.

PyModuleDef_Base **m_base**

Always initialize this member to **PyModuleDef_HEAD_INIT**.

char* **m_name**

Name for the new module.

char* **m_doc**

Docstring for the module; usually a docstring variable created with `PyDoc_STRVAR()` is used.

`Py_ssize_t m_size`

If the module object needs additional memory, this should be set to the number of bytes to allocate; a pointer to the block of memory can be retrieved with `PyModule_GetState()`. If no memory is needed, set this to `-1`.

This memory should be used, rather than static globals, to hold per-module state, since it is then safe for use in multiple sub-interpreters. It is freed when the module object is deallocated, after the `m_free` function has been called, if present.

`PyMethodDef* m_methods`

A pointer to a table of module-level functions, described by `PyMethodDef` values. Can be `NULL` if no functions are present.

`inquiry m_reload`

Currently unused, should be `NULL`.

`traverseproc m_traverse`

A traversal function to call during GC traversal of the module object, or `NULL` if not needed.

`inquiry m_clear`

A clear function to call during GC clearing of the module object, or `NULL` if not needed.

`freefunc m_free`

A function to call during deallocation of the module object, or `NULL` if not needed.

```
int PyModule_AddObject(PyObject *module, const char *name,
```

`PyObject *value)`

Add an object to *module* as *name*. This is a convenience function which can be used from the module's initialization function. This steals a reference to *value*. Return `-1` on error, `0` on success.

`int PyModule_AddIntConstant(PyObject *module, const char *name, long value)`

Add an integer constant to *module* as *name*. This convenience function can be used from the module's initialization function. Return `-1` on error, `0` on success.

`int PyModule_AddStringConstant(PyObject *module, const char *name, const char *value)`

Add a string constant to *module* as *name*. This convenience function can be used from the module's initialization function. The string *value* must be null-terminated. Return `-1` on error, `0` on success.

`int PyModule_AddIntMacro(PyObject *module, macro)`

Add an int constant to *module*. The name and the value are taken from *macro*. For example `PyModule_AddConstant(module, AF_INET)` adds the int constant `AF_INET` with the value of `AF_INET` to *module*. Return `-1` on error, `0` on success.

`int PyModule_AddStringMacro(PyObject *module, macro)`

Add a string constant to *module*.

Iterator Objects

Python provides two general-purpose iterator objects. The first, a sequence iterator, works with an arbitrary sequence supporting the `__getitem__()` method. The second works with a callable object and a sentinel value, calling the callable for each item in the sequence, and ending the iteration when the sentinel value is returned.

PyObject PySeqIter_Type

Type object for iterator objects returned by `PySeqIter_New()` and the one-argument form of the `iter()` built-in function for built-in sequence types.

`int PySeqIter_Check(op)`

Return true if the type of `op` is `PySeqIter_Type`.

`PyObject* PySeqIter_New(PyObject *seq)`

Return value: New reference.

Return an iterator that works with a general sequence object, `seq`. The iteration ends when the sequence raises `IndexError` for the subscripting operation.

PyObject PyCallIter_Type

Type object for iterator objects returned by `PyCallIter_New()` and the two-argument form of the `iter()` built-in function.

`int PyCallIter_Check(op)`

Return true if the type of `op` is `PyCallIter_Type`.

`PyObject* PyCallIter_New(PyObject *callable, PyObject *sentinel)`

Return value: New reference.

Return a new iterator. The first parameter, `callable`, can be any Python callable object that can be called with no parameters;

each call to it should return the next item in the iteration. When *callable* returns a value equal to *sentinel*, the iteration will be terminated.

Descriptor Objects

“Descriptors” are objects that describe some attribute of an object. They are found in the dictionary of type objects.

`PyTypeObject` **PyProperty_Type**

The type object for the built-in descriptor types.

`PyObject*` **PyDescr_NewGetSet**(`PyTypeObject` *type, struct `PyGetSetDef` *getset)

Return value: New reference.

`PyObject*` **PyDescr_NewMember**(`PyTypeObject` *type, struct `PyMemberDef` *meth)

Return value: New reference.

`PyObject*` **PyDescr_NewMethod**(`PyTypeObject` *type, struct `PyMethodDef` *meth)

Return value: New reference.

`PyObject*` **PyDescr_NewWrapper**(`PyTypeObject` *type, struct `wrapperbase` *wrapper, void *wrapped)

Return value: New reference.

`PyObject*` **PyDescr_NewClassMethod**(`PyTypeObject` *type, `PyMethodDef` *method)

Return value: New reference.

`int` **PyDescr_IsData**(`PyObject` *descr)

Return true if the descriptor objects *descr* describes a data attribute, or false if it describes a method. *descr* must be a descriptor object; there is no error checking.

`PyObject*` **PyWrapper_New**(`PyObject` *, `PyObject` *)

Return value: New reference.

 Python v3.2 documentation » Python/C API Reference [previous](#) | [next](#) | [modules](#) | [index](#)
Manual » Concrete Objects Layer »

Slice Objects

PyObject PySlice_Type

The type object for slice objects. This is the same as `slice` in the Python layer.

int PySlice_Check(PyObject *ob)

Return true if *ob* is a slice object; *ob* must not be *NULL*.

PyObject* PySlice_New(PyObject *start, PyObject *stop, PyObject *step)

Return value: New reference.

Return a new slice object with the given values. The *start*, *stop*, and *step* parameters are used as the values of the slice object attributes of the same names. Any of the values may be *NULL*, in which case the `None` will be used for the corresponding attribute. Return *NULL* if the new object could not be allocated.

int PySlice_GetIndices(PyObject *slice, Py_ssize_t length, Py_ssize_t *start, Py_ssize_t *stop, Py_ssize_t *step)

Retrieve the start, stop and step indices from the slice object *slice*, assuming a sequence of length *length*. Treats indices greater than *length* as errors.

Returns 0 on success and -1 on error with no exception set (unless one of the indices was not `None` and failed to be converted to an integer, in which case -1 is returned with an exception set).

You probably do not want to use this function.

Changed in version 3.2: The parameter type for the *slice* parameter was `PySliceObject*` before.

```
int PySlice_GetIndicesEx(PyObject *slice, Py_ssize_t length,
Py_ssize_t *start, Py_ssize_t *stop, Py_ssize_t *step, Py_ssize_t
*slicelength)
```

Usable replacement for `PySlice_GetIndices()`. Retrieve the start, stop, and step indices from the slice object `slice` assuming a sequence of length `length`, and store the length of the slice in `slicelength`. Out of bounds indices are clipped in a manner consistent with the handling of normal slices.

Returns 0 on success and -1 on error with exception set.

Changed in version 3.2: The parameter type for the `slice` parameter was `PySliceObject*` before.

MemoryView objects

A `memoryview` object exposes the C level *buffer interface* as a Python object which can then be passed around like any other object.

`PyObject *PyMemoryView_FromObject(PyObject *obj)`

Create a memoryview object from an object that provides the buffer interface. If *obj* supports writable buffer exports, the memoryview object will be readable and writable, other it will be read-only.

`PyObject *PyMemoryView_FromBuffer(Py_buffer *view)`

Create a memoryview object wrapping the given buffer structure *view*. The memoryview object then owns the buffer represented by *view*, which means you shouldn't try to call `PyBuffer_Release()` yourself: it will be done on deallocation of the memoryview object.

`PyObject *PyMemoryView_GetContiguous(PyObject *obj, int buffertype, char order)`

Create a memoryview object to a contiguous chunk of memory (in either 'C' or 'F'ortran *order*) from an object that defines the buffer interface. If memory is contiguous, the memoryview object points to the original memory. Otherwise copy is made and the memoryview points to a new bytes object.

`int PyMemoryView_Check(PyObject *obj)`

Return true if the object *obj* is a memoryview object. It is not currently allowed to create subclasses of `memoryview`.

`Py_buffer *PyMemoryView_GET_BUFFER(PyObject *obj)`

Return a pointer to the buffer structure wrapped by the given memoryview object. The object **must** be a memoryview instance;

this macro doesn't check its type, you must do it yourself or you will risk crashes.

 [Python v3.2 documentation](#) » [Python/C API Reference](#) [previous](#) | [next](#) | [modules](#) | [index](#)
[Manual](#) » [Concrete Objects Layer](#) »

Weak Reference Objects

Python supports *weak references* as first-class objects. There are two specific object types which directly implement weak references. The first is a simple reference object, and the second acts as a proxy for the original object as much as it can.

`int PyWeakref_Check(ob)`

Return true if *ob* is either a reference or proxy object.

`int PyWeakref_CheckRef(ob)`

Return true if *ob* is a reference object.

`int PyWeakref_CheckProxy(ob)`

Return true if *ob* is a proxy object.

`PyObject* PyWeakref_NewRef(PyObject *ob, PyObject *callback)`

Return value: New reference.

Return a weak reference object for the object *ob*. This will always return a new reference, but is not guaranteed to create a new object; an existing reference object may be returned. The second parameter, *callback*, can be a callable object that receives notification when *ob* is garbage collected; it should accept a single parameter, which will be the weak reference object itself. *callback* may also be `None` or `NULL`. If *ob* is not a weakly-referencable object, or if *callback* is not callable, `None`, or `NULL`, this will return `NULL` and raise `TypeError`.

`PyObject* PyWeakref_NewProxy(PyObject *ob, PyObject *callback)`

Return value: New reference.

Return a weak reference proxy object for the object *ob*. This will always return a new reference, but is not guaranteed to create a new object; an existing proxy object may be returned. The

second parameter, *callback*, can be a callable object that receives notification when *ob* is garbage collected; it should accept a single parameter, which will be the weak reference object itself. *callback* may also be `None` or `NULL`. If *ob* is not a weakly-referencable object, or if *callback* is not callable, `None`, or `NULL`, this will return `NULL` and raise `TypeError`.

`PyObject*` `PyWeakref_GetObject(PyObject *ref)`

Return value: Borrowed reference.

Return the referenced object from a weak reference, *ref*. If the referent is no longer live, returns `Py_None`.

Warning: This function returns a **borrowed reference** to the referenced object. This means that you should always call `Py_INCREF()` on the object except if you know that it cannot be destroyed while you are still using it.

`PyObject*` `PyWeakref_GET_OBJECT(PyObject *ref)`

Return value: Borrowed reference.

Similar to `PyWeakref_GetObject()`, but implemented as a macro that does no error checking.

Capsules

Refer to *Providing a C API for an Extension Module* for more information on using these objects.

PyCapsule

This subtype of `PyObject` represents an opaque value, useful for C extension modules who need to pass an opaque value (as a `void*` pointer) through Python code to other C code. It is often used to make a C function pointer defined in one module available to other modules, so the regular import mechanism can be used to access C APIs defined in dynamically loaded modules.

PyCapsule_Destructor

The type of a destructor callback for a capsule. Defined as:

```
typedef void (*PyCapsule_Destructor)(PyObject *);
```

See `PyCapsule_New()` for the semantics of `PyCapsule_Destructor` callbacks.

`int PyCapsule_CheckExact(PyObject *p)`

Return true if its argument is a `PyCapsule`.

`PyObject* PyCapsule_New(void *pointer, const char *name, PyCapsule_Destructor destructor)`

Return value: New reference.

Create a `PyCapsule` encapsulating the *pointer*. The *pointer* argument may not be `NULL`.

On failure, set an exception and return `NULL`.

The *name* string may either be `NULL` or a pointer to a valid C

string. If non-*NULL*, this string must outlive the capsule. (Though it is permitted to free it inside the *destructor*.)

If the *destructor* argument is not *NULL*, it will be called with the capsule as its argument when it is destroyed.

If this capsule will be stored as an attribute of a module, the *name* should be specified as `modulename.attributename`. This will enable other modules to import the capsule using `PyCapsule_Import()`.

```
void* PyCapsule_GetPointer(PyObject *capsule, const char *name)
```

Retrieve the *pointer* stored in the capsule. On failure, set an exception and return *NULL*.

The *name* parameter must compare exactly to the name stored in the capsule. If the name stored in the capsule is *NULL*, the *name* passed in must also be *NULL*. Python uses the C function `strcmp()` to compare capsule names.

```
PyCapsule_Destructor PyCapsule_GetDestructor(PyObject *capsule)
```

Return the current destructor stored in the capsule. On failure, set an exception and return *NULL*.

It is legal for a capsule to have a *NULL* destructor. This makes a *NULL* return code somewhat ambiguous; use `PyCapsule_IsValid()` or `PyErr_Occurred()` to disambiguate.

```
void* PyCapsule_GetContext(PyObject *capsule)
```

Return the current context stored in the capsule. On failure, set an exception and return *NULL*.

It is legal for a capsule to have a *NULL* context. This makes a

NULL return code somewhat ambiguous; use `PyCapsule_IsValid()` or `PyErr_Occurred()` to disambiguate.

`const char* PyCapsule_GetName(PyObject *capsule)`

Return the current name stored in the capsule. On failure, set an exception and return *NULL*.

It is legal for a capsule to have a *NULL* name. This makes a *NULL* return code somewhat ambiguous; use `PyCapsule_IsValid()` or `PyErr_Occurred()` to disambiguate.

`void* PyCapsule_Import(const char *name, int no_block)`

Import a pointer to a C object from a capsule attribute in a module. The *name* parameter should specify the full name to the attribute, as in `module.attribute`. The *name* stored in the capsule must match this string exactly. If *no_block* is true, import the module without blocking (using `PyImport_ImportModuleNoBlock()`). If *no_block* is false, import the module conventionally (using `PyImport_ImportModule()`).

Return the capsule's internal *pointer* on success. On failure, set an exception and return *NULL*. However, if `PyCapsule_Import()` failed to import the module, and *no_block* was true, no exception is set.

`int PyCapsule_IsValid(PyObject *capsule, const char *name)`

Determines whether or not *capsule* is a valid capsule. A valid capsule is non-*NULL*, passes `PyCapsule_CheckExact()`, has a non-*NULL* pointer stored in it, and its internal name matches the *name* parameter. (See `PyCapsule_GetPointer()` for information on how capsule names are compared.)

In other words, if `PyCapsule_IsValid()` returns a true value, calls to any of the accessors (any function starting with

`PyCapsule_Get()` are guaranteed to succeed.

Return a nonzero value if the object is valid and matches the name passed in. Return 0 otherwise. This function will not fail.

`int PyCapsule_SetContext(PyObject *capsule, void *context)`

Set the context pointer inside *capsule* to *context*.

Return 0 on success. Return nonzero and set an exception on failure.

`int PyCapsule_SetDestructor(PyObject *capsule, PyCapsule_Destructor destructor)`

Set the destructor inside *capsule* to *destructor*.

Return 0 on success. Return nonzero and set an exception on failure.

`int PyCapsule_SetName(PyObject *capsule, const char *name)`

Set the name inside *capsule* to *name*. If non-*NULL*, the name must outlive the capsule. If the previous *name* stored in the capsule was not *NULL*, no attempt is made to free it.

Return 0 on success. Return nonzero and set an exception on failure.

`int PyCapsule_SetPointer(PyObject *capsule, void *pointer)`

Set the void pointer inside *capsule* to *pointer*. The pointer may not be *NULL*.

Return 0 on success. Return nonzero and set an exception on failure.

Manual » Concrete Objects Layer »

Cell Objects

“Cell” objects are used to implement variables referenced by multiple scopes. For each such variable, a cell object is created to store the value; the local variables of each stack frame that references the value contains a reference to the cells from outer scopes which also use that variable. When the value is accessed, the value contained in the cell is used instead of the cell object itself. This de-referencing of the cell object requires support from the generated byte-code; these are not automatically de-referenced when accessed. Cell objects are not likely to be useful elsewhere.

PyObject PyCellObject

The C structure used for cell objects.

PyObject PyCell_Type

The type object corresponding to cell objects.

int PyCell_Check(PyObject *ob)

Return true if *ob* is a cell object; *ob* must not be *NULL*.

PyObject* PyCell_New(PyObject *ob)

Return value: New reference.

Create and return a new cell object containing the value *ob*. The parameter may be *NULL*.

PyObject* PyCell_Get(PyObject *cell)

Return value: New reference.

Return the contents of the cell *cell*.

PyObject* PyCell_GET(PyObject *cell)

Return value: Borrowed reference.

Return the contents of the cell *cell*, but without checking that *cell* is non-*NULL* and a cell object.

`int PyCell_Set(PyObject *cell, PyObject *value)`

Set the contents of the cell object *cell* to *value*. This releases the reference to any current content of the cell. *value* may be *NULL*. *cell* must be non-*NULL*; if it is not a cell object, `-1` will be returned. On success, `0` will be returned.

`void PyCell_SET(PyObject *cell, PyObject *value)`

Sets the value of the cell object *cell* to *value*. No reference counts are adjusted, and no checks are made for safety; *cell* must be non-*NULL* and must be a cell object.

Manual » Concrete Objects Layer »

Generator Objects

Generator objects are what Python uses to implement generator iterators. They are normally created by iterating over a function that yields values, rather than explicitly calling `PyGen_New()`.

PyGenObject

The C structure used for generator objects.

PyTypeObject PyGen_Type

The type object corresponding to generator objects

int PyGen_Check(ob)

Return true if *ob* is a generator object; *ob* must not be *NULL*.

int PyGen_CheckExact(ob)

Return true if *ob*'s type is *PyGen_Type* is a generator object; *ob* must not be *NULL*.

PyObject* PyGen_New(PyFrameObject *frame)

Return value: New reference.

Create and return a new generator object based on the *frame* object. A reference to *frame* is stolen by this function. The parameter must not be *NULL*.

Python v3.2 documentation » Python/C API Reference

[previous](#) | [next](#) | [modules](#) | [index](#)

[Manual](#) » [Concrete Objects Layer](#) »

DateTime Objects

Various date and time objects are supplied by the `datetime` module. Before using any of these functions, the header file `datetime.h` must be included in your source (note that this is not included by `Python.h`), and the macro `PyDateTime_IMPORT` must be invoked, usually as part of the module initialisation function. The macro puts a pointer to a C structure into a static variable, `PyDateTimeAPI`, that is used by the following macros.

Type-check macros:

`int PyDate_Check(PyObject *ob)`

Return true if *ob* is of type `PyDateTime_DateType` or a subtype of `PyDateTime_DateType`. *ob* must not be `NULL`.

`int PyDate_CheckExact(PyObject *ob)`

Return true if *ob* is of type `PyDateTime_DateType`. *ob* must not be `NULL`.

`int PyDateTime_Check(PyObject *ob)`

Return true if *ob* is of type `PyDateTime_DateTimeType` or a subtype of `PyDateTime_DateTimeType`. *ob* must not be `NULL`.

`int PyDateTime_CheckExact(PyObject *ob)`

Return true if *ob* is of type `PyDateTime_DateTimeType`. *ob* must not be `NULL`.

`int PyTime_Check(PyObject *ob)`

Return true if *ob* is of type `PyDateTime_TimeType` or a subtype of `PyDateTime_TimeType`. *ob* must not be `NULL`.

`int PyTime_CheckExact(PyObject *ob)`

Return true if *ob* is of type `PyDateTime_TimeType`. *ob* must not be `NULL`.

`int PyDelta_Check(PyObject *ob)`

Return true if *ob* is of type `PyDateTime_DeltaType` or a subtype of `PyDateTime_DeltaType`. *ob* must not be `NULL`.

`int PyDelta_CheckExact(PyObject *ob)`

Return true if *ob* is of type `PyDateTime_DeltaType`. *ob* must not be `NULL`.

`int PyTZInfo_Check(PyObject *ob)`

Return true if *ob* is of type `PyDateTime_TZInfoType` or a subtype of `PyDateTime_TZInfoType`. *ob* must not be `NULL`.

`int PyTZInfo_CheckExact(PyObject *ob)`

Return true if *ob* is of type `PyDateTime_TZInfoType`. *ob* must not be `NULL`.

Macros to create objects:

`PyObject* PyDate_FromDate(int year, int month, int day)`

Return value: New reference.

Return a `datetime.date` object with the specified year, month and day.

`PyObject* PyDateTime_FromDateAndTime(int year, int month, int day, int hour, int minute, int second, int usecond)`

Return value: New reference.

Return a `datetime.datetime` object with the specified year, month, day, hour, minute, second and microsecond.

`PyObject* PyTime_FromTime(int hour, int minute, int second, int usecond)`

Return value: New reference.

Return a `datetime.time` object with the specified hour, minute, second and microsecond.

PyObject* **PyDelta_FromDSU**(int *days*, int *seconds*, int *useconds*)

Return value: New reference.

Return a `datetime.timedelta` object representing the given number of days, seconds and microseconds. Normalization is performed so that the resulting number of microseconds and seconds lie in the ranges documented for `datetime.timedelta` objects.

Macros to extract fields from date objects. The argument must be an instance of `PyDateTime_Date`, including subclasses (such as `PyDateTime_DateTime`). The argument must not be *NULL*, and the type is not checked:

int **PyDateTime_GET_YEAR**(PyDateTime_Date *o)

Return the year, as a positive int.

int **PyDateTime_GET_MONTH**(PyDateTime_Date *o)

Return the month, as an int from 1 through 12.

int **PyDateTime_GET_DAY**(PyDateTime_Date *o)

Return the day, as an int from 1 through 31.

Macros to extract fields from datetime objects. The argument must be an instance of `PyDateTime_DateTime`, including subclasses. The argument must not be *NULL*, and the type is not checked:

int **PyDateTime_DATE_GET_HOUR**(PyDateTime_DateTime *o)

Return the hour, as an int from 0 through 23.

int **PyDateTime_DATE_GET_MINUTE**(PyDateTime_DateTime *o)

Return the minute, as an int from 0 through 59.

`int PyDateTime_DATE_GET_SECOND(PyDateTime_DateTime *o)`

Return the second, as an int from 0 through 59.

`int PyDateTime_DATE_GET_MICROSECOND(PyDateTime_DateTime *o)`

Return the microsecond, as an int from 0 through 999999.

Macros to extract fields from time objects. The argument must be an instance of `PyDateTime_Time`, including subclasses. The argument must not be `NULL`, and the type is not checked:

`int PyDateTime_TIME_GET_HOUR(PyDateTime_Time *o)`

Return the hour, as an int from 0 through 23.

`int PyDateTime_TIME_GET_MINUTE(PyDateTime_Time *o)`

Return the minute, as an int from 0 through 59.

`int PyDateTime_TIME_GET_SECOND(PyDateTime_Time *o)`

Return the second, as an int from 0 through 59.

`int PyDateTime_TIME_GET_MICROSECOND(PyDateTime_Time *o)`

Return the microsecond, as an int from 0 through 999999.

Macros for the convenience of modules implementing the DB API:

`PyObject* PyDateTime_FromTimestamp(PyObject *args)`

Return value: New reference.

Create and return a new `datetime.datetime` object given an argument tuple suitable for passing to `datetime.datetime.fromtimestamp()`.

`PyObject* PyDate_FromTimestamp(PyObject *args)`

Return value: New reference.

Create and return a new `datetime.date` object given an argument

tuple suitable for passing to `datetime.date.fromtimestamp()`.

Code Objects

Code objects are a low-level detail of the CPython implementation. Each one represents a chunk of executable code that hasn't yet been bound into a function.

PyCodeObject

The C structure of the objects used to describe code objects. The fields of this type are subject to change at any time.

PyTypeObject PyCode_Type

This is an instance of **PyTypeObject** representing the Python **code** type.

int PyCode_Check(PyObject *co)

Return true if *co* is a **code** object

int PyCode_GetNumFree(PyObject *co)

Return the number of free variables in *co*.

PyCodeObject *PyCode_New(int argcount, int nlocals, int stacksize, int flags, PyObject *code, PyObject *consts, PyObject *names, PyObject *varnames, PyObject *freevars, PyObject *cellvars, PyObject *filename, PyObject *name, int firstlineno, PyObject *notab)

Return a new code object. If you need a dummy code object to create a frame, use **PyCode_NewEmpty()** instead. Calling **PyCode_New()** directly can bind you to a precise Python version since the definition of the bytecode changes often.

int PyCode_NewEmpty(const char *filename, const char *funcname, int firstlineno)

Return a new empty code object with the specified filename, function name, and first line number. It is illegal to **exec()** or

`eval()` the resulting code object.

Initialization, Finalization, and Threads

Initializing and finalizing the interpreter

void **Py_Initialize()**

Initialize the Python interpreter. In an application embedding Python, this should be called before using any other Python/C API functions; with the exception of **Py_SetProgramName()**, **Py_SetPath()**, and **PyEval_InitThreads()**. This initializes the table of loaded modules (`sys.modules`), and creates the fundamental modules `builtins`, `__main__` and `sys`. It also initializes the module search path (`sys.path`). It does not set `sys.argv`; use **PySys_SetArgvEx()** for that. This is a no-op when called for a second time (without calling **Py_Finalize()** first). There is no return value; it is a fatal error if the initialization fails.

void **Py_InitializeEx(int initsigs)**

This function works like **Py_Initialize()** if *initsigs* is 1. If *initsigs* is 0, it skips initialization registration of signal handlers, which might be useful when Python is embedded.

int **Py_IsInitialized()**

Return true (nonzero) when the Python interpreter has been initialized, false (zero) if not. After **Py_Finalize()** is called, this returns false until **Py_Initialize()** is called again.

void **Py_Finalize()**

Undo all initializations made by **Py_Initialize()** and subsequent use of Python/C API functions, and destroy all sub-interpreters (see **Py_NewInterpreter()** below) that were created and not yet destroyed since the last call to **Py_Initialize()**. Ideally, this frees all memory allocated by the Python interpreter. This is a no-op when called for a second time (without calling **Py_Initialize()**

again first). There is no return value; errors during finalization are ignored.

This function is provided for a number of reasons. An embedding application might want to restart Python without having to restart the application itself. An application that has loaded the Python interpreter from a dynamically loadable library (or DLL) might want to free all memory allocated by Python before unloading the DLL. During a hunt for memory leaks in an application a developer might want to free all memory allocated by Python before exiting from the application.

Bugs and caveats: The destruction of modules and objects in modules is done in random order; this may cause destructors (`__del__()` methods) to fail when they depend on other objects (even functions) or modules. Dynamically loaded extension modules loaded by Python are not unloaded. Small amounts of memory allocated by the Python interpreter may not be freed (if you find a leak, please report it). Memory tied up in circular references between objects is not freed. Some memory allocated by extension modules may not be freed. Some extensions may not work properly if their initialization routine is called more than once; this can happen if an application calls `Py_Initialize()` and `Py_Finalize()` more than once.

Process-wide parameters

`void Py_SetProgramName(wchar_t *name)`

This function should be called before `Py_Initialize()` is called for the first time, if it is called at all. It tells the interpreter the value of the `argv[0]` argument to the `main()` function of the program (converted to wide characters). This is used by `Py_GetPath()` and some other functions below to find the Python run-time libraries relative to the interpreter executable. The default value is `'python'`. The argument should point to a zero-terminated wide character string in static storage whose contents will not change for the duration of the program's execution. No code in the Python interpreter will change the contents of this storage.

`wchar* Py_GetProgramName()`

Return the program name set with `Py_SetProgramName()`, or the default. The returned string points into static storage; the caller should not modify its value.

`wchar_t* Py_GetPrefix()`

Return the *prefix* for installed platform-independent files. This is derived through a number of complicated rules from the program name set with `Py_SetProgramName()` and some environment variables; for example, if the program name is `'/usr/local/bin/python'`, the prefix is `'/usr/local'`. The returned string points into static storage; the caller should not modify its value. This corresponds to the `prefix` variable in the top-level `Makefile` and the `--prefix` argument to the `configure` script at build time. The value is available to Python code as `sys.prefix`. It is only useful on Unix. See also the next function.

`wchar_t* Py_GetExecPrefix()`

Return the *exec-prefix* for installed platform-*dependent* files. This is derived through a number of complicated rules from the program name set with `Py_SetProgramName()` and some environment variables; for example, if the program name is `'/usr/local/bin/python'`, the *exec-prefix* is `'/usr/local'`. The returned string points into static storage; the caller should not modify its value. This corresponds to the **exec_prefix** variable in the top-level `Makefile` and the `--exec-prefix` argument to the **configure** script at build time. The value is available to Python code as `sys.exec_prefix`. It is only useful on Unix.

Background: The *exec-prefix* differs from the *prefix* when platform dependent files (such as executables and shared libraries) are installed in a different directory tree. In a typical installation, platform dependent files may be installed in the `/usr/local/plat` subtree while platform independent may be installed in `/usr/local`.

Generally speaking, a platform is a combination of hardware and software families, e.g. Sparc machines running the Solaris 2.x operating system are considered the same platform, but Intel machines running Solaris 2.x are another platform, and Intel machines running Linux are yet another platform. Different major revisions of the same operating system generally also form different platforms. Non-Unix operating systems are a different story; the installation strategies on those systems are so different that the *prefix* and *exec-prefix* are meaningless, and set to the empty string. Note that compiled Python bytecode files are platform independent (but not independent from the Python version by which they were compiled!).

System administrators will know how to configure the **mount** or **automount** programs to share `/usr/local` between platforms while having `/usr/local/plat` be a different filesystem for each

platform.

wchar_t* **Py_GetProgramFullPath()**

Return the full program name of the Python executable; this is computed as a side-effect of deriving the default module search path from the program name (set by **Py_SetProgramName()** above). The returned string points into static storage; the caller should not modify its value. The value is available to Python code as `sys.executable`.

wchar_t* **Py_GetPath()**

Return the default module search path; this is computed from the program name (set by **Py_SetProgramName()** above) and some environment variables. The returned string consists of a series of directory names separated by a platform dependent delimiter character. The delimiter character is ':' on Unix and Mac OS X, ';' on Windows. The returned string points into static storage; the caller should not modify its value. The list `sys.path` is initialized with this value on interpreter startup; it can be (and usually is) modified later to change the search path for loading modules.

void **Py_SetPath(const wchar_t *)**

Set the default module search path. If this function is called before **Py_Initialize()**, then **Py_GetPath()** won't attempt to compute a default search path but uses the one provided instead. This is useful if Python is embedded by an application that has full knowledge of the location of all modules. The path components should be separated by semicolons.

This also causes `sys.executable` to be set only to the raw program name (see **Py_SetProgramName()**) and for `sys.prefix` and `sys.exec_prefix` to be empty. It is up to the caller to modify

these if required after calling `Py_Initialize()`.

`const char* Py_GetVersion()`

Return the version of this Python interpreter. This is a string that looks something like

```
"3.0a5+ (py3k:63103M, May 12 2008, 00:53:55) \n[GCC 4.2.3]"
```

The first word (up to the first space character) is the current Python version; the first three characters are the major and minor version separated by a period. The returned string points into static storage; the caller should not modify its value. The value is available to Python code as `sys.version`.

`const char* Py_GetPlatform()`

Return the platform identifier for the current platform. On Unix, this is formed from the “official” name of the operating system, converted to lower case, followed by the major revision number; e.g., for Solaris 2.x, which is also known as SunOS 5.x, the value is `'sunos5'`. On Mac OS X, it is `'darwin'`. On Windows, it is `'win'`. The returned string points into static storage; the caller should not modify its value. The value is available to Python code as `sys.platform`.

`const char* Py_GetCopyright()`

Return the official copyright string for the current Python version, for example

```
'Copyright 1991-1995 Stichting Mathematisch Centrum,  
Amsterdam'
```

The returned string points into static storage; the caller should not modify its value. The value is available to Python code as `sys.copyright`.

`const char* Py_GetCompiler()`

Return an indication of the compiler used to build the current Python version, in square brackets, for example:

```
"[GCC 2.7.2.2]"
```

The returned string points into static storage; the caller should not modify its value. The value is available to Python code as part of the variable `sys.version`.

`const char* Py_BuildInfo()`

Return information about the sequence number and build date and time of the current Python interpreter instance, for example

```
"#67, Aug 1 1997, 22:34:28"
```

The returned string points into static storage; the caller should not modify its value. The value is available to Python code as part of the variable `sys.version`.

`void PySys_SetArgvEx(int argc, wchar_t **argv, int updatepath)`

Set `sys.argv` based on `argc` and `argv`. These parameters are similar to those passed to the program's `main()` function with the difference that the first entry should refer to the script file to be executed rather than the executable hosting the Python interpreter. If there isn't a script that will be run, the first entry in `argv` can be an empty string. If this function fails to initialize `sys.argv`, a fatal condition is signalled using `Py_FatalError()`.

If `updatepath` is zero, this is all the function does. If `updatepath` is non-zero, the function also modifies `sys.path` according to the following algorithm:

- If the name of an existing script is passed in `argv[0]`, the absolute path of the directory where the script is located is

prepended to `sys.path`.

- Otherwise (that is, if `argc` is 0 or `argv[0]` doesn't point to an existing file name), an empty string is prepended to `sys.path`, which is the same as prepending the current working directory (`"."`).

Note: It is recommended that applications embedding the Python interpreter for purposes other than executing a single script pass 0 as `updatepath`, and update `sys.path` themselves if desired. See [CVE-2008-5983](#).

On versions before 3.1.3, you can achieve the same effect by manually popping the first `sys.path` element after having called `PySys_SetArgv()`, for example using:

```
PyRun_SimpleString("import sys; sys.path.pop(0)\n");
```

New in version 3.1.3.

`void PySys_SetArgv(int argc, wchar_t **argv)`

This function works like `PySys_SetArgvEx()` with `updatepath` set to 1.

`void Py_SetPythonHome(wchar_t *home)`

Set the default “home” directory, that is, the location of the standard Python libraries. See `PYTHONHOME` for the meaning of the argument string.

The argument should point to a zero-terminated character string in static storage whose contents will not change for the duration of the program's execution. No code in the Python interpreter will change the contents of this storage.

`w_char* Py_GetPythonHome()`

Return the default “home”, that is, the value set by a previous call

to `Py_SetPythonHome()`, or the value of the `PYTHONHOME` environment variable if it is set.

Thread State and the Global Interpreter Lock

The Python interpreter is not fully thread-safe. In order to support multi-threaded Python programs, there's a global lock, called the *global interpreter lock* or *GIL*, that must be held by the current thread before it can safely access Python objects. Without the lock, even the simplest operations could cause problems in a multi-threaded program: for example, when two threads simultaneously increment the reference count of the same object, the reference count could end up being incremented only once instead of twice.

Therefore, the rule exists that only the thread that has acquired the *GIL* may operate on Python objects or call Python/C API functions. In order to emulate concurrency of execution, the interpreter regularly tries to switch threads (see `sys.setswitchinterval()`). The lock is also released around potentially blocking I/O operations like reading or writing a file, so that other Python threads can run in the meantime.

The Python interpreter keeps some thread-specific bookkeeping information inside a data structure called `PyThreadState`. There's also one global variable pointing to the current `PyThreadState`: it can be retrieved using `PyThreadState_Get()`.

Releasing the GIL from extension code

Most extension code manipulating the *GIL* has the following simple structure:

```
Save the thread state in a local variable.  
Release the global interpreter lock.  
... Do some blocking I/O operation ...
```

```
Reacquire the global interpreter lock.  
Restore the thread state from the local variable.
```

This is so common that a pair of macros exists to simplify it:

```
Py_BEGIN_ALLOW_THREADS  
... Do some blocking I/O operation ...  
Py_END_ALLOW_THREADS
```

The `Py_BEGIN_ALLOW_THREADS` macro opens a new block and declares a hidden local variable; the `Py_END_ALLOW_THREADS` macro closes the block. These two macros are still available when Python is compiled without thread support (they simply have an empty expansion).

When thread support is enabled, the block above expands to the following code:

```
PyThreadState *_save;  
  
_save = PyEval_SaveThread();  
...Do some blocking I/O operation...  
PyEval_RestoreThread(_save);
```

Here is how these functions work: the global interpreter lock is used to protect the pointer to the current thread state. When releasing the lock and saving the thread state, the current thread state pointer must be retrieved before the lock is released (since another thread could immediately acquire the lock and store its own thread state in the global variable). Conversely, when acquiring the lock and restoring the thread state, the lock must be acquired before storing the thread state pointer.

Note: Calling system I/O functions is the most common use case for releasing the GIL, but it can also be useful before calling long-running computations which don't need access to Python objects, such as compression or cryptographic functions operating over memory buffers. For example, the standard `zlib` and `hashlib`

modules release the GIL when compressing or hashing data.

Non-Python created threads

When threads are created using the dedicated Python APIs (such as the `threading` module), a thread state is automatically associated to them and the code showed above is therefore correct. However, when threads are created from C (for example by a third-party library with its own thread management), they don't hold the GIL, nor is there a thread state structure for them.

If you need to call Python code from these threads (often this will be part of a callback API provided by the aforementioned third-party library), you must first register these threads with the interpreter by creating a thread state data structure, then acquiring the GIL, and finally storing their thread state pointer, before you can start using the Python/C API. When you are done, you should reset the thread state pointer, release the GIL, and finally free the thread state data structure.

The `PyGILState_Ensure()` and `PyGILState_Release()` functions do all of the above automatically. The typical idiom for calling into Python from a C thread is:

```
PyGILState_STATE gstate;
gstate = PyGILState_Ensure();

/* Perform Python actions here. */
result = CallSomeFunction();
/* evaluate result or handle exception */

/* Release the thread. No Python API allowed beyond this point.
PyGILState_Release(gstate);
```

Note that the `PyGILState_*` functions assume there is only one global interpreter (created automatically by `Py_Initialize()`). Python

supports the creation of additional interpreters (using `Py_NewInterpreter()`), but mixing multiple interpreters and the `PyGILState_*` API is unsupported.

Another important thing to note about threads is their behaviour in the face of the C `fork()` call. On most systems with `fork()`, after a process forks only the thread that issued the fork will exist. That also means any locks held by other threads will never be released. Python solves this for `os.fork()` by acquiring the locks it uses internally before the fork, and releasing them afterwards. In addition, it resets any *Lock Objects* in the child. When extending or embedding Python, there is no way to inform Python of additional (non-Python) locks that need to be acquired before or reset after a fork. OS facilities such as `posix_atfork()` would need to be used to accomplish the same thing. Additionally, when extending or embedding Python, calling `fork()` directly rather than through `os.fork()` (and returning to or calling into Python) may result in a deadlock by one of Python's internal locks being held by a thread that is defunct after the fork. `PyOS_AfterFork()` tries to reset the necessary locks, but is not always able to.

High-level API

These are the most commonly used types and functions when writing C extension code, or when embedding the Python interpreter:

PyInterpreterState

This data structure represents the state shared by a number of cooperating threads. Threads belonging to the same interpreter share their module administration and a few other internal items. There are no public members in this structure.

Threads belonging to different interpreters initially share nothing, except process state like available memory, open file descriptors

and such. The global interpreter lock is also shared by all threads, regardless of to which interpreter they belong.

PyThreadState

This data structure represents the state of a single thread. The only public data member is `PyInterpreterState *interp`, which points to this thread's interpreter state.

void PyEval_InitThreads()

Initialize and acquire the global interpreter lock. It should be called in the main thread before creating a second thread or engaging in any other thread operations such as `PyEval_ReleaseThread(tstate)`. It is not needed before calling `PyEval_SaveThread()` or `PyEval_RestoreThread()`.

This is a no-op when called for a second time. It is safe to call this function before calling `Py_Initialize()`.

Note: When only the main thread exists, no GIL operations are needed. This is a common situation (most Python programs do not use threads), and the lock operations slow the interpreter down a bit. Therefore, the lock is not created initially. This situation is equivalent to having acquired the lock: when there is only a single thread, all object accesses are safe. Therefore, when this function initializes the global interpreter lock, it also acquires it. Before the Python `_thread` module creates a new thread, knowing that either it has the lock or the lock hasn't been created yet, it calls `PyEval_InitThreads()`. When this call returns, it is guaranteed that the lock has been created and that the calling thread has acquired it. It is **not** safe to call this function when it is unknown which thread (if any) currently has the global interpreter lock. This function is not available when thread support is disabled at compile time.

int PyEval_ThreadsInitialized()

Returns a non-zero value if `PyEval_InitThreads()` has been called. This function can be called without holding the GIL, and therefore can be used to avoid calls to the locking API when running single-threaded. This function is not available when thread support is disabled at compile time.

PyThreadState* PyEval_SaveThread()

Release the global interpreter lock (if it has been created and thread support is enabled) and reset the thread state to `NULL`, returning the previous thread state (which is not `NULL`). If the lock has been created, the current thread must have acquired it. (This function is available even when thread support is disabled at compile time.)

void PyEval_RestoreThread(PyThreadState *tstate)

Acquire the global interpreter lock (if it has been created and thread support is enabled) and set the thread state to `tstate`, which must not be `NULL`. If the lock has been created, the current thread must not have acquired it, otherwise deadlock ensues. (This function is available even when thread support is disabled at compile time.)

PyThreadState* PyThreadState_Get()

Return the current thread state. The global interpreter lock must be held. When the current thread state is `NULL`, this issues a fatal error (so that the caller needn't check for `NULL`).

PyThreadState* PyThreadState_Swap(PyThreadState *tstate)

Swap the current thread state with the thread state given by the argument `tstate`, which may be `NULL`. The global interpreter lock must be held and is not released.

void PyEval_ReInitThreads()

This function is called from `PyOS_AfterFork()` to ensure that newly created child processes don't hold locks referring to threads which are not running in the child process.

The following functions use thread-local storage, and are not compatible with sub-interpreters:

PyGILState_STATE PyGILState_Ensure()

Ensure that the current thread is ready to call the Python C API regardless of the current state of Python, or of the global interpreter lock. This may be called as many times as desired by a thread as long as each call is matched with a call to `PyGILState_Release()`. In general, other thread-related APIs may be used between `PyGILState_Ensure()` and `PyGILState_Release()` calls as long as the thread state is restored to its previous state before the `Release()`. For example, normal usage of the `Py_BEGIN_ALLOW_THREADS` and `Py_END_ALLOW_THREADS` macros is acceptable.

The return value is an opaque "handle" to the thread state when `PyGILState_Ensure()` was called, and must be passed to `PyGILState_Release()` to ensure Python is left in the same state. Even though recursive calls are allowed, these handles *cannot* be shared - each unique call to `PyGILState_Ensure()` must save the handle for its call to `PyGILState_Release()`.

When the function returns, the current thread will hold the GIL and be able to call arbitrary Python code. Failure is a fatal error.

void PyGILState_Release(PyGILState_STATE)

Release any resources previously acquired. After this call, Python's state will be the same as it was prior to the corresponding `PyGILState_Ensure()` call (but generally this state

will be unknown to the caller, hence the use of the GILState API).

Every call to `PyGILState_Ensure()` must be matched by a call to `PyGILState_Release()` on the same thread.

The following macros are normally used without a trailing semicolon; look for example usage in the Python source distribution.

Py_BEGIN_ALLOW_THREADS

This macro expands to `{ PyThreadState *_save; _save = PyEval_SaveThread();`. Note that it contains an opening brace; it must be matched with a following `Py_END_ALLOW_THREADS` macro. See above for further discussion of this macro. It is a no-op when thread support is disabled at compile time.

Py_END_ALLOW_THREADS

This macro expands to `PyEval_RestoreThread(_save); }`. Note that it contains a closing brace; it must be matched with an earlier `Py_BEGIN_ALLOW_THREADS` macro. See above for further discussion of this macro. It is a no-op when thread support is disabled at compile time.

Py_BLOCK_THREADS

This macro expands to `PyEval_RestoreThread(_save);`: it is equivalent to `Py_END_ALLOW_THREADS` without the closing brace. It is a no-op when thread support is disabled at compile time.

Py_UNBLOCK_THREADS

This macro expands to `_save = PyEval_SaveThread();`: it is equivalent to `Py_BEGIN_ALLOW_THREADS` without the opening brace and variable declaration. It is a no-op when thread support is disabled at compile time.

Low-level API

All of the following functions are only available when thread support is enabled at compile time, and must be called only when the global interpreter lock has been created.

PyInterpreterState* **PyInterpreterState_New()**

Create a new interpreter state object. The global interpreter lock need not be held, but may be held if it is necessary to serialize calls to this function.

void PyInterpreterState_Clear(PyInterpreterState *interp)

Reset all information in an interpreter state object. The global interpreter lock must be held.

void PyInterpreterState_Delete(PyInterpreterState *interp)

Destroy an interpreter state object. The global interpreter lock need not be held. The interpreter state must have been reset with a previous call to **PyInterpreterState_Clear()**.

PyThreadState* **PyThreadState_New(PyInterpreterState *interp)**

Create a new thread state object belonging to the given interpreter object. The global interpreter lock need not be held, but may be held if it is necessary to serialize calls to this function.

void PyThreadState_Clear(PyThreadState *tstate)

Reset all information in a thread state object. The global interpreter lock must be held.

void PyThreadState_Delete(PyThreadState *tstate)

Destroy a thread state object. The global interpreter lock need not be held. The thread state must have been reset with a previous call to **PyThreadState_Clear()**.

PyObject* **PyThreadState_GetDict()**

Return value: Borrowed reference.

Return a dictionary in which extensions can store thread-specific state information. Each extension should use a unique key to use to store state in the dictionary. It is okay to call this function when no current thread state is available. If this function returns *NULL*, no exception has been raised and the caller should assume no current thread state is available.

int PyThreadState_SetAsyncExc(long *id*, PyObject **exc*)

Asynchronously raise an exception in a thread. The *id* argument is the thread id of the target thread; *exc* is the exception object to be raised. This function does not steal any references to *exc*. To prevent naive misuse, you must write your own C extension to call this. Must be called with the GIL held. Returns the number of thread states modified; this is normally one, but will be zero if the thread id isn't found. If *exc* is **NULL**, the pending exception (if any) for the thread is cleared. This raises no exceptions.

void PyEval_AcquireThread(PyThreadState **tstate*)

Acquire the global interpreter lock and set the current thread state to *tstate*, which should not be *NULL*. The lock must have been created earlier. If this thread already has the lock, deadlock ensues.

PyEval_RestoreThread() is a higher-level function which is always available (even when thread support isn't enabled or when threads have not been initialized).

void PyEval_ReleaseThread(PyThreadState **tstate*)

Reset the current thread state to *NULL* and release the global interpreter lock. The lock must have been created earlier and must be held by the current thread. The *tstate* argument, which must not be *NULL*, is only used to check that it represents the current thread state — if it isn't, a fatal error is reported.

`PyEval_SaveThread()` is a higher-level function which is always available (even when thread support isn't enabled or when threads have not been initialized).

void `PyEval_AcquireLock()`

Acquire the global interpreter lock. The lock must have been created earlier. If this thread already has the lock, a deadlock ensues.

Deprecated since version 3.2: This function does not update the current thread state. Please use `PyEval_RestoreThread()` or `PyEval_AcquireThread()` instead.

void `PyEval_ReleaseLock()`

Release the global interpreter lock. The lock must have been created earlier.

Deprecated since version 3.2: This function does not update the current thread state. Please use `PyEval_SaveThread()` or `PyEval_ReleaseThread()` instead.

Sub-interpreter support

While in most uses, you will only embed a single Python interpreter, there are cases where you need to create several independent interpreters in the same process and perhaps even in the same thread. Sub-interpreters allow you to do that. You can switch between sub-interpreters using the `PyThreadState_Swap()` function. You can create and destroy them using the following functions:

`PyThreadState*` `Py_NewInterpreter()`

Create a new sub-interpreter. This is an (almost) totally separate environment for the execution of Python code. In particular, the new interpreter has separate, independent versions of all imported modules, including the fundamental modules `builtins`, `__main__` and `sys`. The table of loaded modules (`sys.modules`) and the module search path (`sys.path`) are also separate. The new environment has no `sys.argv` variable. It has new standard I/O stream file objects `sys.stdin`, `sys.stdout` and `sys.stderr` (however these refer to the same underlying file descriptors).

The return value points to the first thread state created in the new sub-interpreter. This thread state is made in the current thread state. Note that no actual thread is created; see the discussion of thread states below. If creation of the new interpreter is unsuccessful, `NULL` is returned; no exception is set since the exception state is stored in the current thread state and there may not be a current thread state. (Like all other Python/C API functions, the global interpreter lock must be held before calling this function and is still held when it returns; however, unlike most other Python/C API functions, there needn't be a current thread state on entry.)

Extension modules are shared between (sub-)interpreters as

follows: the first time a particular extension is imported, it is initialized normally, and a (shallow) copy of its module's dictionary is squirreled away. When the same extension is imported by another (sub-)interpreter, a new module is initialized and filled with the contents of this copy; the extension's `init` function is not called. Note that this is different from what happens when an extension is imported after the interpreter has been completely re-initialized by calling `Py_Finalize()` and `Py_Initialize()`; in that case, the extension's `inittestmodule` function *is* called again.

void Py_EndInterpreter(PyThreadState *tstate)

Destroy the (sub-)interpreter represented by the given thread state. The given thread state must be the current thread state. See the discussion of thread states below. When the call returns, the current thread state is `NULL`. All thread states associated with this interpreter are destroyed. (The global interpreter lock must be held before calling this function and is still held when it returns.) `Py_Finalize()` will destroy all sub-interpreters that haven't been explicitly destroyed at that point.

Bugs and caveats

Because sub-interpreters (and the main interpreter) are part of the same process, the insulation between them isn't perfect — for example, using low-level file operations like `os.close()` they can (accidentally or maliciously) affect each other's open files. Because of the way extensions are shared between (sub-)interpreters, some extensions may not work properly; this is especially likely when the extension makes use of (static) global variables, or when the extension manipulates its module's dictionary after its initialization. It is possible to insert objects created in one sub-interpreter into a namespace of another sub-interpreter; this should be done with great care to avoid sharing user-defined functions, methods,

instances or classes between sub-interpreters, since import operations executed by such objects may affect the wrong (sub-)interpreter's dictionary of loaded modules.

Also note that combining this functionality with `PyGILState_*` APIs is delicate, because these APIs assume a bijection between Python thread states and OS-level threads, an assumption broken by the presence of sub-interpreters. It is highly recommended that you don't switch sub-interpreters between a pair of matching `PyGILState_Ensure()` and `PyGILState_Release()` calls. Furthermore, extensions (such as `ctypes`) using these APIs to allow calling of Python code from non-Python created threads will probably be broken when using sub-interpreters.

Asynchronous Notifications

A mechanism is provided to make asynchronous notifications to the main interpreter thread. These notifications take the form of a function pointer and a void argument.

Every check interval, when the global interpreter lock is released and reacquired, Python will also call any such provided functions. This can be used for example by asynchronous IO handlers. The notification can be scheduled from a worker thread and the actual call than made at the earliest convenience by the main thread where it has possession of the global interpreter lock and can perform any Python API calls.

`void Py_AddPendingCall(int (*func)(void *, void *arg))`

Post a notification to the Python main thread. If successful, *func* will be called with the argument *arg* at the earliest convenience. *func* will be called having the global interpreter lock held and can thus use the full Python API and can take any action such as setting object attributes to signal IO completion. It must return 0 on success, or -1 signalling an exception. The notification function won't be interrupted to perform another asynchronous notification recursively, but it can still be interrupted to switch threads if the global interpreter lock is released, for example, if it calls back into Python code.

This function returns 0 on success in which case the notification has been scheduled. Otherwise, for example if the notification buffer is full, it returns -1 without setting any exception.

This function can be called on any thread, be it a Python thread or some other system thread. If it is a Python thread, it doesn't matter if it holds the global interpreter lock or not.

New in version 3.1.

Profiling and Tracing

The Python interpreter provides some low-level support for attaching profiling and execution tracing facilities. These are used for profiling, debugging, and coverage analysis tools.

This C interface allows the profiling or tracing code to avoid the overhead of calling through Python-level callable objects, making a direct C function call instead. The essential attributes of the facility have not changed; the interface allows trace functions to be installed per-thread, and the basic events reported to the trace function are the same as had been reported to the Python-level trace functions in previous versions.

`int (*Py_tracefunc)(PyObject *obj, PyFrameObject *frame, int what, PyObject *arg)`

The type of the trace function registered using `PyEval_SetProfile()` and `PyEval_SetTrace()`. The first parameter is the object passed to the registration function as *obj*, *frame* is the frame object to which the event pertains, *what* is one of the constants `PyTrace_CALL`, `PyTrace_EXCEPTION`, `PyTrace_LINE`, `PyTrace_RETURN`, `PyTrace_C_CALL`, `PyTrace_C_EXCEPTION`, or `PyTrace_C_RETURN`, and *arg* depends on the value of *what*:

Value of <i>what</i>	Meaning of <i>arg</i>
<code>PyTrace_CALL</code>	Always <i>NULL</i> .
<code>PyTrace_EXCEPTION</code>	Exception information as returned by <code>sys.exc_info()</code> .
<code>PyTrace_LINE</code>	Always <i>NULL</i> .
<code>PyTrace_RETURN</code>	Value being returned to the caller, or <i>NULL</i> if caused by an exception.
<code>PyTrace_C_CALL</code>	Function object being called.
<code>PyTrace_C_EXCEPTION</code>	Function object being called.

PyTrace_C_RETURN	Function object being called.
-------------------------	-------------------------------

int **PyTrace_CALL**

The value of the *what* parameter to a **Py_tracefunc** function when a new call to a function or method is being reported, or a new entry into a generator. Note that the creation of the iterator for a generator function is not reported as there is no control transfer to the Python bytecode in the corresponding frame.

int **PyTrace_EXCEPTION**

The value of the *what* parameter to a **Py_tracefunc** function when an exception has been raised. The callback function is called with this value for *what* when after any bytecode is processed after which the exception becomes set within the frame being executed. The effect of this is that as exception propagation causes the Python stack to unwind, the callback is called upon return to each frame as the exception propagates. Only trace functions receives these events; they are not needed by the profiler.

int **PyTrace_LINE**

The value passed as the *what* parameter to a trace function (but not a profiling function) when a line-number event is being reported.

int **PyTrace_RETURN**

The value for the *what* parameter to **Py_tracefunc** functions when a call is returning without propagating an exception.

int **PyTrace_C_CALL**

The value for the *what* parameter to **Py_tracefunc** functions when a C function is about to be called.

int **PyTrace_C_EXCEPTION**

The value for the *what* parameter to **Py_tracefunc** functions when

a C function has raised an exception.

int PyTrace_C_RETURN

The value for the *what* parameter to `Py_tracefunc` functions when a C function has returned.

void PyEval_SetProfile(Py_tracefunc func, PyObject *obj)

Set the profiler function to *func*. The *obj* parameter is passed to the function as its first parameter, and may be any Python object, or *NULL*. If the profile function needs to maintain state, using a different value for *obj* for each thread provides a convenient and thread-safe place to store it. The profile function is called for all monitored events except the line-number events.

void PyEval_SetTrace(Py_tracefunc func, PyObject *obj)

Set the tracing function to *func*. This is similar to `PyEval_SetProfile()`, except the tracing function does receive line-number events.

PyObject* PyEval_GetCallStats(PyObject *self)

Return a tuple of function call counts. There are constants defined for the positions within the tuple:

Name	Value
PCALL_ALL	0
PCALL_FUNCTION	1
PCALL_FAST_FUNCTION	2
PCALL_FASTER_FUNCTION	3
PCALL_METHOD	4
PCALL_BOUND_METHOD	5
PCALL_CFUNCTION	6
PCALL_TYPE	7
PCALL_GENERATOR	8
PCALL_OTHER	9

PCALL_FAST_FUNCTION means no argument tuple needs to be created. **PCALL_FASTER_FUNCTION** means that the fast-path frame setup code is used.

If there is a method call where the call can be optimized by changing the argument tuple and calling the function directly, it gets recorded twice.

This function is only present if Python is compiled with **CALL_PROFILE** defined.

Advanced Debugger Support

These functions are only intended to be used by advanced debugging tools.

`PyInterpreterState*` **PyInterpreterState_Head**()

Return the interpreter state object at the head of the list of all such objects.

`PyInterpreterState*` **PyInterpreterState_Next**(`PyInterpreterState *interp`)

Return the next interpreter state object after *interp* from the list of all such objects.

`PyThreadState *`

PyInterpreterState_ThreadHead(`PyInterpreterState *interp`)

Return the a pointer to the first `PyThreadState` object in the list of threads associated with the interpreter *interp*.

`PyThreadState*` **PyThreadState_Next**(`PyThreadState *tstate`)

Return the next thread state object after *tstate* from the list of all such objects belonging to the same `PyInterpreterState` object.

Memory Management

Overview

Memory management in Python involves a private heap containing all Python objects and data structures. The management of this private heap is ensured internally by the *Python memory manager*. The Python memory manager has different components which deal with various dynamic storage management aspects, like sharing, segmentation, preallocation or caching.

At the lowest level, a raw memory allocator ensures that there is enough room in the private heap for storing all Python-related data by interacting with the memory manager of the operating system. On top of the raw memory allocator, several object-specific allocators operate on the same heap and implement distinct memory management policies adapted to the peculiarities of every object type. For example, integer objects are managed differently within the heap than strings, tuples or dictionaries because integers imply different storage requirements and speed/space tradeoffs. The Python memory manager thus delegates some of the work to the object-specific allocators, but ensures that the latter operate within the bounds of the private heap.

It is important to understand that the management of the Python heap is performed by the interpreter itself and that the user has no control over it, even if she regularly manipulates object pointers to memory blocks inside that heap. The allocation of heap space for Python objects and other internal buffers is performed on demand by the Python memory manager through the Python/C API functions listed in this document.

To avoid memory corruption, extension writers should never try to operate on Python objects with the functions exported by the C library: `malloc()`, `calloc()`, `realloc()` and `free()`. This will result in

mixed calls between the C allocator and the Python memory manager with fatal consequences, because they implement different algorithms and operate on different heaps. However, one may safely allocate and release memory blocks with the C library allocator for individual purposes, as shown in the following example:

```
PyObject *res;
char *buf = (char *) malloc(BUFSIZ); /* for I/O */

if (buf == NULL)
    return PyErr_NoMemory();
...Do some I/O operation involving buf...
res = PyString_FromString(buf);
free(buf); /* malloc'ed */
return res;
```

In this example, the memory request for the I/O buffer is handled by the C library allocator. The Python memory manager is involved only in the allocation of the string object returned as a result.

In most situations, however, it is recommended to allocate memory from the Python heap specifically because the latter is under control of the Python memory manager. For example, this is required when the interpreter is extended with new object types written in C. Another reason for using the Python heap is the desire to *inform* the Python memory manager about the memory needs of the extension module. Even when the requested memory is used exclusively for internal, highly-specific purposes, delegating all memory requests to the Python memory manager causes the interpreter to have a more accurate image of its memory footprint as a whole. Consequently, under certain circumstances, the Python memory manager may or may not trigger appropriate actions, like garbage collection, memory compaction or other preventive procedures. Note that by using the C library allocator as shown in the previous example, the allocated memory for the I/O buffer escapes completely the Python memory manager.

Memory Interface

The following function sets, modeled after the ANSI C standard, but specifying behavior when requesting zero bytes, are available for allocating and releasing memory from the Python heap:

`void* PyMem_Malloc(size_t n)`

Allocates n bytes and returns a pointer of type `void*` to the allocated memory, or `NULL` if the request fails. Requesting zero bytes returns a distinct non-`NULL` pointer if possible, as if `PyMem_Malloc(1)()` had been called instead. The memory will not have been initialized in any way.

`void* PyMem_Realloc(void *p, size_t n)`

Resizes the memory block pointed to by p to n bytes. The contents will be unchanged to the minimum of the old and the new sizes. If p is `NULL`, the call is equivalent to `PyMem_Malloc(n)()`; else if n is equal to zero, the memory block is resized but is not freed, and the returned pointer is non-`NULL`. Unless p is `NULL`, it must have been returned by a previous call to `PyMem_Malloc()` or `PyMem_Realloc()`. If the request fails, `PyMem_Realloc()` returns `NULL` and p remains a valid pointer to the previous memory area.

`void PyMem_Free(void *p)`

Frees the memory block pointed to by p , which must have been returned by a previous call to `PyMem_Malloc()` or `PyMem_Realloc()`. Otherwise, or if `PyMem_Free(p)()` has been called before, undefined behavior occurs. If p is `NULL`, no operation is performed.

The following type-oriented macros are provided for convenience.

Note that *TYPE* refers to any C type.

TYPE* **PyMem_New**(TYPE, size_t *n*)

Same as **PyMem_Malloc()**, but allocates ($n * \text{sizeof}(\text{TYPE})$) bytes of memory. Returns a pointer cast to **TYPE***. The memory will not have been initialized in any way.

TYPE* **PyMem_Resize**(void **p*, TYPE, size_t *n*)

Same as **PyMem_Realloc()**, but the memory block is resized to ($n * \text{sizeof}(\text{TYPE})$) bytes. Returns a pointer cast to **TYPE***. On return, *p* will be a pointer to the new memory area, or *NULL* in the event of failure. This is a C preprocessor macro; *p* is always reassigned. Save the original value of *p* to avoid losing memory when handling errors.

void **PyMem_Del**(void **p*)

Same as **PyMem_Free()**.

In addition, the following macro sets are provided for calling the Python memory allocator directly, without involving the C API functions listed above. However, note that their use does not preserve binary compatibility across Python versions and is therefore deprecated in extension modules.

PyMem_MALLOC(), **PyMem_REALLOC()**, **PyMem_FREE()**.

PyMem_NEW(), **PyMem_RESIZE()**, **PyMem_DEL()**.

Examples

Here is the example from section [Overview](#), rewritten so that the I/O buffer is allocated from the Python heap by using the first function set:

```
PyObject *res;
char *buf = (char *) PyMem_Malloc(BUFSIZ); /* for I/O */

if (buf == NULL)
    return PyErr_NoMemory();
/* ...Do some I/O operation involving buf... */
res = PyString_FromString(buf);
PyMem_Free(buf); /* allocated with PyMem_Malloc */
return res;
```

The same code using the type-oriented function set:

```
PyObject *res;
char *buf = PyMem_New(char, BUFSIZ); /* for I/O */

if (buf == NULL)
    return PyErr_NoMemory();
/* ...Do some I/O operation involving buf... */
res = PyString_FromString(buf);
PyMem_Del(buf); /* allocated with PyMem_New */
return res;
```

Note that in the two examples above, the buffer is always manipulated via functions belonging to the same set. Indeed, it is required to use the same memory API family for a given memory block, so that the risk of mixing different allocators is reduced to a minimum. The following code sequence contains two errors, one of which is labeled as *fatal* because it mixes two different allocators operating on different heaps.

```
char *buf1 = PyMem_New(char, BUFSIZ);
char *buf2 = (char *) malloc(BUFSIZ);
```

```
char *buf3 = (char *) PyMem_Malloc(BUFSIZ);
...
PyMem_Del(buf3); /* Wrong -- should be PyMem_Free() */
free(buf2);      /* Right -- allocated via malloc() */
free(buf1);      /* Fatal -- should be PyMem_Del() */
```

In addition to the functions aimed at handling raw memory blocks from the Python heap, objects in Python are allocated and released with `PyObject_New()`, `PyObject_NewVar()` and `PyObject_De1()`.

These will be explained in the next chapter on defining and implementing new object types in C.

Object Implementation Support

This chapter describes the functions, types, and macros used when defining new object types.

Allocating Objects on the Heap

`PyObject* _PyObject_New(PyTypeObject *type)`

Return value: New reference.

`PyVarObject* _PyObject_NewVar(PyTypeObject *type, Py_ssize_t size)`

Return value: New reference.

`PyObject* PyObject_Init(PyObject *op, PyTypeObject *type)`

Return value: Borrowed reference.

Initialize a newly-allocated object `op` with its type and initial reference. Returns the initialized object. If `type` indicates that the object participates in the cyclic garbage detector, it is added to the detector's set of observed objects. Other fields of the object are not affected.

`PyVarObject* PyObject_InitVar(PyVarObject *op, PyTypeObject *type, Py_ssize_t size)`

Return value: Borrowed reference.

This does everything `PyObject_Init()` does, and also initializes the length information for a variable-size object.

`TYPE* PyObject_New(TYPE, PyTypeObject *type)`

Return value: New reference.

Allocate a new Python object using the C structure type `TYPE` and the Python type object `type`. Fields not defined by the Python object header are not initialized; the object's reference count will be one. The size of the memory allocation is determined from the `tp_basicsize` field of the type object.

`TYPE* PyObject_NewVar(TYPE, PyTypeObject *type, Py_ssize_t size)`

Return value: New reference.

Allocate a new Python object using the C structure type *TYPE* and the Python type object *type*. Fields not defined by the Python object header are not initialized. The allocated memory allows for the *TYPE* structure plus *size* fields of the size given by the `tp_itemsize` field of *type*. This is useful for implementing objects like tuples, which are able to determine their size at construction time. Embedding the array of fields into the same allocation decreases the number of allocations, improving the memory management efficiency.

`void PyObject_De1(PyObject *op)`

Releases memory allocated to an object using `PyObject_New()` or `PyObject_NewVar()`. This is normally called from the `tp_dealloc` handler specified in the object's type. The fields of the object should not be accessed after this call as the memory is no longer a valid Python object.

`PyObject _Py_NoneStruct`

Object which is visible in Python as `None`. This should only be accessed using the `Py_None` macro, which evaluates to a pointer to this object.

Common Object Structures

There are a large number of structures which are used in the definition of object types for Python. This section describes these structures and how they are used.

All Python objects ultimately share a small number of fields at the beginning of the object's representation in memory. These are represented by the `PyObject` and `PyVarObject` types, which are defined, in turn, by the expansions of some macros also used, whether directly or indirectly, in the definition of all other Python objects.

PyObject

All object types are extensions of this type. This is a type which contains the information Python needs to treat a pointer to an object as an object. In a normal “release” build, it contains only the object's reference count and a pointer to the corresponding type object. It corresponds to the fields defined by the expansion of the `PyObject_HEAD` macro.

PyVarObject

This is an extension of `PyObject` that adds the `ob_size` field. This is only used for objects that have some notion of *length*. This type does not often appear in the Python/C API. It corresponds to the fields defined by the expansion of the `PyObject_VAR_HEAD` macro.

These macros are used in the definition of `PyObject` and `PyVarObject`:

PyObject_HEAD

This is a macro which expands to the declarations of the fields of the `PyObject` type; it is used when declaring new types which represent objects without a varying length. The specific fields it

expands to depend on the definition of `Py_TRACE_REFS`. By default, that macro is not defined, and `PyObject_HEAD` expands to:

```
Py_ssize_t ob_refcnt;
PyObject *ob_type;
```

When `Py_TRACE_REFS` is defined, it expands to:

```
PyObject *_ob_next, *_ob_prev;
Py_ssize_t ob_refcnt;
PyObject *ob_type;
```

PyObject_VAR_HEAD

This is a macro which expands to the declarations of the fields of the `PyVarObject` type; it is used when declaring new types which represent objects with a length that varies from instance to instance. This macro always expands to:

```
PyObject_HEAD
Py_ssize_t ob_size;
```

Note that `PyObject_HEAD` is part of the expansion, and that its own expansion varies depending on the definition of `Py_TRACE_REFS`.

PyObject_HEAD_INIT(type)

This is a macro which expands to initialization values for a new `PyObject` type. This macro expands to:

```
_PyObject_EXTRA_INIT
1, type,
```

PyVarObject_HEAD_INIT(type, size)

This is a macro which expands to initialization values for a new `PyVarObject` type, including the `ob_size` field. This macro expands to:

```
_PyObject_EXTRA_INIT  
1, type, size,
```

PyCFunction

Type of the functions used to implement most Python callables in C. Functions of this type take two `PyObject*` parameters and return one such value. If the return value is `NULL`, an exception shall have been set. If not `NULL`, the return value is interpreted as the return value of the function as exposed in Python. The function must return a new reference.

PyCFunctionWithKeywords

Type of the functions used to implement Python callables in C that take keyword arguments: they take three `PyObject*` parameters and return one such value. See `PyCFunction` above for the meaning of the return value.

PyMethodDef

Structure used to describe a method of an extension type. This structure has four fields:

Field	C Type	Meaning
<code>m1_name</code>	<code>char *</code>	name of the method
<code>m1_meth</code>	<code>PyCFunction</code>	pointer to the C implementation
<code>m1_flags</code>	<code>int</code>	flag bits indicating how the call should be constructed
<code>m1_doc</code>	<code>char *</code>	points to the contents of the docstring

The `m1_meth` is a C function pointer. The functions may be of different types, but they always return `PyObject*`. If the function is not of the `PyCFunction`, the compiler will require a cast in the method table. Even though `PyCFunction` defines the first parameter as `PyObject*`, it is common that the method implementation uses a the specific C

type of the *self* object.

The `m1_flags` field is a bitfield which can include the following flags. The individual flags indicate either a calling convention or a binding convention. Of the calling convention flags, only `METH_VARARGS` and `METH_KEYWORDS` can be combined (but note that `METH_KEYWORDS` alone is equivalent to `METH_VARARGS | METH_KEYWORDS`). Any of the calling convention flags can be combined with a binding flag.

METH_VARARGS

This is the typical calling convention, where the methods have the type `PyCFunction`. The function expects two `PyObject*` values. The first one is the *self* object for methods; for module functions, it is the module object. The second parameter (often called *args*) is a tuple object representing all arguments. This parameter is typically processed using `PyArg_ParseTuple()` or `PyArg_UnpackTuple()`.

METH_KEYWORDS

Methods with these flags must be of type `PyCFunctionWithKeywords`. The function expects three parameters: *self*, *args*, and a dictionary of all the keyword arguments. The flag is typically combined with `METH_VARARGS`, and the parameters are typically processed using `PyArg_ParseTupleAndKeywords()`.

METH_NOARGS

Methods without parameters don't need to check whether arguments are given if they are listed with the `METH_NOARGS` flag. They need to be of type `PyCFunction`. The first parameter is typically named *self* and will hold a reference to the module or object instance. In all cases the second parameter will be `NULL`.

METH_O

Methods with a single object argument can be listed with the `METH_O` flag, instead of invoking `PyArg_ParseTuple()` with a `"0"` argument. They have the type `PyCFunction`, with the `self` parameter, and a `PyObject*` parameter representing the single argument.

These two constants are not used to indicate the calling convention but the binding when use with methods of classes. These may not be used for functions defined for modules. At most one of these flags may be set for any given method.

METH_CLASS

The method will be passed the type object as the first parameter rather than an instance of the type. This is used to create *class methods*, similar to what is created when using the `classmethod()` built-in function.

METH_STATIC

The method will be passed `NULL` as the first parameter rather than an instance of the type. This is used to create *static methods*, similar to what is created when using the `staticmethod()` built-in function.

One other constant controls whether a method is loaded in place of another definition with the same method name.

METH_COEXIST

The method will be loaded in place of existing definitions. Without `METH_COEXIST`, the default is to skip repeated definitions. Since slot wrappers are loaded before the method table, the existence of a `sq_contains` slot, for example, would generate a wrapped method named `__contains__()` and preclude the loading of a corresponding `PyCFunction` with the same name. With the flag defined, the `PyCFunction` will be loaded in place of the wrapper object and will co-exist with the slot. This is helpful

because calls to PyCFunctions are optimized more than wrapper object calls.

PyMemberDef

Structure which describes an attribute of a type which corresponds to a C struct member. Its fields are:

Field	C Type	Meaning
name	char *	name of the member
type	int	the type of the member in the C struct
offset	Py_ssize_t	the offset in bytes that the member is located on the type's object struct
flags	int	flag bits indicating if the field should be read-only or writable
doc	char *	points to the contents of the docstring

type can be one of many `T_` macros corresponding to various C types. When the member is accessed in Python, it will be converted to the equivalent Python type.

Macro name	C type
T_SHORT	short
T_INT	int
T_LONG	long
T_FLOAT	float
T_DOUBLE	double
T_STRING	char *
T_OBJECT	PyObject *
T_OBJECT_EX	PyObject *
T_CHAR	char
T_BYTE	char
T_UBYTE	unsigned char

T_UINT	unsigned int
T_USHORT	unsigned short
T_ULONG	unsigned long
T_BOOL	char
T_LONGLONG	long long
T_ULONGLONG	unsigned long long
T_PYSSIZET	Py_ssize_t

T_OBJECT and T_OBJECT_EX differ in that T_OBJECT returns `None` if the member is `NULL` and T_OBJECT_EX raises an `AttributeError`. Try to use T_OBJECT_EX over T_OBJECT because T_OBJECT_EX handles use of the `del` statement on that attribute more correctly than T_OBJECT.

`flags` can be 0 for write and read access or `READONLY` for read-only access. Using T_STRING for `type` implies `READONLY`. Only T_OBJECT and T_OBJECT_EX members can be deleted. (They are set to `NULL`).

Type Objects

Perhaps one of the most important structures of the Python object system is the structure that defines a new type: the `PyTypeObject` structure. Type objects can be handled using any of the `PyObject_*` () or `PyType_*` () functions, but do not offer much that's interesting to most Python applications. These objects are fundamental to how objects behave, so they are very important to the interpreter itself and to any extension module that implements new types.

Type objects are fairly large compared to most of the standard types. The reason for the size is that each type object stores a large number of values, mostly C function pointers, each of which implements a small part of the type's functionality. The fields of the type object are examined in detail in this section. The fields will be described in the order in which they occur in the structure.

Typedefs: unaryfunc, binaryfunc, ternaryfunc, inquiry, intargfunc, intintargfunc, intobjargproc, intintobjargproc, objobjargproc, destructor, freefunc, printfunc, getattrofunc, getattrofunc, setattrofunc, setattrofunc, reprfunc, hashfunc

The structure definition for `PyTypeObject` can be found in `Include/object.h`. For convenience of reference, this repeats the definition found there:

```
typedef struct _typeobject {
    PyObject_VAR_HEAD
    char *tp_name; /* For printing, in format "<module>.<name>"
    int tp_basicsize, tp_itemsize; /* For allocation */

    /* Methods to implement standard operations */

    destructor tp_dealloc;
    printfunc tp_print;
    getattrofunc tp_getattr;
```

```

setattrfunc tp_setattr;
void *tp_reserved;
reprfunc tp_repr;

/* Method suites for standard classes */

PyNumberMethods *tp_as_number;
PySequenceMethods *tp_as_sequence;
PyMappingMethods *tp_as_mapping;

/* More standard operations (here for binary compatibility)

hashfunc tp_hash;
ternaryfunc tp_call;
reprfunc tp_str;
getattrofunc tp_getattro;
setattrofunc tp_setattro;

/* Functions to access object as input/output buffer */
PyBufferProcs *tp_as_buffer;

/* Flags to define presence of optional/expanded features */
long tp_flags;

char *tp_doc; /* Documentation string */

/* call function for all accessible objects */
traverseproc tp_traverse;

/* delete references to contained objects */
inquiry tp_clear;

/* rich comparisons */
richcmpfunc tp_richcompare;

/* weak reference enabler */
long tp_weaklistoffset;

/* Iterators */
getiterfunc tp_iter;
iternextfunc tp_iternext;

/* Attribute descriptor and subclassing stuff */
struct PyMethodDef *tp_methods;
struct PyMemberDef *tp_members;
struct PyGetSetDef *tp_getset;
struct _typeobject *tp_base;

```

```

PyObject *tp_dict;
descrgetfunc tp_descr_get;
descrsetfunc tp_descr_set;
long tp_dictoffset;
initproc tp_init;
allocfunc tp_alloc;
newfunc tp_new;
freefunc tp_free; /* Low-level free-memory routine */
inquiry tp_is_gc; /* For PyObject_IS_GC */
PyObject *tp_bases;
PyObject *tp_mro; /* method resolution order */
PyObject *tp_cache;
PyObject *tp_subclasses;
PyObject *tp_weaklist;

} PyTypeObject;

```

The type object structure extends the `PyVarObject` structure. The `ob_size` field is used for dynamic types (created by `type_new()`, usually called from a class statement). Note that `PyType_Type` (the metatype) initializes `tp_itemsize`, which means that its instances (i.e. type objects) *must* have the `ob_size` field.

`PyObject*` `PyObject._ob_next`

`PyObject*` `PyObject._ob_prev`

These fields are only present when the macro `Py_TRACE_REFS` is defined. Their initialization to `NULL` is taken care of by the `PyObject_HEAD_INIT` macro. For statically allocated objects, these fields always remain `NULL`. For dynamically allocated objects, these two fields are used to link the object into a doubly-linked list of *all* live objects on the heap. This could be used for various debugging purposes; currently the only use is to print the objects that are still alive at the end of a run when the environment variable `PYTHONDUMPREFS` is set.

These fields are not inherited by subtypes.

`Py_ssize_t` `PyObject.ob_refcnt`

This is the type object's reference count, initialized to `1` by the `PyObject_HEAD_INIT` macro. Note that for statically allocated type objects, the type's instances (objects whose `ob_type` points back to the type) do *not* count as references. But for dynamically allocated type objects, the instances *do* count as references.

This field is not inherited by subtypes.

`PyTypeObject*` `PyObject.ob_type`

This is the type's type, in other words its metatype. It is initialized by the argument to the `PyObject_HEAD_INIT` macro, and its value should normally be `&PyType_Type`. However, for dynamically loadable extension modules that must be usable on Windows (at least), the compiler complains that this is not a valid initializer. Therefore, the convention is to pass `NULL` to the `PyObject_HEAD_INIT` macro and to initialize this field explicitly at the start of the module's initialization function, before doing anything else. This is typically done like this:

```
Foo_Type.ob_type = &PyType_Type;
```

This should be done before any instances of the type are created. `PyType_Ready()` checks if `ob_type` is `NULL`, and if so, initializes it to the `ob_type` field of the base class. `PyType_Ready()` will not change this field if it is non-zero.

This field is inherited by subtypes.

`Py_ssize_t` `PyVarObject.ob_size`

For statically allocated type objects, this should be initialized to zero. For dynamically allocated type objects, this field has a special internal meaning.

This field is not inherited by subtypes.

char* `PyObject.tp_name`

Pointer to a NUL-terminated string containing the name of the type. For types that are accessible as module globals, the string should be the full module name, followed by a dot, followed by the type name; for built-in types, it should be just the type name. If the module is a submodule of a package, the full package name is part of the full module name. For example, a type named `T` defined in module `M` in subpackage `Q` in package `P` should have the `tp_name` initializer `"P.Q.M.T"`.

For dynamically allocated type objects, this should just be the type name, and the module name explicitly stored in the type dict as the value for key `'__module__'`.

For statically allocated type objects, the `tp_name` field should contain a dot. Everything before the last dot is made accessible as the `__module__` attribute, and everything after the last dot is made accessible as the `__name__` attribute.

If no dot is present, the entire `tp_name` field is made accessible as the `__name__` attribute, and the `__module__` attribute is undefined (unless explicitly set in the dictionary, as explained above). This means your type will be impossible to pickle.

This field is not inherited by subtypes.

`Py_ssize_t PyObject.tp_basicsize`

`Py_ssize_t PyObject.tp_itemsize`

These fields allow calculating the size in bytes of instances of the type.

There are two kinds of types: types with fixed-length instances have a zero `tp_itemsize` field, types with variable-length instances have a non-zero `tp_itemsize` field. For a type with

fixed-length instances, all instances have the same size, given in `tp_basicsize`.

For a type with variable-length instances, the instances must have an `ob_size` field, and the instance size is `tp_basicsize` plus N times `tp_itemsize`, where N is the “length” of the object. The value of N is typically stored in the instance’s `ob_size` field. There are exceptions: for example, ints use a negative `ob_size` to indicate a negative number, and N is `abs(ob_size)` there. Also, the presence of an `ob_size` field in the instance layout doesn’t mean that the instance structure is variable-length (for example, the structure for the list type has fixed-length instances, yet those instances have a meaningful `ob_size` field).

The basic size includes the fields in the instance declared by the macro `PyObject_HEAD` or `PyObject_VAR_HEAD` (whichever is used to declare the instance struct) and this in turn includes the `_ob_prev` and `_ob_next` fields if they are present. This means that the only correct way to get an initializer for the `tp_basicsize` is to use the `sizeof` operator on the struct used to declare the instance layout. The basic size does not include the GC header size.

These fields are inherited separately by subtypes. If the base type has a non-zero `tp_itemsize`, it is generally not safe to set `tp_itemsize` to a different non-zero value in a subtype (though this depends on the implementation of the base type).

A note about alignment: if the variable items require a particular alignment, this should be taken care of by the value of `tp_basicsize`. Example: suppose a type implements an array of `double`. `tp_itemsize` is `sizeof(double)`. It is the programmer’s responsibility that `tp_basicsize` is a multiple of `sizeof(double)` (assuming this is the alignment requirement for `double`).

destructor `PyTypeObject.tp_dealloc`

A pointer to the instance destructor function. This function must be defined unless the type guarantees that its instances will never be deallocated (as is the case for the singletons `None` and `Ellipsis`).

The destructor function is called by the `Py_DECREF()` and `Py_XDECREF()` macros when the new reference count is zero. At this point, the instance is still in existence, but there are no references to it. The destructor function should free all references which the instance owns, free all memory buffers owned by the instance (using the freeing function corresponding to the allocation function used to allocate the buffer), and finally (as its last action) call the type's `tp_free` function. If the type is not subtypable (doesn't have the `Py_TPFLAGS_BASETYPE` flag bit set), it is permissible to call the object deallocator directly instead of via `tp_free`. The object deallocator should be the one used to allocate the instance; this is normally `PyObject_De1()` if the instance was allocated using `PyObject_New()` or `PyObject_VarNew()`, or `PyObject_GC_De1()` if the instance was allocated using `PyObject_GC_New()` or `PyObject_GC_NewVar()`.

This field is inherited by subtypes.

printfunc `PyTypeObject.tp_print`

An optional pointer to the instance print function.

The print function is only called when the instance is printed to a *real* file; when it is printed to a pseudo-file (like a `StringIO` instance), the instance's `tp_repr` or `tp_str` function is called to convert it to a string. These are also called when the type's `tp_print` field is `NULL`. A type should never implement `tp_print` in a way that produces different output than `tp_repr` or `tp_str`

would.

The `print` function is called with the same signature as `PyObject_Print(): int tp_print(PyObject *self, FILE *file, int flags)`. The *self* argument is the instance to be printed. The *file* argument is the stdio file to which it is to be printed. The *flags* argument is composed of flag bits. The only flag bit currently defined is `Py_PRINT_RAW`. When the `Py_PRINT_RAW` flag bit is set, the instance should be printed the same way as `tp_str` would format it; when the `Py_PRINT_RAW` flag bit is clear, the instance should be printed the same way as `tp_repr` would format it. It should return `-1` and set an exception condition when an error occurred during the comparison.

It is possible that the `tp_print` field will be deprecated. In any case, it is recommended not to define `tp_print`, but instead to rely on `tp_repr` and `tp_str` for printing.

This field is inherited by subtypes.

getattrfunc `PyTypeObject.tp_getattr`

An optional pointer to the get-attribute-string function.

This field is deprecated. When it is defined, it should point to a function that acts the same as the `tp_getattro` function, but taking a C string instead of a Python string object to give the attribute name. The signature is the same as for `PyObject_GetAttrString()`.

This field is inherited by subtypes together with `tp_getattro`: a subtype inherits both `tp_getattr` and `tp_getattro` from its base type when the subtype's `tp_getattr` and `tp_getattro` are both `NULL`.

setattrfunc `PyTypeObject.tp_setattr`

An optional pointer to the set-attribute-string function.

This field is deprecated. When it is defined, it should point to a function that acts the same as the `tp_setattro` function, but taking a C string instead of a Python string object to give the attribute name. The signature is the same as for `PyObject_SetAttrString()`.

This field is inherited by subtypes together with `tp_setattro`: a subtype inherits both `tp_setattr` and `tp_setattro` from its base type when the subtype's `tp_setattr` and `tp_setattro` are both `NULL`.

void* `PyTypeObject.tp_reserved`

Reserved slot, formerly known as `tp_compare`.

reprfunc `PyTypeObject.tp_repr`

An optional pointer to a function that implements the built-in function `repr()`.

The signature is the same as for `PyObject_Repr()`; it must return a string or a Unicode object. Ideally, this function should return a string that, when passed to `eval()`, given a suitable environment, returns an object with the same value. If this is not feasible, it should return a string starting with `'<'` and ending with `'>'` from which both the type and the value of the object can be deduced.

When this field is not set, a string of the form `<%s object at %p>` is returned, where `%s` is replaced by the type name, and `%p` by the object's memory address.

This field is inherited by subtypes.

`PyNumberMethods*` `tp_as_number`

Pointer to an additional structure that contains fields relevant only to objects which implement the number protocol. These fields are documented in *Number Object Structures*.

The `tp_as_number` field is not inherited, but the contained fields are inherited individually.

PySequenceMethods* `tp_as_sequence`

Pointer to an additional structure that contains fields relevant only to objects which implement the sequence protocol. These fields are documented in *Sequence Object Structures*.

The `tp_as_sequence` field is not inherited, but the contained fields are inherited individually.

PyMappingMethods* `tp_as_mapping`

Pointer to an additional structure that contains fields relevant only to objects which implement the mapping protocol. These fields are documented in *Mapping Object Structures*.

The `tp_as_mapping` field is not inherited, but the contained fields are inherited individually.

hashfunc `PyObject.tp_hash`

An optional pointer to a function that implements the built-in function `hash()`.

The signature is the same as for `PyObject_Hash()`; it must return a value of the type `Py_hash_t`. The value `-1` should not be returned as a normal return value; when an error occurs during the computation of the hash value, the function should set an exception and return `-1`.

This field can be set explicitly to `PyObject_HashNotImplemented()` to block inheritance of the hash method from a parent type. This

is interpreted as the equivalent of `__hash__ = None` at the Python level, causing `isinstance(o, collections.Hashable)` to correctly return `False`. Note that the converse is also true - setting `__hash__ = None` on a class at the Python level will result in the `tp_hash` slot being set to `PyObject_HashNotImplemented()`.

When this field is not set, an attempt to take the hash of the object raises `TypeError`.

This field is inherited by subtypes together with `tp_richcompare`: a subtype inherits both of `tp_richcompare` and `tp_hash`, when the subtype's `tp_richcompare` and `tp_hash` are both `NULL`.

ternaryfunc `PyTypeObject.tp_call`

An optional pointer to a function that implements calling the object. This should be `NULL` if the object is not callable. The signature is the same as for `PyObject_Call()`.

This field is inherited by subtypes.

reprfunc `PyTypeObject.tp_str`

An optional pointer to a function that implements the built-in operation `str()`. (Note that `str` is a type now, and `str()` calls the constructor for that type. This constructor calls `PyObject_Str()` to do the actual work, and `PyObject_Str()` will call this handler.)

The signature is the same as for `PyObject_Str()`; it must return a string or a Unicode object. This function should return a “friendly” string representation of the object, as this is the representation that will be used, among other things, by the `print()` function.

When this field is not set, `PyObject_Repr()` is called to return a string representation.

This field is inherited by subtypes.

`getattrofunc PyTypeObject.tp_getattro`

An optional pointer to the get-attribute function.

The signature is the same as for `PyObject_GetAttr()`. It is usually convenient to set this field to `PyObject_GenericGetAttr()`, which implements the normal way of looking for object attributes.

This field is inherited by subtypes together with `tp_getattr`: a subtype inherits both `tp_getattr` and `tp_getattro` from its base type when the subtype's `tp_getattr` and `tp_getattro` are both `NULL`.

`setattrofunc PyTypeObject.tp_setattro`

An optional pointer to the set-attribute function.

The signature is the same as for `PyObject_SetAttr()`. It is usually convenient to set this field to `PyObject_GenericSetAttr()`, which implements the normal way of setting object attributes.

This field is inherited by subtypes together with `tp_setattr`: a subtype inherits both `tp_setattr` and `tp_setattro` from its base type when the subtype's `tp_setattr` and `tp_setattro` are both `NULL`.

`PyBufferProcs*` `PyTypeObject.tp_as_buffer`

Pointer to an additional structure that contains fields relevant only to objects which implement the buffer interface. These fields are documented in *Buffer Object Structures*.

The `tp_as_buffer` field is not inherited, but the contained fields are inherited individually.

`long PyTypeObject.tp_flags`

This field is a bit mask of various flags. Some flags indicate variant semantics for certain situations; others are used to indicate that certain fields in the type object (or in the extension structures referenced via `tp_as_number`, `tp_as_sequence`, `tp_as_mapping`, and `tp_as_buffer`) that were historically not always present are valid; if such a flag bit is clear, the type fields it guards must not be accessed and must be considered to have a zero or *NULL* value instead.

Inheritance of this field is complicated. Most flag bits are inherited individually, i.e. if the base type has a flag bit set, the subtype inherits this flag bit. The flag bits that pertain to extension structures are strictly inherited if the extension structure is inherited, i.e. the base type's value of the flag bit is copied into the subtype together with a pointer to the extension structure. The `Py_TPFLAGS_HAVE_GC` flag bit is inherited together with the `tp_traverse` and `tp_clear` fields, i.e. if the `Py_TPFLAGS_HAVE_GC` flag bit is clear in the subtype and the `tp_traverse` and `tp_clear` fields in the subtype exist and have *NULL* values.

The following bit masks are currently defined; these can be ORed together using the `|` operator to form the value of the `tp_flags` field. The macro `PyType_HasFeature()` takes a type and a flags value, `tp` and `f`, and checks whether `tp->tp_flags & f` is non-zero.

Py_TPFLAGS_HEAPTYPE

This bit is set when the type object itself is allocated on the heap. In this case, the `ob_type` field of its instances is considered a reference to the type, and the type object is INCREMENTED when a new instance is created, and DECREMENTED when an instance is destroyed (this does not apply to instances of subtypes; only the type referenced by the instance's `ob_type` gets INCREMENTED or DECREMENTED).

Py_TPFLAGS_BASETYPE

This bit is set when the type can be used as the base type of another type. If this bit is clear, the type cannot be subtyped (similar to a “final” class in Java).

Py_TPFLAGS_READY

This bit is set when the type object has been fully initialized by `PyType_Ready()`.

Py_TPFLAGS_READYING

This bit is set while `PyType_Ready()` is in the process of initializing the type object.

Py_TPFLAGS_HAVE_GC

This bit is set when the object supports garbage collection. If this bit is set, instances must be created using `PyObject_GC_New()` and destroyed using `PyObject_GC_Del()`. More information in section *Supporting Cyclic Garbage Collection*. This bit also implies that the GC-related fields `tp_traverse` and `tp_clear` are present in the type object.

Py_TPFLAGS_DEFAULT

This is a bitmask of all the bits that pertain to the existence of certain fields in the type object and its extension structures. Currently, it includes the following bits:

`Py_TPFLAGS_HAVE_STACKLESS_EXTENSION`,

`Py_TPFLAGS_HAVE_VERSION_TAG`.

char* PyObject.tp_doc

An optional pointer to a NUL-terminated C string giving the docstring for this type object. This is exposed as the `__doc__` attribute on the type and instances of the type.

This field is *not* inherited by subtypes.

traverseproc PyTypeObject.tp_traverse

An optional pointer to a traversal function for the garbage collector. This is only used if the `Py_TPFLAGS_HAVE_GC` flag bit is set. More information about Python's garbage collection scheme can be found in section [Supporting Cyclic Garbage Collection](#).

The `tp_traverse` pointer is used by the garbage collector to detect reference cycles. A typical implementation of a `tp_traverse` function simply calls `Py_VISIT()` on each of the instance's members that are Python objects. For example, this is function `local_traverse()` from the `_thread` extension module:

```
static int
local_traverse(localobject *self, visitproc visit, void *arg)
{
    Py_VISIT(self->args);
    Py_VISIT(self->kw);
    Py_VISIT(self->dict);
    return 0;
}
```

Note that `Py_VISIT()` is called only on those members that can participate in reference cycles. Although there is also a `self->key` member, it can only be `NULL` or a Python string and therefore cannot be part of a reference cycle.

On the other hand, even if you know a member can never be part of a cycle, as a debugging aid you may want to visit it anyway just so the `gc` module's `get_referents()` function will include it.

Note that `Py_VISIT()` requires the `visit` and `arg` parameters to `local_traverse()` to have these specific names; don't name them just anything.

This field is inherited by subtypes together with `tp_clear` and the

`Py_TPFLAGS_HAVE_GC` flag bit: the flag bit, `tp_traverse`, and `tp_clear` are all inherited from the base type if they are all zero in the subtype.

inquiry `PyObject.tp_clear`

An optional pointer to a clear function for the garbage collector. This is only used if the `Py_TPFLAGS_HAVE_GC` flag bit is set.

The `tp_clear` member function is used to break reference cycles in cyclic garbage detected by the garbage collector. Taken together, all `tp_clear` functions in the system must combine to break all reference cycles. This is subtle, and if in any doubt supply a `tp_clear` function. For example, the tuple type does not implement a `tp_clear` function, because it's possible to prove that no reference cycle can be composed entirely of tuples. Therefore the `tp_clear` functions of other types must be sufficient to break any cycle containing a tuple. This isn't immediately obvious, and there's rarely a good reason to avoid implementing `tp_clear`.

Implementations of `tp_clear` should drop the instance's references to those of its members that may be Python objects, and set its pointers to those members to `NULL`, as in the following example:

```
static int
local_clear(localobject *self)
{
    Py_CLEAR(self->key);
    Py_CLEAR(self->args);
    Py_CLEAR(self->kw);
    Py_CLEAR(self->dict);
    return 0;
}
```

The `Py_CLEAR()` macro should be used, because clearing

references is delicate: the reference to the contained object must not be decremented until after the pointer to the contained object is set to *NULL*. This is because decrementing the reference count may cause the contained object to become trash, triggering a chain of reclamation activity that may include invoking arbitrary Python code (due to finalizers, or weakref callbacks, associated with the contained object). If it's possible for such code to reference *self* again, it's important that the pointer to the contained object be *NULL* at that time, so that *self* knows the contained object can no longer be used. The `Py_CLEAR()` macro performs the operations in a safe order.

Because the goal of `tp_clear` functions is to break reference cycles, it's not necessary to clear contained objects like Python strings or Python integers, which can't participate in reference cycles. On the other hand, it may be convenient to clear all contained Python objects, and write the type's `tp_dealloc` function to invoke `tp_clear`.

More information about Python's garbage collection scheme can be found in section [Supporting Cyclic Garbage Collection](#).

This field is inherited by subtypes together with `tp_traverse` and the `Py_TPFLAGS_HAVE_GC` flag bit: the flag bit, `tp_traverse`, and `tp_clear` are all inherited from the base type if they are all zero in the subtype.

`richcmpfunc PyTypeObject.tp_richcompare`

An optional pointer to the rich comparison function, whose signature is `PyObject *tp_richcompare(PyObject *a, PyObject *b, int op)`.

The function should return the result of the comparison (usually `Py_True` or `Py_False`). If the comparison is undefined, it must

return `Py_NotImplemented`, if another error occurred it must return `NULL` and set an exception condition.

Note: If you want to implement a type for which only a limited set of comparisons makes sense (e.g. `==` and `!=`, but not `<` and friends), directly raise `TypeError` in the rich comparison function.

This field is inherited by subtypes together with `tp_hash`: a subtype inherits `tp_richcompare` and `tp_hash` when the subtype's `tp_richcompare` and `tp_hash` are both `NULL`.

The following constants are defined to be used as the third argument for `tp_richcompare` and for `PyObject_RichCompare()`:

Constant	Comparison
<code>Py_LT</code>	<code><</code>
<code>Py_LE</code>	<code><=</code>
<code>Py_EQ</code>	<code>==</code>
<code>Py_NE</code>	<code>!=</code>
<code>Py_GT</code>	<code>></code>
<code>Py_GE</code>	<code>>=</code>

`long PyObject.tp_weaklistoffset`

If the instances of this type are weakly referenceable, this field is greater than zero and contains the offset in the instance structure of the weak reference list head (ignoring the GC header, if present); this offset is used by `PyObject_ClearWeakRefs()` and the `PyWeakref_*()` functions. The instance structure needs to include a field of type `PyObject*` which is initialized to `NULL`.

Do not confuse this field with `tp_weaklist`; that is the list head for weak references to the type object itself.

This field is inherited by subtypes, but see the rules listed below.

A subtype may override this offset; this means that the subtype uses a different weak reference list head than the base type. Since the list head is always found via `tp_weaklistoffset`, this should not be a problem.

When a type defined by a class statement has no `__slots__` declaration, and none of its base types are weakly referenceable, the type is made weakly referenceable by adding a weak reference list head slot to the instance layout and setting the `tp_weaklistoffset` of that slot's offset.

When a type's `__slots__` declaration contains a slot named `__weakref__`, that slot becomes the weak reference list head for instances of the type, and the slot's offset is stored in the type's `tp_weaklistoffset`.

When a type's `__slots__` declaration does not contain a slot named `__weakref__`, the type inherits its `tp_weaklistoffset` from its base type.

`getiterfunc PyTypeObject.tp_iter`

An optional pointer to a function that returns an iterator for the object. Its presence normally signals that the instances of this type are iterable (although sequences may be iterable without this function).

This function has the same signature as `PyObject_GetIter()`.

This field is inherited by subtypes.

`iternextfunc PyTypeObject.tp_iternext`

An optional pointer to a function that returns the next item in an iterator. When the iterator is exhausted, it must return `NULL`; a `StopIteration` exception may or may not be set. When another error occurs, it must return `NULL` too. Its presence signals that

the instances of this type are iterators.

Iterator types should also define the `tp_iter` function, and that function should return the iterator instance itself (not a new iterator instance).

This function has the same signature as `PyIter_Next()`.

This field is inherited by subtypes.

struct `PyMethodDef*` `PyTypeObject.tp_methods`

An optional pointer to a static *NULL*-terminated array of `PyMethodDef` structures, declaring regular methods of this type.

For each entry in the array, an entry is added to the type's dictionary (see `tp_dict` below) containing a method descriptor.

This field is not inherited by subtypes (methods are inherited through a different mechanism).

struct `PyMemberDef*` `PyTypeObject.tp_members`

An optional pointer to a static *NULL*-terminated array of `PyMemberDef` structures, declaring regular data members (fields or slots) of instances of this type.

For each entry in the array, an entry is added to the type's dictionary (see `tp_dict` below) containing a member descriptor.

This field is not inherited by subtypes (members are inherited through a different mechanism).

struct `PyGetSetDef*` `PyTypeObject.tp_getset`

An optional pointer to a static *NULL*-terminated array of `PyGetSetDef` structures, declaring computed attributes of instances of this type.

For each entry in the array, an entry is added to the type's dictionary (see `tp_dict` below) containing a getset descriptor.

This field is not inherited by subtypes (computed attributes are inherited through a different mechanism).

Docs for `PyGetSetDef`:

```
typedef PyObject *(*getter)(PyObject *, void *);
typedef int (*setter)(PyObject *, PyObject *, void *);

typedef struct PyGetSetDef {
    char *name; /* attribute name */
    getter get; /* C function to get the attribute */
    setter set; /* C function to set the attribute */
    char *doc; /* optional doc string */
    void *closure; /* optional additional data for getter and setter */
} PyGetSetDef;
```

`PyObject*` `PyTypeObject.tp_base`

An optional pointer to a base type from which type properties are inherited. At this level, only single inheritance is supported; multiple inheritance require dynamically creating a type object by calling the metatype.

This field is not inherited by subtypes (obviously), but it defaults to `&PyBaseObject_Type` (which to Python programmers is known as the type `object`).

`PyObject*` `PyTypeObject.tp_dict`

The type's dictionary is stored here by `PyType_Ready()`.

This field should normally be initialized to `NULL` before `PyType_Ready` is called; it may also be initialized to a dictionary containing initial attributes for the type. Once `PyType_Ready()` has initialized the type, extra attributes for the type may be added to this dictionary only if they don't correspond to overloaded

operations (like `__add__()`).

This field is not inherited by subtypes (though the attributes defined in here are inherited through a different mechanism).

descrgetfunc **PyObject.tp_descr_get**

An optional pointer to a “descriptor get” function.

The function signature is

```
PyObject * tp_descr_get(PyObject *self, PyObject *obj, PyObj
```

This field is inherited by subtypes.

descrsetfunc **PyObject.tp_descr_set**

An optional pointer to a “descriptor set” function.

The function signature is

```
int tp_descr_set(PyObject *self, PyObject *obj, PyObject *va
```

This field is inherited by subtypes.

long **PyObject.tp_dictoffset**

If the instances of this type have a dictionary containing instance variables, this field is non-zero and contains the offset in the instances of the type of the instance variable dictionary; this offset is used by `PyObject_GenericGetAttr()`.

Do not confuse this field with `tp_dict`; that is the dictionary for attributes of the type object itself.

If the value of this field is greater than zero, it specifies the offset from the start of the instance structure. If the value is less than zero, it specifies the offset from the *end* of the instance structure.

A negative offset is more expensive to use, and should only be used when the instance structure contains a variable-length part. This is used for example to add an instance variable dictionary to subtypes of `str` or `tuple`. Note that the `tp_basicsize` field should account for the dictionary added to the end in that case, even though the dictionary is not included in the basic object layout. On a system with a pointer size of 4 bytes, `tp_dictoffset` should be set to `-4` to indicate that the dictionary is at the very end of the structure.

The real dictionary offset in an instance can be computed from a negative `tp_dictoffset` as follows:

```
dictoffset = tp_basicsize + abs(ob_size)*tp_itemsize + tp_di  
if dictoffset is not aligned on sizeof(void*):  
    round up to sizeof(void*)
```

where `tp_basicsize`, `tp_itemsize` and `tp_dictoffset` are taken from the type object, and `ob_size` is taken from the instance. The absolute value is taken because ints use the sign of `ob_size` to store the sign of the number. (There's never a need to do this calculation yourself; it is done for you by `_PyObject_GetDictPtr()`.)

This field is inherited by subtypes, but see the rules listed below. A subtype may override this offset; this means that the subtype instances store the dictionary at a difference offset than the base type. Since the dictionary is always found via `tp_dictoffset`, this should not be a problem.

When a type defined by a class statement has no `__slots__` declaration, and none of its base types has an instance variable dictionary, a dictionary slot is added to the instance layout and the `tp_dictoffset` is set to that slot's offset.

When a type defined by a class statement has a `__slots__` declaration, the type inherits its `tp_dictoffset` from its base type.

(Adding a slot named `__dict__` to the `__slots__` declaration does not have the expected effect, it just causes confusion. Maybe this should be added as a feature just like `__weakref__` though.)

initproc `PyTypeObject.tp_init`

An optional pointer to an instance initialization function.

This function corresponds to the `__init__()` method of classes. Like `__init__()`, it is possible to create an instance without calling `__init__()`, and it is possible to reinitialize an instance by calling its `__init__()` method again.

The function signature is

```
int tp_init(PyObject *self, PyObject *args, PyObject *kwds)
```

The `self` argument is the instance to be initialized; the `args` and `kwds` arguments represent positional and keyword arguments of the call to `__init__()`.

The `tp_init` function, if not `NULL`, is called when an instance is created normally by calling its type, after the type's `tp_new` function has returned an instance of the type. If the `tp_new` function returns an instance of some other type that is not a subtype of the original type, no `tp_init` function is called; if `tp_new` returns an instance of a subtype of the original type, the subtype's `tp_init` is called.

This field is inherited by subtypes.

allocfunc `PyTypeObject.tp_alloc`

An optional pointer to an instance allocation function.

The function signature is

```
PyObject *tp_alloc(PyTypeObject *self, Py_ssize_t nitems)
```

The purpose of this function is to separate memory allocation from memory initialization. It should return a pointer to a block of memory of adequate length for the instance, suitably aligned, and initialized to zeros, but with `ob_refcnt` set to `1` and `ob_type` set to the type argument. If the type's `tp_itemsize` is non-zero, the object's `ob_size` field should be initialized to `nitems` and the length of the allocated memory block should be `tp_basicsize + nitems*tp_itemsize`, rounded up to a multiple of `sizeof(void*)`; otherwise, `nitems` is not used and the length of the block should be `tp_basicsize`.

Do not use this function to do any other instance initialization, not even to allocate additional memory; that should be done by `tp_new`.

This field is inherited by static subtypes, but not by dynamic subtypes (subtypes created by a class statement); in the latter, this field is always set to `PyType_GenericAlloc()`, to force a standard heap allocation strategy. That is also the recommended value for statically defined types.

newfunc PyTypeObject . tp_new

An optional pointer to an instance creation function.

If this function is `NULL` for a particular type, that type cannot be called to create new instances; presumably there is some other way to create instances, like a factory function.

The function signature is

```
PyObject *tp_new(PyTypeObject *subtype, PyObject *args, PyOb
```

The `subtype` argument is the type of the object being created; the `args` and `kwds` arguments represent positional and keyword arguments of the call to the type. Note that `subtype` doesn't have to equal the type whose `tp_new` function is called; it may be a subtype of that type (but not an unrelated type).

The `tp_new` function should call `subtype->tp_alloc(subtype, nitems)` to allocate space for the object, and then do only as much further initialization as is absolutely necessary. Initialization that can safely be ignored or repeated should be placed in the `tp_init` handler. A good rule of thumb is that for immutable types, all initialization should take place in `tp_new`, while for mutable types, most initialization should be deferred to `tp_init`.

This field is inherited by subtypes, except it is not inherited by static types whose `tp_base` is `NULL` or `&PyBaseObject_Type`.

destructor `PyTypeObject.tp_free`

An optional pointer to an instance deallocation function. Its signature is `freefunc`:

```
void tp_free(void *)
```

An initializer that is compatible with this signature is `PyObject_Free()`.

This field is inherited by static subtypes, but not by dynamic subtypes (subtypes created by a class statement); in the latter, this field is set to a deallocator suitable to match `PyType_GenericAlloc()` and the value of the `Py_TPFLAGS_HAVE_GC` flag bit.

inquiry `PyTypeObject.tp_is_gc`

An optional pointer to a function called by the garbage collector.

The garbage collector needs to know whether a particular object is collectible or not. Normally, it is sufficient to look at the object's type's `tp_flags` field, and check the `Py_TPFLAGS_HAVE_GC` flag bit. But some types have a mixture of statically and dynamically allocated instances, and the statically allocated instances are not collectible. Such types should define this function; it should return `1` for a collectible instance, and `0` for a non-collectible instance. The signature is

```
int tp_is_gc(PyObject *self)
```

(The only example of this are types themselves. The metatype, `PyType_Type`, defines this function to distinguish between statically and dynamically allocated types.)

This field is inherited by subtypes.

PyObject* `PyTypeObject.tp_bases`

Tuple of base types.

This is set for types created by a class statement. It should be `NULL` for statically defined types.

This field is not inherited.

PyObject* `PyTypeObject.tp_mro`

Tuple containing the expanded set of base types, starting with the type itself and ending with `object`, in Method Resolution Order.

This field is not inherited; it is calculated fresh by `PyType_Ready()`.

PyObject* `PyTypeObject.tp_cache`

Unused. Not inherited. Internal use only.

PyObject* **PyTypeObject.tp_subclasses**

List of weak references to subclasses. Not inherited. Internal use only.

PyObject* **PyTypeObject.tp_weaklist**

Weak reference list head, for weak references to this type object. Not inherited. Internal use only.

The remaining fields are only defined if the feature test macro **COUNT_ALLOCS** is defined, and are for internal use only. They are documented here for completeness. None of these fields are inherited by subtypes.

Py_ssize_t **PyTypeObject.tp_allocs**

Number of allocations.

Py_ssize_t **PyTypeObject.tp_frees**

Number of frees.

Py_ssize_t **PyTypeObject.tp_maxalloc**

Maximum simultaneously allocated objects.

PyTypeObject* **PyTypeObject.tp_next**

Pointer to the next type object with a non-zero **tp_allocs** field.

Also, note that, in a garbage collected Python, **tp_dealloc** may be called from any Python thread, not just the thread which created the object (if the object becomes part of a refcount cycle, that cycle might be collected by a garbage collection on any thread). This is not a problem for Python API calls, since the thread on which **tp_dealloc** is called will own the Global Interpreter Lock (GIL). However, if the object being destroyed in turn destroys objects from some other C or C++ library, care should be taken to ensure that destroying those objects on the thread which called **tp_dealloc** will not violate any

assumptions of the library.

Number Object Structures

PyNumberMethods

This structure holds pointers to the functions which an object uses to implement the number protocol. Each function is used by the function of similar name documented in the *Number Protocol* section.

Here is the structure definition:

```
typedef struct {
    binaryfunc nb_add;
    binaryfunc nb_subtract;
    binaryfunc nb_multiply;
    binaryfunc nb_remainder;
    binaryfunc nb_divmod;
    ternaryfunc nb_power;
    unaryfunc nb_negative;
    unaryfunc nb_positive;
    unaryfunc nb_absolute;
    inquiry nb_bool;
    unaryfunc nb_invert;
    binaryfunc nb_lshift;
    binaryfunc nb_rshift;
    binaryfunc nb_and;
    binaryfunc nb_xor;
    binaryfunc nb_or;
    unaryfunc nb_int;
    void *nb_reserved;
    unaryfunc nb_float;

    binaryfunc nb_inplace_add;
    binaryfunc nb_inplace_subtract;
    binaryfunc nb_inplace_multiply;
    binaryfunc nb_inplace_remainder;
    ternaryfunc nb_inplace_power;
    binaryfunc nb_inplace_lshift;
    binaryfunc nb_inplace_rshift;
    binaryfunc nb_inplace_and;
    binaryfunc nb_inplace_xor;
    binaryfunc nb_inplace_or;
```

```
binaryfunc nb_floor_divide;
binaryfunc nb_true_divide;
binaryfunc nb_inplace_floor_divide;
binaryfunc nb_inplace_true_divide;

unaryfunc nb_index;
} PyNumberMethods;
```

Note: Binary and ternary functions must check the type of all their operands, and implement the necessary conversions (at least one of the operands is an instance of the defined type). If the operation is not defined for the given operands, binary and ternary functions must return `Py_NotImplemented`, if another error occurred they must return `NULL` and set an exception.

Note: The `nb_reserved` field should always be `NULL`. It was previously called `nb_long`, and was renamed in Python 3.0.1.

Mapping Object Structures

PyMappingMethods

This structure holds pointers to the functions which an object uses to implement the mapping protocol. It has three members:

lenfunc **PyMappingMethods.mp_length**

This function is used by `PyMapping_Length()` and `PyObject_Size()`, and has the same signature. This slot may be set to `NULL` if the object has no defined length.

binaryfunc **PyMappingMethods.mp_subscript**

This function is used by `PyObject_GetItem()` and has the same signature. This slot must be filled for the `PyMapping_Check()` function to return `1`, it can be `NULL` otherwise.

objobjargproc **PyMappingMethods.mp_ass_subscript**

This function is used by `PyObject_SetItem()` and has the same signature. If this slot is `NULL`, the object does not support item assignment.

Sequence Object Structures

PySequenceMethods

This structure holds pointers to the functions which an object uses to implement the sequence protocol.

lenfunc **PySequenceMethods.sq_length**

This function is used by `PySequence_Size()` and `PyObject_Size()`, and has the same signature.

binaryfunc **PySequenceMethods.sq_concat**

This function is used by `PySequence_Concat()` and has the same signature. It is also used by the `+` operator, after trying the numeric addition via the `tp_as_number.nb_add` slot.

ssizeargfunc **PySequenceMethods.sq_repeat**

This function is used by `PySequence_Repeat()` and has the same signature. It is also used by the `*` operator, after trying numeric multiplication via the `tp_as_number.nb_mul` slot.

ssizeargfunc **PySequenceMethods.sq_item**

This function is used by `PySequence_GetItem()` and has the same signature. This slot must be filled for the `PySequence_Check()` function to return `1`, it can be `NULL` otherwise.

Negative indexes are handled as follows: if the `sq_length` slot is filled, it is called and the sequence length is used to compute a positive index which is passed to `sq_item`. If `sq_length` is `NULL`, the index is passed as is to the function.

ssizeobjargproc **PySequenceMethods.sq_ass_item**

This function is used by `PySequence_SetItem()` and has the same signature. This slot may be left to `NULL` if the object does not

support item assignment.

objobjproc **PySequenceMethods.sq_contains**

This function may be used by **PySequence_Contains()** and has the same signature. This slot may be left to *NULL*, in this case **PySequence_Contains()** simply traverses the sequence until it finds a match.

binaryfunc **PySequenceMethods.sq_inplace_concat**

This function is used by **PySequence_InPlaceConcat()** and has the same signature. It should modify its first operand, and return it.

ssizeargfunc **PySequenceMethods.sq_inplace_repeat**

This function is used by **PySequence_InPlaceRepeat()** and has the same signature. It should modify its first operand, and return it.

Buffer Object Structures

The *buffer interface* exports a model where an object can expose its internal data.

If an object does not export the buffer interface, then its `tp_as_buffer` member in the `PyTypeObject` structure should be `NULL`. Otherwise, the `tp_as_buffer` will point to a `PyBufferProcs` structure.

`PyBufferProcs`

Structure used to hold the function pointers which define an implementation of the buffer protocol.

getbufferproc `bf_getbuffer`

This should fill a `Py_buffer` with the necessary data for exporting the type. The signature of `getbufferproc` is `int (PyObject *obj, Py_buffer *view, int flags)`. `obj` is the object to export, `view` is the `Py_buffer` struct to fill, and `flags` gives the conditions the caller wants the memory under. (See `PyObject_GetBuffer()` for all flags.) `bf_getbuffer` is responsible for filling `view` with the appropriate information. (`PyBuffer_FillView()` can be used in simple cases.) See `Py_buffer`'s docs for what needs to be filled in.

releasebufferproc `bf_releasebuffer`

This should release the resources of the buffer. The signature of `releasebufferproc` is `void (PyObject *obj, Py_buffer *view)`. If the `bf_releasebuffer` function is not provided (i.e. it is `NULL`), then it does not ever need to be called.

The exporter of the buffer interface must make sure that any memory pointed to in the `Py_buffer` structure remains valid

until `releasebuffer` is called. Exporters will need to define a `bf_releasebuffer` function if they can re-allocate their memory, strides, shape, suboffsets, or format variables which they might share through the struct `bufferinfo`.

See `PyBuffer_Release()`.

Supporting Cyclic Garbage Collection

Python's support for detecting and collecting garbage which involves circular references requires support from object types which are "containers" for other objects which may also be containers. Types which do not store references to other objects, or which only store references to atomic types (such as numbers or strings), do not need to provide any explicit support for garbage collection.

To create a container type, the `tp_flags` field of the type object must include the `Py_TPFLAGS_HAVE_GC` and provide an implementation of the `tp_traverse` handler. If instances of the type are mutable, a `tp_clear` implementation must also be provided.

`Py_TPFLAGS_HAVE_GC`

Objects with a type with this flag set must conform with the rules documented here. For convenience these objects will be referred to as container objects.

Constructors for container types must conform to two rules:

1. The memory for the object must be allocated using `PyObject_GC_New()` or `PyObject_GC_NewVar()`.
2. Once all the fields which may contain references to other containers are initialized, it must call `PyObject_GC_Track()`.

`TYPE* PyObject_GC_New(TYPE, PyTypeObject *type)`

Analogous to `PyObject_New()` but for container objects with the `Py_TPFLAGS_HAVE_GC` flag set.

`TYPE* PyObject_GC_NewVar(TYPE, PyTypeObject *type, Py_ssize_t size)`

Analogous to `PyObject_NewVar()` but for container objects with the `Py_TPFLAGS_HAVE_GC` flag set.

`TYPE* PyObject_GC_Resize(TYPE, PyVarObject *op, Py_ssize_t newsize)`

Resize an object allocated by `PyObject_NewVar()`. Returns the resized object or `NULL` on failure.

`void PyObject_GC_Track(PyObject *op)`

Adds the object `op` to the set of container objects tracked by the collector. The collector can run at unexpected times so objects must be valid while being tracked. This should be called once all the fields followed by the `tp_traverse` handler become valid, usually near the end of the constructor.

`void _PyObject_GC_TRACK(PyObject *op)`

A macro version of `PyObject_GC_Track()`. It should not be used for extension modules.

Similarly, the deallocator for the object must conform to a similar pair of rules:

1. Before fields which refer to other containers are invalidated, `PyObject_GC_UnTrack()` must be called.
2. The object's memory must be deallocated using `PyObject_GC_De1()`.

`void PyObject_GC_De1(void *op)`

Releases memory allocated to an object using `PyObject_GC_New()` or `PyObject_GC_NewVar()`.

`void PyObject_GC_UnTrack(void *op)`

Remove the object `op` from the set of container objects tracked by the collector. Note that `PyObject_GC_Track()` can be called

again on this object to add it back to the set of tracked objects. The deallocator (`tp_dealloc` handler) should call this for the object before any of the fields used by the `tp_traverse` handler become invalid.

```
void _PyObject_GC_UNTRACK(PyObject *op)
```

A macro version of `PyObject_GC_UnTrack()`. It should not be used for extension modules.

The `tp_traverse` handler accepts a function parameter of this type:

```
int (*visitproc)(PyObject *object, void *arg)
```

Type of the visitor function passed to the `tp_traverse` handler. The function should be called with an object to traverse as *object* and the third parameter to the `tp_traverse` handler as *arg*. The Python core uses several visitor functions to implement cyclic garbage detection; it's not expected that users will need to write their own visitor functions.

The `tp_traverse` handler must have the following type:

```
int (*traverseproc)(PyObject *self, visitproc visit, void *arg)
```

Traversal function for a container object. Implementations must call the *visit* function for each object directly contained by *self*, with the parameters to *visit* being the contained object and the *arg* value passed to the handler. The *visit* function must not be called with a *NULL* object argument. If *visit* returns a non-zero value that value should be returned immediately.

To simplify writing `tp_traverse` handlers, a `Py_VISIT()` macro is provided. In order to use this macro, the `tp_traverse` implementation must name its arguments exactly *visit* and *arg*:

```
void Py_VISIT(PyObject *o)
```

Call the *visit* callback, with arguments *o* and *arg*. If *visit* returns a non-zero value, then return it. Using this macro, `tp_traverse` handlers look like:

```
static int
my_traverse(Noddy *self, visitproc visit, void *arg)
{
    Py_VISIT(self->foo);
    Py_VISIT(self->bar);
    return 0;
}
```

The `tp_clear` handler must be of the `inquiry` type, or `NULL` if the object is immutable.

`int (*inquiry)(PyObject *self)`

Drop references that may have created reference cycles. Immutable objects do not have to define this method since they can never directly create reference cycles. Note that the object must still be valid after calling this method (don't just call `Py_DECREF()` on a reference). The collector will call this method if it detects that this object is involved in a reference cycle.

1. An Introduction to Distutils

This document covers using the Distutils to distribute your Python modules, concentrating on the role of developer/distributor: if you're looking for information on installing Python modules, you should refer to the *Installing Python Modules* chapter.

1.1. Concepts & Terminology

Using the Distutils is quite simple, both for module developers and for users/administrators installing third-party modules. As a developer, your responsibilities (apart from writing solid, well-documented and well-tested code, of course!) are:

- write a setup script (`setup.py` by convention)
- (optional) write a setup configuration file
- create a source distribution
- (optional) create one or more built (binary) distributions

Each of these tasks is covered in this document.

Not all module developers have access to a multitude of platforms, so it's not always feasible to expect them to create a multitude of built distributions. It is hoped that a class of intermediaries, called *packagers*, will arise to address this need. Packagers will take source distributions released by module developers, build them on one or more platforms, and release the resulting built distributions. Thus, users on the most popular platforms will be able to install most popular Python module distributions in the most natural way for their platform, without having to run a single setup script or compile a line of code.

1.2. A Simple Example

The setup script is usually quite simple, although since it's written in Python, there are no arbitrary limits to what you can do with it, though you should be careful about putting arbitrarily expensive operations in your setup script. Unlike, say, Autoconf-style configure scripts, the setup script may be run multiple times in the course of building and installing your module distribution.

If all you want to do is distribute a module called `foo`, contained in a file `foo.py`, then your setup script can be as simple as this:

```
from distutils.core import setup
setup(name='foo',
      version='1.0',
      py_modules=['foo'],
      )
```

Some observations:

- most information that you supply to the Distutils is supplied as keyword arguments to the `setup()` function
- those keyword arguments fall into two categories: package metadata (name, version number) and information about what's in the package (a list of pure Python modules, in this case)
- modules are specified by module name, not filename (the same will hold true for packages and extensions)
- it's recommended that you supply a little more metadata, in particular your name, email address and a URL for the project (see section [Writing the Setup Script](#) for an example)

To create a source distribution for this module, you would create a setup script, `setup.py`, containing the above code, and run:

```
python setup.py sdist
```

which will create an archive file (e.g., tarball on Unix, ZIP file on Windows) containing your setup script `setup.py`, and your module `foo.py`. The archive file will be named `foo-1.0.tar.gz` (or `.zip`), and will unpack into a directory `foo-1.0`.

If an end-user wishes to install your `foo` module, all she has to do is download `foo-1.0.tar.gz` (or `.zip`), unpack it, and—from the `foo-1.0` directory—run

```
python setup.py install
```

which will ultimately copy `foo.py` to the appropriate directory for third-party modules in their Python installation.

This simple example demonstrates some fundamental concepts of the Distutils. First, both developers and installers have the same basic user interface, i.e. the setup script. The difference is which Distutils *commands* they use: the **sdist** command is almost exclusively for module developers, while **install** is more often for installers (although most developers will want to install their own code occasionally).

If you want to make things really easy for your users, you can create one or more built distributions for them. For instance, if you are running on a Windows machine, and want to make things easy for other Windows users, you can create an executable installer (the most appropriate type of built distribution for this platform) with the **bdist_wininst** command. For example:

```
python setup.py bdist_wininst
```

will create an executable installer, `foo-1.0.win32.exe`, in the current directory.

Other useful built distribution formats are RPM, implemented by the **bdist_rpm** command, Solaris **pkgtool** (**bdist_pkgtool**), and HP-UX **swinstall** (**bdist_sdux**). For example, the following command will create an RPM file called `foo-1.0.noarch.rpm`:

```
python setup.py bdist_rpm
```

(The **bdist_rpm** command uses the **rpm** executable, therefore this has to be run on an RPM-based system such as Red Hat Linux, SuSE Linux, or Mandrake Linux.)

You can find out what distribution formats are available at any time by running

```
python setup.py bdist --help-formats
```

1.3. General Python terminology

If you're reading this document, you probably have a good idea of what modules, extensions, and so forth are. Nevertheless, just to be sure that everyone is operating from a common starting point, we offer the following glossary of common Python terms:

module

the basic unit of code reusability in Python: a block of code imported by some other code. Three types of modules concern us here: pure Python modules, extension modules, and packages.

pure Python module

a module written in Python and contained in a single `.py` file (and possibly associated `.pyc` and/or `.pyo` files). Sometimes referred to as a “pure module.”

extension module

a module written in the low-level language of the Python implementation: C/C++ for Python, Java for Jython. Typically contained in a single dynamically loadable pre-compiled file, e.g. a shared object (`.so`) file for Python extensions on Unix, a DLL (given the `.pyd` extension) for Python extensions on Windows, or a Java class file for Jython extensions. (Note that currently, the Distutils only handles C/C++ extensions for Python.)

package

a module that contains other modules; typically contained in a directory in the filesystem and distinguished from other directories by the presence of a file `__init__.py`.

root package

the root of the hierarchy of packages. (This isn't really a package, since it doesn't have an `__init__.py` file. But we have to call it

something.) The vast majority of the standard library is in the root package, as are many small, standalone third-party modules that don't belong to a larger module collection. Unlike regular packages, modules in the root package can be found in many directories: in fact, every directory listed in `sys.path` contributes modules to the root package.

1.4. Distutils-specific terminology

The following terms apply more specifically to the domain of distributing Python modules using the Distutils:

module distribution

a collection of Python modules distributed together as a single downloadable resource and meant to be installed *en masse*. Examples of some well-known module distributions are Numeric Python, PyXML, PIL (the Python Imaging Library), or mxBase. (This would be called a *package*, except that term is already taken in the Python context: a single module distribution may contain zero, one, or many Python packages.)

pure module distribution

a module distribution that contains only pure Python modules and packages. Sometimes referred to as a “pure distribution.”

non-pure module distribution

a module distribution that contains at least one extension module. Sometimes referred to as a “non-pure distribution.”

distribution root

the top-level directory of your source tree (or source distribution); the directory where `setup.py` exists. Generally `setup.py` will be run from this directory.

2. Writing the Setup Script

The setup script is the centre of all activity in building, distributing, and installing modules using the Distutils. The main purpose of the setup script is to describe your module distribution to the Distutils, so that the various commands that operate on your modules do the right thing. As we saw in section *A Simple Example* above, the setup script consists mainly of a call to `setup()`, and most information supplied to the Distutils by the module developer is supplied as keyword arguments to `setup()`.

Here's a slightly more involved example, which we'll follow for the next couple of sections: the Distutils' own setup script. (Keep in mind that although the Distutils are included with Python 1.6 and later, they also have an independent existence so that Python 1.5.2 users can use them to install other module distributions. The Distutils' own setup script, shown here, is used to install the package into Python 1.5.2.)

```
#!/usr/bin/env python

from distutils.core import setup

setup(name='Distutils',
      version='1.0',
      description='Python Distribution Utilities',
      author='Greg Ward',
      author_email='gward@python.net',
      url='http://www.python.org/sigs/distutils-sig/',
      packages=['distutils', 'distutils.command'],
      )
```

There are only two differences between this and the trivial one-file distribution presented in section *A Simple Example*: more metadata, and the specification of pure Python modules by package, rather than by module. This is important since the Distutils consist of a

couple of dozen modules split into (so far) two packages; an explicit list of every module would be tedious to generate and difficult to maintain. For more information on the additional meta-data, see section *Additional meta-data*.

Note that any pathnames (files or directories) supplied in the setup script should be written using the Unix convention, i.e. slash-separated. The Distutils will take care of converting this platform-neutral representation into whatever is appropriate on your current platform before actually using the pathname. This makes your setup script portable across operating systems, which of course is one of the major goals of the Distutils. In this spirit, all pathnames in this document are slash-separated.

This, of course, only applies to pathnames given to Distutils functions. If you, for example, use standard Python functions such as `glob.glob()` or `os.listdir()` to specify files, you should be careful to write portable code instead of hardcoding path separators:

```
glob.glob(os.path.join('mydir', 'subdir', '*.html'))
os.listdir(os.path.join('mydir', 'subdir'))
```

2.1. Listing whole packages

The *packages* option tells the Distutils to process (build, distribute, install, etc.) all pure Python modules found in each package mentioned in the *packages* list. In order to do this, of course, there has to be a correspondence between package names and directories in the filesystem. The default correspondence is the most obvious one, i.e. package `distutils` is found in the directory `distutils` relative to the distribution root. Thus, when you say `packages = ['foo']` in your setup script, you are promising that the Distutils will find a file `foo/__init__.py` (which might be spelled differently on your system, but you get the idea) relative to the directory where your setup script lives. If you break this promise, the Distutils will issue a warning but still process the broken package anyways.

If you use a different convention to lay out your source directory, that's no problem: you just have to supply the *package_dir* option to tell the Distutils about your convention. For example, say you keep all Python source under `lib`, so that modules in the “root package” (i.e., not in any package at all) are in `lib`, modules in the `foo` package are in `lib/foo`, and so forth. Then you would put

```
package_dir = {'': 'lib'}
```

in your setup script. The keys to this dictionary are package names, and an empty package name stands for the root package. The values are directory names relative to your distribution root. In this case, when you say `packages = ['foo']`, you are promising that the file `lib/foo/__init__.py` exists.

Another possible convention is to put the `foo` package right in `lib`,

the `foo.bar` package in `lib/bar`, etc. This would be written in the setup script as

```
package_dir = {'foo': 'lib'}
```

A `package: dir` entry in the `package_dir` dictionary implicitly applies to all packages below `package`, so the `foo.bar` case is automatically handled here. In this example, having `packages = ['foo', 'foo.bar']` tells the Distutils to look for `lib/__init__.py` and `lib/bar/__init__.py`. (Keep in mind that although `package_dir` applies recursively, you must explicitly list all packages in `packages`: the Distutils will *not* recursively scan your source tree looking for any directory with an `__init__.py` file.)

2.2. Listing individual modules

For a small module distribution, you might prefer to list all modules rather than listing packages—especially the case of a single module that goes in the “root package” (i.e., no package at all). This simplest case was shown in section *A Simple Example*; here is a slightly more involved example:

```
py_modules = ['mod1', 'pkg.mod2']
```

This describes two modules, one of them in the “root” package, the other in the `pkg` package. Again, the default package/directory layout implies that these two modules can be found in `mod1.py` and `pkg/mod2.py`, and that `pkg/__init__.py` exists as well. And again, you can override the package/directory correspondence using the `package_dir` option.

2.3. Describing extension modules

Just as writing Python extension modules is a bit more complicated than writing pure Python modules, describing them to the Distutils is a bit more complicated. Unlike pure modules, it's not enough just to list modules or packages and expect the Distutils to go out and find the right files; you have to specify the extension name, source file(s), and any compile/link requirements (include directories, libraries to link with, etc.).

All of this is done through another keyword argument to `setup()`, the `ext_modules` option. `ext_modules` is just a list of `Extension` instances, each of which describes a single extension module. Suppose your distribution includes a single extension, called `foo` and implemented by `foo.c`. If no additional instructions to the compiler/linker are needed, describing this extension is quite simple:

```
Extension('foo', ['foo.c'])
```

The `Extension` class can be imported from `distutils.core` along with `setup()`. Thus, the setup script for a module distribution that contains only this one extension and nothing else might be:

```
from distutils.core import setup, Extension
setup(name='foo',
      version='1.0',
      ext_modules=[Extension('foo', ['foo.c'])],
      )
```

The `Extension` class (actually, the underlying extension-building machinery implemented by the `build_ext` command) supports a great deal of flexibility in describing Python extensions, which is explained in the following sections.

2.3.1. Extension names and packages

The first argument to the `Extension` constructor is always the name of the extension, including any package names. For example,

```
Extension('foo', ['src/foo1.c', 'src/foo2.c'])
```

describes an extension that lives in the root package, while

```
Extension('pkg.foo', ['src/foo1.c', 'src/foo2.c'])
```

describes the same extension in the `pkg` package. The source files and resulting object code are identical in both cases; the only difference is where in the filesystem (and therefore where in Python's namespace hierarchy) the resulting extension lives.

If you have a number of extensions all in the same package (or all under the same base package), use the `ext_package` keyword argument to `setup()`. For example,

```
setup(...,
      ext_package='pkg',
      ext_modules=[Extension('foo', ['foo.c']),
                  Extension('subpkg.bar', ['bar.c'])],
      )
```

will compile `foo.c` to the extension `pkg.foo`, and `bar.c` to `pkg.subpkg.bar`.

2.3.2. Extension source files

The second argument to the `Extension` constructor is a list of source files. Since the Distutils currently only support C, C++, and Objective-C extensions, these are normally C/C++/Objective-C source files. (Be sure to use appropriate extensions to distinguish

C++source files: `.cc` and `.cpp` seem to be recognized by both Unix and Windows compilers.)

However, you can also include SWIG interface (`.i`) files in the list; the **build_ext** command knows how to deal with SWIG extensions: it will run SWIG on the interface file and compile the resulting C/C++ file into your extension.

This warning notwithstanding, options to SWIG can be currently passed like this:

```
setup(...,
      ext_modules=[Extension('_foo', ['foo.i'],
                             swig_opts=['-modern', '-I../include'],
                             py_modules=['foo'],
                             )
    ]
)
```

Or on the commandline like this:

```
> python setup.py build_ext --swig-opts="-modern -I../include"
```

On some platforms, you can include non-source files that are processed by the compiler and included in your extension. Currently, this just means Windows message text (`.mc`) files and resource definition (`.rc`) files for Visual C++. These will be compiled to binary resource (`.res`) files and linked into the executable.

2.3.3. Preprocessor options

Three optional arguments to **Extension** will help if you need to specify include directories to search or preprocessor macros to define/undefine: `include_dirs`, `define_macros`, and `undef_macros`.

For example, if your extension requires header files in the `include` directory under your distribution root, use the `include_dirs` option:

```
Extension('foo', ['foo.c'], include_dirs=['include'])
```

You can specify absolute directories there; if you know that your extension will only be built on Unix systems with X11R6 installed to `/usr`, you can get away with

```
Extension('foo', ['foo.c'], include_dirs=['/usr/include/X11'])
```

You should avoid this sort of non-portable usage if you plan to distribute your code: it's probably better to write C code like

```
#include <X11/Xlib.h>
```

If you need to include header files from some other Python extension, you can take advantage of the fact that header files are installed in a consistent way by the Distutils `install_header` command. For example, the Numerical Python header files are installed (on a standard Unix installation) to `/usr/local/include/python1.5/Numerical`. (The exact location will differ according to your platform and Python installation.) Since the Python include directory—`/usr/local/include/python1.5` in this case—is always included in the search path when building Python extensions, the best approach is to write C code like

```
#include <Numerical/arrayobject.h>
```

If you must put the `Numerical` include directory right into your header search path, though, you can find that directory using the Distutils `distutils.sysconfig` module:

```
from distutils.sysconfig import get_python_inc
includir = os.path.join(get_python_inc(plat_specific=1), 'Numeric
setup(...,
    Extension(..., include_dirs=[includir]),
    )
```

Even though this is quite portable—it will work on any Python installation, regardless of platform—it’s probably easier to just write your C code in the sensible way.

You can define and undefine pre-processor macros with the `define_macros` and `undef_macros` options. `define_macros` takes a list of `(name, value)` tuples, where `name` is the name of the macro to define (a string) and `value` is its value: either a string or `None`. (Defining a macro `FOO` to `None` is the equivalent of a bare `#define FOO` in your C source: with most compilers, this sets `FOO` to the string `1`.) `undef_macros` is just a list of macros to undefine.

For example:

```
Extension(...,
           define_macros=[('NDEBUG', '1'),
                          ('HAVE_STRFTIME', None)],
           undef_macros=['HAVE_FOO', 'HAVE_BAR'])
```

is the equivalent of having this at the top of every C source file:

```
#define NDEBUG 1
#define HAVE_STRFTIME
#undef HAVE_FOO
#undef HAVE_BAR
```

2.3.4. Library options

You can also specify the libraries to link against when building your extension, and the directories to search for those libraries. The `libraries` option is a list of libraries to link against, `library_dirs` is a list of directories to search for libraries at link-time, and `runtime_library_dirs` is a list of directories to search for shared (dynamically loaded) libraries at run-time.

For example, if you need to link against libraries known to be in the

standard library search path on target systems

```
Extension(...,  
          libraries=['gdbm', 'readline'])
```

If you need to link with libraries in a non-standard location, you'll have to include the location in `library_dirs`:

```
Extension(...,  
          library_dirs=['/usr/X11R6/lib'],  
          libraries=['X11', 'Xt'])
```

(Again, this sort of non-portable construct should be avoided if you intend to distribute your code.)

2.3.5. Other options

There are still some other options which can be used to handle special cases.

The *optional* option is a boolean; if it is true, a build failure in the extension will not abort the build process, but instead simply not install the failing extension.

The *extra_objects* option is a list of object files to be passed to the linker. These files must not have extensions, as the default extension for the compiler is used.

extra_compile_args and *extra_link_args* can be used to specify additional command line options for the respective compiler and linker command lines.

export_symbols is only useful on Windows. It can contain a list of symbols (functions or variables) to be exported. This option is not needed when building compiled extensions: Distutils will automatically add `initmodule` to the list of exported symbols.

The *depends* option is a list of files that the extension depends on (for example header files). The build command will call the compiler on the sources to rebuild extension if any on this files has been modified since the previous build.

2.4. Relationships between Distributions and Packages

A distribution may relate to packages in three specific ways:

1. It can require packages or modules.
2. It can provide packages or modules.
3. It can obsolete packages or modules.

These relationships can be specified using keyword arguments to the `distutils.core.setup()` function.

Dependencies on other Python modules and packages can be specified by supplying the *requires* keyword argument to `setup()`. The value must be a list of strings. Each string specifies a package that is required, and optionally what versions are sufficient.

To specify that any version of a module or package is required, the string should consist entirely of the module or package name. Examples include `'myModule'` and `'xml.parsers.expat'`.

If specific versions are required, a sequence of qualifiers can be supplied in parentheses. Each qualifier may consist of a comparison operator and a version number. The accepted comparison operators are:

```
<      >      ==  
<=     >=     !=
```

These can be combined by using multiple qualifiers separated by commas (and optional whitespace). In this case, all of the qualifiers must be matched; a logical AND is used to combine the evaluations.

Let's look at a bunch of examples:

Requires Expression	Explanation
<code>==1.0</code>	Only version 1.0 is compatible
<code>>1.0, !=1.5.1, <2.0</code>	Any version after 1.0 and before 2.0 is compatible, except 1.5.1

Now that we can specify dependencies, we also need to be able to specify what we provide that other distributions can require. This is done using the *provides* keyword argument to `setup()`. The value for this keyword is a list of strings, each of which names a Python module or package, and optionally identifies the version. If the version is not specified, it is assumed to match that of the distribution.

Some examples:

Provides Expression	Explanation
<code>mypkg</code>	Provide <code>mypkg</code> , using the distribution version
<code>mypkg (1.1)</code>	Provide <code>mypkg</code> version 1.1, regardless of the distribution version

A package can declare that it obsoletes other packages using the *obsoletes* keyword argument. The value for this is similar to that of the *requires* keyword: a list of strings giving module or package specifiers. Each specifier consists of a module or package name optionally followed by one or more version qualifiers. Version qualifiers are given in parentheses after the module or package name.

The versions identified by the qualifiers are those that are obsoleted by the distribution being described. If no qualifiers are given, all versions of the named module or package are understood to be obsoleted.

2.5. Installing Scripts

So far we have been dealing with pure and non-pure Python modules, which are usually not run by themselves but imported by scripts.

Scripts are files containing Python source code, intended to be started from the command line. Scripts don't require Distutils to do anything very complicated. The only clever feature is that if the first line of the script starts with `#!` and contains the word "python", the Distutils will adjust the first line to refer to the current interpreter location. By default, it is replaced with the current interpreter location. The `--executable` (or `-e`) option will allow the interpreter path to be explicitly overridden.

The `scripts` option simply is a list of files to be handled in this way. From the PyXML setup script:

```
setup(...,
      scripts=['scripts/xmlproc_parse', 'scripts/xmlproc_val']
    )
```

Changed in version 3.1: All the scripts will also be added to the `MANIFEST` file if no template is provided. See [Specifying the files to distribute](#).

2.6. Installing Package Data

Often, additional files need to be installed into a package. These files are often data that's closely related to the package's implementation, or text files containing documentation that might be of interest to programmers using the package. These files are called *package data*.

Package data can be added to packages using the `package_data` keyword argument to the `setup()` function. The value must be a mapping from package name to a list of relative path names that should be copied into the package. The paths are interpreted as relative to the directory containing the package (information from the `package_dir` mapping is used if appropriate); that is, the files are expected to be part of the package in the source directories. They may contain glob patterns as well.

The path names may contain directory portions; any necessary directories will be created in the installation.

For example, if a package should contain a subdirectory with several data files, the files can be arranged like this in the source tree:

```
setup.py
src/
  mypkg/
    __init__.py
    module.py
    data/
      tables.dat
      spoons.dat
      forks.dat
```

The corresponding call to `setup()` might be:

```
setup(...,
```

```
packages=['mypkg'],
package_dir={'mypkg': 'src/mypkg'},
package_data={'mypkg': ['data/*.dat']},
)
```

Changed in version 3.1: All the files that match `package_data` will be added to the `MANIFEST` file if no template is provided. See [Specifying the files to distribute](#).

2.7. Installing Additional Files

The `data_files` option can be used to specify additional files needed by the module distribution: configuration files, message catalogs, data files, anything which doesn't fit in the previous categories.

`data_files` specifies a sequence of (*directory*, *files*) pairs in the following way:

```
setup(...,
      data_files=[('bitmaps', ['bm/b1.gif', 'bm/b2.gif']),
                  ('config', ['cfg/data.cfg']),
                  ('/etc/init.d', ['init-script'])]
      )
```

Note that you can specify the directory names where the data files will be installed, but you cannot rename the data files themselves.

Each (*directory*, *files*) pair in the sequence specifies the installation directory and the files to install there. If *directory* is a relative path, it is interpreted relative to the installation prefix (Python's `sys.prefix` for pure-Python packages, `sys.exec_prefix` for packages that contain extension modules). Each file name in *files* is interpreted relative to the `setup.py` script at the top of the package source distribution. No directory information from *files* is used to determine the final location of the installed file; only the name of the file is used.

You can specify the `data_files` options as a simple sequence of files without specifying a target directory, but this is not recommended, and the **install** command will print a warning in this case. To install data files directly in the target directory, an empty string should be given as the directory.

Changed in version 3.1: All the files that match `data_files` will be added to the `MANIFEST` file if no template is provided. See [Specifying](#)

the files to distribute.

2.8. Additional meta-data

The setup script may include additional meta-data beyond the name and version. This information includes:

Meta-Data	Description	Value	Notes
name	name of the package	short string	(1)
version	version of this release	short string	(1)(2)
author	package author's name	short string	(3)
author_email	email address of the package author	email address	(3)
maintainer	package maintainer's name	short string	(3)
maintainer_email	email address of the package maintainer	email address	(3)
url	home page for the package	URL	(1)
description	short, summary description of the package	short string	
long_description	longer description of the package	long string	(5)
download_url	location where the package may be downloaded	URL	(4)
classifiers	a list of classifiers	list of strings	(4)
platforms	a list of platforms	list of strings	
license	license for the package	short string	(6)

Notes:

1. These fields are required.
2. It is recommended that versions take the form

major.minor[.patch[.sub]].

3. Either the author or the maintainer must be identified.
4. These fields should not be used if your package is to be compatible with Python versions prior to 2.2.3 or 2.3. The list is available from the [PyPI website](#).
5. The `long_description` field is used by PyPI when you are registering a package, to build its home page.
6. The `license` field is a text indicating the license covering the package where the license is not a selection from the “License” Trove classifiers. See the `classifier` field. Notice that there’s a `licence` distribution option which is deprecated but still acts as an alias for `license`.

‘short string’

A single line of text, not more than 200 characters.

‘long string’

Multiple lines of plain text in reStructuredText format (see <http://docutils.sf.net/>).

‘list of strings’

See below.

Encoding the version information is an art in itself. Python packages generally adhere to the version format *major.minor[.patch][sub]*. The major number is 0 for initial, experimental releases of software. It is incremented for releases that represent major milestones in a package. The minor number is incremented when important new features are added to the package. The patch number increments when bug-fix releases are made. Additional trailing version information is sometimes used to indicate sub-releases. These are “a1,a2,...,aN” (for alpha releases, where functionality and API may change), “b1,b2,...,bN” (for beta releases, which only fix bugs) and “pr1,pr2,...,prN” (for final pre-release release testing). Some examples:

0.1.0

the first, experimental release of a package

1.0.1a2

the second alpha release of the first patch version of 1.0

classifiers are specified in a Python list:

```
setup(...,
      classifiers=[
          'Development Status :: 4 - Beta',
          'Environment :: Console',
          'Environment :: Web Environment',
          'Intended Audience :: End Users/Desktop',
          'Intended Audience :: Developers',
          'Intended Audience :: System Administrators',
          'License :: OSI Approved :: Python Software Foundatio
          'Operating System :: MacOS :: MacOS X',
          'Operating System :: Microsoft :: Windows',
          'Operating System :: POSIX',
          'Programming Language :: Python',
          'Topic :: Communications :: Email',
          'Topic :: Office/Business',
          'Topic :: Software Development :: Bug Tracking',
      ],
  )
```

If you wish to include classifiers in your `setup.py` file and also wish to remain backwards-compatible with Python releases prior to 2.2.3, then you can include the following code fragment in your `setup.py` before the `setup()` call.

```
# patch distutils if it can't cope with the "classifiers" or
# "download_url" keywords
from sys import version
if version < '2.2.3':
    from distutils.dist import DistributionMetadata
    DistributionMetadata.classifiers = None
    DistributionMetadata.download_url = None
```

2.9. Debugging the setup script

Sometimes things go wrong, and the setup script doesn't do what the developer wants.

Distutils catches any exceptions when running the setup script, and print a simple error message before the script is terminated. The motivation for this behaviour is to not confuse administrators who don't know much about Python and are trying to install a package. If they get a big long traceback from deep inside the guts of Distutils, they may think the package or the Python installation is broken because they don't read all the way down to the bottom and see that it's a permission problem.

On the other hand, this doesn't help the developer to find the cause of the failure. For this purpose, the `DISTUTILS_DEBUG` environment variable can be set to anything except an empty string, and distutils will now print detailed information what it is doing, and prints the full traceback in case an exception occurs.

3. Writing the Setup Configuration File

Often, it's not possible to write down everything needed to build a distribution *a priori*: you may need to get some information from the user, or from the user's system, in order to proceed. As long as that information is fairly simple—a list of directories to search for C header files or libraries, for example—then providing a configuration file, `setup.cfg`, for users to edit is a cheap and easy way to solicit it. Configuration files also let you provide default values for any command option, which the installer can then override either on the command-line or by editing the config file.

The setup configuration file is a useful middle-ground between the setup script—which, ideally, would be opaque to installers [1]—and the command-line to the setup script, which is outside of your control and entirely up to the installer. In fact, `setup.cfg` (and any other Distutils configuration files present on the target system) are processed after the contents of the setup script, but before the command-line. This has several useful consequences:

- installers can override some of what you put in `setup.py` by editing `setup.cfg`
- you can provide non-standard defaults for options that are not easily set in `setup.py`
- installers can override anything in `setup.cfg` using the command-line options to `setup.py`

The basic syntax of the configuration file is simple:

```
[command]
option=value
...
```

where *command* is one of the Distutils commands (e.g. **build_py**, **install**), and *option* is one of the options that command supports. Any number of options can be supplied for each command, and any number of command sections can be included in the file. Blank lines are ignored, as are comments, which run from a '#' character until the end of the line. Long option values can be split across multiple lines simply by indenting the continuation lines.

You can find out the list of options supported by a particular command with the universal *--help* option, e.g.

```
> python setup.py --help build_ext
[...]
Options for 'build_ext' command:
--build-lib (-b)      directory for compiled extension modules
--build-temp (-t)     directory for temporary files (build by-
--inplace (-i)        ignore build-lib and put compiled extens
                       source directory alongside your pure Pyt
--include-dirs (-I)   list of directories to search for header
--define (-D)         C preprocessor macros to define
--undef (-U)          C preprocessor macros to undefine
--swig-opts           list of SWIG command line options
[...]

```

Note that an option spelled *--foo-bar* on the command-line is spelled *foo_bar* in configuration files.

For example, say you want your extensions to be built “in-place”—that is, you have an extension `pkg.ext`, and you want the compiled extension file (`ext.so` on Unix, say) to be put in the same source directory as your pure Python modules `pkg.mod1` and `pkg.mod2`. You can always use the *--inplace* option on the command-line to ensure this:

```
python setup.py build_ext --inplace
```

But this requires that you always specify the **build_ext** command

explicitly, and remember to provide `--inplace`. An easier way is to “set and forget” this option, by encoding it in `setup.cfg`, the configuration file for this distribution:

```
[build_ext]
inplace=1
```

This will affect all builds of this module distribution, whether or not you explicitly specify `build_ext`. If you include `setup.cfg` in your source distribution, it will also affect end-user builds—which is probably a bad idea for this option, since always building extensions in-place would break installation of the module distribution. In certain peculiar cases, though, modules are built right in their installation directory, so this is conceivably a useful ability. (Distributing extensions that expect to be built in their installation directory is almost always a bad idea, though.)

Another example: certain commands take a lot of options that don’t change from run to run; for example, `bdist_rpm` needs to know everything required to generate a “spec” file for creating an RPM distribution. Some of this information comes from the setup script, and some is automatically generated by the Distutils (such as the list of files installed). But some of it has to be supplied as options to `bdist_rpm`, which would be very tedious to do on the command-line for every run. Hence, here is a snippet from the Distutils’ own `setup.cfg`:

```
[bdist_rpm]
release = 1
packager = Greg Ward <gward@python.net>
doc_files = CHANGES.txt
           README.txt
           USAGE.txt
           doc/
           examples/
```

Note that the `doc_files` option is simply a whitespace-separated

string split across multiple lines for readability.

See also:

***Syntax of config files* in “Installing Python Modules”**

More information on the configuration files is available in the manual for system administrators.

Footnotes

- [1] This ideal probably won't be achieved until auto-configuration is fully supported by the Distutils.

4. Creating a Source Distribution

As shown in section *A Simple Example*, you use the **sdist** command to create a source distribution. In the simplest case,

```
python setup.py sdist
```

(assuming you haven't specified any **sdist** options in the setup script or config file), **sdist** creates the archive of the default format for the current platform. The default format is a gzip'ed tar file (`.tar.gz`) on Unix, and ZIP file on Windows.

You can specify as many formats as you like using the `--formats` option, for example:

```
python setup.py sdist --formats=gztar,zip
```

to create a gzipped tarball and a zip file. The available formats are:

Format	Description	Notes
zip	zip file (<code>.zip</code>)	(1),(3)
gztar	gzip'ed tar file (<code>.tar.gz</code>)	(2),(4)
bztar	bzip2'ed tar file (<code>.tar.bz2</code>)	(4)
ztar	compressed tar file (<code>.tar.Z</code>)	(4)
tar	tar file (<code>.tar</code>)	(4)

Notes:

1. default on Windows
2. default on Unix
3. requires either external **zip** utility or **zipfile** module (part of the standard Python library since Python 1.6)
4. requires external utilities: **tar** and possibly one of **gzip**, **bzip2**, or **compress**

4.1. Specifying the files to distribute

If you don't supply an explicit list of files (or instructions on how to generate one), the **sdist** command puts a minimal default set into the source distribution:

- all Python source files implied by the `py_modules` and `packages` options
- all C source files mentioned in the `ext_modules` or `libraries` options (
- scripts identified by the `scripts` option See *Installing Scripts*.
- anything that looks like a test script: `test/test*.py` (currently, the Distutils don't do anything with test scripts except include them in source distributions, but in the future there will be a standard for testing Python module distributions)
- `README.txt` (OR `README`), `setup.py` (or whatever you called your setup script), and `setup.cfg`
- all files that matches the `package_data` metadata. See *Installing Package Data*.
- all files that matches the `data_files` metadata. See *Installing Additional Files*.

Sometimes this is enough, but usually you will want to specify additional files to distribute. The typical way to do this is to write a *manifest template*, called `MANIFEST.in` by default. The manifest template is just a list of instructions for how to generate your manifest file, `MANIFEST`, which is the exact list of files to include in your source distribution. The **sdist** command processes this template and generates a manifest based on its instructions and what it finds in the filesystem.

If you prefer to roll your own manifest file, the format is simple: one filename per line, regular files (or symlinks to them) only. If you do

supply your own `MANIFEST`, you must specify everything: the default set of files described above does not apply in this case.

New in version 3.1: `MANIFEST` files start with a comment indicating they are generated. Files without this comment are not overwritten or removed.

The manifest template has one command per line, where each command specifies a set of files to include or exclude from the source distribution. For an example, again we turn to the Distutils' own manifest template:

```
include *.txt
recursive-include examples *.txt *.py
prune examples/sample?/build
```

The meanings should be fairly clear: include all files in the distribution root matching `*.txt`, all files anywhere under the `examples` directory matching `*.txt` or `*.py`, and exclude all directories matching `examples/sample?/build`. All of this is done *after* the standard include set, so you can exclude files from the standard set with explicit instructions in the manifest template. (Or, you can use the `--no-defaults` option to disable the standard set entirely.) There are several other commands available in the manifest template mini-language; see section [Creating a source distribution: the `sdist` command](#).

The order of commands in the manifest template matters: initially, we have the list of default files as described above, and each command in the template adds to or removes from that list of files. Once we have fully processed the manifest template, we remove files that should not be included in the source distribution:

- all files in the Distutils “build” tree (default `build/`)
- all files in directories named `RCS`, `CVS`, `.svn`, `.hg`, `.git`, `.bzip` or

`_darcs`

Now we have our complete list of files, which is written to the manifest for future reference, and then used to build the source distribution archive(s).

You can disable the default set of included files with the `--no-defaults` option, and you can disable the standard exclude set with `--no-prune`.

Following the Distutils' own manifest template, let's trace how the **sdist** command builds the list of files to include in the Distutils source distribution:

1. include all Python source files in the `distutils` and `distutils/command` subdirectories (because packages corresponding to those two directories were mentioned in the `packages` option in the setup script—see section [Writing the Setup Script](#))
2. include `README.txt`, `setup.py`, and `setup.cfg` (standard files)
3. include `test/test*.py` (standard files)
4. include `*.txt` in the distribution root (this will find `README.txt` a second time, but such redundancies are weeded out later)
5. include anything matching `*.txt` or `*.py` in the sub-tree under `examples`,
6. exclude all files in the sub-trees starting at directories matching `examples/sample?/build`—this may exclude files included by the previous two steps, so it's important that the `prune` command in the manifest template comes after the `recursive-include` command
7. exclude the entire `build` tree, and any `RCS`, `CVS`, `.svn`, `.hg`, `.git`, `.bzip` and `_darcs` directories

Just like in the setup script, file and directory names in the manifest

template should always be slash-separated; the Distutils will take care of converting them to the standard representation on your platform. That way, the manifest template is portable across operating systems.

4.2. Manifest-related options

The normal course of operations for the **sdist** command is as follows:

- if the manifest file, `MANIFEST` doesn't exist, read `MANIFEST.in` and create the manifest
- if neither `MANIFEST` nor `MANIFEST.in` exist, create a manifest with just the default file set
- use the list of files now in `MANIFEST` (either just generated or read in) to create the source distribution archive(s)

There are a couple of options that modify this behaviour. First, use the `--no-defaults` and `--no-prune` to disable the standard “include” and “exclude” sets.

Second, you might just want to (re)generate the manifest, but not create a source distribution:

```
python setup.py sdist --manifest-only
```

`-o` is a shortcut for `--manifest-only`.

Changed in version 3.1: An existing generated `MANIFEST` will be regenerated without **sdist** comparing its modification time to the one of `MANIFEST.in` or `setup.py`.

5. Creating Built Distributions

A “built distribution” is what you’re probably used to thinking of either as a “binary package” or an “installer” (depending on your background). It’s not necessarily binary, though, because it might contain only Python source code and/or byte-code; and we don’t call it a package, because that word is already spoken for in Python. (And “installer” is a term specific to the world of mainstream desktop systems.)

A built distribution is how you make life as easy as possible for installers of your module distribution: for users of RPM-based Linux systems, it’s a binary RPM; for Windows users, it’s an executable installer; for Debian-based Linux users, it’s a Debian package; and so forth. Obviously, no one person will be able to create built distributions for every platform under the sun, so the Distutils are designed to enable module developers to concentrate on their specialty—writing code and creating source distributions—while an intermediary species called *packagers* springs up to turn source distributions into built distributions for as many platforms as there are packagers.

Of course, the module developer could be his own packager; or the packager could be a volunteer “out there” somewhere who has access to a platform which the original developer does not; or it could be software periodically grabbing new source distributions and turning them into built distributions for as many platforms as the software has access to. Regardless of who they are, a packager uses the setup script and the **bdist** command family to generate built distributions.

As a simple example, if I run the following command in the Distutils source tree:

```
python setup.py bdist
```

then the Distutils builds my module distribution (the Distutils itself in this case), does a “fake” installation (also in the `build` directory), and creates the default type of built distribution for my platform. The default format for built distributions is a “dumb” tar file on Unix, and a simple executable installer on Windows. (That tar file is considered “dumb” because it has to be unpacked in a specific location to work.)

Thus, the above command on a Unix system creates `Distutils-1.0.plat.tar.gz`; unpacking this tarball from the right place installs the Distutils just as though you had downloaded the source distribution and run `python setup.py install`. (The “right place” is either the root of the filesystem or Python’s `prefix` directory, depending on the options given to the `bdist_dumb` command; the default is to make dumb distributions relative to `prefix`.)

Obviously, for pure Python distributions, this isn’t any simpler than just running `python setup.py install`—but for non-pure distributions, which include extensions that would need to be compiled, it can mean the difference between someone being able to use your extensions or not. And creating “smart” built distributions, such as an RPM package or an executable installer for Windows, is far more convenient for users even if your distribution doesn’t include any extensions.

The `bdist` command has a `--formats` option, similar to the `sdist` command, which you can use to select the types of built distribution to generate: for example,

```
python setup.py bdist --format=zip
```

would, when run on a Unix system, create `Distutils-1.0.plat.zip`—again, this archive would be unpacked from the root directory to

install the Distutils.

The available formats for built distributions are:

Format	Description	Notes
gztar	gzipped tar file (.tar.gz)	(1),(3)
ztar	compressed tar file (.tar.z)	(3)
tar	tar file (.tar)	(3)
zip	zip file (.zip)	(2),(4)
rpm	RPM	(5)
pkgtool	Solaris pkgtool	
sdux	HP-UX swinstall	
rpm	RPM	(5)
wininst	self-extracting ZIP file for Windows	(4)
msi	Microsoft Installer.	

Notes:

1. default on Unix
2. default on Windows
3. requires external utilities: **tar** and possibly one of **gzip**, **bzip2**, or **compress**
4. requires either external **zip** utility or **zipfile** module (part of the standard Python library since Python 1.6)
5. requires external **rpm** utility, version 3.0.4 or better (use `rpm --version` to find out which version you have)

You don't have to use the **bdist** command with the `--formats` option; you can also use the command that directly implements the format you're interested in. Some of these **bdist** "sub-commands" actually generate several similar formats; for instance, the **bdist_dumb** command generates all the "dumb" archive formats (`tar`, `ztar`, `gztar`, and `zip`), and **bdist_rpm** generates both binary and source RPMs. The **bdist** sub-commands, and the formats generated by

each, are:

Command	Formats
bdist_dumb	tar, ztar, gztar, zip
bdist_rpm	rpm, srpm
bdist_wininst	wininst
bdist_msi	msi

The following sections give details on the individual **bdist_*** commands.

5.1. Creating RPM packages

The RPM format is used by many popular Linux distributions, including Red Hat, SuSE, and Mandrake. If one of these (or any of the other RPM-based Linux distributions) is your usual environment, creating RPM packages for other users of that same distribution is trivial. Depending on the complexity of your module distribution and differences between Linux distributions, you may also be able to create RPMs that work on different RPM-based distributions.

The usual way to create an RPM of your module distribution is to run the **bdist_rpm** command:

```
python setup.py bdist_rpm
```

or the **bdist** command with the *--format* option:

```
python setup.py bdist --formats=rpm
```

The former allows you to specify RPM-specific options; the latter allows you to easily specify multiple formats in one run. If you need to do both, you can explicitly specify multiple **bdist_*** commands and their options:

```
python setup.py bdist_rpm --packager="John Doe <jdoe@example.or  
bdist_wininst --target-version="2.0"
```

Creating RPM packages is driven by a `.spec` file, much as using the Distutils is driven by the setup script. To make your life easier, the **bdist_rpm** command normally creates a `.spec` file based on the information you supply in the setup script, on the command line, and in any Distutils configuration files. Various options and sections in the `.spec` file are derived from options in the setup script as follows:

RPM .spec file option or section	Distutils setup script option
Name	<i>name</i>
Summary (in preamble)	<i>description</i>
Version	<i>version</i>
Vendor	<i>author</i> and <i>author_email</i> , or — & <i>maintainer</i> and <i>maintainer_email</i>
Copyright	<i>license</i>
Url	<i>url</i>
%description (section)	<i>long_description</i>

Additionally, there are many options in `.spec` files that don't have corresponding options in the setup script. Most of these are handled through options to the `bdist_rpm` command as follows:

RPM .spec file option or section	bdist_rpm option	default value
Release	<i>release</i>	"1"
Group	<i>group</i>	"Development/Libraries"
Vendor	<i>vendor</i>	(see above)
Packager	<i>packager</i>	(none)
Provides	<i>provides</i>	(none)
Requires	<i>requires</i>	(none)
Conflicts	<i>conflicts</i>	(none)
Obsoletes	<i>obsoletes</i>	(none)
Distribution	<i>distribution_name</i>	(none)
BuildRequires	<i>build_requires</i>	(none)
Icon	<i>icon</i>	(none)

Obviously, supplying even a few of these options on the command-line would be tedious and error-prone, so it's usually best to put them in the setup configuration file, `setup.cfg`—see section [Writing the Setup Configuration File](#). If you distribute or package many Python

module distributions, you might want to put options that apply to all of them in your personal Distutils configuration file (`~/pydistutils.cfg`).

There are three steps to building a binary RPM package, all of which are handled automatically by the Distutils:

1. create a `.spec` file, which describes the package (analogous to the Distutils setup script; in fact, much of the information in the setup script winds up in the `.spec` file)
2. create the source RPM
3. create the “binary” RPM (which may or may not contain binary code, depending on whether your module distribution contains Python extensions)

Normally, RPM bundles the last two steps together; when you use the Distutils, all three steps are typically bundled together.

If you wish, you can separate these three steps. You can use the `--spec-only` option to make `bdist_rpm` just create the `.spec` file and exit; in this case, the `.spec` file will be written to the “distribution directory”—normally `dist/`, but customizable with the `--dist-dir` option. (Normally, the `.spec` file winds up deep in the “build tree,” in a temporary directory created by `bdist_rpm`.)

5.2. Creating Windows Installers

Executable installers are the natural format for binary distributions on Windows. They display a nice graphical user interface, display some information about the module distribution to be installed taken from the metadata in the setup script, let the user select a few options, and start or cancel the installation.

Since the metadata is taken from the setup script, creating Windows installers is usually as easy as running:

```
python setup.py bdist_wininst
```

or the **bdist** command with the *--formats* option:

```
python setup.py bdist --formats=wininst
```

If you have a pure module distribution (only containing pure Python modules and packages), the resulting installer will be version independent and have a name like `foo-1.0.win32.exe`. These installers can even be created on Unix platforms or Mac OS X.

If you have a non-pure distribution, the extensions can only be created on a Windows platform, and will be Python version dependent. The installer filename will reflect this and now has the form `foo-1.0.win32-py2.0.exe`. You have to create a separate installer for every Python version you want to support.

The installer will try to compile pure modules into *bytecode* after installation on the target system in normal and optimizing mode. If you don't want this to happen for some reason, you can run the **bdist_wininst** command with the *--no-target-compile* and/or the *--no-target-optimize* option.

By default the installer will display the cool “Python Powered” logo when it is run, but you can also supply your own 152x261 bitmap which must be a Windows `.bmp` file with the `--bitmap` option.

The installer will also display a large title on the desktop background window when it is run, which is constructed from the name of your distribution and the version number. This can be changed to another text by using the `--title` option.

The installer file will be written to the “distribution directory” — normally `dist/`, but customizable with the `--dist-dir` option.

5.3. Cross-compiling on Windows

Starting with Python 2.6, distutils is capable of cross-compiling between Windows platforms. In practice, this means that with the correct tools installed, you can use a 32bit version of Windows to create 64bit extensions and vice-versa.

To build for an alternate platform, specify the `--plat-name` option to the build command. Valid values are currently 'win32', 'win-amd64' and 'win-ia64'. For example, on a 32bit version of Windows, you could execute:

```
python setup.py build --plat-name=win-amd64
```

to build a 64bit version of your extension. The Windows Installers also support this option, so the command:

```
python setup.py build --plat-name=win-amd64 bdist_wininst
```

would create a 64bit installation executable on your 32bit version of Windows.

To cross-compile, you must download the Python source code and cross-compile Python itself for the platform you are targeting - it is not possible from a binary installation of Python (as the `.lib` etc file for other platforms are not included.) In practice, this means the user of a 32 bit operating system will need to use Visual Studio 2008 to open the `PCBuild/PCbuild.sln` solution in the Python source tree and build the "x64" configuration of the 'pythoncore' project before cross-compiling extensions is possible.

Note that by default, Visual Studio 2008 does not install 64bit compilers or tools. You may need to reexecute the Visual Studio setup process and select these tools (using Control Panel->

[Add/Remove] Programs is a convenient way to check or modify your existing install.)

5.3.1. The Postinstallation script

Starting with Python 2.3, a postinstallation script can be specified with the `--install-script` option. The basename of the script must be specified, and the script filename must also be listed in the `scripts` argument to the `setup` function.

This script will be run at installation time on the target system after all the files have been copied, with `argv[1]` set to `-install`, and again at uninstallation time before the files are removed with `argv[1]` set to `-remove`.

The installation script runs embedded in the windows installer, every output (`sys.stdout`, `sys.stderr`) is redirected into a buffer and will be displayed in the GUI after the script has finished.

Some functions especially useful in this context are available as additional built-in functions in the installation script.

`directory_created(path)`

`file_created(path)`

These functions should be called when a directory or file is created by the postinstall script at installation time. It will register `path` with the uninstaller, so that it will be removed when the distribution is uninstalled. To be safe, directories are only removed if they are empty.

`get_special_folder_path(csidl_string)`

This function can be used to retrieve special folder locations on Windows like the Start Menu or the Desktop. It returns the full path to the folder. `csidl_string` must be one of the following strings:

```
"CSIDL_APPDATA"  
  
"CSIDL_COMMON_STARTMENU"  
"CSIDL_STARTMENU"  
  
"CSIDL_COMMON_DESKTOPDIRECTORY"  
"CSIDL_DESKTOPDIRECTORY"  
  
"CSIDL_COMMON_STARTUP"  
"CSIDL_STARTUP"  
  
"CSIDL_COMMON_PROGRAMS"  
"CSIDL_PROGRAMS"  
  
"CSIDL_FONTS"
```

If the folder cannot be retrieved, **OSError** is raised.

Which folders are available depends on the exact Windows version, and probably also the configuration. For details refer to Microsoft's documentation of the **SHGetSpecialFolderPath()** function.

create_shortcut(*target*, *description*, *filename*[, *arguments*[,
workdir[, *iconpath*[, *iconindex*]]]])

This function creates a shortcut. *target* is the path to the program to be started by the shortcut. *description* is the description of the shortcut. *filename* is the title of the shortcut that the user will see. *arguments* specifies the command line arguments, if any. *workdir* is the working directory for the program. *iconpath* is the file containing the icon for the shortcut, and *iconindex* is the index of the icon in the file *iconpath*. Again, for details consult the Microsoft documentation for the **IShellLink** interface.

5.4. Vista User Access Control (UAC)

Starting with Python 2.6, `bdist_wininst` supports a `--user-access-control` option. The default is 'none' (meaning no UAC handling is done), and other valid values are 'auto' (meaning prompt for UAC elevation if Python was installed for all users) and 'force' (meaning always prompt for elevation).

6. Registering with the Package Index

The Python Package Index (PyPI) holds meta-data describing distributions packaged with distutils. The distutils command **register** is used to submit your distribution's meta-data to the index. It is invoked as follows:

```
python setup.py register
```

Distutils will respond with the following prompt:

```
running register
We need to know who you are, so please choose either:
  1. use your existing login,
  2. register as a new user,
  3. have the server generate a new password for you (and ema
  4. quit
Your selection [default 1]:
```

Note: if your username and password are saved locally, you will not see this menu.

If you have not registered with PyPI, then you will need to do so now. You should choose option 2, and enter your details as required. Soon after submitting your details, you will receive an email which will be used to confirm your registration.

Once you are registered, you may choose option 1 from the menu. You will be prompted for your PyPI username and password, and **register** will then submit your meta-data to the index.

You may submit any number of versions of your distribution to the index. If you alter the meta-data for a particular version, you may submit it again and the index will be updated.

PyPI holds a record for each (name, version) combination submitted. The first user to submit information for a given name is designated the Owner of that name. They may submit changes through the **register** command or through the web interface. They may also designate other users as Owners or Maintainers. Maintainers may edit the package information, but not designate other Owners or Maintainers.

By default PyPI will list all versions of a given package. To hide certain versions, the Hidden property should be set to yes. This must be edited through the web interface.

6.1. The `.pypirc` file

The format of the `.pypirc` file is as follows:

```
[distutils]
index-servers =
    pypi

[pypi]
repository: <repository-url>
username: <username>
password: <password>
```

The *distutils* section defines a *index-servers* variable that lists the name of all sections describing a repository.

Each section describing a repository defines three variables:

- *repository*, that defines the url of the PyPI server. Defaults to `http://www.python.org/pypi`.
- *username*, which is the registered username on the PyPI server.
- *password*, that will be used to authenticate. If omitted the user will be prompt to type it when needed.

If you want to define another server a new section can be created and listed in the *index-servers* variable:

```
[distutils]
index-servers =
    pypi
    other

[pypi]
repository: <repository-url>
username: <username>
password: <password>
```

```
[other]
repository: http://example.com/pypi
username: <username>
password: <password>
```

register can then be called with the `-r` option to point the repository to work with:

```
python setup.py register -r http://example.com/pypi
```

For convenience, the name of the section that describes the repository may also be used:

```
python setup.py register -r other
```

7. Uploading Packages to the Package Index

The Python Package Index (PyPI) not only stores the package info, but also the package data if the author of the package wishes to. The `distutils` command **upload** pushes the distribution files to PyPI.

The command is invoked immediately after building one or more distribution files. For example, the command

```
python setup.py sdist bdist_wininst upload
```

will cause the source distribution and the Windows installer to be uploaded to PyPI. Note that these will be uploaded even if they are built using an earlier invocation of `setup.py`, but that only distributions named on the command line for the invocation including the **upload** command are uploaded.

The **upload** command uses the username, password, and repository URL from the `$HOME/.pypirc` file (see section [The .pypirc file](#) for more on this file). If a **register** command was previously called in the same command, and if the password was entered in the prompt, **upload** will reuse the entered password. This is useful if you do not want to store a clear text password in the `$HOME/.pypirc` file.

You can specify another PyPI server with the `--repository=*url*` option:

```
python setup.py sdist bdist_wininst upload -r http://example.co
```

See section [The .pypirc file](#) for more on defining several servers.

You can use the `--sign` option to tell **upload** to sign each uploaded

file using GPG (GNU Privacy Guard). The **gpg** program must be available for execution on the system **PATH**. You can also specify which key to use for signing using the *--identity=*name** option.

Other **upload** options include *--repository=* or *--repository=* where *url* is the url of the server and *section* the name of the section in `$HOME/.pypirc`, and *--show-response* (which displays the full response text from the PyPI server for help in debugging upload problems).

7.1. PyPI package display

The `long_description` field plays a special role at PyPI. It is used by the server to display a home page for the registered package.

If you use the `reStructuredText` syntax for this field, PyPI will parse it and display an HTML output for the package home page.

The `long_description` field can be attached to a text file located in the package:

```
from distutils.core import setup

setup(name='Distutils',
      long_description=open('README.txt'))
```

In that case, `README.txt` is a regular `reStructuredText` text file located in the root of the package besides `setup.py`.

To prevent registering broken `reStructuredText` content, you can use the `rst2html` program that is provided by the `docutils` package and check the `long_description` from the command line:

```
$ python setup.py --long-description | rst2html.py > output.htm
```

`docutils` will display a warning if there's something wrong with your syntax.

8. Examples

This chapter provides a number of basic examples to help get started with distutils. Additional information about using distutils can be found in the Distutils Cookbook.

See also:

Distutils Cookbook

Collection of recipes showing how to achieve more control over distutils.

8.1. Pure Python distribution (by module)

If you're just distributing a couple of modules, especially if they don't live in a particular package, you can specify them individually using the `py_modules` option in the setup script.

In the simplest case, you'll have two files to worry about: a setup script and the single module you're distributing, `foo.py` in this example:

```
<root>/
  setup.py
  foo.py
```

(In all diagrams in this section, `<root>` will refer to the distribution root directory.) A minimal setup script to describe this situation would be:

```
from distutils.core import setup
setup(name='foo',
      version='1.0',
      py_modules=['foo'],
      )
```

Note that the name of the distribution is specified independently with the `name` option, and there's no rule that says it has to be the same as the name of the sole module in the distribution (although that's probably a good convention to follow). However, the distribution name is used to generate filenames, so you should stick to letters, digits, underscores, and hyphens.

Since `py_modules` is a list, you can of course specify multiple modules, eg. if you're distributing modules `foo` and `bar`, your setup might look like this:

```
<root>/
  setup.py
```

```
foo.py  
bar.py
```

and the setup script might be

```
from distutils.core import setup  
setup(name='foobar',  
      version='1.0',  
      py_modules=['foo', 'bar'],  
      )
```

You can put module source files into another directory, but if you have enough modules to do that, it's probably easier to specify modules by package rather than listing them individually.

8.2. Pure Python distribution (by package)

If you have more than a couple of modules to distribute, especially if they are in multiple packages, it's probably easier to specify whole packages rather than individual modules. This works even if your modules are not in a package; you can just tell the Distutils to process modules from the root package, and that works the same as any other package (except that you don't have to have an `__init__.py` file).

The setup script from the last example could also be written as

```
from distutils.core import setup
setup(name='foobar',
      version='1.0',
      packages=[''],
      )
```

(The empty string stands for the root package.)

If those two files are moved into a subdirectory, but remain in the root package, e.g.:

```
<root>/
  setup.py
  src/   foo.py
         bar.py
```

then you would still specify the root package, but you have to tell the Distutils where source files in the root package live:

```
from distutils.core import setup
setup(name='foobar',
      version='1.0',
      package_dir={'': 'src'},
      packages=[''],
      )
```

More typically, though, you will want to distribute multiple modules in the same package (or in sub-packages). For example, if the `foo` and `bar` modules belong in package `foobar`, one way to layout your source tree is

```
<root>/
  setup.py
  foobar/
    __init__.py
    foo.py
    bar.py
```

This is in fact the default layout expected by the Distutils, and the one that requires the least work to describe in your setup script:

```
from distutils.core import setup
setup(name='foobar',
      version='1.0',
      packages=['foobar'],
    )
```

If you want to put modules in directories not named for their package, then you need to use the `package_dir` option again. For example, if the `src` directory holds modules in the `foobar` package:

```
<root>/
  setup.py
  src/
    __init__.py
    foo.py
    bar.py
```

an appropriate setup script would be

```
from distutils.core import setup
setup(name='foobar',
      version='1.0',
      package_dir={'foobar': 'src'},
      packages=['foobar'],
    )
```

Or, you might put modules from your main package right in the distribution root:

```
<root>/
  setup.py
  __init__.py
  foo.py
  bar.py
```

in which case your setup script would be

```
from distutils.core import setup
setup(name='foobar',
      version='1.0',
      package_dir={'foobar': ''},
      packages=['foobar'],
      )
```

(The empty string also stands for the current directory.)

If you have sub-packages, they must be explicitly listed in *packages*, but any entries in *package_dir* automatically extend to sub-packages. (In other words, the Distutils does *not* scan your source tree, trying to figure out which directories correspond to Python packages by looking for `__init__.py` files.) Thus, if the default layout grows a sub-package:

```
<root>/
  setup.py
  foobar/
    __init__.py
    foo.py
    bar.py
    subfoo/
      __init__.py
      blah.py
```

then the corresponding setup script would be

```
from distutils.core import setup
```

```
setup(name='foobar',  
      version='1.0',  
      packages=['foobar', 'foobar.subfoo'],  
      )
```

(Again, the empty string in *package_dir* stands for the current directory.)

8.3. Single extension module

Extension modules are specified using the `ext_modules` option. `package_dir` has no effect on where extension source files are found; it only affects the source for pure Python modules. The simplest case, a single extension module in a single C source file, is:

```
<root>/
  setup.py
  foo.c
```

If the `foo` extension belongs in the root package, the setup script for this could be

```
from distutils.core import setup
from distutils.extension import Extension
setup(name='foobar',
      version='1.0',
      ext_modules=[Extension('foo', ['foo.c'])],
    )
```

If the extension actually belongs in a package, say `foopkg`, then

With exactly the same source tree layout, this extension can be put in the `foopkg` package simply by changing the name of the extension:

```
from distutils.core import setup
from distutils.extension import Extension
setup(name='foobar',
      version='1.0',
      ext_modules=[Extension('foopkg.foo', ['foo.c'])],
    )
```

8.4. Checking a package

The `check` command allows you to verify if your package meta-data meet the minimum requirements to build a distribution.

To run it, just call it using your `setup.py` script. If something is missing, `check` will display a warning.

Let's take an example with a simple script:

```
from distutils.core import setup

setup(name='foobar')
```

Running the `check` command will display some warnings:

```
$ python setup.py check
running check
warning: check: missing required meta-data: version, url
warning: check: missing meta-data: either (author and author_em
          (maintainer and maintainer_email) must be supplied
```

If you use the reStructuredText syntax in the `long_description` field and `docutils` is installed you can check if the syntax is fine with the `check` command, using the `restructuredtext` option.

For example, if the `setup.py` script is changed like this:

```
from distutils.core import setup

desc = """\
My description
=====

This is the description of the ``foobar`` package.
"""
```

```
setup(name='foobar', version='1', author='tarek',
      author_email='tarek@ziade.org',
      url='http://example.com', long_description=desc)
```

Where the long description is broken, `check` will be able to detect it by using the `docutils` parser:

```
$ pythontrunk setup.py check --restructuredtext
running check
warning: check: Title underline too short. (line 2)
warning: check: Could not finish the parsing.
```

9. Extending Distutils

Distutils can be extended in various ways. Most extensions take the form of new commands or replacements for existing commands. New commands may be written to support new types of platform-specific packaging, for example, while replacements for existing commands may be made to modify details of how the command operates on a package.

Most extensions of the distutils are made within `setup.py` scripts that want to modify existing commands; many simply add a few file extensions that should be copied into packages in addition to `.py` files as a convenience.

Most distutils command implementations are subclasses of the `Command` class from `distutils.cmd`. New commands may directly inherit from `Command`, while replacements often derive from `Command` indirectly, directly subclassing the command they are replacing. Commands are required to derive from `Command`.

9.1. Integrating new commands

There are different ways to integrate new command implementations into distutils. The most difficult is to lobby for the inclusion of the new features in distutils itself, and wait for (and require) a version of Python that provides that support. This is really hard for many reasons.

The most common, and possibly the most reasonable for most needs, is to include the new implementations with your `setup.py` script, and cause the `distutils.core.setup()` function use them:

```
from distutils.command.build_py import build_py as _build_py
from distutils.core import setup

class build_py(_build_py):
    """Specialized Python source builder."""

    # implement whatever needs to be different...

setup(cmdclass={'build_py': build_py},
      ...)
```

This approach is most valuable if the new implementations must be used to use a particular package, as everyone interested in the package will need to have the new command implementation.

Beginning with Python 2.4, a third option is available, intended to allow new commands to be added which can support existing `setup.py` scripts without requiring modifications to the Python installation. This is expected to allow third-party extensions to provide support for additional packaging systems, but the commands can be used for anything distutils commands can be used for. A new configuration option, `command_packages` (command-line option `--command-packages`), can be used to specify additional packages to be searched for modules implementing commands. Like all distutils

options, this can be specified on the command line or in a configuration file. This option can only be set in the `[global]` section of a configuration file, or before any commands on the command line. If set in a configuration file, it can be overridden from the command line; setting it to an empty string on the command line causes the default to be used. This should never be set in a configuration file provided with a package.

This new option can be used to add any number of packages to the list of packages searched for command implementations; multiple package names should be separated by commas. When not specified, the search is only performed in the `distutils.command` package. When `setup.py` is run with the option `--command-packages distcmds,buildcmds`, however, the packages `distutils.command`, `distcmds`, and `buildcmds` will be searched in that order. New commands are expected to be implemented in modules of the same name as the command by classes sharing the same name. Given the example command line option above, the command `bdist_openpkg` could be implemented by the class `distcmds.bdist_openpkg.bdist_openpkg` or `buildcmds.bdist_openpkg.bdist_openpkg`.

9.2. Adding new distribution types

Commands that create distributions (files in the `dist/` directory) need to add `(command, filename)` pairs to `self.distribution.dist_files` so that **upload** can upload it to PyPI. The *filename* in the pair contains no path information, only the name of the file itself. In dry-run mode, pairs should still be added to represent what would have been created.

10. Command Reference

10.1. Installing modules: the **install** command family

The `install` command ensures that the build commands have been run and then runs the subcommands **`install_lib`**, **`install_data`** and **`install_scripts`**.

10.1.1. **`install_data`**

This command installs all data files provided with the distribution.

10.1.2. **`install_scripts`**

This command installs all (Python) scripts in the distribution.

10.2. Creating a source distribution: the **sdist** command

The manifest template commands are:

Command	Description
include pat1 pat2 ...	include all files matching any of the listed patterns
exclude pat1 pat2 ...	exclude all files matching any of the listed patterns
recursive-include dir pat1 pat2 ...	include all files under <i>dir</i> matching any of the listed patterns
recursive-exclude dir pat1 pat2 ...	exclude all files under <i>dir</i> matching any of the listed patterns
global-include pat1 pat2 ...	include all files anywhere in the source tree matching — & any of the listed patterns
global-exclude pat1 pat2 ...	exclude all files anywhere in the source tree matching — & any of the listed patterns
prune dir	exclude all files under <i>dir</i>
graft dir	include all files under <i>dir</i>

The patterns here are Unix-style “glob” patterns: `*` matches any sequence of regular filename characters, `?` matches any single regular filename character, and `[range]` matches any of the characters in *range* (e.g., `a-z`, `a-zA-Z`, `a-f0-9_.`). The definition of “regular filename character” is platform-specific: on Unix it is anything except slash; on Windows anything except backslash or colon.

11. API Reference

11.1. `distutils.core` — Core Distutils functionality

The `distutils.core` module is the only module that needs to be installed to use the Distutils. It provides the `setup()` (which is called from the `setup` script). Indirectly provides the `distutils.dist.Distribution` and `distutils.cmd.Command` class.

`distutils.core.setup(arguments)`

The basic do-everything function that does most everything you could ever ask for from a Distutils method. See XXXXX

The `setup` function takes a large number of arguments. These are laid out in the following table.

argument name	value	type
<i>name</i>	The name of the package	a string
<i>version</i>	The version number of the package	See <code>distutils.version</code>
<i>description</i>	A single line describing the package	a string
<i>long_description</i>	Longer description of the package	a string
<i>author</i>	The name of the package author	a string
<i>author_email</i>	The email address of	a string

	the package author	
<i>maintainer</i>	The name of the current maintainer, if different from the author	a string
<i>maintainer_email</i>	The email address of the current maintainer, if different from the author	
<i>url</i>	A URL for the package (homepage)	a URL
<i>download_url</i>	A URL to download the package	a URL
<i>packages</i>	A list of Python packages that distutils will manipulate	a list of strings
<i>py_modules</i>	A list of Python modules that distutils will manipulate	a list of strings
<i>scripts</i>	A list of standalone script files to be built and installed	a list of strings
	A list of Python	

<i>ext_modules</i>	extensions to be built	A list of instances of <code>distutils.com</code>
<i>classifiers</i>	A list of categories for the package	The list of available categorization: http://pypi.python.org/pypi?:action=
<i>distclass</i>	the <code>Distribution</code> class to use	A subclass of <code>distutils.core.Dist</code>
<i>script_name</i>	The name of the setup.py script - defaults to <code>sys.argv[0]</code>	a string
<i>script_args</i>	Arguments to supply to the setup script	a list of strings
<i>options</i>	default options for the setup script	a string
<i>license</i>	The license for the package	a string
<i>keywords</i>	Descriptive meta-data, see PEP 314	
<i>platforms</i>		
<i>cmdclass</i>	A mapping of command names to <code>Command</code> subclasses	a dictionary
<i>data_files</i>	A list of data files to install	a list

<code>package_dir</code>	A mapping of package to directory names	a dictionary
--------------------------	---	--------------

`distutils.core.run_setup(script_name[, script_args=None, stop_after='run'])`

Run a setup script in a somewhat controlled environment, and return the `distutils.dist.Distribution` instance that drives things. This is useful if you need to find out the distribution meta-data (passed as keyword args from `script` to `setup()`), or the contents of the config files or command-line.

`script_name` is a file that will be read and run with `exec()`. `sys.argv[0]` will be replaced with `script` for the duration of the call. `script_args` is a list of strings; if supplied, `sys.argv[1:]` will be replaced by `script_args` for the duration of the call.

`stop_after` tells `setup()` when to stop processing; possible values:

value	description
<code>init</code>	Stop after the <code>Distribution</code> instance has been created and populated with the keyword arguments to <code>setup()</code>
<code>config</code>	Stop after config files have been parsed (and their data stored in the <code>Distribution</code> instance)
<code>commandline</code>	Stop after the command-line (<code>sys.argv[1:]</code> or <code>script_args</code>) have been parsed (and the data stored in the <code>Distribution</code> instance.)
<code>run</code>	Stop after all commands have been run (the same as if <code>setup()</code> had been called in the usual way). This is the default value.

In addition, the `distutils.core` module exposed a number of classes that live elsewhere.

- **Extension** from `distutils.extension`
- **Command** from `distutils.cmd`
- **Distribution** from `distutils.dist`

A short description of each of these follows, but see the relevant module for the full reference.

`class distutils.core.`**Extension**

The `Extension` class describes a single C or C++ extension module in a setup script. It accepts the following keyword arguments in its constructor

argument name	value	type
<i>name</i>	the full name of the extension, including any packages — ie. <i>not</i> a filename or pathname, but Python dotted name	string
<i>sources</i>	list of source filenames, relative to the distribution root (where the setup script lives), in Unix form (slash-separated) for portability. Source files may be C, C++, SWIG (.i), platform-specific resource files, or whatever else is recognized by the build_ext command as source for a Python extension.	string
<i>include_dirs</i>	list of directories to search for C/C++ header files (in Unix	string

	form for portability)	
<i>define_macros</i>	list of macros to define; each macro is defined using a 2-tuple (name, value), where <i>value</i> is either the string to define it to or None to define it without a particular value (equivalent of #define FOO in source or -DFOO on Unix C compiler command line)	(string, string) tuple or (name, None)
<i>undef_macros</i>	list of macros to undefine explicitly	string
<i>library_dirs</i>	list of directories to search for C/C++ libraries at link time	string
<i>libraries</i>	list of library names (not filenames or paths) to link against	string
<i>runtime_library_dirs</i>	list of directories to search for C/C++ libraries at run time (for shared extensions, this is when the extension is loaded)	string
<i>extra_objects</i>	list of extra files to link with (eg. object files not implied by 'sources', static library that must be explicitly specified, binary resource files, etc.)	string
	any extra platform- and compiler-specific information to use	

<i>extra_compile_args</i>	when compiling the source files in 'sources'. For platforms and compilers where a command line makes sense, this is typically a list of command-line arguments, but for other platforms it could be anything.	string
<i>extra_link_args</i>	any extra platform- and compiler-specific information to use when linking object files together to create the extension (or to create a new static Python interpreter). Similar interpretation as for 'extra_compile_args'.	string
<i>export_symbols</i>	list of symbols to be exported from a shared extension. Not used on all platforms, and not generally necessary for Python extensions, which typically export exactly one symbol: init + extension_name.	string
<i>depends</i>	list of files that the extension depends on	string
<i>language</i>	extension language (i.e. 'c', 'c++', 'objc'). Will be detected from the source extensions if not provided.	string

class distutils.core.**Distribution**

A **Distribution** describes how to build, install and package up a Python software package.

See the **setup()** function for a list of keyword arguments accepted by the Distribution constructor. **setup()** creates a Distribution instance.

class distutils.core.**Command**

A **Command** class (or rather, an instance of one of its subclasses) implement a single distutils command.

11.2. `distutils.ccompiler` — CCompiler base class

This module provides the abstract base class for the `CCompiler` classes. A `CCompiler` instance can be used for all the compile and link steps needed to build a single project. Methods are provided to set options for the compiler — macro definitions, include directories, link path, libraries and the like.

This module provides the following functions.

`distutils.ccompiler.gen_lib_options(compiler, library_dirs, runtime_library_dirs, libraries)`

Generate linker options for searching library directories and linking with specific libraries. *libraries* and *library_dirs* are, respectively, lists of library names (not filenames!) and search directories. Returns a list of command-line options suitable for use with some compiler (depending on the two format strings passed in).

`distutils.ccompiler.gen_preprocess_options(macros, include_dirs)`

Generate C pre-processor options (*-D*, *-U*, *-I*) as used by at least two types of compilers: the typical Unix compiler and Visual C++. *macros* is the usual thing, a list of 1- or 2-tuples, where `(name,)` means undefine (*-U*) macro *name*, and `(name, value)` means define (*-D*) macro *name* to *value*. *include_dirs* is just a list of directory names to be added to the header file search path (*-I*). Returns a list of command-line options suitable for either Unix compilers or Visual C++.

`distutils.ccompiler.get_default_compiler(osname, platform)`

Determine the default compiler to use for the given platform.

osname should be one of the standard Python OS names (i.e. the ones returned by `os.name`) and *platform* the common value returned by `sys.platform` for the platform in question.

The default values are `os.name` and `sys.platform` in case the parameters are not given.

```
distutils.ccompiler.new_compiler(plat=None, compiler=None,  
verbose=0, dry_run=0, force=0)
```

Factory function to generate an instance of some `CCompiler` subclass for the supplied platform/compiler combination. *plat* defaults to `os.name` (eg. `'posix'`, `'nt'`), and *compiler* defaults to the default compiler for that platform. Currently only `'posix'` and `'nt'` are supported, and the default compilers are “traditional Unix interface” (`UnixCCompiler` class) and Visual C++ (`MSVCCompiler` class). Note that it’s perfectly possible to ask for a Unix compiler object under Windows, and a Microsoft compiler object under Unix—if you supply a value for *compiler*, *plat* is ignored.

```
distutils.ccompiler.show_compilers()
```

Print list of available compilers (used by the `--help-compiler` options to `build`, `build_ext`, `build_clib`).

```
class distutils.ccompiler.CCompiler([verbose=0, dry_run=0,  
force=0])
```

The abstract base class `CCompiler` defines the interface that must be implemented by real compiler classes. The class also has some utility methods used by several compiler classes.

The basic idea behind a compiler abstraction class is that each

instance can be used for all the compile/link steps in building a single project. Thus, attributes common to all of those compile and link steps — include directories, macros to define, libraries to link against, etc. — are attributes of the compiler instance. To allow for variability in how individual files are treated, most of those attributes may be varied on a per-compilation or per-link basis.

The constructor for each subclass creates an instance of the Compiler object. Flags are *verbose* (show verbose output), *dry_run* (don't actually execute the steps) and *force* (rebuild everything, regardless of dependencies). All of these flags default to 0 (off). Note that you probably don't want to instantiate `CCompiler` or one of its subclasses directly - use the `distutils.CCompiler.new_compiler()` factory function instead.

The following methods allow you to manually alter compiler options for the instance of the Compiler class.

`add_include_dir(dir)`

Add *dir* to the list of directories that will be searched for header files. The compiler is instructed to search directories in the order in which they are supplied by successive calls to `add_include_dir()`.

`set_include_dirs(dirs)`

Set the list of directories that will be searched to *dirs* (a list of strings). Overrides any preceding calls to `add_include_dir()`; subsequent calls to `add_include_dir()` add to the list passed to `set_include_dirs()`. This does not affect any list of standard include directories that the compiler may search by default.

`add_library(libname)`

Add *libname* to the list of libraries that will be included in all links driven by this compiler object. Note that *libname* should *not* be the name of a file containing a library, but the name of the library itself: the actual filename will be inferred by the linker, the compiler, or the compiler class (depending on the platform).

The linker will be instructed to link against libraries in the order they were supplied to `add_library()` and/or `set_libraries()`. It is perfectly valid to duplicate library names; the linker will be instructed to link against libraries as many times as they are mentioned.

set_libraries(*libnames*)

Set the list of libraries to be included in all links driven by this compiler object to *libnames* (a list of strings). This does not affect any standard system libraries that the linker may include by default.

add_library_dir(*dir*)

Add *dir* to the list of directories that will be searched for libraries specified to `add_library()` and `set_libraries()`. The linker will be instructed to search for libraries in the order they are supplied to `add_library_dir()` and/or `set_library_dirs()`.

set_library_dirs(*dirs*)

Set the list of library search directories to *dirs* (a list of strings). This does not affect any standard library search path that the linker may search by default.

add_runtime_library_dir(*dir*)

Add *dir* to the list of directories that will be searched for shared libraries at runtime.

set_runtime_library_dirs(*dirs*)

Set the list of directories to search for shared libraries at runtime to *dirs* (a list of strings). This does not affect any standard search path that the runtime linker may search by default.

define_macro(*name*[, *value=None*])

Define a preprocessor macro for all compilations driven by this compiler object. The optional parameter *value* should be a string; if it is not supplied, then the macro will be defined without an explicit value and the exact outcome depends on the compiler used (XXX true? does ANSI say anything about this?)

undefine_macro(*name*)

Undefine a preprocessor macro for all compilations driven by this compiler object. If the same macro is defined by **define_macro()** and undefined by **undefine_macro()** the last call takes precedence (including multiple redefinitions or undefinitions). If the macro is redefined/undefined on a per-compilation basis (ie. in the call to **compile()**), then that takes precedence.

add_link_object(*object*)

Add *object* to the list of object files (or analogues, such as explicitly named library files or the output of “resource compilers”) to be included in every link driven by this compiler object.

set_link_objects(*objects*)

Set the list of object files (or analogues) to be included in every link to *objects*. This does not affect any standard object files that the linker may include by default (such as system libraries).

The following methods implement methods for autodetection of compiler options, providing some functionality similar to GNU **autoconf**.

detect_language(*sources*)

Detect the language of a given file, or list of files. Uses the instance attributes **language_map** (a dictionary), and **language_order** (a list) to do the job.

find_library_file(*dirs*, *lib*[, *debug=0*])

Search the specified list of directories for a static or shared library file *lib* and return the full path to that file. If *debug* is true, look for a debugging version (if that makes sense on the current platform). Return **None** if *lib* wasn't found in any of the specified directories.

has_function(*funcname*[, *includes=None*, *include_dirs=None*, *libraries=None*, *library_dirs=None*])

Return a boolean indicating whether *funcname* is supported on the current platform. The optional arguments can be used to augment the compilation environment by providing additional include files and paths and libraries and paths.

library_dir_option(*dir*)

Return the compiler option to add *dir* to the list of directories searched for libraries.

library_option(*lib*)

Return the compiler option to add *lib* to the list of libraries linked into the shared library or executable.

runtime_library_dir_option(*dir*)

Return the compiler option to add *dir* to the list of directories searched for runtime libraries.

`set_executables(**args)`

Define the executables (and options for them) that will be run to perform the various stages of compilation. The exact set of executables that may be specified here depends on the compiler class (via the 'executables' class attribute), but most will have:

attribute	description
<i>compiler</i>	the C/C++ compiler
<i>linker_so</i>	linker used to create shared objects and libraries
<i>linker_exe</i>	linker used to create binary executables
<i>archiver</i>	static library creator

On platforms with a command-line (Unix, DOS/Windows), each of these is a string that will be split into executable name and (optional) list of arguments. (Splitting the string is done similarly to how Unix shells operate: words are delimited by spaces, but quotes and backslashes can override this. See [distutils.util.split_quoted\(\)](#).)

The following methods invoke stages in the build process.

`compile(sources[, output_dir=None, macros=None, include_dirs=None, debug=0, extra_preargs=None, extra_postargs=None, depends=None])`

Compile one or more source files. Generates object files (e.g. transforms a `.c` file to a `.o` file.)

sources must be a list of filenames, most likely C/C++ files, but in reality anything that can be handled by a particular compiler and compiler class (eg. `MSVCCompiler` can handle resource files in *sources*). Return a list of object filenames,

one per source filename in *sources*. Depending on the implementation, not all source files will necessarily be compiled, but all corresponding object filenames will be returned.

If *output_dir* is given, object files will be put under it, while retaining their original path component. That is, `foo/bar.c` normally compiles to `foo/bar.o` (for a Unix implementation); if *output_dir* is *build*, then it would compile to `build/foo/bar.o`.

macros, if given, must be a list of macro definitions. A macro definition is either a `(name, value)` 2-tuple or a `(name,)` 1-tuple. The former defines a macro; if the value is `None`, the macro is defined without an explicit value. The 1-tuple case undefines a macro. Later definitions/redefinitions/undefinitions take precedence.

include_dirs, if given, must be a list of strings, the directories to add to the default include file search path for this compilation only.

debug is a boolean; if true, the compiler will be instructed to output debug symbols in (or alongside) the object file(s).

extra_preargs and *extra_postargs* are implementation-dependent. On platforms that have the notion of a command-line (e.g. Unix, DOS/Windows), they are most likely lists of strings: extra command-line arguments to prepend/append to the compiler command line. On other platforms, consult the implementation class documentation. In any event, they are intended as an escape hatch for those occasions when the abstract compiler framework doesn't cut the mustard.

depends, if given, is a list of filenames that all targets depend on. If a source file is older than any file in *depends*, then the

source file will be recompiled. This supports dependency tracking, but only at a coarse granularity.

Raises `CompileError` on failure.

`create_static_lib(objects, output_libname[, output_dir=None, debug=0, target_lang=None])`

Link a bunch of stuff together to create a static library file. The “bunch of stuff” consists of the list of object files supplied as *objects*, the extra object files supplied to `add_link_object()` and/or `set_link_objects()`, the libraries supplied to `add_library()` and/or `set_libraries()`, and the libraries supplied as *libraries* (if any).

output_libname should be a library name, not a filename; the filename will be inferred from the library name. *output_dir* is the directory where the library file will be put. XXX defaults to what?

debug is a boolean; if true, debugging information will be included in the library (note that on most platforms, it is the compile step where this matters: the *debug* flag is included here just for consistency).

target_lang is the target language for which the given objects are being compiled. This allows specific linkage time treatment of certain languages.

Raises `LibError` on failure.

`link(target_desc, objects, output_filename[, output_dir=None, libraries=None, library_dirs=None, runtime_library_dirs=None, export_symbols=None, debug=0, extra_preargs=None, extra_postargs=None, build_temp=None, target_lang=None])`

Link a bunch of stuff together to create an executable or shared library file.

The “bunch of stuff” consists of the list of object files supplied as *objects*. *output_filename* should be a filename. If *output_dir* is supplied, *output_filename* is relative to it (i.e. *output_filename* can provide directory components if needed).

libraries is a list of libraries to link against. These are library names, not filenames, since they’re translated into filenames in a platform-specific way (eg. *foo* becomes `libfoo.a` on Unix and `foo.lib` on DOS/Windows). However, they can include a directory component, which means the linker will look in that specific directory rather than searching all the normal locations.

library_dirs, if supplied, should be a list of directories to search for libraries that were specified as bare library names (ie. no directory component). These are on top of the system default and those supplied to `add_library_dir()` and/or `set_library_dirs()`. *runtime_library_dirs* is a list of directories that will be embedded into the shared library and used to search for other shared libraries that *it* depends on at runtime. (This may only be relevant on Unix.)

export_symbols is a list of symbols that the shared library will export. (This appears to be relevant only on Windows.)

debug is as for `compile()` and `create_static_lib()`, with the slight distinction that it actually matters on most platforms (as opposed to `create_static_lib()`, which includes a *debug* flag mostly for form’s sake).

extra_preargs and *extra_postargs* are as for `compile()` (except of course that they supply command-line arguments

for the particular linker being used).

target_lang is the target language for which the given objects are being compiled. This allows specific linkage time treatment of certain languages.

Raises `LinkError` on failure.

link_executable(*objects*, *output_progname*[, *output_dir*=None, *libraries*=None, *library_dirs*=None, *runtime_library_dirs*=None, *debug*=0, *extra_preargs*=None, *extra_postargs*=None, *target_lang*=None])

Link an executable. *output_progname* is the name of the file executable, while *objects* are a list of object filenames to link in. Other arguments are as for the `link()` method.

link_shared_lib(*objects*, *output_libname*[, *output_dir*=None, *libraries*=None, *library_dirs*=None, *runtime_library_dirs*=None, *export_symbols*=None, *debug*=0, *extra_preargs*=None, *extra_postargs*=None, *build_temp*=None, *target_lang*=None])

Link a shared library. *output_libname* is the name of the output library, while *objects* is a list of object filenames to link in. Other arguments are as for the `link()` method.

link_shared_object(*objects*, *output_filename*[, *output_dir*=None, *libraries*=None, *library_dirs*=None, *runtime_library_dirs*=None, *export_symbols*=None, *debug*=0, *extra_preargs*=None, *extra_postargs*=None, *build_temp*=None, *target_lang*=None])

Link a shared object. *output_filename* is the name of the shared object that will be created, while *objects* is a list of object filenames to link in. Other arguments are as for the `link()` method.

preprocess(*source*[, *output_file*=None, *macros*=None, *include_dirs*=None, *extra_preargs*=None, *extra_postargs*=None])

Preprocess a single C/C++ source file, named in *source*. Output will be written to file named *output_file*, or *stdout* if *output_file* not supplied. *macros* is a list of macro definitions as for `compile()`, which will augment the macros set with `define_macro()` and `undefine_macro()`. *include_dirs* is a list of directory names that will be added to the default list, in the same way as `add_include_dir()`.

Raises `PreprocessError` on failure.

The following utility methods are defined by the `CCompiler` class, for use by the various concrete subclasses.

executable_filename(*basename*[, *strip_dir*=0, *output_dir*=""])

Returns the filename of the executable for the given *basename*. Typically for non-Windows platforms this is the same as the *basename*, while Windows will get a `.exe` added.

library_filename(*libname*[, *lib_type*='static', *strip_dir*=0, *output_dir*=""])

Returns the filename for the given library name on the current platform. On Unix a library with *lib_type* of `'static'` will typically be of the form `liblibname.a`, while a *lib_type* of `'dynamic'` will be of the form `liblibname.so`.

object_filenames(*source_filenames*[, *strip_dir*=0, *output_dir*=""])

Returns the name of the object files for the given source files. *source_filenames* should be a list of filenames.

shared_object_filename(*basename*[, *strip_dir=0*,
output_dir=""])

Returns the name of a shared object file for the given file name *basename*.

execute(*func*, *args*[, *msg=None*, *level=1*])

Invokes `distutils.util.execute()` This method invokes a Python function *func* with the given arguments *args*, after logging and taking into account the *dry_run* flag. XXX see also.

spawn(*cmd*)

Invokes `distutils.util.spawn()`. This invokes an external process to run the given command. XXX see also.

mkpath(*name*[, *mode=511*])

Invokes `distutils.dir_util.mkpath()`. This creates a directory and any missing ancestor directories. XXX see also.

move_file(*src*, *dst*)

Invokes `distutils.file_util.move_file()`. Renames *src* to *dst*. XXX see also.

announce(*msg*[, *level=1*])

Write a message using `distutils.log.debug()`. XXX see also.

warn(*msg*)

Write a warning message *msg* to standard error.

debug_print(*msg*)

If the *debug* flag is set on this `CCompiler` instance, print *msg* to standard output, otherwise do nothing.

11.3. `distutils.unixccompiler` — Unix C Compiler

This module provides the `UnixCCompiler` class, a subclass of `CCompiler` that handles the typical Unix-style command-line C compiler:

- macros defined with `-Dname[=value]`
- macros undefined with `-Uname`
- include search directories specified with `-Idir`
- libraries specified with `-llib`
- library search directories specified with `-Ldir`
- compile handled by `cc` (or similar) executable with `-c` option: compiles `.c` to `.o`
- link static library handled by `ar` command (possibly with `ranlib`)
- link shared library handled by `cc -shared`

11.4. `distutils.msvccompiler` — Microsoft Compiler

This module provides `MSVCCompiler`, an implementation of the abstract `CCompiler` class for Microsoft Visual Studio. Typically, extension modules need to be compiled with the same compiler that was used to compile Python. For Python 2.3 and earlier, the compiler was Visual Studio 6. For Python 2.4 and 2.5, the compiler is Visual Studio .NET 2003. The AMD64 and Itanium binaries are created using the Platform SDK.

`MSVCCompiler` will normally choose the right compiler, linker etc. on its own. To override this choice, the environment variables `DISTUTILS_USE_SDK` and `MSSdk` must be both set. `MSSdk` indicates that the current environment has been setup by the SDK's `SetEnv.cmd` script, or that the environment variables had been registered when the SDK was installed; `DISTUTILS_USE_SDK` indicates that the `distutils` user has made an explicit choice to override the compiler selection by `MSVCCompiler`.

11.5. `distutils.bcppcompiler` — Borland Compiler

This module provides `BorlandCCompiler`, an subclass of the abstract `CCompiler` class for the Borland C++ compiler.

11.6. `distutils.cygwincompiler` — Cygwin Compiler

This module provides the `CygwinCompiler` class, a subclass of `UnixCompiler` that handles the Cygwin port of the GNU C compiler to Windows. It also contains the `Mingw32Compiler` class which handles the mingw32 port of GCC (same as cygwin in no-cygwin mode).

11.7. `distutils.emxcompiler` — OS/2 EMX Compiler

This module provides the `EMXCompiler` class, a subclass of `UnixCompiler` that handles the EMX port of the GNU C compiler to OS/2.

11.8. `distutils.archive_util` — Archiving utilities

This module provides a few functions for creating archive files, such as tarballs or zipfiles.

```
distutils.archive_util.make_archive(base_name, format[,  
root_dir=None, base_dir=None, verbose=0, dry_run=0])
```

Create an archive file (eg. `zip` or `tar`). `base_name` is the name of the file to create, minus any format-specific extension; `format` is the archive format: one of `zip`, `tar`, `ztar`, or `gztar`. `root_dir` is a directory that will be the root directory of the archive; ie. we typically `chdir` into `root_dir` before creating the archive. `base_dir` is the directory where we start archiving from; ie. `base_dir` will be the common prefix of all files and directories in the archive. `root_dir` and `base_dir` both default to the current directory. Returns the name of the archive file.

```
distutils.archive_util.make_tarball(base_name, base_dir[,  
compress='gzip', verbose=0, dry_run=0])
```

Create an (optional compressed) archive as a tar file from all files in and under `base_dir`. `compress` must be `'gzip'` (the default), `'compress'`, `'bzip2'`, or `None`. Both `tar` and the compression utility named by `compress` must be on the default program search path, so this is probably Unix-specific. The output tar file will be named `base_dir.tar`, possibly plus the appropriate compression extension (`.gz`, `.bz2` or `.z`). Return the output filename.

```
distutils.archive_util.make_zipfile(base_name, base_dir[,
```

`verbose=0, dry_run=0])`

Create a zip file from all files in and under *base_dir*. The output zip file will be named *base_name* + `.zip`. Uses either the `zipfile` Python module (if available) or the InfoZIP `zip` utility (if installed and found on the default search path). If neither tool is available, raises `DistutilsExecError`. Returns the name of the output zip file.

11.9. `distutils.dep_util` — Dependency checking

This module provides functions for performing simple, timestamp-based dependency of files and groups of files; also, functions based entirely on such timestamp dependency analysis.

`distutils.dep_util.newer(source, target)`

Return true if *source* exists and is more recently modified than *target*, or if *source* exists and *target* doesn't. Return false if both exist and *target* is the same age or newer than *source*. Raise `DistutilsFileError` if *source* does not exist.

`distutils.dep_util.newer_pairwise(sources, targets)`

Walk two filename lists in parallel, testing if each source is newer than its corresponding target. Return a pair of lists (*sources*, *targets*) where source is newer than target, according to the semantics of `newer()`

`distutils.dep_util.newer_group(sources, target[, missing='error'])`

Return true if *target* is out-of-date with respect to any file listed in *sources*. In other words, if *target* exists and is newer than every file in *sources*, return false; otherwise return true. *missing* controls what we do when a source file is missing; the default ('error') is to blow up with an `OSError` from inside `os.stat()`; if it is 'ignore', we silently drop any missing source files; if it is 'newer', any missing source files make us assume that *target* is out-of-date (this is handy in “dry-run” mode: it'll make you pretend to carry out commands that wouldn't work because inputs are missing, but that doesn't matter because you're not actually going to run the commands).

11.10. `distutils.dir_util` — Directory tree operations

This module provides functions for operating on directories and trees of directories.

```
distutils.dir_util.mkpath(name[, mode=0o777, verbose=0,
dry_run=0])
```

Create a directory and any missing ancestor directories. If the directory already exists (or if *name* is the empty string, which means the current directory, which of course exists), then do nothing. Raise `DistutilsFileError` if unable to create some directory along the way (eg. some sub-path exists, but is a file rather than a directory). If *verbose* is true, print a one-line summary of each `mkdir` to `stdout`. Return the list of directories actually created.

```
distutils.dir_util.create_tree(base_dir, files[, mode=0o777,
verbose=0, dry_run=0])
```

Create all the empty directories under *base_dir* needed to put *files* there. *base_dir* is just the a name of a directory which doesn't necessarily exist yet; *files* is a list of filenames to be interpreted relative to *base_dir*. *base_dir* + the directory portion of every file in *files* will be created if it doesn't already exist. *mode*, *verbose* and *dry_run* flags are as for `mkpath()`.

```
distutils.dir_util.copy_tree(src, dst[, preserve_mode=1,
preserve_times=1, preserve_symlinks=0, update=0, verbose=0,
dry_run=0])
```

Copy an entire directory tree *src* to a new location *dst*. Both *src* and *dst* must be directory names. If *src* is not a directory, raise

DistutilsFileError. If *dst* does not exist, it is created with `mkpath()`. The end result of the copy is that every file in *src* is copied to *dst*, and directories under *src* are recursively copied to *dst*. Return the list of files that were copied or might have been copied, using their output name. The return value is unaffected by *update* or *dry_run*: it is simply the list of all files under *src*, with the names changed to be under *dst*.

preserve_mode and *preserve_times* are the same as for `copy_file()` in `distutils.file_util`; note that they only apply to regular files, not to directories. If *preserve_symlinks* is true, symlinks will be copied as symlinks (on platforms that support them!); otherwise (the default), the destination of the symlink will be copied. *update* and *verbose* are the same as for `copy_file()`.

`distutils.dir_util.remove_tree(directory[, verbose=0, dry_run=0])`

Recursively remove *directory* and all files and directories underneath it. Any errors are ignored (apart from being reported to `sys.stdout` if *verbose* is true).

11.11. `distutils.file_util` — Single file operations

This module contains some utility functions for operating on individual files.

```
distutils.file_util.copy_file(src, dst[, preserve_mode=1,
preserve_times=1, update=0, link=None, verbose=0, dry_run=0])
```

Copy file *src* to *dst*. If *dst* is a directory, then *src* is copied there with the same name; otherwise, it must be a filename. (If the file exists, it will be ruthlessly clobbered.) If *preserve_mode* is true (the default), the file's mode (type and permission bits, or whatever is analogous on the current platform) is copied. If *preserve_times* is true (the default), the last-modified and last-access times are copied as well. If *update* is true, *src* will only be copied if *dst* does not exist, or if *dst* does exist but is older than *src*.

link allows you to make hard links (using `os.link()`) or symbolic links (using `os.symlink()`) instead of copying: set it to `'hard'` or `'sym'`; if it is `None` (the default), files are copied. Don't set *link* on systems that don't support it: `copy_file()` doesn't check if hard or symbolic linking is available. It uses `_copy_file_contents()` to copy file contents.

Return a tuple `(dest_name, copied)`: *dest_name* is the actual name of the output file, and *copied* is true if the file was copied (or would have been copied, if *dry_run* true).

```
distutils.file_util.move_file(src, dst[, verbose, dry_run])
```

Move file *src* to *dst*. If *dst* is a directory, the file will be moved into it with the same name; otherwise, *src* is just renamed to *dst*.

Returns the new full name of the file.

Warning: Handles cross-device moves on Unix using `copy_file()`. What about other systems?

`distutils.file_util.write_file(filename, contents)`

Create a file called *filename* and write *contents* (a sequence of strings without line terminators) to it.

11.12. `distutils.util` — Miscellaneous other utility functions

This module contains other assorted bits and pieces that don't fit into any other utility module.

`distutils.util.get_platform()`

Return a string that identifies the current platform. This is used mainly to distinguish platform-specific build directories and platform-specific built distributions. Typically includes the OS name and version and the architecture (as supplied by `'os.uname()'`), although the exact information included depends on the OS; eg. for IRIX the architecture isn't particularly important (IRIX only runs on SGI hardware), but for Linux the kernel version isn't particularly important.

Examples of returned values:

- `linux-i586`
- `linux-alpha`
- `solaris-2.6-sun4u`
- `irix-5.3`
- `irix64-6.2`

For non-POSIX platforms, currently just returns `sys.platform`.

For Mac OS X systems the OS version reflects the minimal version on which binaries will run (that is, the value of `MACOSX_DEPLOYMENT_TARGET` during the build of Python), not the OS version of the current system.

For universal binary builds on Mac OS X the architecture value reflects the universal binary status instead of the architecture of

the current processor. For 32-bit universal binaries the architecture is `fat`, for 64-bit universal binaries the architecture is `fat64`, and for 4-way universal binaries the architecture is `universal`. Starting from Python 2.7 and Python 3.2 the architecture `fat3` is used for a 3-way universal build (ppc, i386, x86_64) and `intel` is used for a universal build with the i386 and x86_64 architectures

Examples of returned values on Mac OS X:

- `macosx-10.3-ppc`
- `macosx-10.3-fat`
- `macosx-10.5-universal`
- `macosx-10.6-intel`

`distutils.util.convert_path(pathname)`

Return 'pathname' as a name that will work on the native filesystem, i.e. split it on '/' and put it back together again using the current directory separator. Needed because filenames in the setup script are always supplied in Unix style, and have to be converted to the local convention before we can actually use them in the filesystem. Raises `ValueError` on non-Unix-ish systems if *pathname* either starts or ends with a slash.

`distutils.util.change_root(new_root, pathname)`

Return *pathname* with *new_root* prepended. If *pathname* is relative, this is equivalent to `os.path.join(new_root, pathname)` Otherwise, it requires making *pathname* relative and then joining the two, which is tricky on DOS/Windows.

`distutils.util.check_envron()`

Ensure that 'os.environ' has all the environment variables we guarantee that users can use in config files, command-line options, etc. Currently this includes:

- **HOME** - user's home directory (Unix only)
- **PLAT** - description of the current platform, including hardware and OS (see `get_platform()`)

`distutils.util.subst_vars(s, local_vars)`

Perform shell/Perl-style variable substitution on `s`. Every occurrence of `$` followed by a name is considered a variable, and variable is substituted by the value found in the `local_vars` dictionary, or in `os.environ` if it's not in `local_vars`. `os.environ` is first checked/augmented to guarantee that it contains certain values: see `check_environ()`. Raise `ValueError` for any variables not found in either `local_vars` or `os.environ`.

Note that this is not a fully-fledged string interpolation function. A valid `$variable` can consist only of upper and lower case letters, numbers and an underscore. No `{ }` or `()` style quoting is available.

`distutils.util.grok_environment_error(exc[, prefix='error: '])`

Generate a useful error message from an `EnvironmentError` (`IOError` or `OSError`) exception object. Handles Python 1.5.1 and later styles, and does what it can to deal with exception objects that don't have a filename (which happens when the error is due to a two-file operation, such as `rename()` or `link()`). Returns the error message as a string prefixed with `prefix`.

`distutils.util.split_quoted(s)`

Split a string up according to Unix shell-like rules for quotes and backslashes. In short: words are delimited by spaces, as long as those spaces are not escaped by a backslash, or inside a quoted string. Single and double quotes are equivalent, and the quote characters can be backslash-escaped. The backslash is stripped from any two-character escape sequence, leaving only the

escaped character. The quote characters are stripped from any quoted string. Returns a list of words.

`distutils.util.execute(func, args[, msg=None, verbose=0, dry_run=0])`

Perform some action that affects the outside world (for instance, writing to the filesystem). Such actions are special because they are disabled by the `dry_run` flag. This method takes care of all that bureaucracy for you; all you have to do is supply the function to call and an argument tuple for it (to embody the “external action” being performed), and an optional message to print.

`distutils.util.strtobool(val)`

Convert a string representation of truth to true (1) or false (0).

True values are `y`, `yes`, `t`, `true`, `on` and `1`; false values are `n`, `no`, `f`, `false`, `off` and `0`. Raises `ValueError` if `val` is anything else.

`distutils.util.byte_compile(py_files[, optimize=0, force=0, prefix=None, base_dir=None, verbose=1, dry_run=0, direct=None])`

Byte-compile a collection of Python source files to either `.pyc` or `.pyo` files in the same directory. `py_files` is a list of files to compile; any files that don't end in `.py` are silently skipped. `optimize` must be one of the following:

- `0` - don't optimize (generate `.pyc`)
- `1` - normal optimization (like `python -O`)
- `2` - extra optimization (like `python -OO`)

If `force` is true, all files are recompiled regardless of timestamps.

The source filename encoded in each `bytecode` file defaults to the filenames listed in `py_files`; you can modify these with `prefix` and `basedir`. `prefix` is a string that will be stripped off of each

source filename, and *base_dir* is a directory name that will be prepended (after *prefix* is stripped). You can supply either or both (or neither) of *prefix* and *base_dir*, as you wish.

If *dry_run* is true, doesn't actually do anything that would affect the filesystem.

Byte-compilation is either done directly in this interpreter process with the standard `py_compile` module, or indirectly by writing a temporary script and executing it. Normally, you should let `byte_compile()` figure out to use direct compilation or not (see the source for details). The *direct* flag is used by the script generated in indirect mode; unless you know what you're doing, leave it set to `None`.

`distutils.util.rfc822_escape(header)`

Return a version of *header* escaped for inclusion in an **RFC 822** header, by ensuring there are 8 spaces space after each newline. Note that it does no other modification of the string.

11.13. `distutils.dist` — The Distribution class

This module provides the `Distribution` class, which represents the module distribution being built/installed/distributed.

11.14. `distutils.extension` — The Extension class

This module provides the `Extension` class, used to describe C/C++ extension modules in setup scripts.

11.15. `distutils.debug` — Distutils debug mode

This module provides the DEBUG flag.

11.16. `distutils.errors` — Distutils exceptions

Provides exceptions used by the Distutils modules. Note that Distutils modules may raise standard exceptions; in particular, `SystemExit` is usually raised for errors that are obviously the end-user's fault (eg. bad command-line arguments).

This module is safe to use in `from ... import *` mode; it only exports symbols whose names start with `Distutils` and end with `Error`.

11.17. `distutils.fancy_getopt` — Wrapper around the standard `getopt` module

This module provides a wrapper around the standard `getopt` module that provides the following additional features:

- short and long options are tied together
- options have help strings, so `fancy_getopt()` could potentially create a complete usage summary
- options set attributes of a passed-in object
- boolean options can have “negative aliases” — eg. if `--quiet` is the “negative alias” of `--verbose`, then `--quiet` on the command line sets `verbose` to false.

`distutils.fancy_getopt.fancy_getopt(options, negative_opt, object, args)`

Wrapper function. `options` is a list of `(long_option, short_option, help_string)` 3-tuples as described in the constructor for `FancyGetopt`. `negative_opt` should be a dictionary mapping option names to option names, both the key and value should be in the `options` list. `object` is an object which will be used to store values (see the `getopt()` method of the `FancyGetopt` class). `args` is the argument list. Will use `sys.argv[1:]` if you pass `None` as `args`.

`distutils.fancy_getopt.wrap_text(text, width)`

Wraps `text` to less than `width` wide.

`class distutils.fancy_getopt.FancyGetopt([option_table=None])`

The `option_table` is a list of 3-tuples: `(long_option, short_option, help_string)`

If an option takes an argument, its *long_option* should have '=' appended; *short_option* should just be a single character, no ':' in any case. *short_option* should be `None` if a *long_option* doesn't have a corresponding *short_option*. All option tuples must have long options.

The `FancyGetopt` class provides the following methods:

`FancyGetopt.getopt([args=None, object=None])`

Parse command-line options in *args*. Store as attributes on *object*.

If *args* is `None` or not supplied, uses `sys.argv[1:]`. If *object* is `None` or not supplied, creates a new `OptionDummy` instance, stores option values there, and returns a tuple (*args*, *object*). If *object* is supplied, it is modified in place and `getopt()` just returns *args*; in both cases, the returned *args* is a modified copy of the passed-in *args* list, which is left untouched.

`FancyGetopt.get_option_order()`

Returns the list of (*option*, *value*) tuples processed by the previous run of `getopt()` Raises `RuntimeError` if `getopt()` hasn't been called yet.

`FancyGetopt.generate_help([header=None])`

Generate help text (a list of strings, one per suggested line of output) from the option table for this `FancyGetopt` object.

If supplied, prints the supplied *header* at the top of the help.

11.18. `distutils.filelist` — The `FileList` class

This module provides the `FileList` class, used for poking about the filesystem and building lists of files.

11.19. `distutils.log` — Simple PEP 282-style logging

11.20. `distutils.spawn` — Spawn a sub-process

This module provides the `spawn()` function, a front-end to various platform-specific functions for launching another program in a sub-process. Also provides `find_executable()` to search the path for a given executable name.

11.21. `distutils.sysconfig` — System configuration information

The `distutils.sysconfig` module provides access to Python's low-level configuration information. The specific configuration variables available depend heavily on the platform and configuration. The specific variables depend on the build process for the specific version of Python being run; the variables are those found in the `Makefile` and configuration header that are installed with Python on Unix systems. The configuration header is called `pyconfig.h` for Python versions starting with 2.2, and `config.h` for earlier versions of Python.

Some additional functions are provided which perform some useful manipulations for other parts of the `distutils` package.

`distutils.sysconfig.PREFIX`

The result of `os.path.normpath(sys.prefix)`.

`distutils.sysconfig.EXEC_PREFIX`

The result of `os.path.normpath(sys.exec_prefix)`.

`distutils.sysconfig.get_config_var(name)`

Return the value of a single variable. This is equivalent to `get_config_vars().get(name)`.

`distutils.sysconfig.get_config_vars(...)`

Return a set of variable definitions. If there are no arguments, this returns a dictionary mapping names of configuration variables to values. If arguments are provided, they should be strings, and the return value will be a sequence giving the associated values. If a given name does not have a corresponding value, `None` will be

included for that variable.

`distutils.sysconfig.get_config_h_filename()`

Return the full path name of the configuration header. For Unix, this will be the header generated by the **configure** script; for other platforms the header will have been supplied directly by the Python source distribution. The file is a platform-specific text file.

`distutils.sysconfig.get_makefile_filename()`

Return the full path name of the `Makefile` used to build Python. For Unix, this will be a file generated by the **configure** script; the meaning for other platforms will vary. The file is a platform-specific text file, if it exists. This function is only useful on POSIX platforms.

`distutils.sysconfig.get_python_inc([plat_specific[, prefix]])`

Return the directory for either the general or platform-dependent C include files. If *plat_specific* is true, the platform-dependent include directory is returned; if false or omitted, the platform-independent directory is returned. If *prefix* is given, it is used as either the prefix instead of **PREFIX**, or as the exec-prefix instead of **EXEC_PREFIX** if *plat_specific* is true.

`distutils.sysconfig.get_python_lib([plat_specific[, standard_lib[, prefix]])`

Return the directory for either the general or platform-dependent library installation. If *plat_specific* is true, the platform-dependent include directory is returned; if false or omitted, the platform-independent directory is returned. If *prefix* is given, it is used as either the prefix instead of **PREFIX**, or as the exec-prefix instead of **EXEC_PREFIX** if *plat_specific* is true. If *standard_lib* is true, the directory for the standard library is returned rather than the directory for the installation of third-party extensions.

The following function is only intended for use within the `distutils` package.

`distutils.sysconfig.customize_compiler(compiler)`

Do any platform-specific customization of a `distutils.ccompiler.CCompiler` instance.

This function is only needed on Unix at this time, but should be called consistently to support forward-compatibility. It inserts the information that varies across Unix flavors and is stored in Python's `Makefile`. This information includes the selected compiler, compiler and linker options, and the extension used by the linker for shared objects.

This function is even more special-purpose, and should only be used from Python's own build procedures.

`distutils.sysconfig.set_python_build()`

Inform the `distutils.sysconfig` module that it is being used as part of the build process for Python. This changes a lot of relative locations for files, allowing them to be located in the build area rather than in an installed Python.

11.22. `distutils.text_file` — The `TextFile` class

This module provides the `TextFile` class, which gives an interface to text files that (optionally) takes care of stripping comments, ignoring blank lines, and joining lines with backslashes.

```
class distutils.text_file.TextFile([filename=None, file=None,
**options])
```

This class provides a file-like object that takes care of all the things you commonly want to do when processing a text file that has some line-by-line syntax: strip comments (as long as `#` is your comment character), skip blank lines, join adjacent lines by escaping the newline (ie. backslash at end of line), strip leading and/or trailing whitespace. All of these are optional and independently controllable.

The class provides a `warn()` method so you can generate warning messages that report physical line number, even if the logical line in question spans multiple physical lines. Also provides `unreadline()` for implementing line-at-a-time lookahead.

`TextFile` instances are create with either *filename*, *file*, or both. `RuntimeError` is raised if both are `None`. *filename* should be a string, and *file* a file object (or something that provides `readline()` and `close()` methods). It is recommended that you supply at least *filename*, so that `TextFile` can include it in warning messages. If *file* is not supplied, `TextFile` creates its own using the `open()` built-in function.

The options are all boolean, and affect the values returned by

readline()

option name	description	default
<i>strip_comments</i>	strip from '#' to end-of-line, as well as any whitespace leading up to the '#'—unless it is escaped by a backslash	true
<i>lstrip_ws</i>	strip leading whitespace from each line before returning it	false
<i>rstrip_ws</i>	strip trailing whitespace (including line terminator!) from each line before returning it.	true
<i>skip_blanks</i>	skip lines that are empty <i>after</i> stripping comments and whitespace. (If both <i>lstrip_ws</i> and <i>rstrip_ws</i> are false, then some lines may consist of solely whitespace: these will <i>not</i> be skipped, even if <i>skip_blanks</i> is true.)	true
<i>join_lines</i>	if a backslash is the last non-newline character on a line after stripping comments and whitespace, join the following line to it to form one logical line; if N consecutive lines end with a backslash, then N+1 physical lines will be joined to form one logical line.	false
<i>collapse_join</i>	strip leading whitespace from lines that are joined to their predecessor; only matters if (<i>join_lines</i> and not <i>lstrip_ws</i>)	false

Note that since *rstrip_ws* can strip the trailing newline, the semantics of `readline()` must differ from those of the built-in file object's `readline()` method! In particular, `readline()` returns

None for end-of-file: an empty string might just be a blank line (or an all-whitespace line), if *rstrip_ws* is true but *skip_blanks* is not.

open(*filename*)

Open a new file *filename*. This overrides any *file* or *filename* constructor arguments.

close()

Close the current file and forget everything we know about it (including the filename and the current line number).

warn(*msg*[, *line=None*])

Print (to `stderr`) a warning message tied to the current logical line in the current file. If the current logical line in the file spans multiple physical lines, the warning refers to the whole range, such as `"lines 3-5"`. If *line* is supplied, it overrides the current line number; it may be a list or tuple to indicate a range of physical lines, or an integer for a single physical line.

readline()

Read and return a single logical line from the current file (or from an internal buffer if lines have previously been “unread” with `unreadline()`). If the *join_lines* option is true, this may involve reading multiple physical lines concatenated into a single string. Updates the current line number, so calling `warn()` after `readline()` emits a warning about the physical line(s) just read. Returns **None** on end-of-file, since the empty string can occur if *rstrip_ws* is true but *strip_blanks* is not.

readlines()

Read and return the list of all logical lines remaining in the current file. This updates the current line number to the last line of the file.

unreadline(*line*)

Push *line* (a string) onto an internal buffer that will be checked by future `readline()` calls. Handy for implementing a parser with line-at-a-time lookahead. Note that lines that are “unread” with `unreadline()` are not subsequently re-cleansed (whitespace stripped, or whatever) when read with `readline()`. If multiple calls are made to `unreadline()` before a call to `readline()`, the lines will be returned most in most recent first order.

11.23. `distutils.version` — Version number classes

11.24. `distutils.cmd` — Abstract base class for Distutils commands

This module supplies the abstract base class `Command`.

`class distutils.cmd.Command(dist)`

Abstract base class for defining command classes, the “worker bees” of the Distutils. A useful analogy for command classes is to think of them as subroutines with local variables called *options*. The options are declared in `initialize_options()` and defined (given their final values) in `finalize_options()`, both of which must be defined by every command class. The distinction between the two is necessary because option values might come from the outside world (command line, config file, ...), and any options dependent on other options must be computed after these outside influences have been processed — hence `finalize_options()`. The body of the subroutine, where it does all its work based on the values of its options, is the `run()` method, which must also be implemented by every command class.

The class constructor takes a single argument *dist*, a `Distribution` instance.

11.25. `distutils.command` — Individual Distutils commands

11.26. `distutils.command.bdist` — Build a binary installer

11.27. `distutils.command.bdist_packager` — Abstract base class for packagers

11.28. `distutils.command.bdist_dumb` — Build a “dumb” installer

11.29. `distutils.command.bdist_msi` — Build a Microsoft Installer binary package

```
class distutils.command.bdist_msi.bdist_msi(Command)
```

Builds a [Windows Installer](#) (.msi) binary package.

In most cases, the `bdist_msi` installer is a better choice than the `bdist_wininst` installer, because it provides better support for Win64 platforms, allows administrators to perform non-interactive installations, and allows installation through group policies.

11.30. `distutils.command.bdist_rpm` — Build a binary distribution as a Redhat RPM and SRPM

11.31. `distutils.command.bdist_wininst` — Build a Windows installer

11.32. `distutils.command.sdist` — Build a source distribution

11.33. `distutils.command.build` — Build all files of a package

11.34. `distutils.command.build_clib` — Build any C libraries in a package

11.35. `distutils.command.build_ext` — Build any extensions in a package

11.36. `distutils.command.build_py` — Build the `.py/.pyc` files of a package

```
class distutils.command.build_py.build_py(Command)
```

```
class distutils.command.build_py.build_py_2to3(build_py)
```

Alternative implementation of `build_py` which also runs the 2to3 conversion library on each `.py` file that is going to be installed. To use this in a `setup.py` file for a distribution that is designed to run with both Python 2.x and 3.x, add:

```
try:  
    from distutils.command.build_py import build_py_2to3 as b  
except ImportError:  
    from distutils.command.build_py import build_py
```

to your `setup.py`, and later:

```
cmdclass = {'build_py': build_py}
```

to the invocation of `setup()`.

11.37. `distutils.command.build_scripts` — Build the scripts of a package

11.38. `distutils.command.clean` — Clean a package build area

11.39. `distutils.command.config` — Perform package configuration

11.40. `distutils.command.install` — Install a package

11.41. `distutils.command.install_data` — Install data files from a package

11.42. `distutils.command.install_headers` —
Install C/C++ header files from a package

11.43. `distutils.command.install_lib` — Install library files from a package

11.44. `distutils.command.install_scripts` — Install script files from a package

11.45. `distutils.command.register` — Register a module with the Python Package Index

The `register` command registers the package with the Python Package Index. This is described in more detail in [PEP 301](#).

11.46. `distutils.command.check` — Check the meta-data of a package

The `check` command performs some tests on the meta-data of a package. For example, it verifies that all required meta-data are provided as the arguments passed to the `setup()` function.

11.47. Creating a new Distutils command

This section outlines the steps to create a new Distutils command.

A new command lives in a module in the `distutils.command` package. There is a sample template in that directory called `command_template`. Copy this file to a new module with the same name as the new command you're implementing. This module should implement a class with the same name as the module (and the command). So, for instance, to create the command `peel_banana` (so that users can run `setup.py peel_banana`), you'd copy `command_template` to `distutils/command/peel_banana.py`, then edit it so that it's implementing the class `peel_banana`, a subclass of `distutils.cmd.Command`.

Subclasses of `command` must define the following methods.

`Command.initialize_options()`

Set default values for all the options that this command supports. Note that these defaults may be overridden by other commands, by the setup script, by config files, or by the command-line. Thus, this is not the place to code dependencies between options; generally, `initialize_options()` implementations are just a bunch of `self.foo = None` assignments.

`Command.finalize_options()`

Set final values for all the options that this command supports. This is always called as late as possible, ie. after any option assignments from the command-line or from other commands have been done. Thus, this is the place to to code option dependencies: if *foo* depends on *bar*, then it is safe to set *foo* from *bar* as long as *foo* still has the same value it was assigned

in `initialize_options()`.

Command. `run()`

A command's raison d'être: carry out the action it exists to perform, controlled by the options initialized in `initialize_options()`, customized by other commands, the setup script, the command-line, and config files, and finalized in `finalize_options()`. All terminal output and filesystem interaction should be done by `run()`.

`sub_commands` formalizes the notion of a “family” of commands, eg. `install` as the parent with sub-commands `install_lib`, `install_headers`, etc. The parent of a family of commands defines `sub_commands` as a class attribute; it's a list of 2-tuples `(command_name, predicate)`, with `command_name` a string and `predicate` a function, a string or None. `predicate` is a method of the parent command that determines whether the corresponding command is applicable in the current situation. (Eg. we `install_headers` is only applicable if we have any C header files to install.) If `predicate` is None, that command is always applicable.

`sub_commands` is usually defined at the `*end*` of a class, because predicates can be methods of the class, so they must already have been defined. The canonical example is the **install** command.

1. Introduction

Python's documentation has long been considered to be good for a free programming language. There are a number of reasons for this, the most important being the early commitment of Python's creator, Guido van Rossum, to providing documentation on the language and its libraries, and the continuing involvement of the user community in providing assistance for creating and maintaining documentation.

The involvement of the community takes many forms, from authoring to bug reports to just plain complaining when the documentation could be more complete or easier to use.

This document is aimed at authors and potential authors of documentation for Python. More specifically, it is for people contributing to the standard documentation and developing additional documents using the same tools as the standard documents. This guide will be less useful for authors using the Python documentation tools for topics other than Python, and less useful still for authors not using the tools at all.

If your interest is in contributing to the Python documentation, but you don't have the time or inclination to learn reStructuredText and the markup structures documented here, there's a welcoming place for you among the Python contributors as well. Any time you feel that you can clarify existing documentation or provide documentation that's missing, the existing documentation team will gladly work with you to integrate your text, dealing with the markup for you. Please don't let the material in this document stand between the documentation and your desire to help out!

2. Style guide

The Python documentation should follow the [Apple Publications Style Guide](#) wherever possible. This particular style guide was selected mostly because it seems reasonable and is easy to get online.

Topics which are either not covered in Apple's style guide or treated differently in Python documentation will be discussed in this document.

2.1. Use of whitespace

All reST files use an indentation of 3 spaces. The maximum line length is 80 characters for normal text, but tables, deeply indented code samples and long links may extend beyond that.

Make generous use of blank lines where applicable; they help grouping things together.

A sentence-ending period may be followed by one or two spaces; while reST ignores the second space, it is customarily put in by some users, for example to aid Emacs' auto-fill mode.

2.2. Footnotes

Footnotes are generally discouraged, though they may be used when they are the best way to present specific information. When a footnote reference is added at the end of the sentence, it should follow the sentence-ending punctuation. The reST markup should appear something like this:

```
This sentence has a footnote reference. [#]_ This is the next s
```

Footnotes should be gathered at the end of a file, or if the file is very long, at the end of a section. The docutils will automatically create backlinks to the footnote reference.

Footnotes may appear in the middle of sentences where appropriate.

2.3. Capitalization

Apple style guide recommends the use of title case in section titles. However, rules for which words should be capitalized in title case vary greatly between publications.

In Python documentation, use of sentence case in section titles is preferable, but consistency within a unit is more important than following this rule. If you add a section to the chapter where most sections are in title case you can either convert all titles to sentence case or use the dominant style in the new section title.

Sentences that start with a word for which specific rules require starting it with a lower case letter should be avoided in titles and elsewhere.

Note: Sections that describe a library module often have titles in the form of “`modulename` — Short description of the module.” In this case, the description should be capitalized as a stand-alone sentence.

Many special names are used in the Python documentation, including the names of operating systems, programming languages, standards bodies, and the like. Most of these entities are not assigned any special markup, but the preferred spellings are given here to aid authors in maintaining the consistency of presentation in the Python documentation.

Sentence case

Sentence case is a set of capitalization rules used in English sentences: the first word is always capitalized and other words are only capitalized if there is a specific rule requiring it.

Other terms and words deserve special mention as well; these conventions should be used to ensure consistency throughout the documentation:

CPU

For “central processing unit.” Many style guides say this should be spelled out on the first use (and if you must use it, do so!). For the Python documentation, this abbreviation should be avoided since there’s no reasonable way to predict which occurrence will be the first seen by the reader. It is better to use the word “processor” instead.

POSIX

The name assigned to a particular group of standards. This is always uppercase.

Python

The name of our favorite programming language is always capitalized.

reST

For “reStructuredText,” an easy to read, plaintext markup syntax used to produce Python documentation. When spelled out, it is always one word and both forms start with a lower case ‘r’.

Unicode

The name of a character coding system. This is always written capitalized.

Unix

The name of the operating system developed at AT&T Bell Labs in the early 1970s.

3. reStructuredText Primer

This section is a brief introduction to reStructuredText (reST) concepts and syntax, intended to provide authors with enough information to author documents productively. Since reST was designed to be a simple, unobtrusive markup language, this will not take too long.

See also: The authoritative [reStructuredText User Documentation](#).

3.1. Paragraphs

The paragraph is the most basic block in a reST document. Paragraphs are simply chunks of text separated by one or more blank lines. As in Python, indentation is significant in reST, so all lines of the same paragraph must be left-aligned to the same level of indentation.

3.2. Inline markup

The standard reST inline markup is quite simple: use

- one asterisk: `*text*` for emphasis (italics),
- two asterisks: `**text**` for strong emphasis (boldface), and
- backquotes: ``text`` for code samples.

If asterisks or backquotes appear in running text and could be confused with inline markup delimiters, they have to be escaped with a backslash.

Be aware of some restrictions of this markup:

- it may not be nested,
- content may not start or end with whitespace: `* text*` is wrong,
- it must be separated from surrounding text by non-word characters. Use a backslash escaped space to work around that: `thisis\ *one*\ word`.

These restrictions may be lifted in future versions of the docutils.

reST also allows for custom “interpreted text roles”, which signify that the enclosed text should be interpreted in a specific way. Sphinx uses this to provide semantic markup and cross-referencing of identifiers, as described in the appropriate section. The general syntax is `:rolename: `content``.

3.3. Lists and Quotes

List markup is natural: just place an asterisk at the start of a paragraph and indent properly. The same goes for numbered lists; they can also be autonumbered using a # sign:

```
* This is a bulleted list.  
* It has two items, the second  
  item uses two lines.  
  
1. This is a numbered list.  
2. It has two items too.  
  
#. This is a numbered list.  
#. It has two items too.
```

Nested lists are possible, but be aware that they must be separated from the parent list items by blank lines:

```
* this is  
* a list  
  
  * with a nested list  
  * and some subitems  
  
* and here the parent list continues
```

Definition lists are created as follows:

```
term (up to a line of text)  
  Definition of the term, which must be indented  
  
  and can even consist of multiple paragraphs  
  
next term  
  Description.
```

Paragraphs are quoted by just indenting them more than the surrounding paragraphs.

3.4. Source Code

Literal code blocks are introduced by ending a paragraph with the special marker `::`. The literal block must be indented:

```
This is a normal text paragraph. The next paragraph is a code s

    It is not processed in any way, except
    that the indentation is removed.

    It can span multiple lines.

This is a normal text paragraph again.
```

The handling of the `::` marker is smart:

- If it occurs as a paragraph of its own, that paragraph is completely left out of the document.
- If it is preceded by whitespace, the marker is removed.
- If it is preceded by non-whitespace, the marker is replaced by a single colon.

That way, the second sentence in the above example's first paragraph would be rendered as "The next paragraph is a code sample:".

3.5. Hyperlinks

3.5.1. External links

Use ``Link text <http://target>`_`` for inline web links. If the link text should be the web address, you don't need special markup at all, the parser finds links and mail addresses in ordinary text.

3.5.2. Internal links

Internal linking is done via a special reST role, see the section on specific markup, *Cross-linking markup*.

3.6. Sections

Section headers are created by underlining (and optionally overlining) the section title with a punctuation character, at least as long as the text:

```
=====  
This is a heading  
=====
```

Normally, there are no heading levels assigned to certain characters as the structure is determined from the succession of headings. However, for the Python documentation, we use this convention:

- # with overline, for parts
- * with overline, for chapters
- =, for sections
- -, for subsections
- ^, for subsubsections
- ", for paragraphs

3.7. Explicit Markup

“Explicit markup” is used in reST for most constructs that need special handling, such as footnotes, specially-highlighted paragraphs, comments, and generic directives.

An explicit markup block begins with a line starting with `..` followed by whitespace and is terminated by the next paragraph at the same level of indentation. (There needs to be a blank line between explicit markup and normal paragraphs. This may all sound a bit complicated, but it is intuitive enough when you write it.)

3.8. Directives

A directive is a generic block of explicit markup. Besides roles, it is one of the extension mechanisms of reST, and Sphinx makes heavy use of it.

Basically, a directive consists of a name, arguments, options and content. (Keep this terminology in mind, it is used in the next chapter describing custom directives.) Looking at this example,

```
.. function:: foo(x)
                foo(y, z)
:bar: no

    Return a line of text input from the user.
```

`function` is the directive name. It is given two arguments here, the remainder of the first line and the second line, as well as one option `bar` (as you can see, options are given in the lines immediately following the arguments and indicated by the colons).

The directive content follows after a blank line and is indented relative to the directive start.

3.9. Footnotes

For footnotes, use `[#]_` to mark the footnote location, and add the footnote body at the bottom of the document after a “Footnotes” rubric heading, like so:

```
Lorem ipsum [#]_ dolor sit amet ... [#]_  
  
.. rubric:: Footnotes  
  
.. [#] Text of the first footnote.  
.. [#] Text of the second footnote.
```

You can also explicitly number the footnotes for better context.

3.10. Comments

Every explicit markup block which isn't a valid markup construct (like the footnotes above) is regarded as a comment.

3.11. Source encoding

Since the easiest way to include special characters like em dashes or copyright signs in reST is to directly write them as Unicode characters, one has to specify an encoding:

All Python documentation source files must be in UTF-8 encoding, and the HTML documents written from them will be in that encoding as well.

3.12. Gotchas

There are some problems one commonly runs into while authoring reST documents:

- **Separation of inline markup:** As said above, inline markup spans must be separated from the surrounding text by non-word characters, you have to use an escaped space to get around that.

4. Additional Markup Constructs

Sphinx adds a lot of new directives and interpreted text roles to standard reST markup. This section contains the reference material for these facilities. Documentation for “standard” reST constructs is not included here, though they are used in the Python documentation.

Note: This is just an overview of Sphinx’ extended markup capabilities; full coverage can be found in [its own documentation](#).

4.1. Meta-information markup

sectionauthor

Identifies the author of the current section. The argument should include the author's name such that it can be used for presentation (though it isn't) and email address. The domain name portion of the address should be lower case. Example:

```
.. sectionauthor:: Guido van Rossum <guido@python.org>
```

Currently, this markup isn't reflected in the output in any way, but it helps keep track of contributions.

4.2. Module-specific markup

The markup described in this section is used to provide information about a module being documented. Each module should be documented in its own file. Normally this markup appears after the title heading of that file; a typical file might start like this:

```
:mod:`parrot` -- Dead parrot access  
=====  
  
.. module:: parrot  
   :platform: Unix, Windows  
   :synopsis: Analyze and reanimate dead parrots.  
.. moduleauthor:: Eric Cleese <eric@python.invalid>  
.. moduleauthor:: John Idle <john@python.invalid>
```

As you can see, the module-specific markup consists of two directives, the `module` directive and the `moduleauthor` directive.

`module`

This directive marks the beginning of the description of a module, package, or submodule. The name should be fully qualified (i.e. including the package name for submodules).

The `platform` option, if present, is a comma-separated list of the platforms on which the module is available (if it is available on all platforms, the option should be omitted). The keys are short identifiers; examples that are in use include “IRIX”, “Mac”, “Windows”, and “Unix”. It is important to use a key which has already been used when applicable.

The `synopsis` option should consist of one sentence describing the module’s purpose – it is currently only used in the Global Module Index.

The `deprecated` option can be given (with no value) to mark a

module as deprecated; it will be designated as such in various locations then.

moduleauthor

The `moduleauthor` directive, which can appear multiple times, names the authors of the module code, just like `sectionauthor` names the author(s) of a piece of documentation. It too does not result in any output currently.

Note: It is important to make the section title of a module-describing file meaningful since that value will be inserted in the table-of-contents trees in overview files.

4.3. Information units

There are a number of directives used to describe specific features provided by modules. Each directive requires one or more signatures to provide basic information about what is being described, and the content should be the description. The basic version makes entries in the general index; if no index entry is desired, you can give the directive option flag `:noindex:`. The following example shows all of the features of this directive type:

```
.. function:: spam(eggs)
                ham(eggs)
:noindex:

Spam or ham the foo.
```

The signatures of object methods or data attributes should always include the type name (`.. method:: FileInput.input(...)`), even if it is obvious from the context which type they belong to; this is to enable consistent cross-references. If you describe methods belonging to an abstract protocol, such as “context managers”, include a (pseudo-)type name too to make the index entries more informative.

The directives are:

c:function

Describes a C function. The signature should be given as in C, e.g.:

```
.. c:function:: PyObject* PyType_GenericAlloc(PyTypeObject *
```

This is also used to describe function-like preprocessor macros. The names of the arguments should be given so they may be

used in the description.

Note that you don't have to backslash-escape asterisks in the signature, as it is not parsed by the reST inliner.

c:member

Describes a C struct member. Example signature:

```
.. c:member:: PyObject* PyTypeObject.tp_bases
```

The text of the description should include the range of values allowed, how the value should be interpreted, and whether the value can be changed. References to structure members in text should use the `member` role.

c:macro

Describes a “simple” C macro. Simple macros are macros which are used for code expansion, but which do not take arguments so cannot be described as functions. This is not to be used for simple constant definitions. Examples of its use in the Python documentation include `PyObject_HEAD` and `Py_BEGIN_ALLOW_THREADS`.

c:type

Describes a C type. The signature should just be the type name.

c:var

Describes a global C variable. The signature should include the type, such as:

```
.. cvar:: PyObject* PyClass_Type
```

data

Describes global data in a module, including both variables and values used as “defined constants.” Class and object attributes are not documented using this environment.

exception

Describes an exception class. The signature can, but need not include parentheses with constructor arguments.

function

Describes a module-level function. The signature should include the parameters, enclosing optional parameters in brackets. Default values can be given if it enhances clarity. For example:

```
.. function:: Timer.repeat([repeat=3[, number=1000000]])
```

Object methods are not documented using this directive. Bound object methods placed in the module namespace as part of the public interface of the module are documented using this, as they are equivalent to normal functions for most purposes.

The description should include information about the parameters required and how they are used (especially whether mutable objects passed as parameters are modified), side effects, and possible exceptions. A small example may be provided.

decorator

Describes a decorator function. The signature should *not* represent the signature of the actual function, but the usage as a decorator. For example, given the functions

```
def removename(func):  
    func.__name__ = ''  
    return func  
  
def setnewname(name):  
    def decorator(func):  
        func.__name__ = name  
        return func  
    return decorator
```

the descriptions should look like this:

```
.. decorator:: removename  
    Remove name of the decorated function.  
.. decorator:: setnewname(name)  
    Set name of the decorated function to *name*.
```

There is no `deco` role to link to a decorator that is marked up with this directive; rather, use the `:func:` role.

class

Describes a class. The signature can include parentheses with parameters which will be shown as the constructor arguments.

attribute

Describes an object data attribute. The description should include information about the type of the data to be expected and whether it may be changed directly.

method

Describes an object method. The parameters should not include the `self` parameter. The description should include similar information to that described for `function`.

decoratormethod

Same as `decorator`, but for decorators that are methods.

Refer to a decorator method using the `:meth:` role.

opcode

Describes a Python *bytecode* instruction.

cmdoption

Describes a Python command line option or switch. Option argument names should be enclosed in angle brackets. Example:

```
.. cmdoption:: -m <module>
```

```
Run a module as a script.
```

envvar

Describes an environment variable that Python uses or defines.

There is also a generic version of these directives:

describe

This directive produces the same formatting as the specific ones explained above but does not create index entries or cross-referencing targets. It is used, for example, to describe the directives in this document. Example:

```
.. describe:: opcode
```

```
Describes a Python bytecode instruction.
```

4.4. Showing code examples

Examples of Python source code or interactive sessions are represented using standard reST literal blocks. They are started by a `::` at the end of the preceding paragraph and delimited by indentation.

Representing an interactive session requires including the prompts and output along with the Python code. No special markup is required for interactive sessions. After the last line of input or output presented, there should not be an “unused” primary prompt; this is an example of what *not* to do:

```
>>> 1 + 1
2
>>>
```

Syntax highlighting is handled in a smart way:

- There is a “highlighting language” for each source file. Per default, this is `'python'` as the majority of files will have to highlight Python snippets.
- Within Python highlighting mode, interactive sessions are recognized automatically and highlighted appropriately.
- The highlighting language can be changed using the `highlightlang` directive, used as follows:

```
.. highlightlang:: c
```

This language is used until the next `highlightlang` directive is encountered.

- The values normally used for the highlighting language are:

- `python` (the default)
 - `c`
 - `rest`
 - `none` (no highlighting)
- If highlighting with the current language fails, the block is not highlighted in any way.

Longer displays of verbatim text may be included by storing the example text in an external file containing only plain text. The file may be included using the `literalinclude` directive. [1] For example, to include the Python source file `example.py`, use:

```
.. literalinclude:: example.py
```

The file name is relative to the current file's path. Documentation-specific include files should be placed in the `Doc/includes` subdirectory.

4.5. Inline markup

As said before, Sphinx uses interpreted text roles to insert semantic markup in documents.

Names of local variables, such as function/method arguments, are an exception, they should be marked simply with `*var*`.

For all other roles, you have to write `:rolename: `content``.

There are some additional facilities that make cross-referencing roles more versatile:

- You may supply an explicit title and reference target, like in reST direct hyperlinks: `:role: `title <target>`` will refer to *target*, but the link text will be *title*.
- If you prefix the content with `!`, no reference/hyperlink will be created.
- For the Python object roles, if you prefix the content with `~`, the link text will only be the last component of the target. For example, `:meth: `~Queue.Queue.get`` will refer to `Queue.Queue.get` but only display `get` as the link text.

In HTML output, the link's `title` attribute (that is e.g. shown as a tool-tip on mouse-hover) will always be the full target name.

The following roles refer to objects in modules and are possibly hyperlinked if a matching identifier is found:

mod

The name of a module; a dotted name may be used. This should also be used for package names.

func

The name of a Python function; dotted names may be used. The role text should not include trailing parentheses to enhance readability. The parentheses are stripped when searching for identifiers.

data

The name of a module-level variable or constant.

const

The name of a “defined” constant. This may be a C-language `#define` or a Python variable that is not intended to be changed.

class

A class name; a dotted name may be used.

meth

The name of a method of an object. The role text should include the type name and the method name. A dotted name may be used.

attr

The name of a data attribute of an object.

exc

The name of an exception. A dotted name may be used.

The name enclosed in this markup can include a module name and/or a class name. For example, `:func:`filter`` could refer to a function named `filter` in the current module, or the built-in function of that name. In contrast, `:func:`foo.filter`` clearly refers to the `filter` function in the `foo` module.

Normally, names in these roles are searched first without any further qualification, then with the current module name prepended, then with the current module and class name (if any) prepended. If you

prefix the name with a dot, this order is reversed. For example, in the documentation of the `codecs` module, `:func:`open`` always refers to the built-in function, while `:func:`.open`` refers to `codecs.open()`.

A similar heuristic is used to determine whether the name is an attribute of the currently documented class.

The following roles create cross-references to C-language constructs if they are defined in the API documentation:

c:data

The name of a C-language variable.

c:func

The name of a C-language function. Should include trailing parentheses.

c:macro

The name of a “simple” C macro, as defined above.

c:type

The name of a C-language type.

c:member

The name of a C type member, as defined above.

The following role does possibly create a cross-reference, but does not refer to objects:

token

The name of a grammar token (used in the reference manual to create links between production displays).

The following role creates a cross-reference to the term in the glossary:

term

Reference to a term in the glossary. The glossary is created using the `glossary` directive containing a definition list with terms and definitions. It does not have to be in the same file as the `term` markup, in fact, by default the Python docs have one global glossary in the `glossary.rst` file.

If you use a term that's not explained in a glossary, you'll get a warning during build.

The following roles don't do anything special except formatting the text in a different style:

command

The name of an OS-level command, such as `rm`.

dfn

Mark the defining instance of a term in the text. (No index entries are generated.)

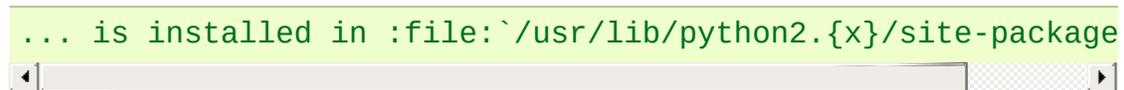

envvar

An environment variable. Index entries are generated.

file

The name of a file or directory. Within the contents, you can use curly braces to indicate a "variable" part, for example:

```
... is installed in :file:`~usr/lib/python2.{x}/site-package
```

In the built documentation, the `x` will be displayed differently to indicate that it is to be replaced by the Python minor version.

gui-label

Labels presented as part of an interactive user interface should be marked using `gui-label`. This includes labels from text-based

interfaces such as those created using `curses` or other text-based libraries. Any label used in the interface should be marked with this role, including button labels, window titles, field names, menu and menu selection names, and even values in selection lists.

kbd

Mark a sequence of keystrokes. What form the key sequence takes may depend on platform- or application-specific conventions. When there are no relevant conventions, the names of modifier keys should be spelled out, to improve accessibility for new users and non-native speakers. For example, an *xemacs* key sequence may be marked like `:kbd: `c-x c-f``, but without reference to a specific application or platform, the same sequence should be marked as `:kbd: `Control-x Control-f``.

keyword

The name of a keyword in Python.

mailheader

The name of an RFC 822-style mail header. This markup does not imply that the header is being used in an email message, but can be used to refer to any header of the same “style.” This is also used for headers defined by the various MIME specifications. The header name should be entered in the same way it would normally be found in practice, with the camel-casing conventions being preferred where there is more than one common usage. For example: `:mailheader: `Content-Type``.

makevar

The name of a **make** variable.

manpage

A reference to a Unix manual page including the section, e.g. `:manpage: `ls(1)``.

menuselection

Menu selections should be marked using the `menuselection` role. This is used to mark a complete sequence of menu selections, including selecting submenus and choosing a specific operation, or any subsequence of such a sequence. The names of individual selections should be separated by `-->`.

For example, to mark the selection “Start > Programs”, use this markup:

```
:menuselection:`Start --> Programs`
```

When including a selection that includes some trailing indicator, such as the ellipsis some operating systems use to indicate that the command opens a dialog, the indicator should be omitted from the selection name.

mimetype

The name of a MIME type, or a component of a MIME type (the major or minor portion, taken alone).

newsgroup

The name of a Usenet newsgroup.

option

A command-line option of Python. The leading hyphen(s) must be included. If a matching `cmdoption` directive exists, it is linked to. For options of other programs or scripts, use simple `code` markup.`

program

The name of an executable program. This may differ from the file name for the executable for some platforms. In particular, the `.exe` (or other) extension should be omitted for Windows programs.

regex

A regular expression. Quotes should not be included.

samp

A piece of literal text, such as code. Within the contents, you can use curly braces to indicate a “variable” part, as in `:file:`.

If you don’t need the “variable part” indication, use the standard ```code``` instead.

The following roles generate external links:

pep

A reference to a Python Enhancement Proposal. This generates appropriate index entries. The text “PEP *number*” is generated; in the HTML output, this text is a hyperlink to an online copy of the specified PEP.

rfc

A reference to an Internet Request for Comments. This generates appropriate index entries. The text “RFC *number*” is generated; in the HTML output, this text is a hyperlink to an online copy of the specified RFC.

Note that there are no special roles for including hyperlinks as you can use the standard reST markup for that purpose.

4.6. Cross-linking markup

To support cross-referencing to arbitrary sections in the documentation, the standard reST labels are “abused” a bit: Every label must precede a section title; and every label name must be unique throughout the entire documentation source.

You can then reference to these sections using the `:ref:`label-name`` role.

Example:

```
.. _my-reference-label:  
  
Section to cross-reference  
-----  
  
This is the text of the section.  
  
It refers to the section itself, see :ref:`my-reference-label`.
```

The `:ref:` invocation is replaced with the section title.

Alternatively, you can reference any label (not just section titles) if you provide the link text `:ref:`link text <reference-label>``.

4.7. Paragraph-level markup

These directives create short paragraphs and can be used inside information units as well as normal text:

note

An especially important bit of information about an API that a user should be aware of when using whatever bit of API the note pertains to. The content of the directive should be written in complete sentences and include all appropriate punctuation.

Example:

```
.. note::
```

```
This function is not suitable for sending spam e-mails.
```

warning

An important bit of information about an API that a user should be aware of when using whatever bit of API the warning pertains to. The content of the directive should be written in complete sentences and include all appropriate punctuation. In the interest of not scaring users away from pages filled with warnings, this directive should only be chosen over `note` for information regarding the possibility of crashes, data loss, or security implications.

versionadded

This directive documents the version of Python which added the described feature to the library or C API. When this applies to an entire module, it should be placed at the top of the module section before any prose.

The first argument must be given and is the version in question; you can add a second argument consisting of a *brief* explanation

of the change.

Example:

```
.. versionadded:: 3.1
   The *spam* parameter.
```

Note that there must be no blank line between the directive head and the explanation; this is to make these blocks visually continuous in the markup.

versionchanged

Similar to `versionadded`, but describes when and what changed in the named feature in some way (new parameters, changed side effects, etc.).

impl-detail

This directive is used to mark CPython-specific information. Use either with a block content or a single sentence as an argument, i.e. either

```
.. impl-detail::

   This describes some implementation detail.

   More explanation.
```

or

```
.. impl-detail:: This shortly mentions an implementation det
```

“CPython implementation detail:” is automatically prepended to the content.

seealso

Many sections include a list of references to module

documentation or external documents. These lists are created using the `seealso` directive.

The `seealso` directive is typically placed in a section just before any sub-sections. For the HTML output, it is shown boxed off from the main flow of the text.

The content of the `seealso` directive should be a reST definition list. Example:

```
.. seealso::  
  
   Module :mod:`zipfile`  
       Documentation of the :mod:`zipfile` standard module.  
  
   `GNU tar manual, Basic Tar Format <http://link>`_  
       Documentation for tar archive files, including GNU tar
```

rubric

This directive creates a paragraph heading that is not used to create a table of contents node. It is currently used for the “Footnotes” caption.

centered

This directive creates a centered boldfaced paragraph. Use it as follows:

```
.. centered::  
  
   Paragraph contents.
```

4.8. Table-of-contents markup

Since reST does not have facilities to interconnect several documents, or split documents into multiple output files, Sphinx uses a custom directive to add relations between the single files the documentation is made of, as well as tables of contents. The `toctree` directive is the central element.

toctree

This directive inserts a “TOC tree” at the current location, using the individual TOCs (including “sub-TOC trees”) of the files given in the directive body. A numeric `maxdepth` option may be given to indicate the depth of the tree; by default, all levels are included.

Consider this example (taken from the library reference index):

```
.. toctree::  
   :maxdepth: 2  
  
   intro  
   strings  
   datatypes  
   numeric  
   (many more files listed here)
```

This accomplishes two things:

- Tables of contents from all those files are inserted, with a maximum depth of two, that means one nested heading. `toctree` directives in those files are also taken into account.
- Sphinx knows that the relative order of the files `intro`, `strings` and so forth, and it knows that they are children of the shown file, the library index. From this information it generates “next chapter”, “previous chapter” and “parent chapter” links.

In the end, all files included in the build process must occur in one `toctree` directive; Sphinx will emit a warning if it finds a file that is not included, because that means that this file will not be reachable through standard navigation.

The special file `contents.rst` at the root of the source directory is the “root” of the TOC tree hierarchy; from it the “Contents” page is generated.

4.9. Index-generating markup

Sphinx automatically creates index entries from all information units (like functions, classes or attributes) like discussed before.

However, there is also an explicit directive available, to make the index more comprehensive and enable index entries in documents where information is not mainly contained in information units, such as the language reference.

The directive is `index` and contains one or more index entries. Each entry consists of a type and a value, separated by a colon.

For example:

```
.. index::  
   single: execution; context  
   module: __main__  
   module: sys  
   triple: module; search; path
```

This directive contains five entries, which will be converted to entries in the generated index which link to the exact location of the index statement (or, in case of offline media, the corresponding page number).

The possible entry types are:

single

Creates a single index entry. Can be made a subentry by separating the subentry text with a semicolon (this notation is also used below to describe what entries are created).

pair

`pair: loop; statement` is a shortcut that creates two index entries, namely `loop; statement` and `statement; loop`.

triple

Likewise, `triple: module; search; path` is a shortcut that creates three index entries, which are `module; search path`, `search; path, module` and `path; module search`.

module, keyword, operator, object, exception, statement, builtin

These all create two index entries. For example, `module: hashlib` creates the entries `module; hashlib` and `hashlib; module`.

For index directives containing only “single” entries, there is a shorthand notation:

```
.. index:: BNF, grammar, syntax, notation
```

This creates four index entries.

4.10. Grammar production displays

Special markup is available for displaying the productions of a formal grammar. The markup is simple and does not attempt to model all aspects of BNF (or any derived forms), but provides enough to allow context-free grammars to be displayed in a way that causes uses of a symbol to be rendered as hyperlinks to the definition of the symbol. There is this directive:

productionlist

This directive is used to enclose a group of productions. Each production is given on a single line and consists of a name, separated by a colon from the following definition. If the definition spans multiple lines, each continuation line must begin with a colon placed at the same column as in the first line.

Blank lines are not allowed within `productionlist` directive arguments.

The definition can contain token names which are marked as interpreted text (e.g. `unaryneg ::= "-" `integer``) – this generates cross-references to the productions of these tokens.

Note that no further reST parsing is done in the production, so that you don't have to escape `*` or `|` characters.

The following is an example taken from the Python Reference Manual:

```
.. productionlist::
try_stmt: try1_stmt | try2_stmt
try1_stmt: "try" ":" `suite`
          : ("except" [`expression` ["," `target`] ] ":" `suite`
          : ["else" ":" `suite`]
          : ["finally" ":" `suite`]
try2_stmt: "try" ":" `suite`
```

```
: "finally" ":" `suite`
```

4.11. Substitutions

The documentation system provides three substitutions that are defined by default. They are set in the build configuration file `conf.py`.

|release|

Replaced by the Python release the documentation refers to. This is the full version string including alpha/beta/release candidate tags, e.g. `2.5.2b3`.

|version|

Replaced by the Python version the documentation refers to. This consists only of the major and minor version parts, e.g. `2.5`, even for version `2.5.1`.

|today|

Replaced by either today's date, or the date set in the build configuration file. Normally has the format `April 14, 2007`.

Footnotes

- [1] There is a standard `.. include` directive, but it raises errors if the file is not found. This one only emits a warning.

5. Differences to the LaTeX markup

Though the markup language is different, most of the concepts and markup types of the old LaTeX docs have been kept – environments as reST directives, inline commands as reST roles and so forth.

However, there are some differences in the way these work, partly due to the differences in the markup languages, partly due to improvements in Sphinx. This section lists these differences, in order to give those familiar with the old format a quick overview of what they might run into.

5.1. Inline markup

These changes have been made to inline markup:

- **Cross-reference roles**

Most of the following semantic roles existed previously as inline commands, but didn't do anything except formatting the content as code. Now, they cross-reference to known targets (some names have also been shortened):

mod (previously *refmodule* or *module*)

func (previously *function*)

data (new)

const

class

meth (previously *method*)

attr (previously *member*)

exc (previously *exception*)

cdata

cfunc (previously *cfunction*)

cmacro (previously *csimplemacro*)

ctype

Also different is the handling of *func* and *meth*: while previously parentheses were added to the callable name (like `\func{str()}}`), they are now appended by the build system – appending them in the source will result in double parentheses. This also means that `:func: `str(object)`` will not work as expected – use ``str(object)``` instead!

- **Inline commands implemented as directives**

These were inline commands in LaTeX, but are now directives in

reST:

deprecated

versionadded

versionchanged

These are used like so:

```
.. deprecated:: 2.5  
   Reason of deprecation.
```

Also, no period is appended to the text for *versionadded* and *versionchanged*.

note

warning

These are used like so:

```
.. note::  
  
   Content of note.
```

- **Otherwise changed commands**

The *samp* command previously formatted code and added quotation marks around it. The *samp* role, however, features a new highlighting system just like *file* does:

```
:samp:`open({filename}, {mode})` results in  
open(filename, mode)
```

- **Dropped commands**

These were commands in LaTeX, but are not available as roles:

bfcode

character (use ```'c'```)

citetitle (use ``Title <URL>`_``)

code (use ```code```)

email (just write the address in body text)

fileeq

filevar (use the `{...}` highlighting feature of *file*)

programopt, *longprogramopt* (use *option*)

ulink (use ``Title <URL>`_``)

url (just write the URL in body text)

var (use `*var*`)

infinity, *plusminus* (use the Unicode character)

shortversion, *version* (use the `|version|` and `|release|` substitutions)

emph, *strong* (use the reST markup)

- **Backslash escaping**

In reST, a backslash must be escaped in normal text, and in the content of roles. However, in code literals and literal blocks, it must not be escaped. Example: `:file:`C:\\Temp\\my.tmp`` vs. ```open("C:\\Temp\\my.tmp")```.

5.2. Information units

Information units (*...desc* environments) have been made reST directives. These changes to information units should be noted:

- **New names**

“desc” has been removed from every name. Additionally, these directives have new names:

cfunction (previously *cfuncdesc*)
cmacro (previously *csimplemacrodesc*)
exception (previously *excdesc*)
function (previously *funcdesc*)
attribute (previously *memberdesc*)

The *classdesc** and *excclassdesc* environments have been dropped, the *class* and *exception* directives support classes documented with and without constructor arguments.

- **Multiple objects**

The equivalent of the *...line* commands is:

```
.. function:: do_foo(bar)
               do_bar(baz)

   Description of the functions.
```

IOW, just give one signatures per line, at the same indentation level.

- **Arguments**

There is no *optional* command. Just give function signatures like they should appear in the output:

```
.. function:: open(filename[, mode[, buffering]])  
Description.
```

Note: markup in the signature is not supported.

- **Indexing**

The *...descni* environments have been dropped. To mark an information unit as unsuitable for index entry generation, use the *noindex* option like so:

```
.. function:: foo_*  
:noindex:  
Description.
```

- **New information units**

There are new generic information units: One is called “describe” and can be used to document things that are not covered by the other units:

```
.. describe:: a == b  
The equals operator.
```

The others are:

```
.. cmdoption:: -0  
Describes a command-line option.  
.. envvar:: PYTHONINSPECT  
Describes an environment variable.
```

5.3. Structure

The LaTeX docs were split in several toplevel manuals. Now, all files are part of the same documentation tree, as indicated by the *toctree* directives in the sources (though individual output formats may choose to split them up into parts again). Every *toctree* directive embeds other files as subdocuments of the current file (this structure is not necessarily mirrored in the filesystem layout). The toplevel file is `contents.rst`.

However, most of the old directory structure has been kept, with the directories renamed as follows:

- `api` -> `c-api`
- `dist` -> `distutils`, with the single TeX file split up
- `doc` -> `documenting`
- `ext` -> `extending`
- `inst` -> `installing`
- `lib` -> `library`
- `mac` -> merged into `library`, with `mac/using.tex` moved to `using/mac.rst`
- `ref` -> `reference`
- `tut` -> `tutorial`, with the single TeX file split up

6. Building the documentation

You need to have Python 2.4 or higher installed; the toolset used to build the docs is written in Python. It is called *Sphinx*, it is not included in this tree, but maintained separately. Also needed are the docutils, supplying the base markup that Sphinx uses, Jinja, a templating engine, and optionally Pygments, a code highlighter.

6.1. Using make

Luckily, a Makefile has been prepared so that on Unix, provided you have installed Python and Subversion, you can just run

```
make html
```

to check out the necessary toolset in the `tools/` subdirectory and build the HTML output files. To view the generated HTML, point your favorite browser at the top-level index `build/html/index.html` after running “make”.

Available make targets are:

- “html”, which builds standalone HTML files for offline viewing.
- “htmlhelp”, which builds HTML files and a HTML Help project file usable to convert them into a single Compiled HTML (.chm) file – these are popular under Microsoft Windows, but very handy on every platform.

To create the CHM file, you need to run the Microsoft HTML Help Workshop over the generated project (.hhp) file.

- “latex”, which builds LaTeX source files as input to “pdflatex” to produce PDF documents.
- “text”, which builds a plain text file for each source file.
- “linkcheck”, which checks all external references to see whether they are broken, redirected or malformed, and outputs this information to stdout as well as a plain-text (.txt) file.

- “changes”, which builds an overview over all versionadded/versionchanged/ deprecated items in the current version. This is meant as a help for the writer of the “What’s New” document.
- “coverage”, which builds a coverage overview for standard library modules and C API.
- “pydoc-topics”, which builds a Python module containing a dictionary with plain text documentation for the labels defined in `tools/sphinxext/pyspecific.py` – pydoc needs these to show topic and keyword help.

A “make update” updates the Subversion checkouts in `tools/`.

6.2. Without make

You'll need to install the Sphinx package, either by checking it out via

```
svn co http://svn.python.org/projects/external/Sphinx-0.6.5/sph
```

or by installing it from PyPI.

Then, you need to install Docutils, either by checking it out via

```
svn co http://svn.python.org/projects/external/docutils-0.6/doc
```

or by installing it from <http://docutils.sf.net/>.

You also need Jinja2, either by checking it out via

```
svn co http://svn.python.org/projects/external/Jinja-2.3.1/jinj
```

or by installing it from PyPI.

You can optionally also install Pygments, either as a checkout via

```
svn co http://svn.python.org/projects/external/Pygments-1.3.1/p
```

or from PyPI at <http://pypi.python.org/pypi/Pygments>.

Then, make an output directory, e.g. under *build/*, and run

```
python tools/sphinx-build.py -b<builder> . build/<outputdirecto
```

where *<builder>* is one of `html`, `text`, `latex`, or `htmlhelp` (for explanations see the make targets above).

Python Advocacy HOWTO

Author: A.M. Kuchling

Release: 0.03

Abstract

It's usually difficult to get your management to accept open source software, and Python is no exception to this rule. This document discusses reasons to use Python, strategies for winning acceptance, facts and arguments you can use, and cases where *you shouldn't* try to use Python.

Reasons to Use Python

There are several reasons to incorporate a scripting language into your development process, and this section will discuss them, and why Python has some properties that make it a particularly good choice.

Programmability

Programs are often organized in a modular fashion. Lower-level operations are grouped together, and called by higher-level functions, which may in turn be used as basic operations by still further upper levels.

For example, the lowest level might define a very low-level set of functions for accessing a hash table. The next level might use hash tables to store the headers of a mail message, mapping a header name like `Date` to a value such as `Tue, 13 May 1997 20:00:54 -0400`. A yet higher level may operate on message objects, without knowing or caring that message headers are stored in a hash table, and so forth.

Often, the lowest levels do very simple things; they implement a data structure such as a binary tree or hash table, or they perform some simple computation, such as converting a date string to a number. The higher levels then contain logic connecting these primitive operations. Using the approach, the primitives can be seen as basic building blocks which are then glued together to produce the complete product.

Why is this design approach relevant to Python? Because Python is well suited to functioning as such a glue language. A common approach is to write a Python module that implements the lower level

operations; for the sake of speed, the implementation might be in C, Java, or even Fortran. Once the primitives are available to Python programs, the logic underlying higher level operations is written in the form of Python code. The high-level logic is then more understandable, and easier to modify.

John Ousterhout wrote a paper that explains this idea at greater length, entitled “Scripting: Higher Level Programming for the 21st Century”. I recommend that you read this paper; see the references for the URL. Ousterhout is the inventor of the Tcl language, and therefore argues that Tcl should be used for this purpose; he only briefly refers to other languages such as Python, Perl, and Lisp/Scheme, but in reality, Ousterhout’s argument applies to scripting languages in general, since you could equally write extensions for any of the languages mentioned above.

Prototyping

In *The Mythical Man-Month*, Fredrick Brooks suggests the following rule when planning software projects: “Plan to throw one away; you will anyway.” Brooks is saying that the first attempt at a software design often turns out to be wrong; unless the problem is very simple or you’re an extremely good designer, you’ll find that new requirements and features become apparent once development has actually started. If these new requirements can’t be cleanly incorporated into the program’s structure, you’re presented with two unpleasant choices: hammer the new features into the program somehow, or scrap everything and write a new version of the program, taking the new features into account from the beginning.

Python provides you with a good environment for quickly developing an initial prototype. That lets you get the overall program structure and logic right, and you can fine-tune small details in the fast development cycle that Python provides. Once you’re satisfied with the GUI interface or program output, you can translate the Python

code into C++, Fortran, Java, or some other compiled language.

Prototyping means you have to be careful not to use too many Python features that are hard to implement in your other language. Using `eval()`, or regular expressions, or the `pickle` module, means that you're going to need C or Java libraries for formula evaluation, regular expressions, and serialization, for example. But it's not hard to avoid such tricky code, and in the end the translation usually isn't very difficult. The resulting code can be rapidly debugged, because any serious logical errors will have been removed from the prototype, leaving only more minor slip-ups in the translation to track down.

This strategy builds on the earlier discussion of programmability. Using Python as glue to connect lower-level components has obvious relevance for constructing prototype systems. In this way Python can help you with development, even if end users never come in contact with Python code at all. If the performance of the Python version is adequate and corporate politics allow it, you may not need to do a translation into C or Java, but it can still be faster to develop a prototype and then translate it, instead of attempting to produce the final version immediately.

One example of this development strategy is Microsoft Merchant Server. Version 1.0 was written in pure Python, by a company that subsequently was purchased by Microsoft. Version 2.0 began to translate the code into C++, shipping with some C++ code and some Python code. Version 3.0 didn't contain any Python at all; all the code had been translated into C++. Even though the product doesn't contain a Python interpreter, the Python language has still served a useful purpose by speeding up development.

This is a very common use for Python. Past conference papers have also described this approach for developing high-level numerical algorithms; see David M. Beazley and Peter S. Lomdahl's paper

“Feeding a Large-scale Physics Application to Python” in the references for a good example. If an algorithm’s basic operations are things like “Take the inverse of this 4000x4000 matrix”, and are implemented in some lower-level language, then Python has almost no additional performance cost; the extra time required for Python to evaluate an expression like `m.invert()` is dwarfed by the cost of the actual computation. It’s particularly good for applications where seemingly endless tweaking is required to get things right. GUI interfaces and Web sites are prime examples.

The Python code is also shorter and faster to write (once you’re familiar with Python), so it’s easier to throw it away if you decide your approach was wrong; if you’d spent two weeks working on it instead of just two hours, you might waste time trying to patch up what you’ve got out of a natural reluctance to admit that those two weeks were wasted. Truthfully, those two weeks haven’t been wasted, since you’ve learnt something about the problem and the technology you’re using to solve it, but it’s human nature to view this as a failure of some sort.

Simplicity and Ease of Understanding

Python is definitely *not* a toy language that’s only usable for small tasks. The language features are general and powerful enough to enable it to be used for many different purposes. It’s useful at the small end, for 10- or 20-line scripts, but it also scales up to larger systems that contain thousands of lines of code.

However, this expressiveness doesn’t come at the cost of an obscure or tricky syntax. While Python has some dark corners that can lead to obscure code, there are relatively few such corners, and proper design can isolate their use to only a few classes or modules. It’s certainly possible to write confusing code by using too many features with too little concern for clarity, but most Python code can

look a lot like a slightly-formalized version of human-understandable pseudocode.

In *The New Hacker's Dictionary*, Eric S. Raymond gives the following definition for “compact”:

Compact *adj.* Of a design, describes the valuable property that it can all be apprehended at once in one's head. This generally means the thing created from the design can be used with greater facility and fewer errors than an equivalent tool that is not compact. Compactness does not imply triviality or lack of power; for example, C is compact and FORTRAN is not, but C is more powerful than FORTRAN. Designs become non-compact through accreting features and cruft that don't merge cleanly into the overall design scheme (thus, some fans of Classic C maintain that ANSI C is no longer compact).

(From <http://www.catb.org/~esr/jargon/html/C/compact.html>)

In this sense of the word, Python is quite compact, because the language has just a few ideas, which are used in lots of places. Take namespaces, for example. Import a module with `import math`, and you create a new namespace called `math`. Classes are also namespaces that share many of the properties of modules, and have a few of their own; for example, you can create instances of a class. Instances? They're yet another namespace. Namespaces are currently implemented as Python dictionaries, so they have the same methods as the standard dictionary data type: `.keys()` returns all the keys, and so forth.

This simplicity arises from Python's development history. The language syntax derives from different sources; ABC, a relatively obscure teaching language, is one primary influence, and Modula-3 is another. (For more information about ABC and Modula-3, consult their respective Web sites at <http://www.cwi.nl/~steven/abc/> and

<http://www.m3.org>.) Other features have come from C, Icon, Algol-68, and even Perl. Python hasn't really innovated very much, but instead has tried to keep the language small and easy to learn, building on ideas that have been tried in other languages and found useful.

Simplicity is a virtue that should not be underestimated. It lets you learn the language more quickly, and then rapidly write code – code that often works the first time you run it.

Java Integration

If you're working with Java, Jython (<http://www.jython.org/>) is definitely worth your attention. Jython is a re-implementation of Python in Java that compiles Python code into Java bytecodes. The resulting environment has very tight, almost seamless, integration with Java. It's trivial to access Java classes from Python, and you can write Python classes that subclass Java classes. Jython can be used for prototyping Java applications in much the same way CPython is used, and it can also be used for test suites for Java code, or embedded in a Java application to add scripting capabilities.

Arguments and Rebuttals

Let's say that you've decided upon Python as the best choice for your application. How can you convince your management, or your fellow developers, to use Python? This section lists some common arguments against using Python, and provides some possible rebuttals.

Python is freely available software that doesn't cost anything. How good can it be?

Very good, indeed. These days Linux and Apache, two other pieces of open source software, are becoming more respected as alternatives to commercial software, but Python hasn't had all the publicity.

Python has been around for several years, with many users and developers. Accordingly, the interpreter has been used by many people, and has gotten most of the bugs shaken out of it. While bugs are still discovered at intervals, they're usually either quite obscure (they'd have to be, for no one to have run into them before) or they involve interfaces to external libraries. The internals of the language itself are quite stable.

Having the source code should be viewed as making the software available for peer review; people can examine the code, suggest (and implement) improvements, and track down bugs. To find out more about the idea of open source code, along with arguments and case studies supporting it, go to <http://www.opensource.org>.

Who's going to support it?

Python has a sizable community of developers, and the number is still growing. The Internet community surrounding the language is an

active one, and is worth being considered another one of Python's advantages. Most questions posted to the comp.lang.python newsgroup are quickly answered by someone.

Should you need to dig into the source code, you'll find it's clear and well-organized, so it's not very difficult to write extensions and track down bugs yourself. If you'd prefer to pay for support, there are companies and individuals who offer commercial support for Python.

Who uses Python for serious work?

Lots of people; one interesting thing about Python is the surprising diversity of applications that it's been used for. People are using Python to:

- Run Web sites
- Write GUI interfaces
- Control number-crunching code on supercomputers
- Make a commercial application scriptable by embedding the Python interpreter inside it
- Process large XML data sets
- Build test suites for C or Java code

Whatever your application domain is, there's probably someone who's used Python for something similar. Yet, despite being useable for such high-end applications, Python's still simple enough to use for little jobs.

See <http://wiki.python.org/moin/OrganizationsUsingPython> for a list of some of the organizations that use Python.

What are the restrictions on Python's use?

They're practically nonexistent. Consult the `Misc/COPYRIGHT` file in the source distribution, or the section *History and License* for the full language, but it boils down to three conditions:

- You have to leave the copyright notice on the software; if you don't include the source code in a product, you have to put the copyright notice in the supporting documentation.
- Don't claim that the institutions that have developed Python endorse your product in any way.
- If something goes wrong, you can't sue for damages. Practically all software licenses contain this condition.

Notice that you don't have to provide source code for anything that contains Python or is built with it. Also, the Python interpreter and accompanying documentation can be modified and redistributed in any way you like, and you don't have to pay anyone any licensing fees at all.

Why should we use an obscure language like Python instead of well-known language X?

I hope this HOWTO, and the documents listed in the final section, will help convince you that Python isn't obscure, and has a healthily growing user base. One word of advice: always present Python's positive advantages, instead of concentrating on language X's failings. People want to know why a solution is good, rather than why all the other solutions are bad. So instead of attacking a competing solution on various grounds, simply show how Python's virtues can help.

Useful Resources

<http://www.pythonology.com/success>

The Python Success Stories are a collection of stories from successful users of Python, with the emphasis on business and corporate users.

<http://home.pacbell.net/ouster/scripting.html>

John Ousterhout's white paper on scripting is a good argument for the utility of scripting languages, though naturally enough, he emphasizes Tcl, the language he developed. Most of the arguments would apply to any scripting language.

<http://www.python.org/workshops/1997-10/proceedings/beazley.html>

The authors, David M. Beazley and Peter S. Lomdahl, describe their use of Python at Los Alamos National Laboratory. It's another good example of how Python can help get real work done. This quotation from the paper has been echoed by many people:

Originally developed as a large monolithic application for massively parallel processing systems, we have used Python to transform our application into a flexible, highly modular, and extremely powerful system for performing simulation, data analysis, and visualization. In addition, we describe how Python has solved a number of important problems related to the development, debugging, deployment, and maintenance of scientific software.

http://pythonjournal.cognizor.com/pyj1/Everitt-Feit_interview98-V1.html

This interview with Andy Feit, discussing Infoseek's use of Python, can be used to show that choosing Python didn't introduce any difficulties into a company's development process,

and provided some substantial benefits.

<http://www.python.org/workshops/1997-10/proceedings/stein.ps>

For the 6th Python conference, Greg Stein presented a paper that traced Python's adoption and usage at a startup called eShop, and later at Microsoft.

<http://www.opensource.org>

Management may be doubtful of the reliability and usefulness of software that wasn't written commercially. This site presents arguments that show how open source software can have considerable advantages over closed-source software.

<http://www.faqs.org/docs/Linux-mini/Advocacy.html>

The Linux Advocacy mini-HOWTO was the inspiration for this document, and is also well worth reading for general suggestions on winning acceptance for a new technology, such as Linux or Python. In general, you won't make much progress by simply attacking existing systems and complaining about their inadequacies; this often ends up looking like unfocused whining. It's much better to point out some of the many areas where Python is an improvement over other systems.

Porting Python 2 Code to Python 3

author: Brett Cannon

Abstract

With Python 3 being the future of Python while Python 2 is still in active use, it is good to have your project available for both major releases of Python. This guide is meant to help you choose which strategy works best for your project to support both Python 2 & 3 along with how to execute that strategy.

If you are looking to port an extension module instead of pure Python code, please see [Porting Extension Modules to 3.0](#).

Choosing a Strategy

When a project makes the decision that it's time to support both Python 2 & 3, a decision needs to be made as to how to go about accomplishing that goal. The chosen strategy will depend on how large the project's existing codebase is and how much divergence you want from your Python 2 codebase from your Python 3 one (e.g., starting a new version with Python 3).

If your project is brand-new or does not have a large codebase, then you may want to consider writing/porting *all of your code for Python 3 and use 3to2* to port your code for Python 2.

If you would prefer to maintain a codebase which is semantically **and** syntactically compatible with Python 2 & 3 simultaneously, you can write *Python 2/3 Compatible Source*. While this tends to lead to somewhat non-idiomatic code, it does mean you keep a rapid development process for you, the developer.

Finally, you do have the option of *using 2to3* to translate Python 2 code into Python 3 code (with some manual help). This can take the form of branching your code and using 2to3 to start a Python 3 branch. You can also have users perform the translation as installation time automatically so that you only have to maintain a Python 2 codebase.

Regardless of which approach you choose, porting is not as hard or time-consuming as you might initially think. You can also tackle the problem piece-meal as a good portion of porting is simply updating your code to follow current best practices in a Python 2/3 compatible way.

Universal Bits of Advice

Regardless of what strategy you pick, there are a few things you should consider.

One is make sure you have a robust test suite. You need to make sure everything continues to work, just like when you support a new minor version of Python. This means making sure your test suite is thorough and is ported properly between Python 2 & 3. You will also most likely want to use something like [tox](#) to automate testing between both a Python 2 and Python 3 VM.

Two, once your project has Python 3 support, make sure to add the proper classifier on the [Cheeseshop \(PyPI\)](#). To have your project listed as Python 3 compatible it must have the [Python 3 classifier](#) (from <http://techspot.zzzeek.org/2011/01/24/zzzeek-s-guide-to-python-3-porting/>):

```
setup(
    name='Your Library',
    version='1.0',
    classifiers=[
        # make sure to use :: Python *and* :: Python :: 3 so
        # that pypi can list the package on the python 3 page
        'Programming Language :: Python',
        'Programming Language :: Python :: 3'
    ],
    packages=['yourlibrary'],
    # make sure to add custom_fixers to the MANIFEST.in
    include_package_data=True,
    # ...
)
```

Doing so will cause your project to show up in the [Python 3 packages list](#). You will know you set the classifier properly as visiting your project page on the Cheeseshop will show a Python 3 logo in the upper-left corner of the page.

Three, the [six](#) project provides a library which helps iron out differences between Python 2 & 3. If you find there is a sticky point that is a continual point of contention in your translation or

maintenance of code, consider using a source-compatible solution relying on six. If you have to create your own Python 2/3 compatible solution, you can use `sys.version_info[0] >= 3` as a guard.

Four, read all the approaches. Just because some bit of advice applies to one approach more than another doesn't mean that some advice doesn't apply to other strategies.

Five, drop support for older Python versions if possible. [Python 2.5](#) introduced a lot of useful syntax and libraries which have become idiomatic in Python 3. [Python 2.6](#) introduced future statements which makes compatibility much easier if you are going from Python 2 to 3. [Python 2.7](#) continues the trend in the stdlib. So choose the newest version of Python which you believe can be your minimum support version and work from there.

Python 3 and 3to2

If you are starting a new project or your codebase is small enough, you may want to consider writing your code for Python 3 and backporting to Python 2 using [3to2](#). Thanks to Python 3 being more strict about things than Python 2 (e.g., bytes vs. strings), the source translation can be easier and more straightforward than from Python 2 to 3. Plus it gives you more direct experience developing in Python 3 which, since it is the future of Python, is a good thing long-term.

A drawback of this approach is that 3to2 is a third-party project. This means that the Python core developers (and thus this guide) can make no promises about how well 3to2 works at any time. There is nothing to suggest, though, that 3to2 is not a high-quality project.

Python 2 and 2to3

Included with Python since 2.6, the [2to3](#) tool (and [lib2to3](#) module) helps with porting Python 2 to Python 3 by performing various source translations. This is a perfect solution for projects which wish to branch their Python 3 code from their Python 2 codebase and maintain them as independent codebases. You can even begin preparing to use this approach today by writing future-compatible Python code which works cleanly in Python 2 in conjunction with 2to3; all steps outlined below will work with Python 2 code up to the point when the actual use of 2to3 occurs.

Use of 2to3 as an on-demand translation step at install time is also possible, preventing the need to maintain a separate Python 3 codebase, but this approach does come with some drawbacks. While users will only have to pay the translation cost once at installation, you as a developer will need to pay the cost regularly during development. If your codebase is sufficiently large enough then the translation step ends up acting like a compilation step, robbing you of the rapid development process you are used to with Python. Obviously the time required to translate a project will vary, so do an experimental translation just to see how long it takes to evaluate whether you prefer this approach compared to using [Python 2/3 Compatible Source](#) or simply keeping a separate Python 3 codebase.

Below are the typical steps taken by a project which uses a 2to3-based approach to supporting Python 2 & 3.

Support Python 2.7

As a first step, make sure that your project is compatible with [Python 2.7](#). This is just good to do as Python 2.7 is the last release of

Python 2 and thus will be used for a rather long time. It also allows for use of the `-3` flag to Python to help discover places in your code which 2to3 cannot handle but are known to cause issues.

Try to Support Python 2.6 and Newer Only

While not possible for all projects, if you can support [Python 2.6](#) and newer **only**, your life will be much easier. Various future statements, stdlib additions, etc. exist only in Python 2.6 and later which greatly assist in porting to Python 3. But if your project must keep support for [Python 2.5](#) (or even [Python 2.4](#)) then it is still possible to port to Python 3.

Below are the benefits you gain if you only have to support Python 2.6 and newer. Some of these options are personal choice while others are **strongly** recommended (the ones that are more for personal choice are labeled as such). If you continue to support older versions of Python then you at least need to watch out for situations that these solutions fix.

```
from __future__ import print_function
```

This is a personal choice. 2to3 handles the translation from the `print` statement to the `print` function rather well so this is an optional step. This future statement does help, though, with getting used to typing `print('Hello, world')` instead of `print 'Hello, world'`.

```
from __future__ import unicode_literals
```

Another personal choice. You can always mark what you want to be a (unicode) string with a `u` prefix to get the same effect. But regardless of whether you use this future statement or not, you **must** make sure you know exactly which Python 2 strings you want to be bytes, and which are to be strings. This means you should, **at minimum** mark all strings that are meant to be text strings with a `u`

prefix if you do not use this future statement.

Bytes literals

This is a **very** important one. The ability to prefix Python 2 strings that are meant to contain bytes with a `b` prefix help to very clearly delineate what is and is not a Python 3 string. When you run 2to3 on code, all Python 2 strings become Python 3 strings **unless** they are prefixed with `b`.

There are some differences between byte literals in Python 2 and those in Python 3 thanks to the bytes type just being an alias to `str` in Python 2. Probably the biggest “gotcha” is that indexing results in different values. In Python 2, the value of `b'py'[1]` is `'y'`, while in Python 3 it's `121`. You can avoid this disparity by always slicing at the size of a single element: `b'py'[1:2]` is `'y'` in Python 2 and `b'y'` in Python 3 (i.e., close enough).

You cannot concatenate bytes and strings in Python 3. But since in Python 2 has bytes aliased to `str`, it will succeed: `b'a' + u'b'` works in Python 2, but `b'a' + 'b'` in Python 3 is a `TypeError`. A similar issue also comes about when doing comparisons between bytes and strings.

Supporting Python 2.5 and Newer Only

If you are supporting Python 2.5 and newer there are still some features of Python that you can utilize.

```
from __future__ import absolute_imports
```

Implicit relative imports (e.g., importing `spam.bacon` from within `spam.eggs` with the statement `import bacon`) does not work in Python 3. This future statement moves away from that and allows the use of

explicit relative imports (e.g., `from . import bacon`).

In [Python 2.5](#) you must use the `__future__` statement to get to use explicit relative imports and prevent implicit ones. In [Python 2.6](#) explicit relative imports are available without the statement, but you still want the `__future__` statement to prevent implicit relative imports. In [Python 2.7](#) the `__future__` statement is not needed. In other words, unless you are only supporting Python 2.7 or a version earlier than Python 2.5, use the `__future__` statement.

Handle Common “Gotchas”

There are a few things that just consistently come up as sticking points for people which 2to3 cannot handle automatically or can easily be done in Python 2 to help modernize your code.

```
from __future__ import division
```

While the exact same outcome can be had by using the `-Qnew` argument to Python, using this future statement lifts the requirement that your users use the flag to get the expected behavior of division in Python 3 (e.g., `1/2 == 0.5`; `1//2 == 0`).

Specify when opening a file as binary

Unless you have been working on Windows, there is a chance you have not always bothered to add the `b` mode when opening a binary file (e.g., `rb` for binary reading). Under Python 3, binary files and text files are clearly distinct and mutually incompatible; see the `io` module for details. Therefore, you **must** make a decision of whether a file will be used for binary access (allowing to read and/or write bytes data) or text access (allowing to read and/or write unicode data).

Text files

Text files created using `open()` under Python 2 return byte strings, while under Python 3 they return unicode strings. Depending on your porting strategy, this can be an issue.

If you want text files to return unicode strings in Python 2, you have two possibilities:

- Under Python 2.6 and higher, use `io.open()`. Since `io.open()` is essentially the same function in both Python 2 and Python 3, it will help iron out any issues that might arise.
- If pre-2.6 compatibility is needed, then you should use `codecs.open()` instead. This will make sure that you get back unicode strings in Python 2.

Subclass `object`

New-style classes have been around since [Python 2.2](#). You need to make sure you are subclassing from `object` to avoid odd edge cases involving method resolution order, etc. This continues to be totally valid in Python 3 (although unneeded as all classes implicitly inherit from `object`).

Deal With the Bytes/String Dichotomy

One of the biggest issues people have when porting code to Python 3 is handling the bytes/string dichotomy. Because Python 2 allowed the `str` type to hold textual data, people have over the years been rather loose in their delineation of what `str` instances held text compared to bytes. In Python 3 you cannot be so care-free anymore and need to properly handle the difference. The key handling this issue is to make sure that **every** string literal in your Python 2 code is either syntactically or functionally marked as either bytes or text

data. After this is done you then need to make sure your APIs are designed to either handle a specific type or made to be properly polymorphic.

Mark Up Python 2 String Literals

First thing you must do is designate every single string literal in Python 2 as either textual or bytes data. If you are only supporting Python 2.6 or newer, this can be accomplished by marking bytes literals with a `b` prefix and then designating textual data with a `u` prefix or using the `unicode_literals` future statement.

If your project supports versions of Python pre-dating 2.6, then you should use the `six` project and its `b()` function to denote bytes literals. For text literals you can either use six's `u()` function or use a `u` prefix.

Decide what APIs Will Accept

In Python 2 it was very easy to accidentally create an API that accepted both bytes and textual data. But in Python 3, thanks to the more strict handling of disparate types, this loose usage of bytes and text together tends to fail.

Take the dict `{b'a': 'bytes', u'a': 'text'}` in Python 2.6. It creates the dict `{u'a': 'text'}` since `b'a' == u'a'`. But in Python 3 the equivalent dict creates `{b'a': 'bytes', 'a': 'text'}`, i.e., no lost data. Similar issues can crop up when transitioning Python 2 code to Python 3.

This means you need to choose what an API is going to accept and create and consistently stick to that API in both Python 2 and 3.

Bytes / Unicode Comparison

In Python 3, mixing bytes and unicode is forbidden in most situations; it will raise a `TypeError` where Python 2 would have attempted an implicit coercion between types. However, there is one case where it doesn't and it can be very misleading:

```
>>> b"" == ""  
False
```

This is because an equality comparison is required by the language to always succeed (and return `False` for incompatible types). However, this also means that code incorrectly ported to Python 3 can display buggy behaviour if such comparisons are silently executed. To detect such situations, Python 3 has a `-b` flag that will display a warning:

```
$ python3 -b  
>>> b"" == ""  
__main__:1: BytesWarning: Comparison between bytes and string  
False
```

To turn the warning into an exception, use the `-bb` flag instead:

```
$ python3 -bb  
>>> b"" == ""  
Traceback (most recent call last):  
  File "<stdin>", line 1, in <module>  
BytesWarning: Comparison between bytes and string
```

Indexing bytes objects

Another potentially surprising change is the indexing behaviour of bytes objects in Python 3:

```
>>> b"xyz"[0]  
120
```

Indeed, Python 3 bytes objects (as well as `bytearray` objects) are

sequences of integers. But code converted from Python 2 will often assume that indexing a bytestring produces another bytestring, not an integer. To reconcile both behaviours, use slicing:

```
>>> b"xyz"[0:1]
b'x'
>>> n = 1
>>> b"xyz"[n:n+1]
b'y'
```

The only remaining gotcha is that an out-of-bounds slice returns an empty bytes object instead of raising `IndexError`:

```
>>> b"xyz"[3]
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
IndexError: index out of range
>>> b"xyz"[3:4]
b''
```

`__str__()/__unicode__()`

In Python 2, objects can specify both a string and unicode representation of themselves. In Python 3, though, there is only a string representation. This becomes an issue as people can inadvertently do things in their `__str__()` methods which have unpredictable results (e.g., infinite recursion if you happen to use the `unicode(self).encode('utf8')` idiom as the body of your `__str__()` method).

There are two ways to solve this issue. One is to use a custom 2to3 fixer. The blog post at <http://lucumr.pocoo.org/2011/1/22/forwards-compatible-python/> specifies how to do this. That will allow 2to3 to change all instances of `def __unicode__(self): ...` to `def __str__(self): ...`. This does require you define your `__str__()` method in Python 2 before your `__unicode__()` method.

The other option is to use a mixin class. This allows you to only define a `__unicode__()` method for your class and let the mixin derive `__str__()` for you (code from <http://lucumr.pocoo.org/2011/1/22/forwards-compatible-python/>):

```
import sys

class UnicodeMixin(object):

    """Mixin class to handle defining the proper __str__/__unicode
    methods in Python 2 or 3."""

    if sys.version_info[0] >= 3: # Python 3
        def __str__(self):
            return self.__unicode__()
    else: # Python 2
        def __str__(self):
            return self.__unicode__().encode('utf8')

class Spam(UnicodeMixin):

    def __unicode__(self):
        return u'spam-spam-bacon-spam' # 2to3 will remove the 'u'
```

Don't Index on Exceptions

In Python 2, the following worked:

```
>>> exc = Exception(1, 2, 3)
>>> exc.args[1]
2
>>> exc[1] # Python 2 only!
2
```

But in Python 3, indexing directly on an exception is an error. You need to make sure to only index on the `BaseException.args` attribute which is a sequence containing all arguments passed to the `__init__()` method.

Even better is to use the documented attributes the exception provides.

Don't use `__getslice__` & Friends

Been deprecated for a while, but Python 3 finally drops support for `__getslice__()`, etc. Move completely over to `__getitem__()` and friends.

Updating doctests

`2to3` will attempt to generate fixes for doctests that it comes across. It's not perfect, though. If you wrote a monolithic set of doctests (e.g., a single docstring containing all of your doctests), you should at least consider breaking the doctests up into smaller pieces to make it more manageable to fix. Otherwise it might very well be worth your time and effort to port your tests to `unittest`.

Eliminate -3 Warnings

When you run your application's test suite, run it using the `-3` flag passed to Python. This will cause various warnings to be raised during execution about things that `2to3` cannot handle automatically (e.g., modules that have been removed). Try to eliminate those warnings to make your code even more portable to Python 3.

Run 2to3

Once you have made your Python 2 code future-compatible with Python 3, it's time to use `2to3` to actually port your code.

Manually

To manually convert source code using `2to3`, you use the `2to3` script

that is installed with Python 2.6 and later.:

```
2to3 <directory or file to convert>
```

This will cause 2to3 to write out a diff with all of the fixers applied for the converted source code. If you would like 2to3 to go ahead and apply the changes you can pass it the `-w` flag:

```
2to3 -w <stuff to convert>
```

There are other flags available to control exactly which fixers are applied, etc.

During Installation

When a user installs your project for Python 3, you can have either `distutils` or `Distribute` run `2to3` on your behalf. For `distutils`, use the following idiom:

```
try: # Python 3
    from distutils.command.build_py import build_py_2to3 as build
except ImportError: # Python 2
    from distutils.command.build_py import build_py

setup(cmdclass = {'build_py': build_py},
      # ...
    )
```

For `Distribute`:

```
setup(use_2to3=True,
      # ...
    )
```

This will allow you to not have to distribute a separate Python 3 version of your project. It does require, though, that when you perform development that you at least build your project and use the

built Python 3 source for testing.

Verify & Test

At this point you should (hopefully) have your project converted in such a way that it works in Python 3. Verify it by running your unit tests and making sure nothing has gone awry. If you miss something then figure out how to fix it in Python 3, backport to your Python 2 code, and run your code through 2to3 again to verify the fix transforms properly.

Python 2/3 Compatible Source

While it may seem counter-intuitive, you can write Python code which is source-compatible between Python 2 & 3. It does lead to code that is not entirely idiomatic Python (e.g., having to extract the currently raised exception from `sys.exc_info()[1]`), but it can be run under Python 2 **and** Python 3 without using `2to3` as a translation step (although the tool should be used to help find potential portability problems). This allows you to continue to have a rapid development process regardless of whether you are developing under Python 2 or Python 3. Whether this approach or using *Python 2 and 2to3* works best for you will be a per-project decision.

To get a complete idea of what issues you will need to deal with, see the [What's New in Python 3.0](#). Others have reorganized the data in other formats such as http://docs.pythonsprints.com/python3_porting/py-porting.html.

The following are some steps to take to try to support both Python 2 & 3 from the same source code.

Follow The Steps for Using 2to3

All of the steps outlined in how to *port Python 2 code with 2to3* apply to creating a Python 2/3 codebase. This includes trying only support Python 2.6 or newer (the `__future__` statements work in Python 3 without issue), eliminating warnings that are triggered by `-3`, etc.

You should even consider running `2to3` over your code (without committing the changes). This will let you know where potential pain points are within your code so that you can fix them properly before they become an issue.

Use six

The `six` project contains many things to help you write portable Python code. You should make sure to read its documentation from beginning to end and use any and all features it provides. That way you will minimize any mistakes you might make in writing cross-version code.

Capturing the Currently Raised Exception

One change between Python 2 and 3 that will require changing how you code (if you support [Python 2.5](#) and earlier) is accessing the currently raised exception. In Python 2.5 and earlier the syntax to access the current exception is:

```
try:
    raise Exception()
except Exception, exc:
    # Current exception is 'exc'
    pass
```

This syntax changed in Python 3 (and backported to [Python 2.6](#) and later) to:

```
try:
    raise Exception()
except Exception as exc:
    # Current exception is 'exc'
    # In Python 3, 'exc' is restricted to the block; Python 2.6 w
    pass
```

Because of this syntax change you must change to capturing the current exception to:

```
try:
    raise Exception()
except Exception:
```

```
import sys
exc = sys.exc_info()[1]
# Current exception is 'exc'
pass
```

You can get more information about the raised exception from `sys.exc_info()` than simply the current exception instance, but you most likely don't need it.

Note: In Python 3, the traceback is attached to the exception instance through the `__traceback__` attribute. If the instance is saved in a local variable that persists outside of the `except` block, the traceback will create a reference cycle with the current frame and its dictionary of local variables. This will delay reclaiming dead resources until the next cyclic *garbage collection* pass.

In Python 2, this problem only occurs if you save the traceback itself (e.g. the third element of the tuple returned by `sys.exc_info()`) in a variable.

Other Resources

The authors of the following blog posts, wiki pages, and books deserve special thanks for making public their tips for porting Python 2 code to Python 3 (and thus helping provide information for this document):

Porting Extension Modules to 3.0

author: Benjamin Peterson

Abstract

Although changing the C-API was not one of Python 3.0's objectives, the many Python level changes made leaving 2.x's API intact impossible. In fact, some changes such as `int()` and `long()` unification are more obvious on the C level. This document endeavors to document incompatibilities and how they can be worked around.

Conditional compilation

The easiest way to compile only some code for 3.0 is to check if `PY_MAJOR_VERSION` is greater than or equal to 3.

```
#if PY_MAJOR_VERSION >= 3
#define IS_PY3K
#endif
```

API functions that are not present can be aliased to their equivalents within conditional blocks.

Changes to Object APIs

Python 3.0 merged together some types with similar functions while cleanly separating others.

str/unicode Unification

Python 3.0's `str()` (`PyString_*` functions in C) type is equivalent to 2.x's `unicode()` (`PyUnicode_*`). The old 8-bit string type has become `bytes()`. Python 2.6 and later provide a compatibility header, `bytesobject.h`, mapping `PyBytes` names to `PyString` ones. For best compatibility with 3.0, `PyUnicode` should be used for textual data and `PyBytes` for binary data. It's also important to remember that `PyBytes` and `PyUnicode` in 3.0 are not interchangeable like `PyString` and `PyUnicode` are in 2.x. The following example shows best practices with regards to `PyUnicode`, `PyString`, and `PyBytes`.

```
#include "stdlib.h"
#include "Python.h"
#include "bytesobject.h"

/* text example */
static PyObject *
say_hello(PyObject *self, PyObject *args) {
    PyObject *name, *result;

    if (!PyArg_ParseTuple(args, "U:say_hello", &name))
        return NULL;

    result = PyUnicode_FromFormat("Hello, %S!", name);
    return result;
}

/* just a forward */
static char * do_encode(PyObject *);

/* bytes example */
```

```

static PyObject *
encode_object(PyObject *self, PyObject *args) {
    char *encoded;
    PyObject *result, *myobj;

    if (!PyArg_ParseTuple(args, "O:encode_object", &myobj))
        return NULL;

    encoded = do_encode(myobj);
    if (encoded == NULL)
        return NULL;
    result = PyBytes_FromString(encoded);
    free(encoded);
    return result;
}

```

long/int Unification

In Python 3.0, there is only one integer type. It is called `int()` on the Python level, but actually corresponds to 2.x's `long()` type. In the C-API, `PyInt_*` functions are replaced by their `PyLong_*` neighbors. The best course of action here is using the `PyInt_*` functions aliased to `PyLong_*` found in `intobject.h`. The abstract `PyNumber_*` APIs can also be used in some cases.

```

#include "Python.h"
#include "intobject.h"

static PyObject *
add_ints(PyObject *self, PyObject *args) {
    int one, two;
    PyObject *result;

    if (!PyArg_ParseTuple(args, "ii:add_ints", &one, &two))
        return NULL;

    return PyInt_FromLong(one + two);
}

```

Module initialization and state

Python 3.0 has a revamped extension module initialization system. (See [PEP 3121](#).) Instead of storing module state in globals, they should be stored in an interpreter specific structure. Creating modules that act correctly in both 2.x and 3.0 is tricky. The following simple example demonstrates how.

```
#include "Python.h"

struct module_state {
    PyObject *error;
};

#if PY_MAJOR_VERSION >= 3
#define GETSTATE(m) ((struct module_state*)PyModule_GetState(m)
#else
#define GETSTATE(m) (&_state)
static struct module_state _state;
#endif

static PyObject *
error_out(PyObject *m) {
    struct module_state *st = GETSTATE(m);
    PyErr_SetString(st->error, "something bad happened");
    return NULL;
}

static PyMethodDef myextension_methods[] = {
    {"error_out", (PyCFunction)error_out, METH_NOARGS, NULL},
    {NULL, NULL}
};

#if PY_MAJOR_VERSION >= 3

static int myextension_traverse(PyObject *m, visitproc visit, v
    Py_VISIT(GETSTATE(m)->error);
    return 0;
}

static int myextension_clear(PyObject *m) {
    Py_CLEAR(GETSTATE(m)->error);
```

```

    return 0;
}

static struct PyModuleDef moduledef = {
    PyModuleDef_HEAD_INIT,
    "myextension",
    NULL,
    sizeof(struct module_state),
    myextension_methods,
    NULL,
    myextension_traverse,
    myextension_clear,
    NULL
};

#define INITERROR return NULL

PyObject *
PyInit_myextension(void)

#else
#define INITERROR return

void
initmyextension(void)
#endif
{
    #if PY_MAJOR_VERSION >= 3
        PyObject *module = PyModule_Create(&moduledef);
    #else
        PyObject *module = Py_InitModule("myextension", myextension
    #endif

    if (module == NULL)
        INITERROR;
    struct module_state *st = GETSTATE(module);

    st->error = PyErr_NewException("myextension.Error", NULL, N
    if (st->error == NULL) {
        Py_DECREF(module);
        INITERROR;
    }

    #if PY_MAJOR_VERSION >= 3
        return module;
    #endif

```

```
}  
|
```

Other options

If you are writing a new extension module, you might consider [Cython](#). It translates a Python-like language to C. The extension modules it creates are compatible with Python 3.x and 2.x.

Curses Programming with Python

Author: A.M. Kuchling, Eric S. Raymond

Release: 2.03

Abstract

This document describes how to write text-mode programs with Python 2.x, using the `curses` extension module to control the display.

What is curses?

The curses library supplies a terminal-independent screen-painting and keyboard-handling facility for text-based terminals; such terminals include VT100s, the Linux console, and the simulated terminal provided by X11 programs such as xterm and rxvt. Display terminals support various control codes to perform common operations such as moving the cursor, scrolling the screen, and erasing areas. Different terminals use widely differing codes, and often have their own minor quirks.

In a world of X displays, one might ask “why bother”? It’s true that character-cell display terminals are an obsolete technology, but there are niches in which being able to do fancy things with them are still valuable. One is on small-footprint or embedded Unixes that don’t carry an X server. Another is for tools like OS installers and kernel configurators that may have to run before X is available.

The curses library hides all the details of different terminals, and provides the programmer with an abstraction of a display, containing multiple non-overlapping windows. The contents of a window can be changed in various ways— adding text, erasing it, changing its appearance—and the curses library will automagically figure out what control codes need to be sent to the terminal to produce the right output.

The curses library was originally written for BSD Unix; the later System V versions of Unix from AT&T added many enhancements and new functions. BSD curses is no longer maintained, having been replaced by ncurses, which is an open-source implementation of the AT&T interface. If you’re using an open-source Unix such as Linux or FreeBSD, your system almost certainly uses ncurses. Since most current commercial Unix versions are based on System V code, all the functions described here will probably be available. The older

versions of curses carried by some proprietary Unixes may not support everything, though.

No one has made a Windows port of the curses module. On a Windows platform, try the Console module written by Fredrik Lundh. The Console module provides cursor-addressable text output, plus full support for mouse and keyboard input, and is available from <http://effbot.org/zone/console-index.htm>.

The Python curses module

The Python module is a fairly simple wrapper over the C functions provided by curses; if you're already familiar with curses programming in C, it's really easy to transfer that knowledge to Python. The biggest difference is that the Python interface makes things simpler, by merging different C functions such as `addstr()`, `mvaddstr()`, `mvwaddstr()`, into a single `addstr()` method. You'll see this covered in more detail later.

This HOWTO is simply an introduction to writing text-mode programs with curses and Python. It doesn't attempt to be a complete guide to the curses API; for that, see the Python library guide's section on ncurses, and the C manual pages for ncurses. It will, however, give you the basic ideas.

Starting and ending a curses application

Before doing anything, curses must be initialized. This is done by calling the `initscr()` function, which will determine the terminal type, send any required setup codes to the terminal, and create various internal data structures. If successful, `initscr()` returns a window object representing the entire screen; this is usually called `stdscr`, after the name of the corresponding C variable.

```
import curses
stdscr = curses.initscr()
```

Usually curses applications turn off automatic echoing of keys to the screen, in order to be able to read keys and only display them under certain circumstances. This requires calling the `noecho()` function.

```
curses.noecho()
```

Applications will also commonly need to react to keys instantly, without requiring the Enter key to be pressed; this is called cbreak mode, as opposed to the usual buffered input mode.

```
curses.cbreak()
```

Terminals usually return special keys, such as the cursor keys or navigation keys such as Page Up and Home, as a multibyte escape sequence. While you could write your application to expect such sequences and process them accordingly, curses can do it for you, returning a special value such as `curses.KEY_LEFT`. To get curses to do the job, you'll have to enable keypad mode.

```
stdscr.keypad(1)
```

Terminating a curses application is much easier than starting one.

You'll need to call

```
curses.nocbreak(); stdscr.keypad(0); curses.echo()
```

to reverse the curses-friendly terminal settings. Then call the `endwin()` function to restore the terminal to its original operating mode.

```
curses.endwin()
```

A common problem when debugging a curses application is to get your terminal messed up when the application dies without restoring the terminal to its previous state. In Python this commonly happens when your code is buggy and raises an uncaught exception. Keys are no longer be echoed to the screen when you type them, for example, which makes using the shell difficult.

In Python you can avoid these complications and make debugging much easier by importing the module `curses.wrapper`. It supplies a `wrapper()` function that takes a callable. It does the initializations described above, and also initializes colors if color support is present. It then runs your provided callable and finally deinitializes appropriately. The callable is called inside a try-catch clause which catches exceptions, performs curses deinitialization, and then passes the exception upwards. Thus, your terminal won't be left in a funny state on exception.

Windows and Pads

Windows are the basic abstraction in curses. A window object represents a rectangular area of the screen, and supports various methods to display text, erase it, allow the user to input strings, and so forth.

The `stdscr` object returned by the `initscr()` function is a window object that covers the entire screen. Many programs may need only this single window, but you might wish to divide the screen into smaller windows, in order to redraw or clear them separately. The `newwin()` function creates a new window of a given size, returning the new window object.

```
begin_x = 20 ; begin_y = 7
height = 5 ; width = 40
win = curses.newwin(height, width, begin_y, begin_x)
```

A word about the coordinate system used in curses: coordinates are always passed in the order y,x , and the top-left corner of a window is coordinate $(0,0)$. This breaks a common convention for handling coordinates, where the x coordinate usually comes first. This is an unfortunate difference from most other computer applications, but it's been part of curses since it was first written, and it's too late to change things now.

When you call a method to display or erase text, the effect doesn't immediately show up on the display. This is because curses was originally written with slow 300-baud terminal connections in mind; with these terminals, minimizing the time required to redraw the screen is very important. This lets curses accumulate changes to the screen, and display them in the most efficient manner. For example, if your program displays some characters in a window, and then clears the window, there's no need to send the original characters

because they'd never be visible.

Accordingly, `curses` requires that you explicitly tell it to redraw windows, using the `refresh()` method of window objects. In practice, this doesn't really complicate programming with `curses` much. Most programs go into a flurry of activity, and then pause waiting for a keypress or some other action on the part of the user. All you have to do is to be sure that the screen has been redrawn before pausing to wait for user input, by simply calling `stdscr.refresh()` or the `refresh()` method of some other relevant window.

A pad is a special case of a window; it can be larger than the actual display screen, and only a portion of it displayed at a time. Creating a pad simply requires the pad's height and width, while refreshing a pad requires giving the coordinates of the on-screen area where a subsection of the pad will be displayed.

```
pad = curses.newpad(100, 100)
# These loops fill the pad with letters; this is
# explained in the next section
for y in range(0, 100):
    for x in range(0, 100):
        try: pad.addch(y,x, ord('a') + (x*x+y*y) % 26 )
        except curses.error: pass

# Displays a section of the pad in the middle of the screen
pad.refresh( 0,0, 5,5, 20,75)
```

The `refresh()` call displays a section of the pad in the rectangle extending from coordinate (5,5) to coordinate (20,75) on the screen; the upper left corner of the displayed section is coordinate (0,0) on the pad. Beyond that difference, pads are exactly like ordinary windows and support the same methods.

If you have multiple windows and pads on screen there is a more efficient way to go, which will prevent annoying screen flicker at refresh time. Use the `noutrefresh()` method of each window to

update the data structure representing the desired state of the screen; then change the physical screen to match the desired state in one go with the function `doupdate()`. The normal `refresh()` method calls `doupdate()` as its last act.

Displaying Text

From a C programmer's point of view, curses may sometimes look like a twisty maze of functions, all subtly different. For example, `addstr()` displays a string at the current cursor location in the `stdscr` window, while `mvaddstr()` moves to a given *y,x* coordinate first before displaying the string. `waddstr()` is just like `addstr()`, but allows specifying a window to use, instead of using `stdscr` by default. `mvwaddstr()` follows similarly.

Fortunately the Python interface hides all these details; `stdscr` is a window object like any other, and methods like `addstr()` accept multiple argument forms. Usually there are four different forms.

Form	Description
<i>str or ch</i>	Display the string <i>str</i> or character <i>ch</i> at the current position
<i>str or ch, attr</i>	Display the string <i>str</i> or character <i>ch</i> , using attribute <i>attr</i> at the current position
<i>y, x, str or ch</i>	Move to position <i>y,x</i> within the window, and display <i>str or ch</i>
<i>y, x, str or ch, attr</i>	Move to position <i>y,x</i> within the window, and display <i>str or ch</i> , using attribute <i>attr</i>

Attributes allow displaying text in highlighted forms, such as in boldface, underline, reverse code, or in color. They'll be explained in more detail in the next subsection.

The `addstr()` function takes a Python string as the value to be displayed, while the `addch()` functions take a character, which can be either a Python string of length 1 or an integer. If it's a string, you're

limited to displaying characters between 0 and 255. SVr4 curses provides constants for extension characters; these constants are integers greater than 255. For example, `ACS_PLMINUS` is a +/- symbol, and `ACS_ULCORNER` is the upper left corner of a box (handy for drawing borders).

Windows remember where the cursor was left after the last operation, so if you leave out the `y,x` coordinates, the string or character will be displayed wherever the last operation left off. You can also move the cursor with the `move(y,x)` method. Because some terminals always display a flashing cursor, you may want to ensure that the cursor is positioned in some location where it won't be distracting; it can be confusing to have the cursor blinking at some apparently random location.

If your application doesn't need a blinking cursor at all, you can call `curs_set(0)` to make it invisible. Equivalently, and for compatibility with older curses versions, there's a `leaveok(bool)` function. When *bool* is true, the curses library will attempt to suppress the flashing cursor, and you won't need to worry about leaving it in odd locations.

Attributes and Color

Characters can be displayed in different ways. Status lines in a text-based application are commonly shown in reverse video; a text viewer may need to highlight certain words. curses supports this by allowing you to specify an attribute for each cell on the screen.

An attribute is an integer, each bit representing a different attribute. You can try to display text with multiple attribute bits set, but curses doesn't guarantee that all the possible combinations are available, or that they're all visually distinct. That depends on the ability of the terminal being used, so it's safest to stick to the most commonly available attributes, listed here.

Attribute	Description
A_BLINK	Blinking text
A_BOLD	Extra bright or bold text
A_DIM	Half bright text
A_REVERSE	Reverse-video text
A_STANDOUT	The best highlighting mode available
A_UNDERLINE	Underlined text

So, to display a reverse-video status line on the top line of the screen, you could code:

```
stdscr.addstr(0, 0, "Current mode: Typing mode",  
             curses.A_REVERSE)  
stdscr.refresh()
```

The curses library also supports color on those terminals that provide it. The most common such terminal is probably the Linux console, followed by color xterms.

To use color, you must call the `start_color()` function soon after calling `initscr()`, to initialize the default color set (the `curses.wrapper.wrapper()` function does this automatically). Once that's done, the `has_colors()` function returns TRUE if the terminal in use can actually display color. (Note: curses uses the American spelling 'color', instead of the Canadian/British spelling 'colour'. If you're used to the British spelling, you'll have to resign yourself to misspelling it for the sake of these functions.)

The curses library maintains a finite number of color pairs, containing a foreground (or text) color and a background color. You can get the attribute value corresponding to a color pair with the `color_pair()` function; this can be bitwise-OR'ed with other attributes such as `A_REVERSE`, but again, such combinations are not guaranteed to work

on all terminals.

An example, which displays a line of text using color pair 1:

```
stdscr.addstr( "Pretty text", curses.color_pair(1) )  
stdscr.refresh()
```

As I said before, a color pair consists of a foreground and background color. `start_color()` initializes 8 basic colors when it activates color mode. They are: 0:black, 1:red, 2:green, 3:yellow, 4:blue, 5:magenta, 6:cyan, and 7:white. The curses module defines named constants for each of these colors: `curses.COLOR_BLACK`, `curses.COLOR_RED`, and so forth.

The `init_pair(n, f, b)` function changes the definition of color pair `n`, to foreground color `f` and background color `b`. Color pair 0 is hard-wired to white on black, and cannot be changed.

Let's put all this together. To change color 1 to red text on a white background, you would call:

```
curses.init_pair(1, curses.COLOR_RED, curses.COLOR_WHITE)
```

When you change a color pair, any text already displayed using that color pair will change to the new colors. You can also display new text in this color with:

```
stdscr.addstr(0,0, "RED ALERT!", curses.color_pair(1) )
```

Very fancy terminals can change the definitions of the actual colors to a given RGB value. This lets you change color 1, which is usually red, to purple or blue or any other color you like. Unfortunately, the Linux console doesn't support this, so I'm unable to try it out, and can't provide any examples. You can check if your terminal can do this by calling `can_change_color()`, which returns `TRUE` if the

capability is there. If you're lucky enough to have such a talented terminal, consult your system's man pages for more information.

User Input

The `curses` library itself offers only very simple input mechanisms. Python's support adds a text-input widget that makes up some of the lack.

The most common way to get input to a window is to use its `getch()` method. `getch()` pauses and waits for the user to hit a key, displaying it if `echo()` has been called earlier. You can optionally specify a coordinate to which the cursor should be moved before pausing.

It's possible to change this behavior with the method `nodelay()`. After `nodelay(1)`, `getch()` for the window becomes non-blocking and returns `curses.ERR` (a value of -1) when no input is ready. There's also a `halfdelay()` function, which can be used to (in effect) set a timer on each `getch()`; if no input becomes available within a specified delay (measured in tenths of a second), `curses` raises an exception.

The `getch()` method returns an integer; if it's between 0 and 255, it represents the ASCII code of the key pressed. Values greater than 255 are special keys such as Page Up, Home, or the cursor keys. You can compare the value returned to constants such as `curses.KEY_PPAGE`, `curses.KEY_HOME`, or `curses.KEY_LEFT`. Usually the main loop of your program will look something like this:

```
while True:
    c = stdscr.getch()
    if c == ord('p'): PrintDocument()
    elif c == ord('q'): break # Exit the while()
    elif c == curses.KEY_HOME: x = y = 0
```

The `curses.ascii` module supplies ASCII class membership

functions that take either integer or 1-character-string arguments; these may be useful in writing more readable tests for your command interpreters. It also supplies conversion functions that take either integer or 1-character-string arguments and return the same type. For example, `curses.ascii.ctrl()` returns the control character corresponding to its argument.

There's also a method to retrieve an entire string, `getstr()`. It isn't used very often, because its functionality is quite limited; the only editing keys available are the backspace key and the Enter key, which terminates the string. It can optionally be limited to a fixed number of characters.

```
curses.echo()           # Enable echoing of characters  
  
# Get a 15-character string, with the cursor on the top line  
s = stdscr.getstr(0,0, 15)
```

The Python `curses.textpad` module supplies something better. With it, you can turn a window into a text box that supports an Emacs-like set of keybindings. Various methods of `Textbox` class support editing with input validation and gathering the edit results either with or without trailing spaces. See the library documentation on `curses.textpad` for the details.

For More Information

This HOWTO didn't cover some advanced topics, such as screen-scraping or capturing mouse events from an xterm instance. But the Python library page for the curses modules is now pretty complete. You should browse it next.

If you're in doubt about the detailed behavior of any of the ncurses entry points, consult the manual pages for your curses implementation, whether it's ncurses or a proprietary Unix vendor's. The manual pages will document any quirks, and provide complete lists of all the functions, attributes, and `ACS_*` characters available to you.

Because the curses API is so large, some functions aren't supported in the Python interface, not because they're difficult to implement, but because no one has needed them yet. Feel free to add them and then submit a patch. Also, we don't yet have support for the menu library associated with ncurses; feel free to add that.

If you write an interesting little program, feel free to contribute it as another demo. We can always use more of them!

Abstract

Defines descriptors, summarizes the protocol, and shows how descriptors are called. Examines a custom descriptor and several built-in python descriptors including functions, properties, static methods, and class methods. Shows how each works by giving a pure Python equivalent and a sample application.

Learning about descriptors not only provides access to a larger toolset, it creates a deeper understanding of how Python works and an appreciation for the elegance of its design.

Definition and Introduction

In general, a descriptor is an object attribute with “binding behavior”, one whose attribute access has been overridden by methods in the descriptor protocol. Those methods are `__get__()`, `__set__()`, and `__delete__()`. If any of those methods are defined for an object, it is said to be a descriptor.

The default behavior for attribute access is to get, set, or delete the attribute from an object’s dictionary. For instance, `a.x` has a lookup chain starting with `a.__dict__['x']`, then `type(a).__dict__['x']`, and continuing through the base classes of `type(a)` excluding metaclasses. If the looked-up value is an object defining one of the descriptor methods, then Python may override the default behavior and invoke the descriptor method instead. Where this occurs in the precedence chain depends on which descriptor methods were defined. Note that descriptors are only invoked for new style objects or classes (a class is new style if it inherits from `object` or `type`).

Descriptors are a powerful, general purpose protocol. They are the mechanism behind properties, methods, static methods, class methods, and `super()`. They are used used throughout Python itself to implement the new style classes introduced in version 2.2. Descriptors simplify the underlying C-code and offer a flexible set of new tools for everyday Python programs.

Descriptor Protocol

```
descr.__get__(self, obj, type=None) --> value
```

```
descr.__set__(self, obj, value) --> None
```

```
descr.__delete__(self, obj) --> None
```

That is all there is to it. Define any of these methods and an object is considered a descriptor and can override default behavior upon being looked up as an attribute.

If an object defines both `__get__()` and `__set__()`, it is considered a data descriptor. Descriptors that only define `__get__()` are called non-data descriptors (they are typically used for methods but other uses are possible).

Data and non-data descriptors differ in how overrides are calculated with respect to entries in an instance's dictionary. If an instance's dictionary has an entry with the same name as a data descriptor, the data descriptor takes precedence. If an instance's dictionary has an entry with the same name as a non-data descriptor, the dictionary entry takes precedence.

To make a read-only data descriptor, define both `__get__()` and `__set__()` with the `__set__()` raising an `AttributeError` when called. Defining the `__set__()` method with an exception raising placeholder is enough to make it a data descriptor.

Invoking Descriptors

A descriptor can be called directly by its method name. For example, `d.__get__(obj)`.

Alternatively, it is more common for a descriptor to be invoked automatically upon attribute access. For example, `obj.d` looks up `d` in the dictionary of `obj`. If `d` defines the method `__get__()`, then `d.__get__(obj)` is invoked according to the precedence rules listed below.

The details of invocation depend on whether `obj` is an object or a class. Either way, descriptors only work for new style objects and classes. A class is new style if it is a subclass of `object`.

For objects, the machinery is in `object.__getattr__()` which transforms `b.x` into `type(b).__dict__['x'].__get__(b, type(b))`. The implementation works through a precedence chain that gives data descriptors priority over instance variables, instance variables priority over non-data descriptors, and assigns lowest priority to `__getattr__()` if provided. The full C implementation can be found in `PyObject_GenericGetAttr()` in `Objects/object.c`.

For classes, the machinery is in `type.__getattr__()` which transforms `B.x` into `B.__dict__['x'].__get__(None, B)`. In pure Python, it looks like:

```
def __getattr__(self, key):
    "Emulate type_getattro() in Objects/typeobject.c"
    v = object.__getattr__(self, key)
    if hasattr(v, '__get__'):
        return v.__get__(None, self)
    return v
```

The important points to remember are:

- descriptors are invoked by the `__getattribute__()` method
- overriding `__getattribute__()` prevents automatic descriptor calls
- `__getattribute__()` is only available with new style classes and objects
- `object.__getattribute__()` and `type.__getattribute__()` make different calls to `__get__()`.
- data descriptors always override instance dictionaries.
- non-data descriptors may be overridden by instance dictionaries.

The object returned by `super()` also has a custom `__getattribute__()` method for invoking descriptors. The call `super(B, obj).m()` searches `obj.__class__.__mro__` for the base class `A` immediately following `B` and then returns `A.__dict__['m'].__get__(obj, A)`. If not a descriptor, `m` is returned unchanged. If not in the dictionary, `m` reverts to a search using `object.__getattribute__()`.

Note, in Python 2.2, `super(B, obj).m()` would only invoke `__get__()` if `m` was a data descriptor. In Python 2.3, non-data descriptors also get invoked unless an old-style class is involved. The implementation details are in `super_getattro()` in `Objects/typeobject.c` and a pure Python equivalent can be found in [Guido's Tutorial](#).

The details above show that the mechanism for descriptors is embedded in the `__getattribute__()` methods for `object`, `type`, and `super()`. Classes inherit this machinery when they derive from `object` or if they have a meta-class providing similar functionality. Likewise, classes can turn-off descriptor invocation by overriding `__getattribute__()`.

Descriptor Example

The following code creates a class whose objects are data descriptors which print a message for each get or set. Overriding `__getattribute__()` is alternate approach that could do this for every attribute. However, this descriptor is useful for monitoring just a few chosen attributes:

```
class RevealAccess(object):
    """A data descriptor that sets and returns values
       normally and prints a message logging their access.
    """

    def __init__(self, initval=None, name='var'):
        self.val = initval
        self.name = name

    def __get__(self, obj, objtype):
        print('Retrieving', self.name)
        return self.val

    def __set__(self, obj, val):
        print('Updating', self.name)
        self.val = val

>>> class MyClass(object):
    x = RevealAccess(10, 'var "x"')
    y = 5

>>> m = MyClass()
>>> m.x
Retrieving var "x"
10
>>> m.x = 20
Updating var "x"
>>> m.x
Retrieving var "x"
20
>>> m.y
5
```

The protocol is simple and offers exciting possibilities. Several use cases are so common that they have been packaged into individual function calls. Properties, bound and unbound methods, static methods, and class methods are all based on the descriptor protocol.

Properties

Calling `property()` is a succinct way of building a data descriptor that triggers function calls upon access to an attribute. Its signature is:

```
property(fget=None, fset=None, fdel=None, doc=None) -> property
```

The documentation shows a typical use to define a managed attribute `x`:

```
class C(object):
    def getx(self): return self.__x
    def setx(self, value): self.__x = value
    def delx(self): del self.__x
    x = property(getx, setx, delx, "I'm the 'x' property.")
```

To see how `property()` is implemented in terms of the descriptor protocol, here is a pure Python equivalent:

```
class Property(object):
    "Emulate PyProperty_Type() in Objects/descrobject.c"

    def __init__(self, fget=None, fset=None, fdel=None, doc=None):
        self.fget = fget
        self.fset = fset
        self.fdel = fdel
        self.__doc__ = doc

    def __get__(self, obj, objtype=None):
        if obj is None:
            return self
        if self.fget is None:
            raise AttributeError, "unreadable attribute"
        return self.fget(obj)

    def __set__(self, obj, value):
        if self.fset is None:
            raise AttributeError, "can't set attribute"
        self.fset(obj, value)
```

```
def __delete__(self, obj):
    if self.fdel is None:
        raise AttributeError, "can't delete attribute"
    self.fdel(obj)
```

The `property()` builtin helps whenever a user interface has granted attribute access and then subsequent changes require the intervention of a method.

For instance, a spreadsheet class may grant access to a cell value through `cell('b10').value`. Subsequent improvements to the program require the cell to be recalculated on every access; however, the programmer does not want to affect existing client code accessing the attribute directly. The solution is to wrap access to the value attribute in a property data descriptor:

```
class Cell(object):
    . . .
    def getvalue(self, obj):
        "Recalculate cell before returning value"
        self.recalc()
        return obj._value
    value = property(getvalue)
```

Functions and Methods

Python's object oriented features are built upon a function based environment. Using non-data descriptors, the two are merged seamlessly.

Class dictionaries store methods as functions. In a class definition, methods are written using `def` and `lambda`, the usual tools for creating functions. The only difference from regular functions is that the first argument is reserved for the object instance. By Python convention, the instance reference is called *self* but may be called *this* or any other variable name.

To support method calls, functions include the `__get__()` method for binding methods during attribute access. This means that all functions are non-data descriptors which return bound or unbound methods depending whether they are invoked from an object or a class. In pure python, it works like this:

```
class Function(object):
    .
    .
    .
    def __get__(self, obj, objtype=None):
        "Simulate func_descr_get() in Objects/funcobject.c"
        return types.MethodType(self, obj, objtype)
```

Running the interpreter shows how the function descriptor works in practice:

```
>>> class D(object):
      def f(self, x):
          return x

>>> d = D()
>>> D.__dict__['f'] # Stored internally as a function
<function f at 0x00C45070>
>>> D.f # Get from a class becomes an unbound metho
<unbound method D.f>
```

```
>>> d.f # Get from an instance becomes a bound meth
<bound method D.f of <__main__.D object at 0x00B18C90>>
```

The output suggests that bound and unbound methods are two different types. While they could have been implemented that way, the actual C implementation of `PyMethod_Type` in `Objects/classobject.c` is a single object with two different representations depending on whether the `im_self` field is set or is `NULL` (the C equivalent of `None`).

Likewise, the effects of calling a method object depend on the `im_self` field. If set (meaning bound), the original function (stored in the `im_func` field) is called as expected with the first argument set to the instance. If unbound, all of the arguments are passed unchanged to the original function. The actual C implementation of `instancemethod_call()` is only slightly more complex in that it includes some type checking.

Static Methods and Class Methods

Non-data descriptors provide a simple mechanism for variations on the usual patterns of binding functions into methods.

To recap, functions have a `__get__()` method so that they can be converted to a method when accessed as attributes. The non-data descriptor transforms a `obj.f(*args)` call into `f(obj, *args)`. Calling `klass.f(*args)` becomes `f(*args)`.

This chart summarizes the binding and its two most useful variants:

Transformation	Called from an Object	Called from a Class
function	<code>f(obj, *args)</code>	<code>f(*args)</code>
staticmethod	<code>f(*args)</code>	<code>f(*args)</code>
classmethod	<code>f(type(obj), *args)</code>	<code>f(klass, *args)</code>

Static methods return the underlying function without changes. Calling either `c.f` or `C.f` is the equivalent of a direct lookup into `object.__getattr__(c, "f")` or `object.__getattr__(C, "f")`. As a result, the function becomes identically accessible from either an object or a class.

Good candidates for static methods are methods that do not reference the `self` variable.

For instance, a statistics package may include a container class for experimental data. The class provides normal methods for computing the average, mean, median, and other descriptive statistics that depend on the data. However, there may be useful functions which are conceptually related but do not depend on the data. For instance, `erf(x)` is handy conversion routine that comes

up in statistical work but does not directly depend on a particular dataset. It can be called either from an object or the class: `s.erf(1.5) --> .9332` Or `Sample.erf(1.5) --> .9332`.

Since staticmethods return the underlying function with no changes, the example calls are unexciting:

```
>>> class E(object):
    def f(x):
        print(x)
    f = staticmethod(f)

>>> print(E.f(3))
3
>>> print(E().f(3))
3
```

Using the non-data descriptor protocol, a pure Python version of `staticmethod()` would look like this:

```
class StaticMethod(object):
    "Emulate PyStaticMethod_Type() in Objects/funcobject.c"

    def __init__(self, f):
        self.f = f

    def __get__(self, obj, objtype=None):
        return self.f
```

Unlike static methods, class methods prepend the class reference to the argument list before calling the function. This format is the same for whether the caller is an object or a class:

```
>>> class E(object):
    def f(klass, x):
        return klass.__name__, x
    f = classmethod(f)

>>> print(E.f(3))
('E', 3)
>>> print(E().f(3))
```

```
('E', 3)
```

This behavior is useful whenever the function only needs to have a class reference and does not care about any underlying data. One use for classmethods is to create alternate class constructors. In Python 2.3, the classmethod `dict.fromkeys()` creates a new dictionary from a list of keys. The pure Python equivalent is:

```
class Dict:
    . . .
    def fromkeys(klass, iterable, value=None):
        "Emulate dict_fromkeys() in Objects/dictobject.c"
        d = klass()
        for key in iterable:
            d[key] = value
        return d
    fromkeys = classmethod(fromkeys)
```

Now a new dictionary of unique keys can be constructed like this:

```
>>> Dict.fromkeys('abracadabra')
{'a': None, 'r': None, 'b': None, 'c': None, 'd': None}
```

Using the non-data descriptor protocol, a pure Python version of `classmethod()` would look like this:

```
class ClassMethod(object):
    "Emulate PyClassMethod_Type() in Objects/funcobject.c"

    def __init__(self, f):
        self.f = f

    def __get__(self, obj, klass=None):
        if klass is None:
            klass = type(obj)
        def newfunc(*args):
            return self.f(klass, *args)
        return newfunc
```

Idioms and Anti-Idioms in Python

Author: Moshe Zadka

This document is placed in the public domain.

Abstract

This document can be considered a companion to the tutorial. It shows how to use Python, and even more importantly, how *not* to use Python.

Language Constructs You Should Not Use

While Python has relatively few gotchas compared to other languages, it still has some constructs which are only useful in corner cases, or are plain dangerous.

from module import *

Inside Function Definitions

`from module import *` is *invalid* inside function definitions. While many versions of Python do not check for the invalidity, it does not make it more valid, no more than having a smart lawyer makes a man innocent. Do not use it like that ever. Even in versions where it was accepted, it made the function execution slower, because the compiler could not be certain which names are local and which are global. In Python 2.1 this construct causes warnings, and sometimes even errors.

At Module Level

While it is valid to use `from module import *` at module level it is usually a bad idea. For one, this loses an important property Python otherwise has — you can know where each toplevel name is defined by a simple “search” function in your favourite editor. You also open yourself to trouble in the future, if some module grows additional functions or classes.

One of the most awful question asked on the newsgroup is why this code:

```
f = open("www")
f.read()
```

does not work. Of course, it works just fine (assuming you have a file called “www”.) But it does not work if somewhere in the module, the statement `from os import *` is present. The `os` module has a function called `open()` which returns an integer. While it is very useful, shadowing a builtin is one of its least useful properties.

Remember, you can never know for sure what names a module exports, so either take what you need — `from module import name1, name2`, or keep them in the module and access on a per-need basis — `import module; print(module.name)`.

When It Is Just Fine

There are situations in which `from module import *` is just fine:

- The interactive prompt. For example, `from math import *` makes Python an amazing scientific calculator.
- When extending a module in C with a module in Python.
- When the module advertises itself as `from import * safe`.

`from module import name1, name2`

This is a “don’t” which is much weaker than the previous “don’t”s but is still something you should not do if you don’t have good reasons to do that. The reason it is usually bad idea is because you suddenly have an object which lives in two separate namespaces. When the binding in one namespace changes, the binding in the other will not, so there will be a discrepancy between them. This happens when, for example, one module is reloaded, or changes the definition of a function at runtime.

Bad example:

```
# foo.py  
a = 1
```

```
# bar.py
from foo import a
if something():
    a = 2 # danger: foo.a != a
```

Good example:

```
# foo.py
a = 1

# bar.py
import foo
if something():
    foo.a = 2
```

except:

Python has the `except:` clause, which catches all exceptions. Since every error in Python raises an exception, using `except:` can make many programming errors look like runtime problems, which hinders the debugging process.

The following code shows a great example of why this is bad:

```
try:
    foo = opne("file") # misspelled "open"
except:
    sys.exit("could not open file!")
```

The second line triggers a `NameError`, which is caught by the `except` clause. The program will exit, and the error message the program prints will make you think the problem is the readability of `"file"` when in fact the real error has nothing to do with `"file"`.

A better way to write the above is

```
try:
    foo = opne("file")
```

```
except IOError:  
    sys.exit("could not open file")
```

When this is run, Python will produce a traceback showing the **NameError**, and it will be immediately apparent what needs to be fixed.

Because `except:` catches *all* exceptions, including **SystemExit**, **KeyboardInterrupt**, and **GeneratorExit** (which is not an error and should not normally be caught by user code), using a bare `except:` is almost never a good idea. In situations where you need to catch all “normal” errors, such as in a framework that runs callbacks, you can catch the base class for all normal exceptions, **Exception**.

Exceptions

Exceptions are a useful feature of Python. You should learn to raise them whenever something unexpected occurs, and catch them only where you can do something about them.

The following is a very popular anti-idiom

```
def get_status(file):
    if not os.path.exists(file):
        print("file not found")
        sys.exit(1)
    return open(file).readline()
```

Consider the case where the file gets deleted between the time the call to `os.path.exists()` is made and the time `open()` is called. In that case the last line will raise an `IOError`. The same thing would happen if `file` exists but has no read permission. Since testing this on a normal machine on existent and non-existent files makes it seem bugless, the test results will seem fine, and the code will get shipped. Later an unhandled `IOError` (or perhaps some other `EnvironmentError`) escapes to the user, who gets to watch the ugly traceback.

Here is a somewhat better way to do it.

```
def get_status(file):
    try:
        return open(file).readline()
    except EnvironmentError as err:
        print("Unable to open file: {}".format(err))
        sys.exit(1)
```

In this version, *either* the file gets opened and the line is read (so it works even on flaky NFS or SMB connections), or an error message is printed that provides all the available information on why the open

failed, and the application is aborted.

However, even this version of `get_status()` makes too many assumptions — that it will only be used in a short running script, and not, say, in a long running server. Sure, the caller could do something like

```
try:
    status = get_status(log)
except SystemExit:
    status = None
```

But there is a better way. You should try to use as few `except` clauses in your code as you can — the ones you do use will usually be inside calls which should always succeed, or a catch-all in a main function.

So, an even better version of `get_status()` is probably

```
def get_status(file):
    return open(file).readline()
```

The caller can deal with the exception if it wants (for example, if it tries several files in a loop), or just let the exception filter upwards to *its* caller.

But the last version still has a serious problem — due to implementation details in CPython, the file would not be closed when an exception is raised until the exception handler finishes; and, worse, in other implementations (e.g., Jython) it might not be closed at all regardless of whether or not an exception is raised.

The best version of this function uses the `open()` call as a context manager, which will ensure that the file gets closed as soon as the function returns:

```
def get_status(file):  
    with open(file) as fp:  
        return fp.readline()
```

Using the Batteries

Every so often, people seem to be writing stuff in the Python library again, usually poorly. While the occasional module has a poor interface, it is usually much better to use the rich standard library and data types that come with Python than inventing your own.

A useful module very few people know about is `os.path`. It always has the correct path arithmetic for your operating system, and will usually be much better than whatever you come up with yourself.

Compare:

```
# ugh!
return dir+"/"+file
# better
return os.path.join(dir, file)
```

More useful functions in `os.path`: `basename()`, `dirname()` and `splitext()`.

There are also many useful built-in functions people seem not to be aware of for some reason: `min()` and `max()` can find the minimum/maximum of any sequence with comparable semantics, for example, yet many people write their own `max()/min()`. Another highly useful function is `functools.reduce()` which can be used to repeatedly apply a binary operation to a sequence, reducing it to a single value. For example, compute a factorial with a series of multiply operations:

```
>>> n = 4
>>> import operator, functools
>>> functools.reduce(operator.mul, range(1, n+1))
24
```

When it comes to parsing numbers, note that `float()`, `int()` and `long()` all accept string arguments and will reject ill-formed strings by raising an `ValueError`.

Using Backslash to Continue Statements

Since Python treats a newline as a statement terminator, and since statements are often more than is comfortable to put in one line, many people do:

```
if foo.bar()['first'][0] == baz.quux(1, 2)[5:9] and \  
    calculate_number(10, 20) != forbulate(500, 360):  
    pass
```

You should realize that this is dangerous: a stray space after the `\` would make this line wrong, and stray spaces are notoriously hard to see in editors. In this case, at least it would be a syntax error, but if the code was:

```
value = foo.bar()['first'][0]*baz.quux(1, 2)[5:9] \  
        + calculate_number(10, 20)*forbulate(500, 360)
```

then it would just be subtly wrong.

It is usually much better to use the implicit continuation inside parenthesis:

This version is bulletproof:

```
value = (foo.bar()['first'][0]*baz.quux(1, 2)[5:9]  
        + calculate_number(10, 20)*forbulate(500, 360))
```

Functional Programming HOWTO

Author: A. M. Kuchling

Release: 0.31

In this document, we'll take a tour of Python's features suitable for implementing programs in a functional style. After an introduction to the concepts of functional programming, we'll look at language features such as *iterators* and *generators* and relevant library modules such as `itertools` and `functools`.

Introduction

This section explains the basic concept of functional programming; if you're just interested in learning about Python language features, skip to the next section.

Programming languages support decomposing problems in several different ways:

- Most programming languages are **procedural**: programs are lists of instructions that tell the computer what to do with the program's input. C, Pascal, and even Unix shells are procedural languages.
- In **declarative** languages, you write a specification that describes the problem to be solved, and the language implementation figures out how to perform the computation efficiently. SQL is the declarative language you're most likely to be familiar with; a SQL query describes the data set you want to retrieve, and the SQL engine decides whether to scan tables or use indexes, which subclauses should be performed first, etc.
- **Object-oriented** programs manipulate collections of objects. Objects have internal state and support methods that query or modify this internal state in some way. Smalltalk and Java are object-oriented languages. C++ and Python are languages that support object-oriented programming, but don't force the use of object-oriented features.
- **Functional** programming decomposes a problem into a set of functions. Ideally, functions only take inputs and produce outputs, and don't have any internal state that affects the output produced for a given input. Well-known functional languages include the ML family (Standard ML, OCaml, and other variants) and Haskell.

The designers of some computer languages choose to emphasize

one particular approach to programming. This often makes it difficult to write programs that use a different approach. Other languages are multi-paradigm languages that support several different approaches. Lisp, C++, and Python are multi-paradigm; you can write programs or libraries that are largely procedural, object-oriented, or functional in all of these languages. In a large program, different sections might be written using different approaches; the GUI might be object-oriented while the processing logic is procedural or functional, for example.

In a functional program, input flows through a set of functions. Each function operates on its input and produces some output. Functional style discourages functions with side effects that modify internal state or make other changes that aren't visible in the function's return value. Functions that have no side effects at all are called **purely functional**. Avoiding side effects means not using data structures that get updated as a program runs; every function's output must only depend on its input.

Some languages are very strict about purity and don't even have assignment statements such as `a=3` or `c = a + b`, but it's difficult to avoid all side effects. Printing to the screen or writing to a disk file are side effects, for example. For example, in Python a call to the `print()` or `time.sleep()` function both return no useful value; they're only called for their side effects of sending some text to the screen or pausing execution for a second.

Python programs written in functional style usually won't go to the extreme of avoiding all I/O or all assignments; instead, they'll provide a functional-appearing interface but will use non-functional features internally. For example, the implementation of a function will still use assignments to local variables, but won't modify global variables or have other side effects.

Functional programming can be considered the opposite of object-

oriented programming. Objects are little capsules containing some internal state along with a collection of method calls that let you modify this state, and programs consist of making the right set of state changes. Functional programming wants to avoid state changes as much as possible and works with data flowing between functions. In Python you might combine the two approaches by writing functions that take and return instances representing objects in your application (e-mail messages, transactions, etc.).

Functional design may seem like an odd constraint to work under. Why should you avoid objects and side effects? There are theoretical and practical advantages to the functional style:

- Formal provability.
- Modularity.
- Composability.
- Ease of debugging and testing.

Formal provability

A theoretical benefit is that it's easier to construct a mathematical proof that a functional program is correct.

For a long time researchers have been interested in finding ways to mathematically prove programs correct. This is different from testing a program on numerous inputs and concluding that its output is usually correct, or reading a program's source code and concluding that the code looks right; the goal is instead a rigorous proof that a program produces the right result for all possible inputs.

The technique used to prove programs correct is to write down **invariants**, properties of the input data and of the program's variables that are always true. For each line of code, you then show that if invariants X and Y are true **before** the line is executed, the slightly different invariants X' and Y' are true **after** the line is

executed. This continues until you reach the end of the program, at which point the invariants should match the desired conditions on the program's output.

Functional programming's avoidance of assignments arose because assignments are difficult to handle with this technique; assignments can break invariants that were true before the assignment without producing any new invariants that can be propagated onward.

Unfortunately, proving programs correct is largely impractical and not relevant to Python software. Even trivial programs require proofs that are several pages long; the proof of correctness for a moderately complicated program would be enormous, and few or none of the programs you use daily (the Python interpreter, your XML parser, your web browser) could be proven correct. Even if you wrote down or generated a proof, there would then be the question of verifying the proof; maybe there's an error in it, and you wrongly believe you've proved the program correct.

Modularity

A more practical benefit of functional programming is that it forces you to break apart your problem into small pieces. Programs are more modular as a result. It's easier to specify and write a small function that does one thing than a large function that performs a complicated transformation. Small functions are also easier to read and to check for errors.

Ease of debugging and testing

Testing and debugging a functional-style program is easier.

Debugging is simplified because functions are generally small and clearly specified. When a program doesn't work, each function is an interface point where you can check that the data are correct. You

can look at the intermediate inputs and outputs to quickly isolate the function that's responsible for a bug.

Testing is easier because each function is a potential subject for a unit test. Functions don't depend on system state that needs to be replicated before running a test; instead you only have to synthesize the right input and then check that the output matches expectations.

Composability

As you work on a functional-style program, you'll write a number of functions with varying inputs and outputs. Some of these functions will be unavoidably specialized to a particular application, but others will be useful in a wide variety of programs. For example, a function that takes a directory path and returns all the XML files in the directory, or a function that takes a filename and returns its contents, can be applied to many different situations.

Over time you'll form a personal library of utilities. Often you'll assemble new programs by arranging existing functions in a new configuration and writing a few functions specialized for the current task.

Iterators

I'll start by looking at a Python language feature that's an important foundation for writing functional-style programs: iterators.

An iterator is an object representing a stream of data; this object returns the data one element at a time. A Python iterator must support a method called `__next__()` that takes no arguments and always returns the next element of the stream. If there are no more elements in the stream, `__next__()` must raise the `StopIteration` exception. Iterators don't have to be finite, though; it's perfectly reasonable to write an iterator that produces an infinite stream of data.

The built-in `iter()` function takes an arbitrary object and tries to return an iterator that will return the object's contents or elements, raising `TypeError` if the object doesn't support iteration. Several of Python's built-in data types support iteration, the most common being lists and dictionaries. An object is called an **iterable** object if you can get an iterator for it.

You can experiment with the iteration interface manually:

```
>>> L = [1,2,3]
>>> it = iter(L)
>>> it
<...iterator object at ...>
>>> it.__next__()
1
>>> next(it)
2
>>> next(it)
3
>>> next(it)
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
StopIteration
```

```
>>>
```

Python expects iterable objects in several different contexts, the most important being the `for` statement. In the statement `for X in Y`, `Y` must be an iterator or some object for which `iter()` can create an iterator. These two statements are equivalent:

```
for i in iter(obj):
    print(i)

for i in obj:
    print(i)
```

Iterators can be materialized as lists or tuples by using the `list()` or `tuple()` constructor functions:

```
>>> L = [1,2,3]
>>> iterator = iter(L)
>>> t = tuple(iterator)
>>> t
(1, 2, 3)
```

Sequence unpacking also supports iterators: if you know an iterator will return `N` elements, you can unpack them into an `N`-tuple:

```
>>> L = [1,2,3]
>>> iterator = iter(L)
>>> a,b,c = iterator
>>> a,b,c
(1, 2, 3)
```

Built-in functions such as `max()` and `min()` can take a single iterator argument and will return the largest or smallest element. The `"in"` and `"not in"` operators also support iterators: `x in iterator` is true if `X` is found in the stream returned by the iterator. You'll run into obvious problems if the iterator is infinite; `max()`, `min()`, and `"not in"` will never return, and if the element `X` never appears in the stream,

the `"in"` operator won't return either.

Note that you can only go forward in an iterator; there's no way to get the previous element, reset the iterator, or make a copy of it. Iterator objects can optionally provide these additional capabilities, but the iterator protocol only specifies the `next()` method. Functions may therefore consume all of the iterator's output, and if you need to do something different with the same stream, you'll have to create a new iterator.

Data Types That Support Iterators

We've already seen how lists and tuples support iterators. In fact, any Python sequence type, such as strings, will automatically support creation of an iterator.

Calling `iter()` on a dictionary returns an iterator that will loop over the dictionary's keys:

```
>>> m = {'Jan': 1, 'Feb': 2, 'Mar': 3, 'Apr': 4, 'May': 5, 'Jun': 6, 'Jul': 7, 'Aug': 8, 'Sep': 9, 'Oct': 10, 'Nov': 11, 'Dec': 12}
...
>>> for key in m:
...     print(key, m[key])
Mar 3
Feb 2
Aug 8
Sep 9
Apr 4
Jun 6
Jul 7
Jan 1
May 5
Nov 11
Dec 12
Oct 10
```

Note that the order is essentially random, because it's based on the hash ordering of the objects in the dictionary.

Applying `iter()` to a dictionary always loops over the keys, but dictionaries have methods that return other iterators. If you want to iterate over values or key/value pairs, you can explicitly call the `values()` or `items()` methods to get an appropriate iterator.

The `dict()` constructor can accept an iterator that returns a finite stream of `(key, value)` tuples:

```
>>> L = [('Italy', 'Rome'), ('France', 'Paris'), ('US', 'Washin  
>>> dict(iter(L))  
{'Italy': 'Rome', 'US': 'Washington DC', 'France': 'Paris'}
```

Files also support iteration by calling the `readline()` method until there are no more lines in the file. This means you can read each line of a file like this:

```
for line in file:  
    # do something for each line  
    ...
```

Sets can take their contents from an iterable and let you iterate over the set's elements:

```
S = {2, 3, 5, 7, 11, 13}  
for i in S:  
    print(i)
```

Generator expressions and list comprehensions

Two common operations on an iterator's output are 1) performing some operation for every element, 2) selecting a subset of elements that meet some condition. For example, given a list of strings, you might want to strip off trailing whitespace from each line or extract all the strings containing a given substring.

List comprehensions and generator expressions (short form: "listcomps" and "genexps") are a concise notation for such operations, borrowed from the functional programming language Haskell (<http://www.haskell.org/>). You can strip all the whitespace from a stream of strings with the following code:

```
line_list = [' line 1\n', 'line 2 \n', ...]

# Generator expression -- returns iterator
stripped_iter = (line.strip() for line in line_list)

# List comprehension -- returns list
stripped_list = [line.strip() for line in line_list]
```

You can select only certain elements by adding an "if" condition:

```
stripped_list = [line.strip() for line in line_list
                 if line != ""]
```

With a list comprehension, you get back a Python list; `stripped_list` is a list containing the resulting lines, not an iterator. Generator expressions return an iterator that computes the values as necessary, not needing to materialize all the values at once. This means that list comprehensions aren't useful if you're working with iterators that return an infinite stream or a very large amount of data. Generator expressions are preferable in these situations.

Generator expressions are surrounded by parentheses (“()”) and list comprehensions are surrounded by square brackets (“[]”). Generator expressions have the form:

```
( expression for expr in sequence1
    if condition1
    for expr2 in sequence2
    if condition2
    for expr3 in sequence3 ...
    if condition3
    for exprN in sequenceN
    if conditionN )
```

Again, for a list comprehension only the outside brackets are different (square brackets instead of parentheses).

The elements of the generated output will be the successive values of `expression`. The `if` clauses are all optional; if present, `expression` is only evaluated and added to the result when `condition` is true.

Generator expressions always have to be written inside parentheses, but the parentheses signalling a function call also count. If you want to create an iterator that will be immediately passed to a function you can write:

```
obj_total = sum(obj.count for obj in list_all_objects())
```

The `for...in` clauses contain the sequences to be iterated over. The sequences do not have to be the same length, because they are iterated over from left to right, **not** in parallel. For each element in `sequence1`, `sequence2` is looped over from the beginning. `sequence3` is then looped over for each resulting pair of elements from `sequence1` and `sequence2`.

To put it another way, a list comprehension or generator expression is equivalent to the following Python code:

```

for expr1 in sequence1:
    if not (condition1):
        continue # Skip this element
    for expr2 in sequence2:
        if not (condition2):
            continue # Skip this element
        ...
    for exprN in sequenceN:
        if not (conditionN):
            continue # Skip this element

        # Output the value of
        # the expression.

```

This means that when there are multiple `for...in` clauses but no `if` clauses, the length of the resulting output will be equal to the product of the lengths of all the sequences. If you have two lists of length 3, the output list is 9 elements long:

```

>>> seq1 = 'abc'
>>> seq2 = (1,2,3)
>>> [(x,y) for x in seq1 for y in seq2]
[('a', 1), ('a', 2), ('a', 3),
 ('b', 1), ('b', 2), ('b', 3),
 ('c', 1), ('c', 2), ('c', 3)]

```

To avoid introducing an ambiguity into Python's grammar, if `expression` is creating a tuple, it must be surrounded with parentheses. The first list comprehension below is a syntax error, while the second one is correct:

```

# Syntax error
[ x,y for x in seq1 for y in seq2]
# Correct
[ (x,y) for x in seq1 for y in seq2]

```

Generators

Generators are a special class of functions that simplify the task of writing iterators. Regular functions compute a value and return it, but generators return an iterator that returns a stream of values.

You're doubtless familiar with how regular function calls work in Python or C. When you call a function, it gets a private namespace where its local variables are created. When the function reaches a `return` statement, the local variables are destroyed and the value is returned to the caller. A later call to the same function creates a new private namespace and a fresh set of local variables. But, what if the local variables weren't thrown away on exiting a function? What if you could later resume the function where it left off? This is what generators provide; they can be thought of as resumable functions.

Here's the simplest example of a generator function:

```
def generate_ints(N):  
    for i in range(N):  
        yield i
```

Any function containing a `yield` keyword is a generator function; this is detected by Python's `bytecode` compiler which compiles the function specially as a result.

When you call a generator function, it doesn't return a single value; instead it returns a generator object that supports the iterator protocol. On executing the `yield` expression, the generator outputs the value of `i`, similar to a `return` statement. The big difference between `yield` and a `return` statement is that on reaching a `yield` the generator's state of execution is suspended and local variables are preserved. On the next call to the generator's `__next__()` method, the function will resume executing.

Here's a sample usage of the `generate_ints()` generator:

```
>>> gen = generate_ints(3)
>>> gen
<generator object generate_ints at ...>
>>> next(gen)
0
>>> next(gen)
1
>>> next(gen)
2
>>> next(gen)
Traceback (most recent call last):
  File "stdin", line 1, in ?
  File "stdin", line 2, in generate_ints
StopIteration
```

You could equally write `for i in generate_ints(5)`, or `a,b,c = generate_ints(3)`.

Inside a generator function, the `return` statement can only be used without a value, and signals the end of the procession of values; after executing a `return` the generator cannot return any further values. `return` with a value, such as `return 5`, is a syntax error inside a generator function. The end of the generator's results can also be indicated by raising `StopIteration` manually, or by just letting the flow of execution fall off the bottom of the function.

You could achieve the effect of generators manually by writing your own class and storing all the local variables of the generator as instance variables. For example, returning a list of integers could be done by setting `self.count` to 0, and having the `__next__()` method increment `self.count` and return it. However, for a moderately complicated generator, writing a corresponding class can be much messier.

The test suite included with Python's library, `test_generators.py`,

contains a number of more interesting examples. Here's one generator that implements an in-order traversal of a tree using generators recursively.

```
# A recursive generator that generates Tree leaves in in-order.  
def inorder(t):  
    if t:  
        for x in inorder(t.left):  
            yield x  
  
        yield t.label  
  
        for x in inorder(t.right):  
            yield x
```

Two other examples in `test_generators.py` produce solutions for the N-Queens problem (placing N queens on an NxN chess board so that no queen threatens another) and the Knight's Tour (finding a route that takes a knight to every square of an NxN chessboard without visiting any square twice).

Passing values into a generator

In Python 2.4 and earlier, generators only produced output. Once a generator's code was invoked to create an iterator, there was no way to pass any new information into the function when its execution is resumed. You could hack together this ability by making the generator look at a global variable or by passing in some mutable object that callers then modify, but these approaches are messy.

In Python 2.5 there's a simple way to pass values into a generator. `yield` became an expression, returning a value that can be assigned to a variable or otherwise operated on:

```
val = (yield i)
```

I recommend that you **always** put parentheses around a `yield` expression when you're doing something with the returned value, as in the above example. The parentheses aren't always necessary, but it's easier to always add them instead of having to remember when they're needed.

(PEP 342 explains the exact rules, which are that a `yield`-expression must always be parenthesized except when it occurs at the top-level expression on the right-hand side of an assignment. This means you can write `val = yield i` but have to use parentheses when there's an operation, as in `val = (yield i) + 12.`)

Values are sent into a generator by calling its `send(value)` method. This method resumes the generator's code and the `yield` expression returns the specified value. If the regular `__next__()` method is called, the `yield` returns `None`.

Here's a simple counter that increments by 1 and allows changing the value of the internal counter.

```
def counter (maximum):
    i = 0
    while i < maximum:
        val = (yield i)
        # If value provided, change counter
        if val is not None:
            i = val
        else:
            i += 1
```

And here's an example of changing the counter:

```
>>> it = counter(10)
>>> next(it)
0
>>> next(it)
1
>>> it.send(8)
```

```
8
>>> next(it)
9
>>> next(it)
Traceback (most recent call last):
  File "t.py", line 15, in ?
    it.next()
StopIteration
```

Because `yield` will often be returning `None`, you should always check for this case. Don't just use its value in expressions unless you're sure that the `send()` method will be the only method used resume your generator function.

In addition to `send()`, there are two other new methods on generators:

- `throw(type, value=None, traceback=None)` is used to raise an exception inside the generator; the exception is raised by the `yield` expression where the generator's execution is paused.
- `close()` raises a `GeneratorExit` exception inside the generator to terminate the iteration. On receiving this exception, the generator's code must either raise `GeneratorExit` or `StopIteration`; catching the exception and doing anything else is illegal and will trigger a `RuntimeError`. `close()` will also be called by Python's garbage collector when the generator is garbage-collected.

If you need to run cleanup code when a `GeneratorExit` occurs, I suggest using a `try: ... finally:` suite instead of catching `GeneratorExit`.

The cumulative effect of these changes is to turn generators from one-way producers of information into both producers and consumers.

Generators also become **coroutines**, a more generalized form of subroutines. Subroutines are entered at one point and exited at another point (the top of the function, and a `return` statement), but coroutines can be entered, exited, and resumed at many different points (the `yield` statements).

Built-in functions

Let's look in more detail at built-in functions often used with iterators.

Two of Python's built-in functions, `map()` and `filter()` duplicate the features of generator expressions:

`map(f, iterA, iterB, ...)` returns an iterator over the sequence `f(iterA[0], iterB[0]), f(iterA[1], iterB[1]), f(iterA[2], iterB[2]), ...`.

```
>>> def upper(s):  
...     return s.upper()
```

```
>>> list(map(upper, ['sentence', 'fragment']))  
['SENTENCE', 'FRAGMENT']  
>>> [upper(s) for s in ['sentence', 'fragment']]  
['SENTENCE', 'FRAGMENT']
```

You can of course achieve the same effect with a list comprehension.

`filter(predicate, iter)` returns an iterator over all the sequence elements that meet a certain condition, and is similarly duplicated by list comprehensions. A **predicate** is a function that returns the truth value of some condition; for use with `filter()`, the predicate must take a single value.

```
>>> def is_even(x):  
...     return (x % 2) == 0
```

```
>>> list(filter(is_even, range(10)))  
[0, 2, 4, 6, 8]
```

This can also be written as a list comprehension:

```
>>> list(x for x in range(10) if is_even(x))
[0, 2, 4, 6, 8]
```

`enumerate(iter)` counts off the elements in the iterable, returning 2-tuples containing the count and each element.

```
>>> for item in enumerate(['subject', 'verb', 'object']):
...     print(item)
(0, 'subject')
(1, 'verb')
(2, 'object')
```

`enumerate()` is often used when looping through a list and recording the indexes at which certain conditions are met:

```
f = open('data.txt', 'r')
for i, line in enumerate(f):
    if line.strip() == '':
        print('Blank line at line #%i' % i)
```

`sorted(iterable, [key=None], [reverse=False])` collects all the elements of the iterable into a list, sorts the list, and returns the sorted result. The `key`, and `reverse` arguments are passed through to the constructed list's `.sort()` method.

```
>>> import random
>>> # Generate 8 random numbers between [0, 10000)
>>> rand_list = random.sample(range(10000), 8)
>>> rand_list
[769, 7953, 9828, 6431, 8442, 9878, 6213, 2207]
>>> sorted(rand_list)
[769, 2207, 6213, 6431, 7953, 8442, 9828, 9878]
>>> sorted(rand_list, reverse=True)
[9878, 9828, 8442, 7953, 6431, 6213, 2207, 769]
```

(For a more detailed discussion of sorting, see the [Sorting mini-HOWTO](http://wiki.python.org/moin/HowTo/Sorting) in the Python wiki at <http://wiki.python.org/moin/HowTo/Sorting>.)

The `any(iter)` and `all(iter)` built-ins look at the truth values of an iterable's contents. `any()` returns True if any element in the iterable is a true value, and `all()` returns True if all of the elements are true values:

```
>>> any([0,1,0])
True
>>> any([0,0,0])
False
>>> any([1,1,1])
True
>>> all([0,1,0])
False
>>> all([0,0,0])
False
>>> all([1,1,1])
True
```

`zip(iterA, iterB, ...)` takes one element from each iterable and returns them in a tuple:

```
zip(['a', 'b', 'c'], (1, 2, 3)) =>
('a', 1), ('b', 2), ('c', 3)
```

It doesn't construct an in-memory list and exhaust all the input iterators before returning; instead tuples are constructed and returned only if they're requested. (The technical term for this behaviour is [lazy evaluation](#).)

This iterator is intended to be used with iterables that are all of the same length. If the iterables are of different lengths, the resulting stream will be the same length as the shortest iterable.

```
zip(['a', 'b'], (1, 2, 3)) =>
('a', 1), ('b', 2)
```

You should avoid doing this, though, because an element may be taken from the longer iterators and discarded. This means you can't

go on to use the iterators further because you risk skipping a discarded element.

The itertools module

The `itertools` module contains a number of commonly-used iterators as well as functions for combining several iterators. This section will introduce the module's contents by showing small examples.

The module's functions fall into a few broad classes:

- Functions that create a new iterator based on an existing iterator.
- Functions for treating an iterator's elements as function arguments.
- Functions for selecting portions of an iterator's output.
- A function for grouping an iterator's output.

Creating new iterators

`itertools.count(n)` returns an infinite stream of integers, increasing by 1 each time. You can optionally supply the starting number, which defaults to 0:

```
itertools.count() =>
 0, 1, 2, 3, 4, 5, 6, 7, 8, 9, ...
itertools.count(10) =>
10, 11, 12, 13, 14, 15, 16, 17, 18, 19, ...
```

`itertools.cycle(iter)` saves a copy of the contents of a provided iterable and returns a new iterator that returns its elements from first to last. The new iterator will repeat these elements infinitely.

```
itertools.cycle([1,2,3,4,5]) =>
 1, 2, 3, 4, 5, 1, 2, 3, 4, 5, ...
```

`itertools.repeat(elem, [n])` returns the provided element `n` times, or returns the element endlessly if `n` is not provided.

```
itertools.repeat('abc') =>
    abc, ...
itertools.repeat('abc', 5) =>
    abc, abc, abc, abc, abc
```

`itertools.chain(iterA, iterB, ...)` takes an arbitrary number of iterables as input, and returns all the elements of the first iterator, then all the elements of the second, and so on, until all of the iterables have been exhausted.

```
itertools.chain(['a', 'b', 'c'], (1, 2, 3)) =>
    a, b, c, 1, 2, 3
```

`itertools.islice(iter, [start], stop, [step])` returns a stream that's a slice of the iterator. With a single `stop` argument, it will return the first `stop` elements. If you supply a starting index, you'll get `stop-start` elements, and if you supply a value for `step`, elements will be skipped accordingly. Unlike Python's string and list slicing, you can't use negative values for `start`, `stop`, or `step`.

```
itertools.islice(range(10), 8) =>
    0, 1, 2, 3, 4, 5, 6, 7
itertools.islice(range(10), 2, 8) =>
    2, 3, 4, 5, 6, 7
itertools.islice(range(10), 2, 8, 2) =>
    2, 4, 6
```

`itertools.tee(iter, [n])` replicates an iterator; it returns `n` independent iterators that will all return the contents of the source iterator. If you don't supply a value for `n`, the default is 2. Replicating iterators requires saving some of the contents of the source iterator, so this can consume significant memory if the iterator is large and one of the new iterators is consumed more than the others.

```
itertools.tee( itertools.count() ) =>
    iterA, iterB

where iterA ->
    0, 1, 2, 3, 4, 5, 6, 7, 8, 9, ...

and iterB ->
    0, 1, 2, 3, 4, 5, 6, 7, 8, 9, ...
```

Calling functions on elements

The `operator` module contains a set of functions corresponding to Python's operators. Some examples are `operator.add(a, b)` (adds two values), `operator.ne(a, b)` (same as `a!=b`), and `operator.attrgetter('id')` (returns a callable that fetches the "id" attribute).

`itertools.starmap(func, iter)` assumes that the iterable will return a stream of tuples, and calls `f()` using these tuples as the arguments:

```
itertools.starmap(os.path.join,
                  [('/usr', 'bin', 'java'), ('/bin', 'python'),
                   ('/usr', 'bin', 'perl'), ('/usr', 'bin', 'rub
=>
    /usr/bin/java, /bin/python, /usr/bin/perl, /usr/bin/ruby
```

Selecting elements

Another group of functions chooses a subset of an iterator's elements based on a predicate.

`itertools.filterfalse(predicate, iter)` is the opposite, returning all elements for which the predicate returns false:

```
itertools.filterfalse(is_even, itertools.count()) =>
```

```
1, 3, 5, 7, 9, 11, 13, 15, ...
```

`itertools.takewhile(predicate, iter)` returns elements for as long as the predicate returns true. Once the predicate returns false, the iterator will signal the end of its results.

```
def less_than_10(x):  
    return (x < 10)  
  
itertools.takewhile(less_than_10, itertools.count()) =>  
    0, 1, 2, 3, 4, 5, 6, 7, 8, 9  
  
itertools.takewhile(is_even, itertools.count()) =>  
    0
```

`itertools.dropwhile(predicate, iter)` discards elements while the predicate returns true, and then returns the rest of the iterable's results.

```
itertools.dropwhile(less_than_10, itertools.count()) =>  
    10, 11, 12, 13, 14, 15, 16, 17, 18, 19, ...  
  
itertools.dropwhile(is_even, itertools.count()) =>  
    1, 2, 3, 4, 5, 6, 7, 8, 9, 10, ...
```

Grouping elements

The last function I'll discuss, `itertools.groupby(iter, key_func=None)`, is the most complicated. `key_func(elem)` is a function that can compute a key value for each element returned by the iterable. If you don't supply a key function, the key is simply each element itself.

`groupby()` collects all the consecutive elements from the underlying iterable that have the same key value, and returns a stream of 2-tuples containing a key value and an iterator for the elements with that key.

```

city_list = [('Decatur', 'AL'), ('Huntsville', 'AL'), ('Selma',
              ('Anchorage', 'AK'), ('Nome', 'AK'),
              ('Flagstaff', 'AZ'), ('Phoenix', 'AZ'), ('Tucson',
              ...
              ]

def get_state (city_state):
    return city_state[1]

itertools.groupby(city_list, get_state) =>
    ('AL', iterator-1),
    ('AK', iterator-2),
    ('AZ', iterator-3), ...

where
iterator-1 =>
    ('Decatur', 'AL'), ('Huntsville', 'AL'), ('Selma', 'AL')
iterator-2 =>
    ('Anchorage', 'AK'), ('Nome', 'AK')
iterator-3 =>
    ('Flagstaff', 'AZ'), ('Phoenix', 'AZ'), ('Tucson', 'AZ')

```

`groupby()` assumes that the underlying iterable's contents will already be sorted based on the key. Note that the returned iterators also use the underlying iterable, so you have to consume the results of `iterator-1` before requesting `iterator-2` and its corresponding key.

The functools module

The `functools` module in Python 2.5 contains some higher-order functions. A **higher-order function** takes one or more functions as input and returns a new function. The most useful tool in this module is the `functools.partial()` function.

For programs written in a functional style, you'll sometimes want to construct variants of existing functions that have some of the parameters filled in. Consider a Python function `f(a, b, c)`; you may wish to create a new function `g(b, c)` that's equivalent to `f(1, b, c)`; you're filling in a value for one of `f()`'s parameters. This is called "partial function application".

The constructor for `partial` takes the arguments `(function, arg1, arg2, ... kwarg1=value1, kwarg2=value2)`. The resulting object is callable, so you can just call it to invoke `function` with the filled-in arguments.

Here's a small but realistic example:

```
import functools

def log (message, subsystem):
    "Write the contents of 'message' to the specified subsystem
    print('%s: %s' % (subsystem, message))
    ...

server_log = functools.partial(log, subsystem='server')
server_log('Unable to open socket')
```

`functools.reduce(func, iter, [initial_value])` cumulatively performs an operation on all the iterable's elements and, therefore, can't be applied to infinite iterables. (Note it is not in `builtins`, but in

the `functools` module.) `func` must be a function that takes two elements and returns a single value. `functools.reduce()` takes the first two elements A and B returned by the iterator and calculates `func(A, B)`. It then requests the third element, C, calculates `func(func(A, B), C)`, combines this result with the fourth element returned, and continues until the iterable is exhausted. If the iterable returns no values at all, a `TypeError` exception is raised. If the initial value is supplied, it's used as a starting point and `func(initial_value, A)` is the first calculation.

```
>>> import operator, functools
>>> functools.reduce(operator.concat, ['A', 'BB', 'C'])
'ABBC'
>>> functools.reduce(operator.concat, [])
Traceback (most recent call last):
...
TypeError: reduce() of empty sequence with no initial value
>>> functools.reduce(operator.mul, [1,2,3], 1)
6
>>> functools.reduce(operator.mul, [], 1)
1
```

If you use `operator.add()` with `functools.reduce()`, you'll add up all the elements of the iterable. This case is so common that there's a special built-in called `sum()` to compute it:

```
>>> import functools
>>> functools.reduce(operator.add, [1,2,3,4], 0)
10
>>> sum([1,2,3,4])
10
>>> sum([])
0
```

For many uses of `functools.reduce()`, though, it can be clearer to just write the obvious `for` loop:

```
import functools
```

```
# Instead of:
product = functools.reduce(operator.mul, [1,2,3], 1)

# You can write:
product = 1
for i in [1,2,3]:
    product *= i
```

The operator module

The `operator` module was mentioned earlier. It contains a set of functions corresponding to Python's operators. These functions are often useful in functional-style code because they save you from writing trivial functions that perform a single operation.

Some of the functions in this module are:

- Math operations: `add()`, `sub()`, `mul()`, `floordiv()`, `abs()`, ...
- Logical operations: `not_()`, `truth()`.
- Bitwise operations: `and_()`, `or_()`, `invert()`.
- Comparisons: `eq()`, `ne()`, `lt()`, `le()`, `gt()`, and `ge()`.
- Object identity: `is_()`, `is_not()`.

Consult the operator module's documentation for a complete list.

The functional module

Collin Winter's `functional` module provides a number of more advanced tools for functional programming. It also reimplements several Python built-ins, trying to make them more intuitive to those used to functional programming in other languages.

This section contains an introduction to some of the most important functions in `functional`; full documentation can be found at [the project's website](#).

```
compose(outer, inner, unpack=False)
```

The `compose()` function implements function composition. In other words, it returns a wrapper around the `outer` and `inner` callables, such that the return value from `inner` is fed directly to `outer`. That is,

```
>>> def add(a, b):  
...     return a + b  
...  
>>> def double(a):  
...     return 2 * a  
...  
>>> compose(double, add)(5, 6)  
22
```

is equivalent to

```
>>> double(add(5, 6))  
22
```

The `unpack` keyword is provided to work around the fact that Python functions are not always **fully curried**. By default, it is expected that the `inner` function will return a single object and that the `outer` function will take a single argument. Setting the `unpack` argument causes `compose` to expect a tuple from `inner` which will be expanded before being passed to `outer`. Put simply,

```
compose(f, g)(5, 6)
```

is equivalent to:

```
f(g(5, 6))
```

while

```
compose(f, g, unpack=True)(5, 6)
```

is equivalent to:

```
f(*g(5, 6))
```

Even though `compose()` only accepts two functions, it's trivial to build up a version that will compose any number of functions. We'll use `functools.reduce()`, `compose()` and `partial()` (the last of which is provided by both `functional` and `functools`).

```
from functional import compose, partial
import functools

multi_compose = partial(functools.reduce, compose)
```

We can also use `map()`, `compose()` and `partial()` to craft a version of `"".join(...)` that converts its arguments to string:

```
from functional import compose, partial

join = compose("".join, partial(map, str))
```

`flip(func)`

`flip()` wraps the callable in `func` and causes it to receive its non-keyword arguments in reverse order.

```
>>> def triple(a, b, c):
...     return (a, b, c)
...
>>> triple(5, 6, 7)
(5, 6, 7)
>>>
>>> flipped_triple = flip(triple)
>>> flipped_triple(5, 6, 7)
(7, 6, 5)
```

`foldl(func, start, iterable)`

`foldl()` takes a binary function, a starting value (usually some kind of 'zero'), and an iterable. The function is applied to the starting value and the first element of the list, then the result of that and the second element of the list, then the result of that and the third element of the list, and so on.

This means that a call such as:

```
foldl(f, 0, [1, 2, 3])
```

is equivalent to:

```
f(f(f(0, 1), 2), 3)
```

`foldl()` is roughly equivalent to the following recursive function:

```
def foldl(func, start, seq):
    if len(seq) == 0:
        return start

    return foldl(func, func(start, seq[0]), seq[1:])
```

Speaking of equivalence, the above `foldl` call can be expressed in terms of the built-in `functools.reduce()` like so:

```
import functools
functools.reduce(f, [1, 2, 3], 0)
```

We can use `foldl()`, `operator.concat()` and `partial()` to write a cleaner, more aesthetically-pleasing version of Python's `"".join(...)` idiom:

```
from functional import foldl, partial
from operator import concat

join = partial(foldl, concat, "")
```

Small functions and the lambda expression

When writing functional-style programs, you'll often need little functions that act as predicates or that combine elements in some way.

If there's a Python built-in or a module function that's suitable, you don't need to define a new function at all:

```
stripped_lines = [line.strip() for line in lines]
existing_files = filter(os.path.exists, file_list)
```

If the function you need doesn't exist, you need to write it. One way to write small functions is to use the `lambda` statement. `lambda` takes a number of parameters and an expression combining these parameters, and creates a small function that returns the value of the expression:

```
lowercase = lambda x: x.lower()

print_assign = lambda name, value: name + '=' + str(value)

adder = lambda x, y: x+y
```

An alternative is to just use the `def` statement and define a function in the usual way:

```
def lowercase(x):
    return x.lower()

def print_assign(name, value):
    return name + '=' + str(value)

def adder(x, y):
    return x + y
```

Which alternative is preferable? That's a style question; my usual

course is to avoid using `lambda`.

One reason for my preference is that `lambda` is quite limited in the functions it can define. The result has to be computable as a single expression, which means you can't have multiway `if... elif... else` comparisons or `try... except` statements. If you try to do too much in a `lambda` statement, you'll end up with an overly complicated expression that's hard to read. Quick, what's the following code doing?

```
import functools
total = functools.reduce(lambda a, b: (0, a[1] + b[1]), items)[
```

You can figure it out, but it takes time to disentangle the expression to figure out what's going on. Using a short nested `def` statements makes things a little bit better:

```
import functools
def combine (a, b):
    return 0, a[1] + b[1]

total = functools.reduce(combine, items)[1]
```

But it would be best of all if I had simply used a `for` loop:

```
total = 0
for a, b in items:
    total += b
```

Or the `sum()` built-in and a generator expression:

```
total = sum(b for a,b in items)
```

Many uses of `functools.reduce()` are clearer when written as `for` loops.

Fredrik Lundh once suggested the following set of rules for refactoring uses of `lambda`:

1. Write a lambda function.
2. Write a comment explaining what the heck that lambda does.
3. Study the comment for a while, and think of a name that captures the essence of the comment.
4. Convert the lambda to a def statement, using that name.
5. Remove the comment.

I really like these rules, but you're free to disagree about whether this lambda-free style is better.

Revision History and Acknowledgements

The author would like to thank the following people for offering suggestions, corrections and assistance with various drafts of this article: Ian Bicking, Nick Coghlan, Nick Efford, Raymond Hettinger, Jim Jewett, Mike Krell, Leandro Lameiro, Jussi Salmela, Collin Winter, Blake Winton.

Version 0.1: posted June 30 2006.

Version 0.11: posted July 1 2006. Typo fixes.

Version 0.2: posted July 10 2006. Merged `genexp` and `listcomp` sections into one. Typo fixes.

Version 0.21: Added more references suggested on the tutor mailing list.

Version 0.30: Adds a section on the `functional` module written by Collin Winter; adds short section on the operator module; a few other edits.

Logging HOWTO

Author: Vinay Sajip <vinay_sajip at red-dove dot com>

Basic Logging Tutorial

Logging is a means of tracking events that happen when some software runs. The software's developer adds logging calls to their code to indicate that certain events have occurred. An event is described by a descriptive message which can optionally contain variable data (i.e. data that is potentially different for each occurrence of the event). Events also have an importance which the developer ascribes to the event; the importance can also be called the *level* or *severity*.

When to use logging

Logging provides a set of convenience functions for simple logging usage. These are `debug()`, `info()`, `warning()`, `error()` and `critical()`. To determine when to use logging, see the table below, which states, for each of a set of common tasks, the best tool to use for it.

Task you want to perform	The best tool for the task
Display console output for ordinary usage of a command line script or program	<code>print()</code>
Report events that occur during normal operation of a program (e.g. for status monitoring or fault investigation)	<code>logging.info()</code> (or <code>logging.debug()</code> for very detailed output for diagnostic purposes)
Issue a warning regarding a particular runtime event	<code>warnings.warn()</code> in library code if the issue is avoidable and the client application should be modified to eliminate the warning <code>logging.warning()</code> if there is

	nothing the client application can do about the situation, but the event should still be noted
Report an error regarding a particular runtime event	Raise an exception
Report suppression of an error without raising an exception (e.g. error handler in a long-running server process)	<code>logging.error()</code> , <code>logging.exception()</code> or <code>logging.critical()</code> as appropriate for the specific error and application domain

The logging functions are named after the level or severity of the events they are used to track. The standard levels and their applicability are described below (in increasing order of severity):

Level	When it's used
DEBUG	Detailed information, typically of interest only when diagnosing problems.
INFO	Confirmation that things are working as expected.
WARNING	An indication that something unexpected happened, or indicative of some problem in the near future (e.g. 'disk space low'). The software is still working as expected.
ERROR	Due to a more serious problem, the software has not been able to perform some function.
CRITICAL	A serious error, indicating that the program itself may be unable to continue running.

The default level is `WARNING`, which means that only events of this level and above will be tracked, unless the logging package is configured to do otherwise.

Events that are tracked can be handled in different ways. The simplest way of handling tracked events is to print them to the console. Another common way is to write them to a disk file.

A simple example

A very simple example is:

```
import logging
logging.warning('Watch out!') # will print a message to the con
logging.info('I told you so') # will not print anything
```

If you type these lines into a script and run it, you'll see:

```
WARNING:root:Watch out!
```

printed out on the console. The `INFO` message doesn't appear because the default level is `WARNING`. The printed message includes the indication of the level and the description of the event provided in the logging call, i.e. 'Watch out!'. Don't worry about the 'root' part for now: it will be explained later. The actual output can be formatted quite flexibly if you need that; formatting options will also be explained later.

Logging to a file

A very common situation is that of recording logging events in a file, so let's look at that next:

```
import logging
logging.basicConfig(filename='example.log', level=logging.DEBUG)
logging.debug('This message should go to the log file')
logging.info('So should this')
logging.warning('And this, too')
```

And now if we open the file and look at what we have, we should find the log messages:

```
DEBUG:root:This message should go to the log file
```

```
INFO:root:So should this
WARNING:root:And this, too
```

This example also shows how you can set the logging level which acts as the threshold for tracking. In this case, because we set the threshold to `DEBUG`, all of the messages were printed.

If you want to set the logging level from a command-line option such as:

```
--log=INFO
```

and you have the value of the parameter passed for `--log` in some variable `loglevel`, you can use:

```
getattr(logging, loglevel.upper())
```

to get the value which you'll pass to `basicConfig()` via the `level` argument. You may want to error check any user input value, perhaps as in the following example:

```
# assuming loglevel is bound to the string value obtained from
# command line argument. Convert to upper case to allow the use
# specify --log=DEBUG or --log=debug
numeric_level = getattr(logging, loglevel.upper(), None)
if not isinstance(numeric_level, int):
    raise ValueError('Invalid log level: %s' % loglevel)
logging.basicConfig(level=numeric_level, ...)
```

The call to `basicConfig()` should come *before* any calls to `debug()`, `info()` etc. As it's intended as a one-off simple configuration facility, only the first call will actually do anything: subsequent calls are effectively no-ops.

If you run the above script several times, the messages from successive runs are appended to the file `example.log`. If you want

each run to start afresh, not remembering the messages from earlier runs, you can specify the *filemode* argument, by changing the call in the above example to:

```
logging.basicConfig(filename='example.log', filemode='w', level
```

The output will be the same as before, but the log file is no longer appended to, so the messages from earlier runs are lost.

Logging from multiple modules

If your program consists of multiple modules, here's an example of how you could organize logging in it:

```
# myapp.py
import logging
import mylib

def main():
    logging.basicConfig(filename='myapp.log', level=logging.INFO)
    logging.info('Started')
    mylib.do_something()
    logging.info('Finished')

if __name__ == '__main__':
    main()
```

```
# mylib.py
import logging

def do_something():
    logging.info('Doing something')
```

If you run *myapp.py*, you should see this in *myapp.log*:

```
INFO:root:Started
INFO:root:Doing something
INFO:root:Finished
```

which is hopefully what you were expecting to see. You can generalize this to multiple modules, using the pattern in *mylib.py*. Note that for this simple usage pattern, you won't know, by looking in the log file, *where* in your application your messages came from, apart from looking at the event description. If you want to track the location of your messages, you'll need to refer to the documentation beyond the tutorial level – see [Advanced Logging Tutorial](#).

Logging variable data

To log variable data, use a format string for the event description message and append the variable data as arguments. For example:

```
import logging
logging.warning('%s before you %s', 'Look', 'leap!')
```

will display:

```
WARNING:root:Look before you leap!
```

As you can see, merging of variable data into the event description message uses the old, %-style of string formatting. This is for backwards compatibility: the logging package pre-dates newer formatting options such as `str.format()` and `string.Template`. These newer formatting options *are* supported, but exploring them is outside the scope of this tutorial.

Changing the format of displayed messages

To change the format which is used to display messages, you need to specify the format you want to use:

```
import logging
logging.basicConfig(format='%(levelname)s:%(message)s', level=logging.DEBUG)
logging.debug('This message should appear on the console')
logging.info('So should this')
```

```
logging.warning('And this, too')
```

which would print:

```
DEBUG:This message should appear on the console  
INFO:So should this  
WARNING:And this, too
```

Notice that the 'root' which appeared in earlier examples has disappeared. For a full set of things that can appear in format strings, you can refer to the documentation for [LogRecord attributes](#), but for simple usage, you just need the *levelname* (severity), *message* (event description, including variable data) and perhaps to display when the event occurred. This is described in the next section.

Displaying the date/time in messages

To display the date and time of an event, you would place '%(asctime)s' in your format string:

```
import logging  
logging.basicConfig(format='%(asctime)s %(message)s')  
logging.warning('is when this event was logged.')
```

which should print something like this:

```
2010-12-12 11:41:42,612 is when this event was logged.
```

The default format for date/time display (shown above) is ISO8601. If you need more control over the formatting of the date/time, provide a *datefmt* argument to `basicConfig`, as in this example:

```
import logging  
logging.basicConfig(format='%(asctime)s %(message)s', datefmt='%m/%d/%Y %H:%M:%S')  
logging.warning('is when this event was logged.')
```

which would display something like this:

```
12/12/2010 11:46:36 AM is when this event was logged.
```

The format of the *datefmt* argument is the same as supported by `time.strftime()`.

Next Steps

That concludes the basic tutorial. It should be enough to get you up and running with logging. There's a lot more that the logging package offers, but to get the best out of it, you'll need to invest a little more of your time in reading the following sections. If you're ready for that, grab some of your favourite beverage and carry on.

If your logging needs are simple, then use the above examples to incorporate logging into your own scripts, and if you run into problems or don't understand something, please post a question on the `comp.lang.python` Usenet group (available at <http://groups.google.com/group/comp.lang.python>) and you should receive help before too long.

Still here? You can carry on reading the next few sections, which provide a slightly more advanced/in-depth tutorial than the basic one above. After that, you can take a look at the *Logging Cookbook*.

Advanced Logging Tutorial

The logging library takes a modular approach and offers several categories of components: loggers, handlers, filters, and formatters.

- Loggers expose the interface that application code directly uses.
- Handlers send the log records (created by loggers) to the appropriate destination.
- Filters provide a finer grained facility for determining which log records to output.
- Formatters specify the layout of log records in the final output.

Logging is performed by calling methods on instances of the `Logger` class (hereafter called *loggers*). Each instance has a name, and they are conceptually arranged in a namespace hierarchy using dots (periods) as separators. For example, a logger named 'scan' is the parent of loggers 'scan.text', 'scan.html' and 'scan.pdf'. Logger names can be anything you want, and indicate the area of an application in which a logged message originates.

A good convention to use when naming loggers is to use a module-level logger, in each module which uses logging, named as follows:

```
logger = logging.getLogger(__name__)
```

This means that logger names track the package/module hierarchy, and it's intuitively obvious where events are logged just from the logger name.

The root of the hierarchy of loggers is called the root logger. That's the logger used by the functions `debug()`, `info()`, `warning()`, `error()` and `critical()`, which just call the same-named method of the root logger. The functions and the methods have the same signatures. The root logger's name is printed as 'root' in the logged output.

It is, of course, possible to log messages to different destinations. Support is included in the package for writing log messages to files, HTTP GET/POST locations, email via SMTP, generic sockets, queues, or OS-specific logging mechanisms such as syslog or the Windows NT event log. Destinations are served by *handler* classes. You can create your own log destination class if you have special requirements not met by any of the built-in handler classes.

By default, no destination is set for any logging messages. You can specify a destination (such as console or file) by using `basicConfig()` as in the tutorial examples. If you call the functions `debug()`, `info()`, `warning()`, `error()` and `critical()`, they will check to see if no destination is set; and if one is not set, they will set a destination of the console (`sys.stderr`) and a default format for the displayed message before delegating to the root logger to do the actual message output.

The default format set by `basicConfig()` for messages is:

```
severity:logger name:message
```

You can change this by passing a format string to `basicConfig()` with the *format* keyword argument. For all options regarding how a format string is constructed, see *Formatter Objects*.

Loggers

Logger objects have a threefold job. First, they expose several methods to application code so that applications can log messages at runtime. Second, logger objects determine which log messages to act upon based upon severity (the default filtering facility) or filter objects. Third, logger objects pass along relevant log messages to all interested log handlers.

The most widely used methods on logger objects fall into two categories: configuration and message sending.

These are the most common configuration methods:

- `Logger.setLevel()` specifies the lowest-severity log message a logger will handle, where debug is the lowest built-in severity level and critical is the highest built-in severity. For example, if the severity level is INFO, the logger will handle only INFO, WARNING, ERROR, and CRITICAL messages and will ignore DEBUG messages.
- `Logger.addHandler()` and `Logger.removeHandler()` add and remove handler objects from the logger object. Handlers are covered in more detail in *Handlers*.
- `Logger.addFilter()` and `Logger.removeFilter()` add and remove filter objects from the logger object. Filters are covered in more detail in *Filter Objects*.

You don't need to always call these methods on every logger you create. See the last two paragraphs in this section.

With the logger object configured, the following methods create log messages:

- `Logger.debug()`, `Logger.info()`, `Logger.warning()`, `Logger.error()`, and `Logger.critical()` all create log records with a message and a level that corresponds to their respective method names. The message is actually a format string, which may contain the standard string substitution syntax of `%s`, `%d`, `%f`, and so on. The rest of their arguments is a list of objects that correspond with the substitution fields in the message. With regard to `**kwargs`, the logging methods care only about a keyword of `exc_info` and use it to determine whether to log exception information.

- `Logger.exception()` creates a log message similar to `Logger.error()`. The difference is that `Logger.exception()` dumps a stack trace along with it. Call this method only from an exception handler.
- `Logger.log()` takes a log level as an explicit argument. This is a little more verbose for logging messages than using the log level convenience methods listed above, but this is how to log at custom log levels.

`getLogger()` returns a reference to a logger instance with the specified name if it is provided, or `root` if not. The names are period-separated hierarchical structures. Multiple calls to `getLogger()` with the same name will return a reference to the same logger object. Loggers that are further down in the hierarchical list are children of loggers higher up in the list. For example, given a logger with a name of `foo`, loggers with names of `foo.bar`, `foo.bar.baz`, and `foo.bam` are all descendants of `foo`.

Loggers have a concept of *effective level*. If a level is not explicitly set on a logger, the level of its parent is used instead as its effective level. If the parent has no explicit level set, *its* parent is examined, and so on - all ancestors are searched until an explicitly set level is found. The root logger always has an explicit level set (`WARNING` by default). When deciding whether to process an event, the effective level of the logger is used to determine whether the event is passed to the logger's handlers.

Child loggers propagate messages up to the handlers associated with their ancestor loggers. Because of this, it is unnecessary to define and configure handlers for all the loggers an application uses. It is sufficient to configure handlers for a top-level logger and create child loggers as needed. (You can, however, turn off propagation by setting the *propagate* attribute of a logger to *False*.)

Handlers

Handler objects are responsible for dispatching the appropriate log messages (based on the log messages' severity) to the handler's specified destination. Logger objects can add zero or more handler objects to themselves with an `addHandler()` method. As an example scenario, an application may want to send all log messages to a log file, all log messages of error or higher to stdout, and all messages of critical to an email address. This scenario requires three individual handlers where each handler is responsible for sending messages of a specific severity to a specific location.

The standard library includes quite a few handler types (see *Useful Handlers*); the tutorials use mainly `StreamHandler` and `FileHandler` in its examples.

There are very few methods in a handler for application developers to concern themselves with. The only handler methods that seem relevant for application developers who are using the built-in handler objects (that is, not creating custom handlers) are the following configuration methods:

- The `Handler.setLevel()` method, just as in logger objects, specifies the lowest severity that will be dispatched to the appropriate destination. Why are there two `setLevel()` methods? The level set in the logger determines which severity of messages it will pass to its handlers. The level set in each handler determines which messages that handler will send on.
- `setFormatter()` selects a `Formatter` object for this handler to use.
- `addFilter()` and `removeFilter()` respectively configure and deconfigure filter objects on handlers.

Application code should not directly instantiate and use instances of

Handler. Instead, the **Handler** class is a base class that defines the interface that all handlers should have and establishes some default behavior that child classes can use (or override).

Formatters

Formatter objects configure the final order, structure, and contents of the log message. Unlike the base `logging.Handler` class, application code may instantiate formatter classes, although you could likely subclass the formatter if your application needs special behavior. The constructor takes three optional arguments – a message format string, a date format string and a style indicator.

```
logging.Formatter.__init__(fmt=None, datefmt=None, style='%')
```

If there is no message format string, the default is to use the raw message. If there is no date format string, the default date format is:

```
%Y-%m-%d %H:%M:%S
```

with the milliseconds tacked on at the end. The `style` is one of `%`, `{` or `$`. If one of these is not specified, then `%` will be used.

If the `style` is `%`, the message format string uses `%(dictionary key)s` styled string substitution; the possible keys are documented in *LogRecord attributes*. If the style is `{`, the message format string is assumed to be compatible with `str.format()` (using keyword arguments), while if the style is `$` then the message format string should conform to what is expected by `string.Template.substitute()`.

Changed in version 3.2: Added the `style` parameter.

The following message format string will log the time in a human-readable format, the severity of the message, and the contents of the

message, in that order:

```
'%(asctime)s - %(levelname)s - %(message)s'
```

Formatters use a user-configurable function to convert the creation time of a record to a tuple. By default, `time.localtime()` is used; to change this for a particular formatter instance, set the `converter` attribute of the instance to a function with the same signature as `time.localtime()` or `time.gmtime()`. To change it for all formatters, for example if you want all logging times to be shown in GMT, set the `converter` attribute in the `Formatter` class (to `time.gmtime` for GMT display).

Configuring Logging

Programmers can configure logging in three ways:

1. Creating loggers, handlers, and formatters explicitly using Python code that calls the configuration methods listed above.
2. Creating a logging config file and reading it using the `fileConfig()` function.
3. Creating a dictionary of configuration information and passing it to the `dictConfig()` function.

For the reference documentation on the last two options, see [Configuration functions](#). The following example configures a very simple logger, a console handler, and a simple formatter using Python code:

```
import logging

# create logger
logger = logging.getLogger('simple_example')
logger.setLevel(logging.DEBUG)

# create console handler and set level to debug
```

```
ch = logging.StreamHandler()
ch.setLevel(logging.DEBUG)

# create formatter
formatter = logging.Formatter('%(asctime)s - %(name)s - %(level

# add formatter to ch
ch.setFormatter(formatter)

# add ch to logger
logger.addHandler(ch)

# 'application' code
logger.debug('debug message')
logger.info('info message')
logger.warn('warn message')
logger.error('error message')
logger.critical('critical message')
```

Running this module from the command line produces the following output:

```
$ python simple_logging_module.py
2005-03-19 15:10:26,618 - simple_example - DEBUG - debug messag
2005-03-19 15:10:26,620 - simple_example - INFO - info message
2005-03-19 15:10:26,695 - simple_example - WARNING - warn messa
2005-03-19 15:10:26,697 - simple_example - ERROR - error messag
2005-03-19 15:10:26,773 - simple_example - CRITICAL - critical
```

The following Python module creates a logger, handler, and formatter nearly identical to those in the example listed above, with the only difference being the names of the objects:

```
import logging
import logging.config

logging.config.fileConfig('logging.conf')

# create logger
logger = logging.getLogger('simpleExample')

# 'application' code
```

```
logger.debug('debug message')
logger.info('info message')
logger.warn('warn message')
logger.error('error message')
logger.critical('critical message')
```

Here is the logging.conf file:

```
[loggers]
keys=root,simpleExample

[handlers]
keys=consoleHandler

[formatters]
keys=simpleFormatter

[logger_root]
level=DEBUG
handlers=consoleHandler

[logger_simpleExample]
level=DEBUG
handlers=consoleHandler
qualname=simpleExample
propagate=0

[handler_consoleHandler]
class=StreamHandler
level=DEBUG
formatter=simpleFormatter
args=(sys.stdout,)

[formatter_simpleFormatter]
format=%(asctime)s - %(name)s - %(levelname)s - %(message)s
datefmt=
```

The output is nearly identical to that of the non-config-file-based example:

```
$ python simple_logging_config.py
2005-03-19 15:38:55,977 - simpleExample - DEBUG - debug message
2005-03-19 15:38:55,979 - simpleExample - INFO - info message
2005-03-19 15:38:56,054 - simpleExample - WARNING - warn messag
```

```
2005-03-19 15:38:56,055 - simpleExample - ERROR - error message
2005-03-19 15:38:56,130 - simpleExample - CRITICAL - critical m
```

You can see that the config file approach has a few advantages over the Python code approach, mainly separation of configuration and code and the ability of noncoders to easily modify the logging properties.

Note that the class names referenced in config files need to be either relative to the logging module, or absolute values which can be resolved using normal import mechanisms. Thus, you could use either `WatchedFileHandler` (relative to the logging module) or `mypackage.mymodule.MyHandler` (for a class defined in package `mypackage` and module `mymodule`, where `mypackage` is available on the Python import path).

In Python 3.2, a new means of configuring logging has been introduced, using dictionaries to hold configuration information. This provides a superset of the functionality of the config-file-based approach outlined above, and is the recommended configuration method for new applications and deployments. Because a Python dictionary is used to hold configuration information, and since you can populate that dictionary using different means, you have more options for configuration. For example, you can use a configuration file in JSON format, or, if you have access to YAML processing functionality, a file in YAML format, to populate the configuration dictionary. Or, of course, you can construct the dictionary in Python code, receive it in pickled form over a socket, or use whatever approach makes sense for your application.

Here's an example of the same configuration as above, in YAML format for the new dictionary-based approach:

```
version: 1
formatters:
```

```
simple:
  format: format=%(asctime)s - %(name)s - %(levelname)s - %(m
handlers:
  console:
    class: logging.StreamHandler
    level: DEBUG
    formatter: simple
    stream: ext://sys.stdout
loggers:
  simpleExample:
    level: DEBUG
    handlers: [console]
    propagate: no
root:
  level: DEBUG
  handlers: [console]
```

For more information about logging using a dictionary, see [Configuration functions](#).

What happens if no configuration is provided

If no logging configuration is provided, it is possible to have a situation where a logging event needs to be output, but no handlers can be found to output the event. The behaviour of the logging package in these circumstances is dependent on the Python version.

For versions of Python prior to 3.2, the behaviour is as follows:

- If `logging.raiseExceptions` is `False` (production mode), the event is silently dropped.
- If `logging.raiseExceptions` is `True` (development mode), a message 'No handlers could be found for logger X.Y.Z' is printed once.

In Python 3.2 and later, the behaviour is as follows:

- The event is output using a 'handler of last resort', stored in `logging.lastResort`. This internal handler is not associated with

any logger, and acts like a `StreamHandler` which writes the event description message to the current value of `sys.stderr` (therefore respecting any redirections which may be in effect). No formatting is done on the message - just the bare event description message is printed. The handler's level is set to `WARNING`, so all events at this and greater severities will be output.

To obtain the pre-3.2 behaviour, `logging.lastResort` can be set to `None`.

Configuring Logging for a Library

When developing a library which uses logging, you should take care to document how the library uses logging - for example, the names of loggers used. Some consideration also needs to be given to its logging configuration. If the using application does not use logging, and library code makes logging calls, then (as described in the previous section) events of severity `WARNING` and greater will be printed to `sys.stderr`. This is regarded as the best default behaviour.

If for some reason you *don't* want these messages printed in the absence of any logging configuration, you can attach a do-nothing handler to the top-level logger for your library. This avoids the message being printed, since a handler will be always be found for the library's events: it just doesn't produce any output. If the library user configures logging for application use, presumably that configuration will add some handlers, and if levels are suitably configured then logging calls made in library code will send output to those handlers, as normal.

A do-nothing handler is included in the logging package: `NullHandler` (since Python 3.1). An instance of this handler could be added to the top-level logger of the logging namespace used by the library (*if* you

want to prevent your library's logged events being output to `sys.stderr` in the absence of logging configuration). If all logging by a library *foo* is done using loggers with names matching 'foo.x', 'foo.x.y', etc. then the code:

```
import logging
logging.getLogger('foo').addHandler(logging.NullHandler())
```

should have the desired effect. If an organisation produces a number of libraries, then the logger name specified can be 'orgname.foo' rather than just 'foo'.

PLEASE NOTE: It is strongly advised that you *do not add any handlers other than `NullHandler` to your library's loggers*. This is because the configuration of handlers is the prerogative of the application developer who uses your library. The application developer knows their target audience and what handlers are most appropriate for their application: if you add handlers 'under the hood', you might well interfere with their ability to carry out unit tests and deliver logs which suit their requirements.

Logging Levels

The numeric values of logging levels are given in the following table. These are primarily of interest if you want to define your own levels, and need them to have specific values relative to the predefined levels. If you define a level with the same numeric value, it overwrites the predefined value; the predefined name is lost.

Level	Numeric value
CRITICAL	50
ERROR	40
WARNING	30
INFO	20
DEBUG	10
NOTSET	0

Levels can also be associated with loggers, being set either by the developer or through loading a saved logging configuration. When a logging method is called on a logger, the logger compares its own level with the level associated with the method call. If the logger's level is higher than the method call's, no logging message is actually generated. This is the basic mechanism controlling the verbosity of logging output.

Logging messages are encoded as instances of the `LogRecord` class. When a logger decides to actually log an event, a `LogRecord` instance is created from the logging message.

Logging messages are subjected to a dispatch mechanism through the use of *handlers*, which are instances of subclasses of the `Handler` class. Handlers are responsible for ensuring that a logged message (in the form of a `LogRecord`) ends up in a particular location

(or set of locations) which is useful for the target audience for that message (such as end users, support desk staff, system administrators, developers). Handlers are passed `LogRecord` instances intended for particular destinations. Each logger can have zero, one or more handlers associated with it (via the `addHandler()` method of `Logger`). In addition to any handlers directly associated with a logger, *all handlers associated with all ancestors of the logger* are called to dispatch the message (unless the *propagate* flag for a logger is set to a false value, at which point the passing to ancestor handlers stops).

Just as for loggers, handlers can have levels associated with them. A handler's level acts as a filter in the same way as a logger's level does. If a handler decides to actually dispatch an event, the `emit()` method is used to send the message to its destination. Most user-defined subclasses of `Handler` will need to override this `emit()`.

Custom Levels

Defining your own levels is possible, but should not be necessary, as the existing levels have been chosen on the basis of practical experience. However, if you are convinced that you need custom levels, great care should be exercised when doing this, and it is possibly *a very bad idea to define custom levels if you are developing a library*. That's because if multiple library authors all define their own custom levels, there is a chance that the logging output from such multiple libraries used together will be difficult for the using developer to control and/or interpret, because a given numeric value might mean different things for different libraries.

Useful Handlers

In addition to the base `Handler` class, many useful subclasses are provided:

1. `StreamHandler` instances send messages to streams (file-like objects).
2. `FileHandler` instances send messages to disk files.
3. `BaseRotatingHandler` is the base class for handlers that rotate log files at a certain point. It is not meant to be instantiated directly. Instead, use `RotatingFileHandler` or `TimedRotatingFileHandler`.
4. `RotatingFileHandler` instances send messages to disk files, with support for maximum log file sizes and log file rotation.
5. `TimedRotatingFileHandler` instances send messages to disk files, rotating the log file at certain timed intervals.
6. `SocketHandler` instances send messages to TCP/IP sockets.
7. `DatagramHandler` instances send messages to UDP sockets.
8. `SMTPHandler` instances send messages to a designated email address.
9. `SysLogHandler` instances send messages to a Unix syslog daemon, possibly on a remote machine.
10. `NTEventLogHandler` instances send messages to a Windows NT/2000/XP event log.
11. `MemoryHandler` instances send messages to a buffer in memory, which is flushed whenever specific criteria are met.
12. `HTTPHandler` instances send messages to an HTTP server using either `GET` or `POST` semantics.
13. `WatchedFileHandler` instances watch the file they are logging to. If the file changes, it is closed and reopened using the file name. This handler is only useful on Unix-like systems; Windows does

not support the underlying mechanism used.

14. **QueueHandler** instances send messages to a queue, such as those implemented in the **queue** or **multiprocessing** modules.
15. **NullHandler** instances do nothing with error messages. They are used by library developers who want to use logging, but want to avoid the 'No handlers could be found for logger XXX' message which can be displayed if the library user has not configured logging. See *Configuring Logging for a Library* for more information.

New in version 3.1: The **NullHandler** class.

New in version 3.2: The **QueueHandler** class.

The **NullHandler**, **StreamHandler** and **FileHandler** classes are defined in the core logging package. The other handlers are defined in a sub- module, **logging.handlers**. (There is also another sub- module, **logging.config**, for configuration functionality.)

Logged messages are formatted for presentation through instances of the **Formatter** class. They are initialized with a format string suitable for use with the % operator and a dictionary.

For formatting multiple messages in a batch, instances of **BufferingFormatter** can be used. In addition to the format string (which is applied to each message in the batch), there is provision for header and trailer format strings.

When filtering based on logger level and/or handler level is not enough, instances of **Filter** can be added to both **Logger** and **Handler** instances (through their **addFilter()** method). Before deciding to process a message further, both loggers and handlers consult all their filters for permission. If any filter returns a false value, the message is not processed further.

The basic **Filter** functionality allows filtering by specific logger name. If this feature is used, messages sent to the named logger and its children are allowed through the filter, and all others dropped.

Exceptions raised during logging

The logging package is designed to swallow exceptions which occur while logging in production. This is so that errors which occur while handling logging events - such as logging misconfiguration, network or other similar errors - do not cause the application using logging to terminate prematurely.

`SystemExit` and `KeyboardInterrupt` exceptions are never swallowed. Other exceptions which occur during the `emit()` method of a `Handler` subclass are passed to its `handleError()` method.

The default implementation of `handleError()` in `Handler` checks to see if a module-level variable, `raiseExceptions`, is set. If set, a traceback is printed to `sys.stderr`. If not set, the exception is swallowed.

Note: The default value of `raiseExceptions` is `True`. This is because during development, you typically want to be notified of any exceptions that occur. It's advised that you set `raiseExceptions` to `False` for production usage.

Using arbitrary objects as messages

In the preceding sections and examples, it has been assumed that the message passed when logging the event is a string. However, this is not the only possibility. You can pass an arbitrary object as a message, and its `__str__()` method will be called when the logging system needs to convert it to a string representation. In fact, if you want to, you can avoid computing a string representation altogether - for example, the `SocketHandler` emits an event by pickling it and sending it over the wire.

Optimization

Formatting of message arguments is deferred until it cannot be avoided. However, computing the arguments passed to the logging method can also be expensive, and you may want to avoid doing it if the logger will just throw away your event. To decide what to do, you can call the `isEnabledFor()` method which takes a level argument and returns true if the event would be created by the Logger for that level of call. You can write code like this:

```
if logger.isEnabledFor(logging.DEBUG):
    logger.debug('Message with %s, %s', expensive_func1(),
                expensive_func2())
```

so that if the logger's threshold is set above `DEBUG`, the calls to `expensive_func1()` and `expensive_func2()` are never made.

There are other optimizations which can be made for specific applications which need more precise control over what logging information is collected. Here's a list of things you can do to avoid processing during logging which you don't need:

What you don't want to collect	How to avoid collecting it
Information about where calls were made from.	Set <code>logging._srcfile</code> to <code>None</code> .
Threading information.	Set <code>logging.logThreads</code> to <code>0</code> .
Process information.	Set <code>logging.logProcesses</code> to <code>0</code> .

Also note that the core logging module only includes the basic handlers. If you don't import `logging.handlers` and `logging.config`, they won't take up any memory.

A logging cookbook

Logging Cookbook

Author: Vinay Sajip <vinay_sajip at red-dove dot com>

This page contains a number of recipes related to logging, which have been found useful in the past.

Using logging in multiple modules

Multiple calls to `logging.getLogger('someLogger')` return a reference to the same logger object. This is true not only within the same module, but also across modules as long as it is in the same Python interpreter process. It is true for references to the same object; additionally, application code can define and configure a parent logger in one module and create (but not configure) a child logger in a separate module, and all logger calls to the child will pass up to the parent. Here is a main module:

```
import logging
import auxiliary_module

# create logger with 'spam_application'
logger = logging.getLogger('spam_application')
logger.setLevel(logging.DEBUG)
# create file handler which logs even debug messages
fh = logging.FileHandler('spam.log')
fh.setLevel(logging.DEBUG)
# create console handler with a higher log level
ch = logging.StreamHandler()
ch.setLevel(logging.ERROR)
# create formatter and add it to the handlers
formatter = logging.Formatter('%(asctime)s - %(name)s - %(levelname)s')
fh.setFormatter(formatter)
ch.setFormatter(formatter)
# add the handlers to the logger
logger.addHandler(fh)
logger.addHandler(ch)

logger.info('creating an instance of auxiliary_module.Auxiliary')
a = auxiliary_module.Auxiliary()
logger.info('created an instance of auxiliary_module.Auxiliary')
logger.info('calling auxiliary_module.Auxiliary.do_something()')
a.do_something()
logger.info('finished auxiliary_module.Auxiliary.do_something()')
logger.info('calling auxiliary_module.some_function()')
auxiliary_module.some_function()
logger.info('done with auxiliary_module.some_function()')
```

Here is the auxiliary module:

```
import logging

# create logger
module_logger = logging.getLogger('spam_application.auxiliary')

class Auxiliary:
    def __init__(self):
        self.logger = logging.getLogger('spam_application.auxiliary')
        self.logger.info('creating an instance of Auxiliary')
    def do_something(self):
        self.logger.info('doing something')
        a = 1 + 1
        self.logger.info('done doing something')

def some_function():
    module_logger.info('received a call to "some_function"')
```

The output looks like this:

```
2005-03-23 23:47:11,663 - spam_application - INFO -
    creating an instance of auxiliary_module.Auxiliary
2005-03-23 23:47:11,665 - spam_application.auxiliary.Auxiliary
    creating an instance of Auxiliary
2005-03-23 23:47:11,665 - spam_application - INFO -
    created an instance of auxiliary_module.Auxiliary
2005-03-23 23:47:11,668 - spam_application - INFO -
    calling auxiliary_module.Auxiliary.do_something
2005-03-23 23:47:11,668 - spam_application.auxiliary.Auxiliary
    doing something
2005-03-23 23:47:11,669 - spam_application.auxiliary.Auxiliary
    done doing something
2005-03-23 23:47:11,670 - spam_application - INFO -
    finished auxiliary_module.Auxiliary.do_something
2005-03-23 23:47:11,671 - spam_application - INFO -
    calling auxiliary_module.some_function()
2005-03-23 23:47:11,672 - spam_application.auxiliary - INFO -
    received a call to 'some_function'
2005-03-23 23:47:11,673 - spam_application - INFO -
    done with auxiliary_module.some_function()
```

Multiple handlers and formatters

Loggers are plain Python objects. The `addHandler()` method has no minimum or maximum quota for the number of handlers you may add. Sometimes it will be beneficial for an application to log all messages of all severities to a text file while simultaneously logging errors or above to the console. To set this up, simply configure the appropriate handlers. The logging calls in the application code will remain unchanged. Here is a slight modification to the previous simple module-based configuration example:

```
import logging

logger = logging.getLogger('simple_example')
logger.setLevel(logging.DEBUG)
# create file handler which logs even debug messages
fh = logging.FileHandler('spam.log')
fh.setLevel(logging.DEBUG)
# create console handler with a higher log level
ch = logging.StreamHandler()
ch.setLevel(logging.ERROR)
# create formatter and add it to the handlers
formatter = logging.Formatter('%(asctime)s - %(name)s - %(levelname)s')
ch.setFormatter(formatter)
fh.setFormatter(formatter)
# add the handlers to logger
logger.addHandler(ch)
logger.addHandler(fh)

# 'application' code
logger.debug('debug message')
logger.info('info message')
logger.warn('warn message')
logger.error('error message')
logger.critical('critical message')
```

Notice that the 'application' code does not care about multiple handlers. All that changed was the addition and configuration of a new handler named *fh*.

The ability to create new handlers with higher- or lower-severity filters can be very helpful when writing and testing an application. Instead of using many `print` statements for debugging, use `logger.debug`: Unlike the `print` statements, which you will have to delete or comment out later, the `logger.debug` statements can remain intact in the source code and remain dormant until you need them again. At that time, the only change that needs to happen is to modify the severity level of the logger and/or handler to debug.

Logging to multiple destinations

Let's say you want to log to console and file with different message formats and in differing circumstances. Say you want to log messages with levels of DEBUG and higher to file, and those messages at level INFO and higher to the console. Let's also assume that the file should contain timestamps, but the console messages should not. Here's how you can achieve this:

```
import logging

# set up logging to file - see previous section for more detail
logging.basicConfig(level=logging.DEBUG,
                    format='%(asctime)s %(name)-12s %(levelname)s %(message)s',
                    datefmt='%m-%d %H:%M',
                    filename='/temp/myapp.log',
                    filemode='w')

# define a Handler which writes INFO messages or higher to the
console = logging.StreamHandler()
console.setLevel(logging.INFO)
# set a format which is simpler for console use
formatter = logging.Formatter('%(name)-12s: %(levelname)-8s %(message)s')
# tell the handler to use this format
console.setFormatter(formatter)
# add the handler to the root logger
logging.getLogger('').addHandler(console)

# Now, we can log to the root logger, or any other logger. First
logging.info('Jackdaws love my big sphinx of quartz.')

# Now, define a couple of other loggers which might represent a
# application:

logger1 = logging.getLogger('myapp.area1')
logger2 = logging.getLogger('myapp.area2')

logger1.debug('Quick zephyrs blow, vexing daft Jim.')
logger1.info('How quickly daft jumping zebras vex.')
logger2.warning('Jail zesty vixen who grabbed pay from quack.')
logger2.error('The five boxing wizards jump quickly.')
```

When you run this, on the console you will see

```
root      : INFO      Jackdaws love my big sphinx of quartz.
myapp.area1 : INFO      How quickly daft jumping zebras vex.
myapp.area2 : WARNING   Jail zesty vixen who grabbed pay from qu
myapp.area2 : ERROR     The five boxing wizards jump quickly.
```

and in the file you will see something like

```
10-22 22:19 root      INFO      Jackdaws love my big sphinx o
10-22 22:19 myapp.area1 DEBUG     Quick zephyrs blow, vexing da
10-22 22:19 myapp.area1 INFO      How quickly daft jumping zebr
10-22 22:19 myapp.area2 WARNING  Jail zesty vixen who grabbed
10-22 22:19 myapp.area2 ERROR     The five boxing wizards jump
```

As you can see, the DEBUG message only shows up in the file. The other messages are sent to both destinations.

This example uses console and file handlers, but you can use any number and combination of handlers you choose.

Configuration server example

Here is an example of a module using the logging configuration server:

```
import logging
import logging.config
import time
import os

# read initial config file
logging.config.fileConfig('logging.conf')

# create and start listener on port 9999
t = logging.config.listen(9999)
t.start()

logger = logging.getLogger('simpleExample')

try:
    # loop through logging calls to see the difference
    # new configurations make, until Ctrl+C is pressed
    while True:
        logger.debug('debug message')
        logger.info('info message')
        logger.warn('warn message')
        logger.error('error message')
        logger.critical('critical message')
        time.sleep(5)
except KeyboardInterrupt:
    # cleanup
    logging.config.stopListening()
    t.join()
```

And here is a script that takes a filename and sends that file to the server, properly preceded with the binary-encoded length, as the new logging configuration:

```
#!/usr/bin/env python
import socket, sys, struct
```

```
with open(sys.argv[1], 'rb') as f:
    data_to_send = f.read()

HOST = 'localhost'
PORT = 9999
s = socket.socket(socket.AF_INET, socket.SOCK_STREAM)
print('connecting...')
s.connect((HOST, PORT))
print('sending config...')
s.send(struct.pack('>L', len(data_to_send)))
s.send(data_to_send)
s.close()
print('complete')
```

Dealing with handlers that block

Sometimes you have to get your logging handlers to do their work without blocking the thread you're logging from. This is common in Web applications, though of course it also occurs in other scenarios.

A common culprit which demonstrates sluggish behaviour is the `SMTPHandler`: sending emails can take a long time, for a number of reasons outside the developer's control (for example, a poorly performing mail or network infrastructure). But almost any network-based handler can block: Even a `SocketHandler` operation may do a DNS query under the hood which is too slow (and this query can be deep in the socket library code, below the Python layer, and outside your control).

One solution is to use a two-part approach. For the first part, attach only a `QueueHandler` to those loggers which are accessed from performance-critical threads. They simply write to their queue, which can be sized to a large enough capacity or initialized with no upper bound to their size. The write to the queue will typically be accepted quickly, though you will probably need to catch the `queue.Full` exception as a precaution in your code. If you are a library developer who has performance-critical threads in their code, be sure to document this (together with a suggestion to attach only `QueueHandlers` to your loggers) for the benefit of other developers who will use your code.

The second part of the solution is `QueueListener`, which has been designed as the counterpart to `QueueHandler`. A `QueueListener` is very simple: it's passed a queue and some handlers, and it fires up an internal thread which listens to its queue for `LogRecords` sent from `QueueHandlers` (or any other source of `LogRecords`, for that

matter). The `LogRecords` are removed from the queue and passed to the handlers for processing.

The advantage of having a separate `QueueListener` class is that you can use the same instance to service multiple `QueueHandlers`. This is more resource-friendly than, say, having threaded versions of the existing handler classes, which would eat up one thread per handler for no particular benefit.

An example of using these two classes follows (imports omitted):

```
que = queue.Queue(-1) # no limit on size
queue_handler = QueueHandler(que)
handler = logging.StreamHandler()
listener = QueueListener(que, handler)
root = logging.getLogger()
root.addHandler(queue_handler)
formatter = logging.Formatter('%(threadName)s: %(message)s')
handler.setFormatter(formatter)
listener.start()
# The log output will display the thread which generated
# the event (the main thread) rather than the internal
# thread which monitors the internal queue. This is what
# you want to happen.
root.warning('Look out!')
listener.stop()
```

which, when run, will produce:

```
MainThread: Look out!
```

Sending and receiving logging events across a network

Let's say you want to send logging events across a network, and handle them at the receiving end. A simple way of doing this is attaching a `SocketHandler` instance to the root logger at the sending end:

```
import logging, logging.handlers

rootLogger = logging.getLogger('')
rootLogger.setLevel(logging.DEBUG)
socketHandler = logging.handlers.SocketHandler('localhost',
                                               logging.handlers.DEFAULT_TCP_LOGGING_PORT)
# don't bother with a formatter, since a socket handler sends t
# an unformatted pickle
rootLogger.addHandler(socketHandler)

# Now, we can log to the root logger, or any other logger. Firs
logging.info('Jackdaws love my big sphinx of quartz.')

# Now, define a couple of other loggers which might represent a
# application:

logger1 = logging.getLogger('myapp.area1')
logger2 = logging.getLogger('myapp.area2')

logger1.debug('Quick zephyrs blow, vexing daft Jim.')
logger1.info('How quickly daft jumping zebras vex.')
logger2.warning('Jail zesty vixen who grabbed pay from quack.')
logger2.error('The five boxing wizards jump quickly.')
```

At the receiving end, you can set up a receiver using the `socketserver` module. Here is a basic working example:

```
import pickle
import logging
import logging.handlers
import socketserver
```

```

import struct

class LogRecordStreamHandler(socketserver.StreamRequestHandler):
    """Handler for a streaming logging request.

    This basically logs the record using whatever logging policy
    configured locally.
    """

    def handle(self):
        """
        Handle multiple requests - each expected to be a 4-byte
        followed by the LogRecord in pickle format. Logs the re
        according to whatever policy is configured locally.
        """
        while True:
            chunk = self.connection.recv(4)
            if len(chunk) < 4:
                break
            slen = struct.unpack('>L', chunk)[0]
            chunk = self.connection.recv(slen)
            while len(chunk) < slen:
                chunk = chunk + self.connection.recv(slen - len
            obj = self.unPickle(chunk)
            record = logging.makeLogRecord(obj)
            self.handleLogRecord(record)

    def unPickle(self, data):
        return pickle.loads(data)

    def handleLogRecord(self, record):
        # if a name is specified, we use the named logger rather
        # implied by the record.
        if self.server.logname is not None:
            name = self.server.logname
        else:
            name = record.name
        logger = logging.getLogger(name)
        # N.B. EVERY record gets logged. This is because Logger
        # is normally called AFTER logger-level filtering. If y
        # to do filtering, do it at the client end to save wast
        # cycles and network bandwidth!
        logger.handle(record)

class LogRecordSocketReceiver(socketserver.ThreadingTCPServer):
    """

```

```
Simple TCP socket-based logging receiver suitable for testing
"""

allow_reuse_address = 1

def __init__(self, host='localhost',
             port=logging.handlers.DEFAULT_TCP_LOGGING_PORT,
             handler=LogRecordStreamHandler):
    socketserver.ThreadingTCPServer.__init__(self, (host, port))
    self.abort = 0
    self.timeout = 1
    self.logname = None

def serve_until_stopped(self):
    import select
    abort = 0
    while not abort:
        rd, wr, ex = select.select([self.socket.fileno()],
                                   [], [],
                                   self.timeout)

        if rd:
            self.handle_request()
            abort = self.abort

def main():
    logging.basicConfig(
        format='%(relativeCreated)5d %(name)-15s %(levelname)-8s\n')
    tcpserver = LogRecordSocketReceiver()
    print('About to start TCP server...')
    tcpserver.serve_until_stopped()

if __name__ == '__main__':
    main()
```

First run the server, and then the client. On the client side, nothing is printed on the console; on the server side, you should see something like:

```
About to start TCP server...
59 root INFO Jackdaws love my big sphinx of quartz
59 myapp.area1 DEBUG Quick zephyrs blow, vexing daft
69 myapp.area1 INFO How quickly daft jumping zebras
69 myapp.area2 WARNING Jail zesty vixen who grabbed pay
69 myapp.area2 ERROR The five boxing wizards jump quickly
```

Note that there are some security issues with pickle in some scenarios. If these affect you, you can use an alternative serialization scheme by overriding the `makePickle()` method and implementing your alternative there, as well as adapting the above script to use your alternative serialization.

Adding contextual information to your logging output

Sometimes you want logging output to contain contextual information in addition to the parameters passed to the logging call. For example, in a networked application, it may be desirable to log client-specific information in the log (e.g. remote client's username, or IP address). Although you could use the *extra* parameter to achieve this, it's not always convenient to pass the information in this way. While it might be tempting to create `Logger` instances on a per-connection basis, this is not a good idea because these instances are not garbage collected. While this is not a problem in practice, when the number of `Logger` instances is dependent on the level of granularity you want to use in logging an application, it could be hard to manage if the number of `Logger` instances becomes effectively unbounded.

Using `LoggerAdapters` to impart contextual information

An easy way in which you can pass contextual information to be output along with logging event information is to use the `LoggerAdapter` class. This class is designed to look like a `Logger`, so that you can call `debug()`, `info()`, `warning()`, `error()`, `exception()`, `critical()` and `log()`. These methods have the same signatures as their counterparts in `Logger`, so you can use the two types of instances interchangeably.

When you create an instance of `LoggerAdapter`, you pass it a `Logger` instance and a dict-like object which contains your contextual information. When you call one of the logging methods on an

instance of `LoggerAdapter`, it delegates the call to the underlying instance of `Logger` passed to its constructor, and arranges to pass the contextual information in the delegated call. Here's a snippet from the code of `LoggerAdapter`:

```
def debug(self, msg, *args, **kwargs):
    """
    Delegate a debug call to the underlying logger, after adding
    contextual information from this adapter instance.
    """
    msg, kwargs = self.process(msg, kwargs)
    self.logger.debug(msg, *args, **kwargs)
```

The `process()` method of `LoggerAdapter` is where the contextual information is added to the logging output. It's passed the message and keyword arguments of the logging call, and it passes back (potentially) modified versions of these to use in the call to the underlying logger. The default implementation of this method leaves the message alone, but inserts an 'extra' key in the keyword argument whose value is the dict-like object passed to the constructor. Of course, if you had passed an 'extra' keyword argument in the call to the adapter, it will be silently overwritten.

The advantage of using 'extra' is that the values in the dict-like object are merged into the `LogRecord` instance's `__dict__`, allowing you to use customized strings with your `Formatter` instances which know about the keys of the dict-like object. If you need a different method, e.g. if you want to prepend or append the contextual information to the message string, you just need to subclass `LoggerAdapter` and override `process()` to do what you need. Here's an example script which uses this class, which also illustrates what dict-like behaviour is needed from an arbitrary 'dict-like' object for use in the constructor:

```
import logging

class ConnInfo:
```

```

"""
An example class which shows how an arbitrary class can be
the 'extra' context information repository passed to a Logg
"""

def __getitem__(self, name):
    """
    To allow this instance to look like a dict.
    """
    from random import choice
    if name == 'ip':
        result = choice(['127.0.0.1', '192.168.0.1'])
    elif name == 'user':
        result = choice(['jim', 'fred', 'sheila'])
    else:
        result = self.__dict__.get(name, '?')
    return result

def __iter__(self):
    """
    To allow iteration over keys, which will be merged into
    the LogRecord dict before formatting and output.
    """
    keys = ['ip', 'user']
    keys.extend(self.__dict__.keys())
    return keys.__iter__()

if __name__ == '__main__':
    from random import choice
    levels = (logging.DEBUG, logging.INFO, logging.WARNING, log
    a1 = logging.LoggerAdapter(logging.getLogger('a.b.c'),
                               { 'ip' : '123.231.231.123', 'use
    logging.basicConfig(level=logging.DEBUG,
                        format='%(asctime)-15s %(name)-5s %(lev
    a1.debug('A debug message')
    a1.info('An info message with %s', 'some parameters')
    a2 = logging.LoggerAdapter(logging.getLogger('d.e.f'), Conn
    for x in range(10):
        lvl = choice(levels)
        lvlname = logging.getLevelName(lvl)
        a2.log(lvl, 'A message at %s level with %d %s', lvlname

```

When this script is run, the output should look something like this:

```

2008-01-18 14:49:54,023 a.b.c DEBUG      IP: 123.231.231.123 User

```

```
2008-01-18 14:49:54,023 a.b.c INFO IP: 123.231.231.123 User
2008-01-18 14:49:54,023 d.e.f CRITICAL IP: 192.168.0.1 User

2008-01-18 14:49:54,033 d.e.f WARNING IP: 192.168.0.1 User
2008-01-18 14:49:54,033 d.e.f WARNING IP: 127.0.0.1 User
```

Using Filters to impart contextual information

You can also add contextual information to log output using a user-defined `Filter`. `Filter` instances are allowed to modify the `LogRecords` passed to them, including adding additional attributes which can then be output using a suitable format string, or if needed a custom `Formatter`.

For example in a web application, the request being processed (or at least, the interesting parts of it) can be stored in a threadlocal (`threading.local`) variable, and then accessed from a `Filter` to add, say, information from the request - say, the remote IP address and remote user's username - to the `LogRecord`, using the attribute names 'ip' and 'user' as in the `LoggerAdapter` example above. In that case, the same format string can be used to get similar output to that shown above. Here's an example script:

```
import logging
from random import choice

class ContextFilter(logging.Filter):
    """
    This is a filter which injects contextual information into

    Rather than use actual contextual information, we just use
    data in this demo.
```

```

"""

USERS = ['jim', 'fred', 'sheila']
IPS = ['123.231.231.123', '127.0.0.1', '192.168.0.1']

def filter(self, record):

    record.ip = choice(ContextFilter.IPS)
    record.user = choice(ContextFilter.USERS)
    return True

if __name__ == '__main__':
    levels = (logging.DEBUG, logging.INFO, logging.WARNING, logging.ERROR)
    a1 = logging.LoggerAdapter(logging.getLogger('a.b.c'),
                              { 'ip' : '123.231.231.123', 'user' : 'jim' })
    logging.basicConfig(level=logging.DEBUG,
                        format='%(asctime)-15s %(name)-5s %(levelname)-8s %(message)s')
    a1 = logging.getLogger('a.b.c')
    a2 = logging.getLogger('d.e.f')

    f = ContextFilter()
    a1.addFilter(f)
    a2.addFilter(f)
    a1.debug('A debug message')
    a1.info('An info message with %s', 'some parameters')
    for x in range(10):
        lvl = choice(levels)
        lvlname = logging.getLevelName(lvl)
        a2.log(lvl, 'A message at %s level with %d %s', lvlname, x)

```

which, when run, produces something like:

```

2010-09-06 22:38:15,292 a.b.c DEBUG      IP: 123.231.231.123 User

```

Logging to a single file from multiple processes

Although logging is thread-safe, and logging to a single file from multiple threads in a single process *is* supported, logging to a single file from *multiple processes* is *not* supported, because there is no standard way to serialize access to a single file across multiple processes in Python. If you need to log to a single file from multiple processes, one way of doing this is to have all the processes log to a `SocketHandler`, and have a separate process which implements a socket server which reads from the socket and logs to file. (If you prefer, you can dedicate one thread in one of the existing processes to perform this function.) The following section documents this approach in more detail and includes a working socket receiver which can be used as a starting point for you to adapt in your own applications.

If you are using a recent version of Python which includes the `multiprocessing` module, you could write your own handler which uses the `Lock` class from this module to serialize access to the file from your processes. The existing `FileHandler` and subclasses do not make use of `multiprocessing` at present, though they may do so in the future. Note that at present, the `multiprocessing` module does not provide working lock functionality on all platforms (see <http://bugs.python.org/issue3770>).

Alternatively, you can use a `Queue` and a `QueueHandler` to send all logging events to one of the processes in your multi-process application. The following example script demonstrates how you can do this; in the example a separate listener process listens for events sent by other processes and logs them according to its own logging configuration. Although the example only demonstrates one way of

doing it (for example, you may want to use a listener thread rather than a separate listener process – the implementation would be analogous) it does allow for completely different logging configurations for the listener and the other processes in your application, and can be used as the basis for code meeting your own specific requirements:

```
# You'll need these imports in your own code
import logging
import logging.handlers
import multiprocessing

# Next two import lines for this demo only
from random import choice, random
import time

#
# Because you'll want to define the logging configurations for
# listener and worker process functions take a configurer param
# for configuring logging for that process. These functions are
# which they use for communication.
#
# In practice, you can configure the listener however you want,
# simple example, the listener does not apply level or filter
# In practice, you would probably want to do this logic in the
# sending events which would be filtered out between processes.
#
# The size of the rotated files is made small so you can see th
def listener_configurer():
    root = logging.getLogger()
    h = logging.handlers.RotatingFileHandler('/tmp/mpctest.log',
    f = logging.Formatter('%(asctime)s %(processName)-10s %(nam
    h.setFormatter(f)
    root.addHandler(h)

# This is the listener process top-level loop: wait for logging
# (LogRecords) on the queue and handle them, quit when you get a
# LogRecord.
def listener_process(queue, configurer):
    configurer()
    while True:
        try:
            record = queue.get()
            if record is None: # We send this as a sentinel to
```

```

        break
        logger = logging.getLogger(record.name)
        logger.handle(record) # No level or filter logic ap
    except (KeyboardInterrupt, SystemExit):
        raise
    except:
        import sys, traceback
        print >> sys.stderr, 'Whoops! Problem:'
        traceback.print_exc(file=sys.stderr)

# Arrays used for random selections in this demo

LEVELS = [logging.DEBUG, logging.INFO, logging.WARNING,
          logging.ERROR, logging.CRITICAL]

LOGGERS = ['a.b.c', 'd.e.f']

MESSAGES = [
    'Random message #1',
    'Random message #2',
    'Random message #3',
]

# The worker configuration is done at the start of the worker p
# Note that on Windows you can't rely on fork semantics, so eac
# will run the logging configuration code when it starts.
def worker_configurer(queue):
    h = logging.handlers.QueueHandler(queue) # Just the one han
    root = logging.getLogger()
    root.addHandler(h)
    root.setLevel(logging.DEBUG) # send all messages, for demo;

# This is the worker process top-level loop, which just logs te
# random intervening delays before terminating.
# The print messages are just so you know it's doing something!
def worker_process(queue, configurer):
    configurer(queue)
    name = multiprocessing.current_process().name
    print('Worker started: %s' % name)
    for i in range(10):
        time.sleep(random())
        logger = logging.getLogger(choice(LOGGERS))
        level = choice(LEVELS)
        message = choice(MESSAGES)
        logger.log(level, message)
    print('Worker finished: %s' % name)

```

```

# Here's where the demo gets orchestrated. Create the queue, cr
# the listener, create ten workers and start them, wait for the
# then send a None to the queue to tell the listener to finish.
def main():
    queue = multiprocessing.Queue(-1)
    listener = multiprocessing.Process(target=listener_process,
                                     args=(queue, listener_co

    listener.start()
    workers = []
    for i in range(10):
        worker = multiprocessing.Process(target=worker_process,
                                       args=(queue, worker_conf

        workers.append(worker)
        worker.start()
    for w in workers:
        w.join()
    queue.put_nowait(None)
    listener.join()

if __name__ == '__main__':
    main()

```

A variant of the above script keeps the logging in the main process, in a separate thread:

```

import logging
import logging.config
import logging.handlers
from multiprocessing import Process, Queue
import random
import threading
import time

def logger_thread(q):
    while True:
        record = q.get()
        if record is None:
            break
        logger = logging.getLogger(record.name)
        logger.handle(record)

def worker_process(q):
    qh = logging.handlers.QueueHandler(q)
    root = logging.getLogger()

```

```

root.setLevel(logging.DEBUG)
root.addHandler(qh)
levels = [logging.DEBUG, logging.INFO, logging.WARNING, logging.CRITICAL]
loggers = ['foo', 'foo.bar', 'foo.bar.baz',
           'spam', 'spam.ham', 'spam.ham.eggs']
for i in range(100):
    lvl = random.choice(levels)
    logger = logging.getLogger(random.choice(loggers))
    logger.log(lvl, 'Message no. %d', i)

if __name__ == '__main__':
    q = Queue()
    d = {
        'version': 1,
        'formatters': {
            'detailed': {
                'class': 'logging.Formatter',
                'format': '%(asctime)s %(name)-15s %(levelname)
            }
        },
        'handlers': {
            'console': {
                'class': 'logging.StreamHandler',
                'level': 'INFO',
            },
            'file': {
                'class': 'logging.FileHandler',
                'filename': 'mplog.log',
                'mode': 'w',
                'formatter': 'detailed',
            },
            'foofile': {
                'class': 'logging.FileHandler',
                'filename': 'mplog-foo.log',
                'mode': 'w',
                'formatter': 'detailed',
            },
            'errors': {
                'class': 'logging.FileHandler',
                'filename': 'mplog-errors.log',
                'mode': 'w',
                'level': 'ERROR',
                'formatter': 'detailed',
            },
        },
        'loggers': {

```

```

        'foo': {
            'handlers' : ['foofile']
        }
    },
    'root': {
        'level': 'DEBUG',
        'handlers': ['console', 'file', 'errors']
    },
}
workers = []
for i in range(5):
    wp = Process(target=worker_process, name='worker %d' %
workers.append(wp)
wp.start()
logging.config.dictConfig(d)
lp = threading.Thread(target=logger_thread, args=(q,))
lp.start()
# At this point, the main process could do some useful work
# Once it's done that, it can wait for the workers to termi
for wp in workers:
    wp.join()
# And now tell the logging thread to finish up, too
q.put(None)
lp.join()

```

This variant shows how you can e.g. apply configuration for particular loggers - e.g. the `foo` logger has a special handler which stores all events in the `foo` subsystem in a file `mplog-foo.log`. This will be used by the logging machinery in the main process (even though the logging events are generated in the worker processes) to direct the messages to the appropriate destinations.

Using file rotation

Sometimes you want to let a log file grow to a certain size, then open a new file and log to that. You may want to keep a certain number of these files, and when that many files have been created, rotate the files so that the number of files and the size of the files both remain bounded. For this usage pattern, the logging package provides a `RotatingFileHandler`:

```
import glob
import logging
import logging.handlers

LOG_FILENAME = 'logging_rotatingfile_example.out'

# Set up a specific logger with our desired output level
my_logger = logging.getLogger('MyLogger')
my_logger.setLevel(logging.DEBUG)

# Add the log message handler to the logger
handler = logging.handlers.RotatingFileHandler(
    LOG_FILENAME, maxBytes=20, backupCount=5)

my_logger.addHandler(handler)

# Log some messages
for i in range(20):
    my_logger.debug('i = %d' % i)

# See what files are created
logfiles = glob.glob('%s*' % LOG_FILENAME)

for filename in logfiles:
    print(filename)
```

The result should be 6 separate files, each with part of the log history for the application:

```
logging_rotatingfile_example.out
logging_rotatingfile_example.out.1
```

```
logging_rotatingfile_example.out.2  
logging_rotatingfile_example.out.3  
logging_rotatingfile_example.out.4  
logging_rotatingfile_example.out.5
```

The most current file is always `logging_rotatingfile_example.out`, and each time it reaches the size limit it is renamed with the suffix `.1`. Each of the existing backup files is renamed to increment the suffix (`.1` becomes `.2`, etc.) and the `.6` file is erased.

Obviously this example sets the log length much much too small as an extreme example. You would want to set *maxBytes* to an appropriate value.

Subclassing QueueHandler - a ZeroMQ example

You can use a `QueueHandler` subclass to send messages to other kinds of queues, for example a ZeroMQ 'publish' socket. In the example below, the socket is created separately and passed to the handler (as its 'queue'):

```
import zmq # using pyzmq, the Python binding for ZeroMQ
import json # for serializing records portably

ctx = zmq.Context()
sock = zmq.Socket(ctx, zmq.PUB) # or zmq.PUSH, or other suitable
sock.bind('tcp://*:5556') # or wherever

class ZeroMQSocketHandler(QueueHandler):
    def enqueue(self, record):
        data = json.dumps(record.__dict__)
        self.queue.send(data)

handler = ZeroMQSocketHandler(sock)
```

Of course there are other ways of organizing this, for example passing in the data needed by the handler to create the socket:

```
class ZeroMQSocketHandler(QueueHandler):
    def __init__(self, uri, socktype=zmq.PUB, ctx=None):
        self.ctx = ctx or zmq.Context()
        socket = zmq.Socket(self.ctx, socktype)
        socket.bind(uri)
        QueueHandler.__init__(self, socket)

    def enqueue(self, record):
        data = json.dumps(record.__dict__)
        self.queue.send(data)

    def close(self):
        self.queue.close()
```

Subclassing QueueListener - a ZeroMQ example

You can also subclass `QueueListener` to get messages from other kinds of queues, for example a ZeroMQ 'subscribe' socket. Here's an example:

```
class ZeroMQSocketListener(QueueListener):
    def __init__(self, uri, *handlers, **kwargs):
        self.ctx = kwargs.get('ctx') or zmq.Context()
        socket = zmq.Socket(self.ctx, zmq.SUB)
        socket.setsockopt(zmq.SUBSCRIBE, '') # subscribe to eve
        socket.connect(uri)

    def dequeue(self):
        msg = self.queue.recv()
        return logging.makeLogRecord(json.loads(msg))
```

Regular Expression HOWTO

Author: A.M. Kuchling <amk@amk.ca>

Abstract

This document is an introductory tutorial to using regular expressions in Python with the `re` module. It provides a gentler introduction than the corresponding section in the Library Reference.

Introduction

Regular expressions (called REs, or regexes, or regex patterns) are essentially a tiny, highly specialized programming language embedded inside Python and made available through the `re` module. Using this little language, you specify the rules for the set of possible strings that you want to match; this set might contain English sentences, or e-mail addresses, or TeX commands, or anything you like. You can then ask questions such as “Does this string match the pattern?”, or “Is there a match for the pattern anywhere in this string?”. You can also use REs to modify a string or to split it apart in various ways.

Regular expression patterns are compiled into a series of bytecodes which are then executed by a matching engine written in C. For advanced use, it may be necessary to pay careful attention to how the engine will execute a given RE, and write the RE in a certain way in order to produce bytecode that runs faster. Optimization isn't covered in this document, because it requires that you have a good understanding of the matching engine's internals.

The regular expression language is relatively small and restricted, so not all possible string processing tasks can be done using regular expressions. There are also tasks that *can* be done with regular expressions, but the expressions turn out to be very complicated. In these cases, you may be better off writing Python code to do the processing; while Python code will be slower than an elaborate regular expression, it will also probably be more understandable.

Simple Patterns

We'll start by learning about the simplest possible regular expressions. Since regular expressions are used to operate on strings, we'll begin with the most common task: matching characters.

For a detailed explanation of the computer science underlying regular expressions (deterministic and non-deterministic finite automata), you can refer to almost any textbook on writing compilers.

Matching Characters

Most letters and characters will simply match themselves. For example, the regular expression `test` will match the string `test` exactly. (You can enable a case-insensitive mode that would let this RE match `Test` or `TEST` as well; more about this later.)

There are exceptions to this rule; some characters are special *metacharacters*, and don't match themselves. Instead, they signal that some out-of-the-ordinary thing should be matched, or they affect other portions of the RE by repeating them or changing their meaning. Much of this document is devoted to discussing various metacharacters and what they do.

Here's a complete list of the metacharacters; their meanings will be discussed in the rest of this HOWTO.

```
. ^ $ * + ? { [ ] \ | ( )
```

The first metacharacters we'll look at are `[` and `]`. They're used for specifying a character class, which is a set of characters that you wish to match. Characters can be listed individually, or a range of

characters can be indicated by giving two characters and separating them by a `'-'`. For example, `[abc]` will match any of the characters `a`, `b`, or `c`; this is the same as `[a-c]`, which uses a range to express the same set of characters. If you wanted to match only lowercase letters, your RE would be `[a-z]`.

Metacharacters are not active inside classes. For example, `[akm$]` will match any of the characters `'a'`, `'k'`, `'m'`, or `'$'`; `'$'` is usually a metacharacter, but inside a character class it's stripped of its special nature.

You can match the characters not listed within the class by *complementing* the set. This is indicated by including a `'^'` as the first character of the class; `'^'` outside a character class will simply match the `'^'` character. For example, `[^5]` will match any character except `'5'`.

Perhaps the most important metacharacter is the backslash, `\`. As in Python string literals, the backslash can be followed by various characters to signal various special sequences. It's also used to escape all the metacharacters so you can still match them in patterns; for example, if you need to match a `[` or `\`, you can precede them with a backslash to remove their special meaning: `\[` or `\\`.

Some of the special sequences beginning with `'\'` represent predefined sets of characters that are often useful, such as the set of digits, the set of letters, or the set of anything that isn't whitespace. The following predefined special sequences are a subset of those available. The equivalent classes are for bytes patterns. For a complete list of sequences and expanded class definitions for Unicode string patterns, see the last part of *Regular Expression Syntax*.

`\d`

Matches any decimal digit; this is equivalent to the class `[0-9]`.

`\D`

Matches any non-digit character; this is equivalent to the class `[^0-9]`.

`\s`

Matches any whitespace character; this is equivalent to the class `[\t\n\r\f\v]`.

`\S`

Matches any non-whitespace character; this is equivalent to the class `[^\t\n\r\f\v]`.

`\w`

Matches any alphanumeric character; this is equivalent to the class `[a-zA-Z0-9_]`.

`\W`

Matches any non-alphanumeric character; this is equivalent to the class `[^a-zA-Z0-9_]`.

These sequences can be included inside a character class. For example, `[\s,.]` is a character class that will match any whitespace character, or `,` or `.`.

The final metacharacter in this section is `.`. It matches anything except a newline character, and there's an alternate mode (`re.DOTALL`) where it will match even a newline. `'.'` is often used where you want to match "any character".

Repeating Things

Being able to match varying sets of characters is the first thing regular expressions can do that isn't already possible with the methods available on strings. However, if that was the only additional capability of regexes, they wouldn't be much of an advance. Another

capability is that you can specify that portions of the RE must be repeated a certain number of times.

The first metacharacter for repeating things that we'll look at is `*`. `*` doesn't match the literal character `*`; instead, it specifies that the previous character can be matched zero or more times, instead of exactly once.

For example, `ca*t` will match `ct` (0 `a` characters), `cat` (1 `a`), `caaat` (3 `a` characters), and so forth. The RE engine has various internal limitations stemming from the size of C's `int` type that will prevent it from matching over 2 billion `a` characters; you probably don't have enough memory to construct a string that large, so you shouldn't run into that limit.

Repetitions such as `*` are *greedy*; when repeating a RE, the matching engine will try to repeat it as many times as possible. If later portions of the pattern don't match, the matching engine will then back up and try again with few repetitions.

A step-by-step example will make this more obvious. Let's consider the expression `a[bcd]*b`. This matches the letter `'a'`, zero or more letters from the class `[bcd]`, and finally ends with a `'b'`. Now imagine matching this RE against the string `abcdb`.

Step	Matched	Explanation
1	a	The <code>a</code> in the RE matches.
2	abcdb	The engine matches <code>[bcd]*</code> , going as far as it can, which is to the end of the string.
3	<i>Failure</i>	The engine tries to match <code>b</code> , but the current position is at the end of the string, so it fails.
4	abc b	Back up, so that <code>[bcd]*</code> matches one less character.
		Try <code>b</code> again, but the current position is at the

5	<i>Failure</i>	last character, which is a 'd'.
6	abc	Back up again, so that <code>[bcd]*</code> is only matching <code>bc</code> .
6	abcb	Try <code>b</code> again. This time the character at the current position is 'b', so it succeeds.

The end of the RE has now been reached, and it has matched `abcb`. This demonstrates how the matching engine goes as far as it can at first, and if no match is found it will then progressively back up and retry the rest of the RE again and again. It will back up until it has tried zero matches for `[bcd]*`, and if that subsequently fails, the engine will conclude that the string doesn't match the RE at all.

Another repeating metacharacter is `+`, which matches one or more times. Pay careful attention to the difference between `*` and `+`; `*` matches *zero* or more times, so whatever's being repeated may not be present at all, while `+` requires at least *one* occurrence. To use a similar example, `ca+t` will match `cat` (1 `a`), `caaat` (3 `a`'s), but won't match `ct`.

There are two more repeating qualifiers. The question mark character, `?`, matches either once or zero times; you can think of it as marking something as being optional. For example, `home-?brew` matches either `homebrew` or `home-brew`.

The most complicated repeated qualifier is `{m,n}`, where *m* and *n* are decimal integers. This qualifier means there must be at least *m* repetitions, and at most *n*. For example, `a/{1,3}b` will match `a/b`, `a//b`, and `a///b`. It won't match `ab`, which has no slashes, or `a////b`, which has four.

You can omit either *m* or *n*; in that case, a reasonable value is assumed for the missing value. Omitting *m* is interpreted as a lower

limit of 0, while omitting n results in an upper bound of infinity — actually, the upper bound is the 2-billion limit mentioned earlier, but that might as well be infinity.

Readers of a reductionist bent may notice that the three other qualifiers can all be expressed using this notation. $\{0, \}$ is the same as $*$, $\{1, \}$ is equivalent to $+$, and $\{0, 1\}$ is the same as $?$. It's better to use $*$, $+$, or $?$ when you can, simply because they're shorter and easier to read.

Using Regular Expressions

Now that we've looked at some simple regular expressions, how do we actually use them in Python? The `re` module provides an interface to the regular expression engine, allowing you to compile REs into objects and then perform matches with them.

Compiling Regular Expressions

Regular expressions are compiled into pattern objects, which have methods for various operations such as searching for pattern matches or performing string substitutions.

```
>>> import re
>>> p = re.compile('ab*')
>>> p
<_sre.SRE_Pattern object at 0x...>
```

`re.compile()` also accepts an optional *flags* argument, used to enable various special features and syntax variations. We'll go over the available settings later, but for now a single example will do:

```
>>> p = re.compile('ab*', re.IGNORECASE)
```

The RE is passed to `re.compile()` as a string. REs are handled as strings because regular expressions aren't part of the core Python language, and no special syntax was created for expressing them. (There are applications that don't need REs at all, so there's no need to bloat the language specification by including them.) Instead, the `re` module is simply a C extension module included with Python, just like the `socket` or `zlib` modules.

Putting REs in strings keeps the Python language simpler, but has one disadvantage which is the topic of the next section.

The Backslash Plague

As stated earlier, regular expressions use the backslash character (`'\'`) to indicate special forms or to allow special characters to be used without invoking their special meaning. This conflicts with Python's usage of the same character for the same purpose in string literals.

Let's say you want to write a RE that matches the string `\section`, which might be found in a LaTeX file. To figure out what to write in the program code, start with the desired string to be matched. Next, you must escape any backslashes and other metacharacters by preceding them with a backslash, resulting in the string `\\section`. The resulting string that must be passed to `re.compile()` must be `\\section`. However, to express this as a Python string literal, both backslashes must be escaped *again*.

Characters	Stage
<code>\section</code>	Text string to be matched
<code>\\section</code>	Escaped backslash for <code>re.compile()</code>
<code>"\\\\"section"</code>	Escaped backslashes for a string literal

In short, to match a literal backslash, one has to write `'\\\\"'` as the RE string, because the regular expression must be `\\`, and each backslash must be expressed as `\\` inside a regular Python string literal. In REs that feature backslashes repeatedly, this leads to lots of repeated backslashes and makes the resulting strings difficult to understand.

The solution is to use Python's raw string notation for regular expressions; backslashes are not handled in any special way in a string literal prefixed with `'r'`, so `r"\n"` is a two-character string

containing `'\'` and `'n'`, while `"\n"` is a one-character string containing a newline. Regular expressions will often be written in Python code using this raw string notation.

Regular String	Raw string
<code>"ab*"</code>	<code>r"ab*"</code>
<code>"\\section"</code>	<code>r"\\section"</code>
<code>"\\w+\\s+\\1"</code>	<code>r"\\w+\\s+\\1"</code>

Performing Matches

Once you have an object representing a compiled regular expression, what do you do with it? Pattern objects have several methods and attributes. Only the most significant ones will be covered here; consult the [re docs](#) for a complete listing.

Method/Attribute	Purpose
<code>match()</code>	Determine if the RE matches at the beginning of the string.
<code>search()</code>	Scan through a string, looking for any location where this RE matches.
<code>findall()</code>	Find all substrings where the RE matches, and returns them as a list.
<code>finditer()</code>	Find all substrings where the RE matches, and returns them as an <i>iterator</i> .

`match()` and `search()` return `None` if no match can be found. If they're successful, a `MatchObject` instance is returned, containing information about the match: where it starts and ends, the substring it matched, and more.

You can learn about this by interactively experimenting with the [re module](#). If you have `tkinter` available, you may also want to look at `Tools/demo/redemo.py`, a demonstration program included with the

Python distribution. It allows you to enter REs and strings, and displays whether the RE matches or fails. `redemo.py` can be quite useful when trying to debug a complicated RE. Phil Schwartz's [Kodos](#) is also an interactive tool for developing and testing RE patterns.

This HOWTO uses the standard Python interpreter for its examples. First, run the Python interpreter, import the `re` module, and compile a RE:

```
>>> import re
>>> p = re.compile('[a-z]+')
>>> p
<_sre.SRE_Pattern object at 0x...>
```

Now, you can try matching various strings against the RE `[a-z]+`. An empty string shouldn't match at all, since `+` means 'one or more repetitions'. `match()` should return `None` in this case, which will cause the interpreter to print no output. You can explicitly print the result of `match()` to make this clear.

```
>>> p.match("")
>>> print(p.match(""))
None
```

Now, let's try it on a string that it should match, such as `tempo`. In this case, `match()` will return a `MatchObject`, so you should store the result in a variable for later use.

```
>>> m = p.match('tempo')
>>> m
<_sre.SRE_Match object at 0x...>
```

Now you can query the `MatchObject` for information about the matching string. `MatchObject` instances also have several methods and attributes; the most important ones are:

Method/Attribute	Purpose
group()	Return the string matched by the RE
start()	Return the starting position of the match
end()	Return the ending position of the match
span()	Return a tuple containing the (start, end) positions of the match

Trying these methods will soon clarify their meaning:

```
>>> m.group()
'tempo'
>>> m.start(), m.end()
(0, 5)
>>> m.span()
(0, 5)
```

group() returns the substring that was matched by the RE. **start()** and **end()** return the starting and ending index of the match. **span()** returns both start and end indexes in a single tuple. Since the **match()** method only checks if the RE matches at the start of a string, **start()** will always be zero. However, the **search()** method of patterns scans through the string, so the match may not start at zero in that case.

```
>>> print(p.match('::: message'))
None
>>> m = p.search('::: message') ; print(m)
<_sre.SRE_Match object at 0x...>
>>> m.group()
'message'
>>> m.span()
(4, 11)
```

In actual programs, the most common style is to store the **MatchObject** in a variable, and then check if it was **None**. This usually looks like:

```
p = re.compile( ... )
```

```
m = p.match( 'string goes here' )
if m:
    print('Match found: ', m.group())
else:
    print('No match')
```

Two pattern methods return all of the matches for a pattern. `findall()` returns a list of matching strings:

```
>>> p = re.compile('\d+')
>>> p.findall('12 drummers drumming, 11 pipers piping, 10 lords
['12', '11', '10']
```

`findall()` has to create the entire list before it can be returned as the result. The `finditer()` method returns a sequence of `MatchObject` instances as an *iterator*:

```
>>> iterator = p.finditer('12 drummers drumming, 11 ... 10 ...')
>>> iterator
<callable_iterator object at 0x...>
>>> for match in iterator:
...     print(match.span())
...
(0, 2)
(22, 24)
(29, 31)
```

Module-Level Functions

You don't have to create a pattern object and call its methods; the `re` module also provides top-level functions called `match()`, `search()`, `findall()`, `sub()`, and so forth. These functions take the same arguments as the corresponding pattern method, with the RE string added as the first argument, and still return either `None` or a `MatchObject` instance.

```
>>> print(re.match(r'From\s+', 'Fromage amk'))
None
>>> re.match(r'From\s+', 'From amk Thu May 14 19:12:10 1998')
<_sre.SRE_Match object at 0x...>
```

Under the hood, these functions simply create a pattern object for you and call the appropriate method on it. They also store the compiled object in a cache, so future calls using the same RE are faster.

Should you use these module-level functions, or should you get the pattern and call its methods yourself? That choice depends on how frequently the RE will be used, and on your personal coding style. If the RE is being used at only one point in the code, then the module functions are probably more convenient. If a program contains a lot of regular expressions, or re-uses the same ones in several locations, then it might be worthwhile to collect all the definitions in one place, in a section of code that compiles all the REs ahead of time. To take an example from the standard library, here's an extract from the now deprecated `xml1lib.py`:

```
ref = re.compile( ... )
entityref = re.compile( ... )
charref = re.compile( ... )
starttagopen = re.compile( ... )
```

I generally prefer to work with the compiled object, even for one-time uses, but few people will be as much of a purist about this as I am.

Compilation Flags

Compilation flags let you modify some aspects of how regular expressions work. Flags are available in the `re` module under two names, a long name such as `IGNORECASE` and a short, one-letter form such as `I`. (If you're familiar with Perl's pattern modifiers, the one-letter forms use the same letters; the short form of `re.VERBOSE` is

`re.X`, for example.) Multiple flags can be specified by bitwise OR-ing them; `re.I | re.M` sets both the `I` and `M` flags, for example.

Here's a table of the available flags, followed by a more detailed explanation of each one.

Flag	Meaning
<code>DOTALL, S</code>	Make <code>.</code> match any character, including newlines
<code>IGNORECASE, I</code>	Do case-insensitive matches
<code>LOCALE, L</code>	Do a locale-aware match
<code>MULTILINE, M</code>	Multi-line matching, affecting <code>^</code> and <code>\$</code>
<code>VERBOSE, X</code>	Enable verbose REs, which can be organized more cleanly and understandably.
<code>ASCII, A</code>	Makes several escapes like <code>\w</code> , <code>\b</code> , <code>\s</code> and <code>\d</code> match only on ASCII characters with the respective property.

I

IGNORECASE

Perform case-insensitive matching; character class and literal strings will match letters by ignoring case. For example, `[A-Z]` will match lowercase letters, too, and `spam` will match `spam`, `spam`, or `spAM`. This lowercasing doesn't take the current locale into account; it will if you also set the `LOCALE` flag.

L

LOCALE

Make `\w`, `\W`, `\b`, and `\B`, dependent on the current locale.

Locales are a feature of the C library intended to help in writing programs that take account of language differences. For example, if you're processing French text, you'd want to be able

to write `\w+` to match words, but `\w` only matches the character class `[A-Za-z]`; it won't match `'é'` or `'ç'`. If your system is configured properly and a French locale is selected, certain C functions will tell the program that `'é'` should also be considered a letter. Setting the `LOCALE` flag when compiling a regular expression will cause the resulting compiled object to use these C functions for `\w`; this is slower, but also enables `\w+` to match French words as you'd expect.

M

MULTILINE

(`^` and `$` haven't been explained yet; they'll be introduced in section [More Metacharacters](#).)

Usually `^` matches only at the beginning of the string, and `$` matches only at the end of the string and immediately before the newline (if any) at the end of the string. When this flag is specified, `^` matches at the beginning of the string and at the beginning of each line within the string, immediately following each newline. Similarly, the `$` metacharacter matches either at the end of the string and at the end of each line (immediately preceding each newline).

S

DOTALL

Makes the `'.'` special character match any character at all, including a newline; without this flag, `'.'` will match anything *except* a newline.

A

ASCII

Make `\w`, `\W`, `\b`, `\B`, `\s` and `\S` perform ASCII-only matching instead of full Unicode matching. This is only meaningful for Unicode patterns, and is ignored for byte patterns.

X

VERBOSE

This flag allows you to write regular expressions that are more readable by granting you more flexibility in how you can format them. When this flag has been specified, whitespace within the RE string is ignored, except when the whitespace is in a character class or preceded by an unescaped backslash; this lets you organize and indent the RE more clearly. This flag also lets you put comments within a RE that will be ignored by the engine; comments are marked by a '#' that's neither in a character class or preceded by an unescaped backslash.

For example, here's a RE that uses `re.VERBOSE`; see how much easier it is to read?

```
charref = re.compile(r"""
    &[#]           # Start of a numeric entity reference
    (
        0[0-7]+   # Octal form
        | [0-9]+   # Decimal form
        | x[0-9a-fA-F]+ # Hexadecimal form
    )
    ;             # Trailing semicolon
""", re.VERBOSE)
```

Without the verbose setting, the RE would look like this:

```
charref = re.compile("&#(0[0-7]+"
                    "|[0-9]+"
                    "|x[0-9a-fA-F]+);")
```

In the above example, Python's automatic concatenation of string literals has been used to break up the RE into smaller pieces, but it's still more difficult to understand than the version using `re.VERBOSE`.

More Pattern Power

So far we've only covered a part of the features of regular expressions. In this section, we'll cover some new metacharacters, and how to use groups to retrieve portions of the text that was matched.

More Metacharacters

There are some metacharacters that we haven't covered yet. Most of them will be covered in this section.

Some of the remaining metacharacters to be discussed are *zero-width assertions*. They don't cause the engine to advance through the string; instead, they consume no characters at all, and simply succeed or fail. For example, `\b` is an assertion that the current position is located at a word boundary; the position isn't changed by the `\b` at all. This means that zero-width assertions should never be repeated, because if they match once at a given location, they can obviously be matched an infinite number of times.

|

Alternation, or the “or” operator. If A and B are regular expressions, `A|B` will match any string that matches either A or B. `|` has very low precedence in order to make it work reasonably when you're alternating multi-character strings. `crow|servo` will match either `crow` or `servo`, not `cro`, a `'w'` or an `'s'`, and `ervo`.

To match a literal `'|'`, use `\|`, or enclose it inside a character class, as in `[|]`.

^

Matches at the beginning of lines. Unless the **MULTILINE** flag has

been set, this will only match at the beginning of the string. In **MULTILINE** mode, this also matches immediately after each newline within the string.

For example, if you wish to match the word `From` only at the beginning of a line, the RE to use is `^From`.

```
>>> print(re.search('^From', 'From Here to Eternity'))
<_sre.SRE_Match object at 0x...>
>>> print(re.search('^From', 'Reciting From Memory'))
None
```

`$`

Matches at the end of a line, which is defined as either the end of the string, or any location followed by a newline character.

```
>>> print(re.search('}$', '{block}'))
<_sre.SRE_Match object at 0x...>
>>> print(re.search('}$', '{block} '))
None
>>> print(re.search('}$', '{block}\n'))
<_sre.SRE_Match object at 0x...>
```

To match a literal `'$'`, use `\$` or enclose it inside a character class, as in `[$]`.

`\A`

Matches only at the start of the string. When not in **MULTILINE** mode, `\A` and `^` are effectively the same. In **MULTILINE** mode, they're different: `\A` still matches only at the beginning of the string, but `^` may match at any location inside the string that follows a newline character.

`\Z`

Matches only at the end of the string.

`\b`

Word boundary. This is a zero-width assertion that matches only at the beginning or end of a word. A word is defined as a

sequence of alphanumeric characters, so the end of a word is indicated by whitespace or a non-alphanumeric character.

The following example matches `class` only when it's a complete word; it won't match when it's contained inside another word.

```
>>> p = re.compile(r'\bclass\b')
>>> print(p.search('no class at all'))
<_sre.SRE_Match object at 0x...>
>>> print(p.search('the declassified algorithm'))
None
>>> print(p.search('one subclass is'))
None
```

There are two subtleties you should remember when using this special sequence. First, this is the worst collision between Python's string literals and regular expression sequences. In Python's string literals, `\b` is the backspace character, ASCII value 8. If you're not using raw strings, then Python will convert the `\b` to a backspace, and your RE won't match as you expect it to. The following example looks the same as our previous RE, but omits the `'r'` in front of the RE string.

```
>>> p = re.compile('\bclass\b')
>>> print(p.search('no class at all'))
None
>>> print(p.search('\b' + 'class' + '\b') )
<_sre.SRE_Match object at 0x...>
```

Second, inside a character class, where there's no use for this assertion, `\b` represents the backspace character, for compatibility with Python's string literals.

`\B`

Another zero-width assertion, this is the opposite of `\b`, only matching when the current position is not at a word boundary.

Grouping

Frequently you need to obtain more information than just whether the RE matched or not. Regular expressions are often used to dissect strings by writing a RE divided into several subgroups which match different components of interest. For example, an RFC-822 header line is divided into a header name and a value, separated by a ':', like this:

```
From: author@example.com
User-Agent: Thunderbird 1.5.0.9 (X11/20061227)
MIME-Version: 1.0
To: editor@example.com
```

This can be handled by writing a regular expression which matches an entire header line, and has one group which matches the header name, and another group which matches the header's value.

Groups are marked by the '(' and ')' metacharacters. '(' and ')' have much the same meaning as they do in mathematical expressions; they group together the expressions contained inside them, and you can repeat the contents of a group with a repeating qualifier, such as *, +, ?, or {m,n}. For example, (ab)* will match zero or more repetitions of ab.

```
>>> p = re.compile('(ab)*')
>>> print(p.match('ababababab').span())
(0, 10)
```

Groups indicated with '(' and ')' also capture the starting and ending index of the text that they match; this can be retrieved by passing an argument to `group()`, `start()`, `end()`, and `span()`. Groups are numbered starting with 0. Group 0 is always present; it's the whole RE, so `MatchObject` methods all have group 0 as their default argument. Later we'll see how to express groups that don't capture

the span of text that they match.

```
>>> p = re.compile('(a)b')
>>> m = p.match('ab')
>>> m.group()
'ab'
>>> m.group(0)
'ab'
```

Subgroups are numbered from left to right, from 1 upward. Groups can be nested; to determine the number, just count the opening parenthesis characters, going from left to right.

```
>>> p = re.compile('(a(b)c)d')
>>> m = p.match('abcd')
>>> m.group(0)
'abcd'
>>> m.group(1)
'abc'
>>> m.group(2)
'b'
```

group() can be passed multiple group numbers at a time, in which case it will return a tuple containing the corresponding values for those groups.

```
>>> m.group(2,1,2)
('b', 'abc', 'b')
```

The **groups()** method returns a tuple containing the strings for all the subgroups, from 1 up to however many there are.

```
>>> m.groups()
('abc', 'b')
```

Backreferences in a pattern allow you to specify that the contents of an earlier capturing group must also be found at the current location in the string. For example, `\1` will succeed if the exact contents of group 1 can be found at the current position, and fails otherwise.

Remember that Python's string literals also use a backslash followed by numbers to allow including arbitrary characters in a string, so be sure to use a raw string when incorporating backreferences in a RE.

For example, the following RE detects doubled words in a string.

```
>>> p = re.compile(r'(\b\w+)\s+\1')
>>> p.search('Paris in the the spring').group()
'the the'
```

Backreferences like this aren't often useful for just searching through a string — there are few text formats which repeat data in this way — but you'll soon find out that they're *very* useful when performing string substitutions.

Non-capturing and Named Groups

Elaborate REs may use many groups, both to capture substrings of interest, and to group and structure the RE itself. In complex REs, it becomes difficult to keep track of the group numbers. There are two features which help with this problem. Both of them use a common syntax for regular expression extensions, so we'll look at that first.

Perl 5 added several additional features to standard regular expressions, and the Python `re` module supports most of them. It would have been difficult to choose new single-keystroke metacharacters or new special sequences beginning with `\` to represent the new features without making Perl's regular expressions confusingly different from standard REs. If you chose `&` as a new metacharacter, for example, old expressions would be assuming that `&` was a regular character and wouldn't have escaped it by writing `\&` or `[&]`.

The solution chosen by the Perl developers was to use `(?...)` as the extension syntax. `?` immediately after a parenthesis was a syntax

error because the `?` would have nothing to repeat, so this didn't introduce any compatibility problems. The characters immediately after the `?` indicate what extension is being used, so `(?=foo)` is one thing (a positive lookahead assertion) and `(?:foo)` is something else (a non-capturing group containing the subexpression `foo`).

Python adds an extension syntax to Perl's extension syntax. If the first character after the question mark is a `P`, you know that it's an extension that's specific to Python. Currently there are two such extensions: `(?P<name>...)` defines a named group, and `(?P=name)` is a backreference to a named group. If future versions of Perl 5 add similar features using a different syntax, the `re` module will be changed to support the new syntax, while preserving the Python-specific syntax for compatibility's sake.

Now that we've looked at the general extension syntax, we can return to the features that simplify working with groups in complex REs. Since groups are numbered from left to right and a complex expression may use many groups, it can become difficult to keep track of the correct numbering. Modifying such a complex RE is annoying, too: insert a new group near the beginning and you change the numbers of everything that follows it.

Sometimes you'll want to use a group to collect a part of a regular expression, but aren't interested in retrieving the group's contents. You can make this fact explicit by using a non-capturing group: `(?:...)`, where you can replace the `...` with any other regular expression.

```
>>> m = re.match("[abc]+", "abc")
>>> m.groups()
('c',)
>>> m = re.match("(?:[abc])+", "abc")
>>> m.groups()
()
```

Except for the fact that you can't retrieve the contents of what the group matched, a non-capturing group behaves exactly the same as a capturing group; you can put anything inside it, repeat it with a repetition metacharacter such as `*`, and nest it within other groups (capturing or non-capturing). `(?:...)` is particularly useful when modifying an existing pattern, since you can add new groups without changing how all the other groups are numbered. It should be mentioned that there's no performance difference in searching between capturing and non-capturing groups; neither form is any faster than the other.

A more significant feature is named groups: instead of referring to them by numbers, groups can be referenced by a name.

The syntax for a named group is one of the Python-specific extensions: `(?P<name>...)`. *name* is, obviously, the name of the group. Named groups also behave exactly like capturing groups, and additionally associate a name with a group. The `MatchObject` methods that deal with capturing groups all accept either integers that refer to the group by number or strings that contain the desired group's name. Named groups are still given numbers, so you can retrieve information about a group in two ways:

```
>>> p = re.compile(r'(?P<word>\b\w+\b)')
>>> m = p.search( '(((( Lots of punctuation )))' )
>>> m.group('word')
'Lots'
>>> m.group(1)
'Lots'
```

Named groups are handy because they let you use easily-remembered names, instead of having to remember numbers. Here's an example RE from the `imaplib` module:

```
InternalDate = re.compile(r'INTERNALDATE "'
                          r'(?P<day>[ 123][0-9])-(?P<mon>[A-Z][a-z][a-z])-
```

```
r'(?P<year>[0-9][0-9][0-9][0-9])'  
r' (?P<hour>[0-9][0-9]):(?P<min>[0-9][0-9]):(?P<sec>[0-9-  
r' (?P<zonen>[-+])(?P<zoneh>[0-9][0-9])(?P<zonem>[0-9][  
r''')
```

It's obviously much easier to retrieve `m.group('zonem')`, instead of having to remember to retrieve group 9.

The syntax for backreferences in an expression such as `(...)\1` refers to the number of the group. There's naturally a variant that uses the group name instead of the number. This is another Python extension: `(?P=name)` indicates that the contents of the group called *name* should again be matched at the current point. The regular expression for finding doubled words, `(\b\w+)\s+\1` can also be written as `(?P<word>\b\w+)\s+(?P=word)`:

```
>>> p = re.compile(r'(?P<word>\b\w+)\s+(?P=word)')  
>>> p.search('Paris in the the spring').group()  
'the the'
```

Lookahead Assertions

Another zero-width assertion is the lookahead assertion. Lookahead assertions are available in both positive and negative form, and look like this:

`(?=...)`

Positive lookahead assertion. This succeeds if the contained regular expression, represented here by `...`, successfully matches at the current location, and fails otherwise. But, once the contained expression has been tried, the matching engine doesn't advance at all; the rest of the pattern is tried right where the assertion started.

`(?!...)`

Negative lookahead assertion. This is the opposite of the positive

assertion; it succeeds if the contained expression *doesn't* match at the current position in the string.

To make this concrete, let's look at a case where a lookahead is useful. Consider a simple pattern to match a filename and split it apart into a base name and an extension, separated by a `.`. For example, in `news.rc`, `news` is the base name, and `rc` is the filename's extension.

The pattern to match this is quite simple:

```
.*[.].*$
```

Notice that the `.` needs to be treated specially because it's a metacharacter; I've put it inside a character class. Also notice the trailing `$`; this is added to ensure that all the rest of the string must be included in the extension. This regular expression matches `foo.bar` and `autoexec.bat` and `sendmail.cf` and `printers.conf`.

Now, consider complicating the problem a bit; what if you want to match filenames where the extension is not `bat`? Some incorrect attempts:

```
.*[.][^b].*$
```

 The first attempt above tries to exclude `bat` by requiring that the first character of the extension is not a `b`. This is wrong, because the pattern also doesn't match `foo.bar`.

```
.*[.](^[^b].|.^[^a].|..^[^t])$
```

The expression gets messier when you try to patch up the first solution by requiring one of the following cases to match: the first character of the extension isn't `b`; the second character isn't `a`; or the third character isn't `t`. This accepts `foo.bar` and rejects `autoexec.bat`, but it requires a three-letter extension and won't

accept a filename with a two-letter extension such as `sendmail.cf`. We'll complicate the pattern again in an effort to fix it.

```
.*[.](^[^b].?|^[^a].?|^[^t].?)$
```

In the third attempt, the second and third letters are all made optional in order to allow matching extensions shorter than three characters, such as `sendmail.cf`.

The pattern's getting really complicated now, which makes it hard to read and understand. Worse, if the problem changes and you want to exclude both `bat` and `exe` as extensions, the pattern would get even more complicated and confusing.

A negative lookahead cuts through all this confusion:

```
.*[.](?!bat$).*$
```

The negative lookahead means: if the expression `bat` doesn't match at this point, try the rest of the pattern; if `bat$` does match, the whole pattern will fail. The trailing `$` is required to ensure that something like `sample.batch`, where the extension only starts with `bat`, will be allowed.

Excluding another filename extension is now easy; simply add it as an alternative inside the assertion. The following pattern excludes filenames that end in either `bat` or `exe`:

```
.*[.](?!bat$|exe$).*$
```

Modifying Strings

Up to this point, we've simply performed searches against a static string. Regular expressions are also commonly used to modify strings in various ways, using the following pattern methods:

Method/Attribute	Purpose
<code>split()</code>	Split the string into a list, splitting it wherever the RE matches
<code>sub()</code>	Find all substrings where the RE matches, and replace them with a different string
<code>subn()</code>	Does the same thing as <code>sub()</code> , but returns the new string and the number of replacements

Splitting Strings

The `split()` method of a pattern splits a string apart wherever the RE matches, returning a list of the pieces. It's similar to the `split()` method of strings but provides much more generality in the delimiters that you can split by; `split()` only supports splitting by whitespace or by a fixed string. As you'd expect, there's a module-level `re.split()` function, too.

`.split(string[, maxsplit=0])`

Split *string* by the matches of the regular expression. If capturing parentheses are used in the RE, then their contents will also be returned as part of the resulting list. If *maxsplit* is nonzero, at most *maxsplit* splits are performed.

You can limit the number of splits made, by passing a value for *maxsplit*. When *maxsplit* is nonzero, at most *maxsplit* splits will be made, and the remainder of the string is returned as the final element of the list. In the following example, the delimiter is any

sequence of non-alphanumeric characters.

```
>>> p = re.compile(r'\W+')
>>> p.split('This is a test, short and sweet, of split().')
['This', 'is', 'a', 'test', 'short', 'and', 'sweet', 'of', 'spl
>>> p.split('This is a test, short and sweet, of split().', 3)
['This', 'is', 'a', 'test, short and sweet, of split().']
```

Sometimes you're not only interested in what the text between delimiters is, but also need to know what the delimiter was. If capturing parentheses are used in the RE, then their values are also returned as part of the list. Compare the following calls:

```
>>> p = re.compile(r'\W+')
>>> p2 = re.compile(r'(\W+)')
>>> p.split('This... is a test.')
['This', 'is', 'a', 'test', '']
>>> p2.split('This... is a test.')
['This', '...', 'is', ' ', 'a', ' ', 'test', '.', '']
```

The module-level function `re.split()` adds the RE to be used as the first argument, but is otherwise the same.

```
>>> re.split('[\W]+', 'Words, words, words.')
['Words', 'words', 'words', '']
>>> re.split('([\W]+)', 'Words, words, words.')
['Words', ',', ' ', 'words', ',', ' ', 'words', '.', '']
>>> re.split('[\W]+', 'Words, words, words.', 1)
['Words', 'words, words.']
```

Search and Replace

Another common task is to find all the matches for a pattern, and replace them with a different string. The `sub()` method takes a replacement value, which can be either a string or a function, and the string to be processed.

```
. sub(replacement, string[, count=0])
```

Returns the string obtained by replacing the leftmost non-overlapping occurrences of the RE in *string* by the replacement *replacement*. If the pattern isn't found, *string* is returned unchanged.

The optional argument *count* is the maximum number of pattern occurrences to be replaced; *count* must be a non-negative integer. The default value of 0 means to replace all occurrences.

Here's a simple example of using the `sub()` method. It replaces colour names with the word `colour`:

```
>>> p = re.compile( '(blue|white|red)')
>>> p.sub( 'colour', 'blue socks and red shoes')
'colour socks and colour shoes'
>>> p.sub( 'colour', 'blue socks and red shoes', count=1)
'colour socks and red shoes'
```

The `subn()` method does the same work, but returns a 2-tuple containing the new string value and the number of replacements that were performed:

```
>>> p = re.compile( '(blue|white|red)')
>>> p.subn( 'colour', 'blue socks and red shoes')
('colour socks and colour shoes', 2)
>>> p.subn( 'colour', 'no colours at all')
('no colours at all', 0)
```

Empty matches are replaced only when they're not adjacent to a previous match.

```
>>> p = re.compile('x*')
>>> p.sub('-', 'abxd')
'-a-b-d-'
```

If *replacement* is a string, any backslash escapes in it are processed. That is, `\n` is converted to a single newline character, `\r` is converted

to a carriage return, and so forth. Unknown escapes such as `\j` are left alone. Backreferences, such as `\6`, are replaced with the substring matched by the corresponding group in the RE. This lets you incorporate portions of the original text in the resulting replacement string.

This example matches the word `section` followed by a string enclosed in `{, }`, and changes `section` to `subsection`:

```
>>> p = re.compile('section{ ( [^}]* ) }', re.VERBOSE)
>>> p.sub(r'subsection{\1}', 'section{First} section{second}')
'subsection{First} subsection{second}'
```

There's also a syntax for referring to named groups as defined by the `(?P<name>...)` syntax. `\g<name>` will use the substring matched by the group named `name`, and `\g<number>` uses the corresponding group number. `\g<2>` is therefore equivalent to `\2`, but isn't ambiguous in a replacement string such as `\g<2>0`. (`\20` would be interpreted as a reference to group 20, not a reference to group 2 followed by the literal character `'0'`.) The following substitutions are all equivalent, but use all three variations of the replacement string.

```
>>> p = re.compile('section{ (?P<name> [^}]* ) }', re.VERBOSE)
>>> p.sub(r'subsection{\1}', 'section{First}')
'subsection{First}'
>>> p.sub(r'subsection{\g<1>}', 'section{First}')
'subsection{First}'
>>> p.sub(r'subsection{\g<name>}', 'section{First}')
'subsection{First}'
```

replacement can also be a function, which gives you even more control. If *replacement* is a function, the function is called for every non-overlapping occurrence of *pattern*. On each call, the function is passed a `MatchObject` argument for the match and can use this information to compute the desired replacement string and return it.

In the following example, the replacement function translates decimals into hexadecimal:

```
>>> def hexrepl( match ):
...     "Return the hex string for a decimal number"
...     value = int( match.group() )
...     return hex(value)
...
>>> p = re.compile(r'\d+')
>>> p.sub(hexrepl, 'Call 65490 for printing, 49152 for user cod
'Call 0xffd2 for printing, 0xc000 for user code.'
```

When using the module-level `re.sub()` function, the pattern is passed as the first argument. The pattern may be provided as an object or as a string; if you need to specify regular expression flags, you must either use a pattern object as the first parameter, or use embedded modifiers in the pattern string, e.g. `sub("(?i)b+", "x", "bbbb BBBB")` returns `'x x'`.

Common Problems

Regular expressions are a powerful tool for some applications, but in some ways their behaviour isn't intuitive and at times they don't behave the way you may expect them to. This section will point out some of the most common pitfalls.

Use String Methods

Sometimes using the `re` module is a mistake. If you're matching a fixed string, or a single character class, and you're not using any `re` features such as the `IGNORECASE` flag, then the full power of regular expressions may not be required. Strings have several methods for performing operations with fixed strings and they're usually much faster, because the implementation is a single small C loop that's been optimized for the purpose, instead of the large, more generalized regular expression engine.

One example might be replacing a single fixed string with another one; for example, you might replace `word` with `deed`. `re.sub()` seems like the function to use for this, but consider the `replace()` method. Note that `replace()` will also replace `word` inside words, turning `swordfish` into `sdeedfish`, but the naive RE `word` would have done that, too. (To avoid performing the substitution on parts of words, the pattern would have to be `\bword\b`, in order to require that `word` have a word boundary on either side. This takes the job beyond `replace()`'s abilities.)

Another common task is deleting every occurrence of a single character from a string or replacing it with another single character. You might do this with something like `re.sub('\n', ' ', s)`, but `translate()` is capable of doing both tasks and will be faster than

any regular expression operation can be.

In short, before turning to the `re` module, consider whether your problem can be solved with a faster and simpler string method.

match() versus search()

The `match()` function only checks if the RE matches at the beginning of the string while `search()` will scan forward through the string for a match. It's important to keep this distinction in mind. Remember, `match()` will only report a successful match which will start at 0; if the match wouldn't start at zero, `match()` will *not* report it.

```
>>> print(re.match('super', 'superstition').span())
(0, 5)
>>> print(re.match('super', 'insuperable'))
None
```

On the other hand, `search()` will scan forward through the string, reporting the first match it finds.

```
>>> print(re.search('super', 'superstition').span())
(0, 5)
>>> print(re.search('super', 'insuperable').span())
(2, 7)
```

Sometimes you'll be tempted to keep using `re.match()`, and just add `.*` to the front of your RE. Resist this temptation and use `re.search()` instead. The regular expression compiler does some analysis of REs in order to speed up the process of looking for a match. One such analysis figures out what the first character of a match must be; for example, a pattern starting with `crow` must match starting with a `'c'`. The analysis lets the engine quickly scan through the string looking for the starting character, only trying the full match if a `'c'` is found.

Adding `.*` defeats this optimization, requiring scanning to the end of the string and then backtracking to find a match for the rest of the RE. Use `re.search()` instead.

Greedy versus Non-Greedy

When repeating a regular expression, as in `a*`, the resulting action is to consume as much of the pattern as possible. This fact often bites you when you're trying to match a pair of balanced delimiters, such as the angle brackets surrounding an HTML tag. The naive pattern for matching a single HTML tag doesn't work because of the greedy nature of `.*`.

```
>>> s = '<html><head><title>Title</title>'
>>> len(s)
32
>>> print(re.match('<.*>', s).span())
(0, 32)
>>> print(re.match('<.*>', s).group())
<html><head><title>Title</title>
```

The RE matches the `'<'` in `<html>`, and the `.*` consumes the rest of the string. There's still more left in the RE, though, and the `>` can't match at the end of the string, so the regular expression engine has to backtrack character by character until it finds a match for the `>`. The final match extends from the `'<'` in `<html>` to the `'>'` in `</title>`, which isn't what you want.

In this case, the solution is to use the non-greedy qualifiers `*?`, `+?`, `??`, or `{m,n}?`, which match as *little* text as possible. In the above example, the `'>'` is tried immediately after the first `'<'` matches, and when it fails, the engine advances a character at a time, retrying the `'>'` at every step. This produces just the right result:

```
>>> print(re.match('<.*?>', s).group())
```

```
<html>
```

(Note that parsing HTML or XML with regular expressions is painful. Quick-and-dirty patterns will handle common cases, but HTML and XML have special cases that will break the obvious regular expression; by the time you've written a regular expression that handles all of the possible cases, the patterns will be very complicated. Use an HTML or XML parser module for such tasks.)

Using `re.VERBOSE`

By now you've probably noticed that regular expressions are a very compact notation, but they're not terribly readable. REs of moderate complexity can become lengthy collections of backslashes, parentheses, and metacharacters, making them difficult to read and understand.

For such REs, specifying the `re.VERBOSE` flag when compiling the regular expression can be helpful, because it allows you to format the regular expression more clearly.

The `re.VERBOSE` flag has several effects. Whitespace in the regular expression that *isn't* inside a character class is ignored. This means that an expression such as `dog | cat` is equivalent to the less readable `dog|cat`, but `[a b]` will still match the characters 'a', 'b', or a space. In addition, you can also put comments inside a RE; comments extend from a `#` character to the next newline. When used with triple-quoted strings, this enables REs to be formatted more neatly:

```
pat = re.compile(r"""
\s*           # Skip leading whitespace
(?:P<header>[^\:]+) # Header name
\s* :        # Whitespace, and a colon
(?:P<value>.*) # The header's value -- *? used to
               # lose the following trailing whitespace
```

```
\s*$           # Trailing whitespace to end-of-line  
""", re.VERBOSE)
```

This is far more readable than:

```
pat = re.compile(r"\s*(?P<header>[^:]+)\s*:(?P<value>.*?)\s*$")
```

Feedback

Regular expressions are a complicated topic. Did this document help you understand them? Were there parts that were unclear, or problems you encountered that weren't covered here? If so, please send suggestions for improvements to the author.

The most complete book on regular expressions is almost certainly Jeffrey Friedl's *Mastering Regular Expressions*, published by O'Reilly. Unfortunately, it exclusively concentrates on Perl and Java's flavours of regular expressions, and doesn't contain any Python material at all, so it won't be useful as a reference for programming in Python. (The first edition covered Python's now-removed `regex` module, which won't help you much.) Consider checking it out from your library.

Socket Programming HOWTO

Author: Gordon McMillan

Abstract

Sockets are used nearly everywhere, but are one of the most severely misunderstood technologies around. This is a 10,000 foot overview of sockets. It's not really a tutorial - you'll still have work to do in getting things operational. It doesn't cover the fine points (and there are a lot of them), but I hope it will give you enough background to begin using them decently.

Sockets

Sockets are used nearly everywhere, but are one of the most severely misunderstood technologies around. This is a 10,000 foot overview of sockets. It's not really a tutorial - you'll still have work to do in getting things working. It doesn't cover the fine points (and there are a lot of them), but I hope it will give you enough background to begin using them decently.

I'm only going to talk about INET sockets, but they account for at least 99% of the sockets in use. And I'll only talk about STREAM sockets - unless you really know what you're doing (in which case this HOWTO isn't for you!), you'll get better behavior and performance from a STREAM socket than anything else. I will try to clear up the mystery of what a socket is, as well as some hints on how to work with blocking and non-blocking sockets. But I'll start by talking about blocking sockets. You'll need to know how they work before dealing with non-blocking sockets.

Part of the trouble with understanding these things is that "socket" can mean a number of subtly different things, depending on context. So first, let's make a distinction between a "client" socket - an endpoint of a conversation, and a "server" socket, which is more like a switchboard operator. The client application (your browser, for example) uses "client" sockets exclusively; the web server it's talking to uses both "server" sockets and "client" sockets.

History

Of the various forms of IPC (*Inter Process Communication*), sockets are by far the most popular. On any given platform, there are likely to be other forms of IPC that are faster, but for cross-platform communication, sockets are about the only game in town.

They were invented in Berkeley as part of the BSD flavor of Unix. They spread like wildfire with the Internet. With good reason — the combination of sockets with INET makes talking to arbitrary machines around the world unbelievably easy (at least compared to other schemes).

Creating a Socket

Roughly speaking, when you clicked on the link that brought you to this page, your browser did something like the following:

```
#create an INET, STREAMing socket
s = socket.socket(socket.AF_INET, socket.SOCK_STREAM)
#now connect to the web server on port 80
# - the normal http port
s.connect(("www.mcmillan-inc.com", 80))
```

When the `connect` completes, the socket `s` can now be used to send in a request for the text of this page. The same socket will read the reply, and then be destroyed. That's right - destroyed. Client sockets are normally only used for one exchange (or a small set of sequential exchanges).

What happens in the web server is a bit more complex. First, the web server creates a “server socket”.

```
#create an INET, STREAMing socket
serversocket = socket.socket(
    socket.AF_INET, socket.SOCK_STREAM)
#bind the socket to a public host,
# and a well-known port
serversocket.bind((socket.gethostname(), 80))
#become a server socket
serversocket.listen(5)
```

A couple things to notice: we used `socket.gethostname()` so that the socket would be visible to the outside world. If we had used `s.bind('', 80)` or `s.bind('localhost', 80)` or `s.bind('127.0.0.1', 80)` we would still have a “server” socket, but one that was only visible within the same machine.

A second thing to note: low number ports are usually reserved for

“well known” services (HTTP, SNMP etc). If you’re playing around, use a nice high number (4 digits).

Finally, the argument to `listen` tells the socket library that we want it to queue up as many as 5 connect requests (the normal max) before refusing outside connections. If the rest of the code is written properly, that should be plenty.

OK, now we have a “server” socket, listening on port 80. Now we enter the mainloop of the web server:

```
while True:
    #accept connections from outside
    (clientsocket, address) = serversocket.accept()
    #now do something with the clientsocket
    #in this case, we'll pretend this is a threaded server
    ct = client_thread(clientsocket)
    ct.run()
```

There’s actually 3 general ways in which this loop could work - dispatching a thread to handle `clientsocket`, create a new process to handle `clientsocket`, or restructure this app to use non-blocking sockets, and multiplex between our “server” socket and any active `clientsockets` using `select`. More about that later. The important thing to understand now is this: this is *all* a “server” socket does. It doesn’t send any data. It doesn’t receive any data. It just produces “client” sockets. Each `clientsocket` is created in response to some *other* “client” socket doing a `connect()` to the host and port we’re bound to. As soon as we’ve created that `clientsocket`, we go back to listening for more connections. The two “clients” are free to chat it up - they are using some dynamically allocated port which will be recycled when the conversation ends.

IPC

If you need fast IPC between two processes on one machine, you

should look into whatever form of shared memory the platform offers. A simple protocol based around shared memory and locks or semaphores is by far the fastest technique.

If you do decide to use sockets, bind the “server” socket to `'localhost'`. On most platforms, this will take a shortcut around a couple of layers of network code and be quite a bit faster.

Using a Socket

The first thing to note, is that the web browser's "client" socket and the web server's "client" socket are identical beasts. That is, this is a "peer to peer" conversation. Or to put it another way, *as the designer, you will have to decide what the rules of etiquette are for a conversation.* Normally, the `connecting` socket starts the conversation, by sending in a request, or perhaps a signon. But that's a design decision - it's not a rule of sockets.

Now there are two sets of verbs to use for communication. You can use `send` and `recv`, or you can transform your client socket into a file-like beast and use `read` and `write`. The latter is the way Java presents their sockets. I'm not going to talk about it here, except to warn you that you need to use `flush` on sockets. These are buffered "files", and a common mistake is to `write` something, and then `read` for a reply. Without a `flush` in there, you may wait forever for the reply, because the request may still be in your output buffer.

Now we come the major stumbling block of sockets - `send` and `recv` operate on the network buffers. They do not necessarily handle all the bytes you hand them (or expect from them), because their major focus is handling the network buffers. In general, they return when the associated network buffers have been filled (`send`) or emptied (`recv`). They then tell you how many bytes they handled. It is *your* responsibility to call them again until your message has been completely dealt with.

When a `recv` returns 0 bytes, it means the other side has closed (or is in the process of closing) the connection. You will not receive any more data on this connection. Ever. You may be able to send data successfully; I'll talk about that some on the next page.

A protocol like HTTP uses a socket for only one transfer. The client sends a request, then reads a reply. That's it. The socket is discarded. This means that a client can detect the end of the reply by receiving 0 bytes.

But if you plan to reuse your socket for further transfers, you need to realize that *there is no "EOT" (End of Transfer) on a socket*. I repeat: if a socket `send` or `recv` returns after handling 0 bytes, the connection has been broken. If the connection has *not* been broken, you may wait on a `recv` forever, because the socket will *not* tell you that there's nothing more to read (for now). Now if you think about that a bit, you'll come to realize a fundamental truth of sockets: *messages must either be fixed length (yuck), or be delimited (shrug), or indicate how long they are (much better), or end by shutting down the connection*. The choice is entirely yours, (but some ways are righter than others).

Assuming you don't want to end the connection, the simplest solution is a fixed length message:

```
class mysocket:
    """demonstration class only
    - coded for clarity, not efficiency
    """

    def __init__(self, sock=None):
        if sock is None:
            self.sock = socket.socket(
                socket.AF_INET, socket.SOCK_STREAM)
        else:
            self.sock = sock

    def connect(self, host, port):
        self.sock.connect((host, port))

    def mysend(self, msg):
        totalsent = 0
        while totalsent < MSGLEN:
            sent = self.sock.send(msg[totalsent:])
            if sent == 0:
```

```
        raise RuntimeError("socket connection broken")
        totalsent = totalsent + sent

def myreceive(self):
    msg = ''
    while len(msg) < MSGLEN:
        chunk = self.sock.recv(MSGLEN-len(msg))
        if chunk == '':
            raise RuntimeError("socket connection broken")
        msg = msg + chunk
    return msg
```

The sending code here is usable for almost any messaging scheme - in Python you send strings, and you can use `len()` to determine its length (even if it has embedded `\0` characters). It's mostly the receiving code that gets more complex. (And in C, it's not much worse, except you can't use `strlen` if the message has embedded `\0`s.)

The easiest enhancement is to make the first character of the message an indicator of message type, and have the type determine the length. Now you have two `recv`s - the first to get (at least) that first character so you can look up the length, and the second in a loop to get the rest. If you decide to go the delimited route, you'll be receiving in some arbitrary chunk size, (4096 or 8192 is frequently a good match for network buffer sizes), and scanning what you've received for a delimiter.

One complication to be aware of: if your conversational protocol allows multiple messages to be sent back to back (without some kind of reply), and you pass `recv` an arbitrary chunk size, you may end up reading the start of a following message. You'll need to put that aside and hold onto it, until it's needed.

Prefixing the message with its length (say, as 5 numeric characters) gets more complex, because (believe it or not), you may not get all 5

characters in one `recv`. In playing around, you'll get away with it; but in high network loads, your code will very quickly break unless you use two `recv` loops - the first to determine the length, the second to get the data part of the message. Nasty. This is also when you'll discover that `send` does not always manage to get rid of everything in one pass. And despite having read this, you will eventually get bit by it!

In the interests of space, building your character, (and preserving my competitive position), these enhancements are left as an exercise for the reader. Lets move on to cleaning up.

Binary Data

It is perfectly possible to send binary data over a socket. The major problem is that not all machines use the same formats for binary data. For example, a Motorola chip will represent a 16 bit integer with the value 1 as the two hex bytes 00 01. Intel and DEC, however, are byte-reversed - that same 1 is 01 00. Socket libraries have calls for converting 16 and 32 bit integers - `ntohl`, `htonl`, `ntohs`, `htons` where "n" means *network* and "h" means *host*, "s" means *short* and "l" means *long*. Where network order is host order, these do nothing, but where the machine is byte-reversed, these swap the bytes around appropriately.

In these days of 32 bit machines, the ascii representation of binary data is frequently smaller than the binary representation. That's because a surprising amount of the time, all those longs have the value 0, or maybe 1. The string "0" would be two bytes, while binary is four. Of course, this doesn't fit well with fixed-length messages. Decisions, decisions.

Disconnecting

Strictly speaking, you're supposed to use `shutdown` on a socket before you `close` it. The `shutdown` is an advisory to the socket at the other end. Depending on the argument you pass it, it can mean "I'm not going to send anymore, but I'll still listen", or "I'm not listening, good riddance!". Most socket libraries, however, are so used to programmers neglecting to use this piece of etiquette that normally a `close` is the same as `shutdown(); close()`. So in most situations, an explicit `shutdown` is not needed.

One way to use `shutdown` effectively is in an HTTP-like exchange. The client sends a request and then does a `shutdown(1)`. This tells the server "This client is done sending, but can still receive." The server can detect "EOF" by a receive of 0 bytes. It can assume it has the complete request. The server sends a reply. If the `send` completes successfully then, indeed, the client was still receiving.

Python takes the automatic shutdown a step further, and says that when a socket is garbage collected, it will automatically do a `close` if it's needed. But relying on this is a very bad habit. If your socket just disappears without doing a `close`, the socket at the other end may hang indefinitely, thinking you're just being slow. *Please close your sockets when you're done.*

When Sockets Die

Probably the worst thing about using blocking sockets is what happens when the other side comes down hard (without doing a `close`). Your socket is likely to hang. SOCKSTREAM is a reliable protocol, and it will wait a long, long time before giving up on a connection. If you're using threads, the entire thread is essentially

dead. There's not much you can do about it. As long as you aren't doing something dumb, like holding a lock while doing a blocking read, the thread isn't really consuming much in the way of resources. Do *not* try to kill the thread - part of the reason that threads are more efficient than processes is that they avoid the overhead associated with the automatic recycling of resources. In other words, if you do manage to kill the thread, your whole process is likely to be screwed up.

Non-blocking Sockets

If you've understood the preceding, you already know most of what you need to know about the mechanics of using sockets. You'll still use the same calls, in much the same ways. It's just that, if you do it right, your app will be almost inside-out.

In Python, you use `socket.setblocking(0)` to make it non-blocking. In C, it's more complex, (for one thing, you'll need to choose between the BSD flavor `O_NONBLOCK` and the almost indistinguishable Posix flavor `O_NDELAY`, which is completely different from `TCP_NODELAY`), but it's the exact same idea. You do this after creating the socket, but before using it. (Actually, if you're nuts, you can switch back and forth.)

The major mechanical difference is that `send`, `recv`, `connect` and `accept` can return without having done anything. You have (of course) a number of choices. You can check return code and error codes and generally drive yourself crazy. If you don't believe me, try it sometime. Your app will grow large, buggy and suck CPU. So let's skip the brain-dead solutions and do it right.

Use `select`.

In C, coding `select` is fairly complex. In Python, it's a piece of cake, but it's close enough to the C version that if you understand `select` in Python, you'll have little trouble with it in C.

```
ready_to_read, ready_to_write, in_error = \
    select.select(
        potential_readers,
        potential_writers,
        potential_errs,
        timeout)
```

You pass `select` three lists: the first contains all sockets that you might want to try reading; the second all the sockets you might want to try writing to, and the last (normally left empty) those that you want to check for errors. You should note that a socket can go into more than one list. The `select` call is blocking, but you can give it a timeout. This is generally a sensible thing to do - give it a nice long timeout (say a minute) unless you have good reason to do otherwise.

In return, you will get three lists. They have the sockets that are actually readable, writable and in error. Each of these lists is a subset (possibly empty) of the corresponding list you passed in. And if you put a socket in more than one input list, it will only be (at most) in one output list.

If a socket is in the output readable list, you can be as-close-to-certain-as-we-ever-get-in-this-business that a `recv` on that socket will return *something*. Same idea for the writable list. You'll be able to send *something*. Maybe not all you want to, but *something* is better than nothing. (Actually, any reasonably healthy socket will return as writable - it just means outbound network buffer space is available.)

If you have a "server" socket, put it in the `potential_readers` list. If it comes out in the readable list, your `accept` will (almost certainly) work. If you have created a new socket to `connect` to someone else, put it in the `potential_writers` list. If it shows up in the writable list, you have a decent chance that it has connected.

One very nasty problem with `select`: if somewhere in those input lists of sockets is one which has died a nasty death, the `select` will fail. You then need to loop through every single damn socket in all those lists and do a `select([sock], [], [], 0)` until you find the bad one. That timeout of 0 means it won't take long, but it's ugly.

Actually, `select` can be handy even with blocking sockets. It's one way of determining whether you will block - the socket returns as readable when there's something in the buffers. However, this still doesn't help with the problem of determining whether the other end is done, or just busy with something else.

Portability alert: On Unix, `select` works both with the sockets and files. Don't try this on Windows. On Windows, `select` works with sockets only. Also note that in C, many of the more advanced socket options are done differently on Windows. In fact, on Windows I usually use threads (which work very, very well) with my sockets. Face it, if you want any kind of performance, your code will look very different on Windows than on Unix.

Performance

There's no question that the fastest sockets code uses non-blocking sockets and `select` to multiplex them. You can put together something that will saturate a LAN connection without putting any strain on the CPU. The trouble is that an app written this way can't do much of anything else - it needs to be ready to shuffle bytes around at all times.

Assuming that your app is actually supposed to do something more than that, threading is the optimal solution, (and using non-blocking sockets will be faster than using blocking sockets). Unfortunately, threading support in Unixes varies both in API and quality. So the normal Unix solution is to fork a subprocess to deal with each connection. The overhead for this is significant (and don't do this on Windows - the overhead of process creation is enormous there). It also means that unless each subprocess is completely independent, you'll need to use another form of IPC, say a pipe, or shared memory and semaphores, to communicate between the parent and child processes.

Finally, remember that even though blocking sockets are somewhat slower than non-blocking, in many cases they are the “right” solution. After all, if your app is driven by the data it receives over a socket, there’s not much sense in complicating the logic just so your app can wait on `select` instead of `recv`.

Sorting HOW TO

Author: Andrew Dalke and Raymond Hettinger

Release: 0.1

Python lists have a built-in `list.sort()` method that modifies the list in-place. There is also a `sorted()` built-in function that builds a new sorted list from an iterable.

In this document, we explore the various techniques for sorting data using Python.

Sorting Basics

A simple ascending sort is very easy: just call the `sorted()` function. It returns a new sorted list:

```
>>> sorted([5, 2, 3, 1, 4])
[1, 2, 3, 4, 5]
```

You can also use the `list.sort()` method. It modifies the list in-place (and returns *None* to avoid confusion). Usually it's less convenient than `sorted()` - but if you don't need the original list, it's slightly more efficient.

```
>>> a = [5, 2, 3, 1, 4]
>>> a.sort()
>>> a
[1, 2, 3, 4, 5]
```

Another difference is that the `list.sort()` method is only defined for lists. In contrast, the `sorted()` function accepts any iterable.

```
>>> sorted({1: 'D', 2: 'B', 3: 'B', 4: 'E', 5: 'A'})
[1, 2, 3, 4, 5]
```

Key Functions

Both `list.sort()` and `sorted()` have *key* parameter to specify a function to be called on each list element prior to making comparisons.

For example, here's a case-insensitive string comparison:

```
>>> sorted("This is a test string from Andrew".split(), key=str.lower)
['a', 'Andrew', 'from', 'is', 'string', 'test', 'This']
```

The value of the *key* parameter should be a function that takes a single argument and returns a key to use for sorting purposes. This technique is fast because the key function is called exactly once for each input record.

A common pattern is to sort complex objects using some of the object's indices as keys. For example:

```
>>> student_tuples = [
    ('john', 'A', 15),
    ('jane', 'B', 12),
    ('dave', 'B', 10),
]
>>> sorted(student_tuples, key=lambda student: student[2]) #
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)]
```

The same technique works for objects with named attributes. For example:

```
>>> class Student:
    def __init__(self, name, grade, age):
        self.name = name
        self.grade = grade
        self.age = age
    def __repr__(self):
```

```
return repr((self.name, self.grade, self.age))
```

```
>>> student_objects = [  
    Student('john', 'A', 15),  
    Student('jane', 'B', 12),  
    Student('dave', 'B', 10),  
]  
>>> sorted(student_objects, key=lambda student: student.age)  
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)]
```

Operator Module Functions

The key-function patterns shown above are very common, so Python provides convenience functions to make accessor functions easier and faster. The `operator` module has `itemgetter()`, `attrgetter()`, and an `methodcaller()` function.

Using those functions, the above examples become simpler and faster:

```
>>> from operator import itemgetter, attrgetter
```

```
>>> sorted(student_tuples, key=itemgetter(2))
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)]
```

```
>>> sorted(student_objects, key=attrgetter('age'))
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)]
```

The operator module functions allow multiple levels of sorting. For example, to sort by *grade* then by *age*:

```
>>> sorted(student_tuples, key=itemgetter(1,2))
[('john', 'A', 15), ('dave', 'B', 10), ('jane', 'B', 12)]
```

```
>>> sorted(student_objects, key=attrgetter('grade', 'age'))
[('john', 'A', 15), ('dave', 'B', 10), ('jane', 'B', 12)]
```

Ascending and Descending

Both `list.sort()` and `sorted()` accept a *reverse* parameter with a boolean value. This is used to flag descending sorts. For example, to get the student data in reverse *age* order:

```
>>> sorted(student_tuples, key=itemgetter(2), reverse=True)
[('john', 'A', 15), ('jane', 'B', 12), ('dave', 'B', 10)]
```

```
>>> sorted(student_objects, key=attrgetter('age'), reverse=True)
[('john', 'A', 15), ('jane', 'B', 12), ('dave', 'B', 10)]
```

Sort Stability and Complex Sorts

Sorts are guaranteed to be *stable*. That means that when multiple records have the same key, their original order is preserved.

```
>>> data = [('red', 1), ('blue', 1), ('red', 2), ('blue', 2)]
>>> sorted(data, key=itemgetter(0))
[('blue', 1), ('blue', 2), ('red', 1), ('red', 2)]
```

Notice how the two records for *blue* retain their original order so that `('blue', 1)` is guaranteed to precede `('blue', 2)`.

This wonderful property lets you build complex sorts in a series of sorting steps. For example, to sort the student data by descending *grade* and then ascending *age*, do the *age* sort first and then sort again using *grade*:

```
>>> s = sorted(student_objects, key=attrgetter('age'))      # so
>>> sorted(s, key=attrgetter('grade'), reverse=True)      # no
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)]
```

The *Timsort* algorithm used in Python does multiple sorts efficiently because it can take advantage of any ordering already present in a dataset.

The Old Way Using Decorate-Sort-Undecorate

This idiom is called Decorate-Sort-Undecorate after its three steps:

- First, the initial list is decorated with new values that control the sort order.
- Second, the decorated list is sorted.
- Finally, the decorations are removed, creating a list that contains only the initial values in the new order.

For example, to sort the student data by *grade* using the DSU approach:

```
>>> decorated = [(student.grade, i, student) for i, student in
>>> decorated.sort()
>>> [student for grade, i, student in decorated]
[('john', 'A', 15), ('jane', 'B', 12), ('dave', 'B', 10)]
```

This idiom works because tuples are compared lexicographically; the first items are compared; if they are the same then the second items are compared, and so on.

It is not strictly necessary in all cases to include the index *i* in the decorated list, but including it gives two benefits:

- The sort is stable – if two items have the same key, their order will be preserved in the sorted list.
- The original items do not have to be comparable because the ordering of the decorated tuples will be determined by at most the first two items. So for example the original list could contain complex numbers which cannot be sorted directly.

Another name for this idiom is [Schwartzian transform](#), after Randal

L. Schwartz, who popularized it among Perl programmers.

Now that Python sorting provides key-functions, this technique is not often needed.

The Old Way Using the *cmp* Parameter

Many constructs given in this HOWTO assume Python 2.4 or later. Before that, there was no `sorted()` builtin and `list.sort()` took no keyword arguments. Instead, all of the Py2.x versions supported a *cmp* parameter to handle user specified comparison functions.

In Py3.0, the *cmp* parameter was removed entirely (as part of a larger effort to simplify and unify the language, eliminating the conflict between rich comparisons and the `__cmp__()` magic method).

In Py2.x, `sort` allowed an optional function which can be called for doing the comparisons. That function should take two arguments to be compared and then return a negative value for less-than, return zero if they are equal, or return a positive value for greater-than. For example, we can do:

```
>>> def numeric_compare(x, y):
    return x - y
>>> sorted([5, 2, 4, 1, 3], cmp=numeric_compare)
[1, 2, 3, 4, 5]
```

Or you can reverse the order of comparison with:

```
>>> def reverse_numeric(x, y):
    return y - x
>>> sorted([5, 2, 4, 1, 3], cmp=reverse_numeric)
[5, 4, 3, 2, 1]
```

When porting code from Python 2.x to 3.x, the situation can arise when you have the user supplying a comparison function and you need to convert that to a key function. The following wrapper makes that easy to do:

```
def cmp_to_key(mycmp):
    'Convert a cmp= function into a key= function'
```

```
class K(object):
    def __init__(self, obj, *args):
        self.obj = obj
    def __lt__(self, other):
        return mycmp(self.obj, other.obj) < 0
    def __gt__(self, other):
        return mycmp(self.obj, other.obj) > 0
    def __eq__(self, other):
        return mycmp(self.obj, other.obj) == 0
    def __le__(self, other):
        return mycmp(self.obj, other.obj) <= 0
    def __ge__(self, other):
        return mycmp(self.obj, other.obj) >= 0
    def __ne__(self, other):
        return mycmp(self.obj, other.obj) != 0
return K
```

To convert to a key function, just wrap the old comparison function:

```
>>> sorted([5, 2, 4, 1, 3], key=cmp_to_key(reverse_numeric))
[5, 4, 3, 2, 1]
```

In Python 3.2, the `functools.cmp_to_key()` function was added to the `functools` module in the standard library.

Odd and Ends

- For locale aware sorting, use `locale.strxfrm()` for a key function or `locale.strcoll()` for a comparison function.
- The `reverse` parameter still maintains sort stability (so that records with equal keys retain the original order). Interestingly, that effect can be simulated without the parameter by using the builtin `reversed()` function twice:

```
>>> data = [('red', 1), ('blue', 1), ('red', 2), ('blue', 2)
>>> assert sorted(data, reverse=True) == list(reversed(sorted(data)))
```

- The sort routines are guaranteed to use `__lt__()` when making comparisons between two objects. So, it is easy to add a standard sort order to a class by defining an `__lt__()` method:

```
>>> Student.__lt__ = lambda self, other: self.age < other.age
>>> sorted(student_objects)
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)]
```

- Key functions need not depend directly on the objects being sorted. A key function can also access external resources. For instance, if the student grades are stored in a dictionary, they can be used to sort a separate list of student names:

```
>>> students = ['dave', 'john', 'jane']
>>> newgrades = {'john': 'F', 'jane': 'A', 'dave': 'C'}
>>> sorted(students, key=newgrades.__getitem__)
['jane', 'dave', 'john']
```

Unicode HOWTO

Release: 1.12

This HOWTO discusses Python support for Unicode, and explains various problems that people commonly encounter when trying to work with Unicode.

Introduction to Unicode

History of Character Codes

In 1968, the American Standard Code for Information Interchange, better known by its acronym ASCII, was standardized. ASCII defined numeric codes for various characters, with the numeric values running from 0 to 127. For example, the lowercase letter 'a' is assigned 97 as its code value.

ASCII was an American-developed standard, so it only defined unaccented characters. There was an 'e', but no 'é' or 'í'. This meant that languages which required accented characters couldn't be faithfully represented in ASCII. (Actually the missing accents matter for English, too, which contains words such as 'naïve' and 'café', and some publications have house styles which require spellings such as 'coöperate'.)

For a while people just wrote programs that didn't display accents. I remember looking at Apple II BASIC programs, published in French-language publications in the mid-1980s, that had lines like these:

```
PRINT "FICHIER EST COMPLETE."  
PRINT "CARACTERE NON ACCEPTE."
```

Those messages should contain accents, and they just look wrong to someone who can read French.

In the 1980s, almost all personal computers were 8-bit, meaning that bytes could hold values ranging from 0 to 255. ASCII codes only went up to 127, so some machines assigned values between 128 and 255 to accented characters. Different machines had different codes, however, which led to problems exchanging files. Eventually various commonly used sets of values for the 128–255 range

emerged. Some were true standards, defined by the International Standards Organization, and some were **de facto** conventions that were invented by one company or another and managed to catch on.

255 characters aren't very many. For example, you can't fit both the accented characters used in Western Europe and the Cyrillic alphabet used for Russian into the 128–255 range because there are more than 127 such characters.

You could write files using different codes (all your Russian files in a coding system called KOI8, all your French files in a different coding system called Latin1), but what if you wanted to write a French document that quotes some Russian text? In the 1980s people began to want to solve this problem, and the Unicode standardization effort began.

Unicode started out using 16-bit characters instead of 8-bit characters. 16 bits means you have $2^{16} = 65,536$ distinct values available, making it possible to represent many different characters from many different alphabets; an initial goal was to have Unicode contain the alphabets for every single human language. It turns out that even 16 bits isn't enough to meet that goal, and the modern Unicode specification uses a wider range of codes, 0 through 1,114,111 (0x10ffff in base 16).

There's a related ISO standard, ISO 10646. Unicode and ISO 10646 were originally separate efforts, but the specifications were merged with the 1.1 revision of Unicode.

(This discussion of Unicode's history is highly simplified. I don't think the average Python programmer needs to worry about the historical details; consult the Unicode consortium site listed in the References for more information.)

Definitions

A **character** is the smallest possible component of a text. 'A', 'B', 'C', etc., are all different characters. So are 'È' and 'Í'. Characters are abstractions, and vary depending on the language or context you're talking about. For example, the symbol for ohms (Ω) is usually drawn much like the capital letter omega (Ω) in the Greek alphabet (they may even be the same in some fonts), but these are two different characters that have different meanings.

The Unicode standard describes how characters are represented by **code points**. A code point is an integer value, usually denoted in base 16. In the standard, a code point is written using the notation U+12ca to mean the character with value 0x12ca (4,810 decimal). The Unicode standard contains a lot of tables listing characters and their corresponding code points:

```
0061    'a'; LATIN SMALL LETTER A
0062    'b'; LATIN SMALL LETTER B
0063    'c'; LATIN SMALL LETTER C
...
007B    '{'; LEFT CURLY BRACKET
```

Strictly, these definitions imply that it's meaningless to say 'this is character U+12ca'. U+12ca is a code point, which represents some particular character; in this case, it represents the character 'ETHIOPIC SYLLABLE WI'. In informal contexts, this distinction between code points and characters will sometimes be forgotten.

A character is represented on a screen or on paper by a set of graphical elements that's called a **glyph**. The glyph for an uppercase A, for example, is two diagonal strokes and a horizontal stroke, though the exact details will depend on the font being used. Most Python code doesn't need to worry about glyphs; figuring out the correct glyph to display is generally the job of a GUI toolkit or a terminal's font renderer.

Encodings

To summarize the previous section: a Unicode string is a sequence of code points, which are numbers from 0 through 0x10ffff (1,114,111 decimal). This sequence needs to be represented as a set of bytes (meaning, values from 0 through 255) in memory. The rules for translating a Unicode string into a sequence of bytes are called an **encoding**.

The first encoding you might think of is an array of 32-bit integers. In this representation, the string “Python” would look like this:

P	y	t	h	o
0x50 00 00 00	79 00 00 00	74 00 00 00	68 00 00 00	6f 00 00 00
0 1 2 3	4 5 6 7	8 9 10 11	12 13 14 15	16 17 18 19

This representation is straightforward but using it presents a number of problems.

1. It's not portable; different processors order the bytes differently.
2. It's very wasteful of space. In most texts, the majority of the code points are less than 127, or less than 255, so a lot of space is occupied by zero bytes. The above string takes 24 bytes compared to the 6 bytes needed for an ASCII representation. Increased RAM usage doesn't matter too much (desktop computers have megabytes of RAM, and strings aren't usually that large), but expanding our usage of disk and network bandwidth by a factor of 4 is intolerable.
3. It's not compatible with existing C functions such as `strlen()`, so a new family of wide string functions would need to be used.
4. Many Internet standards are defined in terms of textual data, and can't handle content with embedded zero bytes.

Generally people don't use this encoding, instead choosing other encodings that are more efficient and convenient. UTF-8 is probably the most commonly supported encoding; it will be discussed below.

Encodings don't have to handle every possible Unicode character, and most encodings don't. The rules for converting a Unicode string into the ASCII encoding, for example, are simple; for each code point:

1. If the code point is < 128 , each byte is the same as the value of the code point.
2. If the code point is 128 or greater, the Unicode string can't be represented in this encoding. (Python raises a `UnicodeEncodeError` exception in this case.)

Latin-1, also known as ISO-8859-1, is a similar encoding. Unicode code points 0–255 are identical to the Latin-1 values, so converting to this encoding simply requires converting code points to byte values; if a code point larger than 255 is encountered, the string can't be encoded into Latin-1.

Encodings don't have to be simple one-to-one mappings like Latin-1. Consider IBM's EBCDIC, which was used on IBM mainframes. Letter values weren't in one block: 'a' through 'i' had values from 129 to 137, but 'j' through 'r' were 145 through 153. If you wanted to use EBCDIC as an encoding, you'd probably use some sort of lookup table to perform the conversion, but this is largely an internal detail.

UTF-8 is one of the most commonly used encodings. UTF stands for "Unicode Transformation Format", and the '8' means that 8-bit numbers are used in the encoding. (There's also a UTF-16 encoding, but it's less frequently used than UTF-8.) UTF-8 uses the following rules:

1. If the code point is < 128 , it's represented by the corresponding byte value.
2. If the code point is between 128 and $0x7ff$, it's turned into two byte values between 128 and 255.
3. Code points $> 0x7ff$ are turned into three- or four-byte

sequences, where each byte of the sequence is between 128 and 255.

UTF-8 has several convenient properties:

1. It can handle any Unicode code point.
2. A Unicode string is turned into a string of bytes containing no embedded zero bytes. This avoids byte-ordering issues, and means UTF-8 strings can be processed by C functions such as `strcpy()` and sent through protocols that can't handle zero bytes.
3. A string of ASCII text is also valid UTF-8 text.
4. UTF-8 is fairly compact; the majority of code points are turned into two bytes, and values less than 128 occupy only a single byte.
5. If bytes are corrupted or lost, it's possible to determine the start of the next UTF-8-encoded code point and resynchronize. It's also unlikely that random 8-bit data will look like valid UTF-8.

References

The Unicode Consortium site at <http://www.unicode.org> has character charts, a glossary, and PDF versions of the Unicode specification. Be prepared for some difficult reading. <http://www.unicode.org/history/> is a chronology of the origin and development of Unicode.

To help understand the standard, Jukka Korpela has written an introductory guide to reading the Unicode character tables, available at <http://www.cs.tut.fi/~jkorpela/unicode/guide.html>.

Another good introductory article was written by Joel Spolsky <http://www.joelonsoftware.com/articles/Unicode.html>. If this introduction didn't make things clear to you, you should try reading this alternate article before continuing.

Wikipedia entries are often helpful; see the entries for “character encoding” <http://en.wikipedia.org/wiki/Character_encoding> and UTF-8 <<http://en.wikipedia.org/wiki/UTF-8>>, for example.

Python's Unicode Support

Now that you've learned the rudiments of Unicode, we can look at Python's Unicode features.

The String Type

Since Python 3.0, the language features a `str` type that contain Unicode characters, meaning any string created using `"unicode rocks!"`, `'unicode rocks!'`, or the triple-quoted string syntax is stored as Unicode.

To insert a Unicode character that is not part ASCII, e.g., any letters with accents, one can use escape sequences in their string literals as such:

```
>>> "\N{GREEK CAPITAL LETTER DELTA}" # Using the character nam
'\u0394'
>>> "\u0394"                         # Using a 16-bit hex valu
'\u0394'
>>> "\U00000394"                     # Using a 32-bit hex valu
'\u0394'
```

In addition, one can create a string using the `decode()` method of `bytes`. This method takes an encoding, such as UTF-8, and, optionally, an `errors` argument.

The `errors` argument specifies the response when the input string can't be converted according to the encoding's rules. Legal values for this argument are 'strict' (raise a `UnicodeDecodeError` exception), 'replace' (use U+FFFD, 'REPLACEMENT CHARACTER'), or 'ignore' (just leave the character out of the Unicode result). The following examples show the differences:

```
>>> b'\x80abc'.decode("utf-8", "strict")
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
UnicodeDecodeError: 'utf8' codec can't decode byte 0x80 in posi
                        unexpected code byte
>>> b'\x80abc'.decode("utf-8", "replace")
'?abc'
>>> b'\x80abc'.decode("utf-8", "ignore")
'abc'
```

(In this code example, the Unicode replacement character has been replaced by a question mark because it may not be displayed on some systems.)

Encodings are specified as strings containing the encoding's name. Python 3.2 comes with roughly 100 different encodings; see the Python Library Reference at [Standard Encodings](#) for a list. Some encodings have multiple names; for example, 'latin-1', 'iso_8859_1' and '8859' are all synonyms for the same encoding.

One-character Unicode strings can also be created with the `chr()` built-in function, which takes integers and returns a Unicode string of length 1 that contains the corresponding code point. The reverse operation is the built-in `ord()` function that takes a one-character Unicode string and returns the code point value:

```
>>> chr(57344)
'\ue000'
>>> ord('\ue000')
57344
```

Converting to Bytes

Another important str method is `.encode([encoding], [errors='strict'])`, which returns a bytes representation of the Unicode string, encoded in the requested encoding. The `errors`

parameter is the same as the parameter of the `decode()` method, with one additional possibility; as well as 'strict', 'ignore', and 'replace' (which in this case inserts a question mark instead of the unencodable character), you can also pass 'xmlcharrefreplace' which uses XML's character references. The following example shows the different results:

```
>>> u = chr(40960) + 'abcd' + chr(1972)
>>> u.encode('utf-8')
b'\xea\x80\x80abcd\xde\xb4'
>>> u.encode('ascii')
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
UnicodeEncodeError: 'ascii' codec can't encode character '\ua00
                        position 0: ordinal not in range(128)
>>> u.encode('ascii', 'ignore')
b'abcd'
>>> u.encode('ascii', 'replace')
b'?abcd?'
>>> u.encode('ascii', 'xmlcharrefreplace')
b'&#40960;abcd&#1972;'
```

The low-level routines for registering and accessing the available encodings are found in the `codecs` module. However, the encoding and decoding functions returned by this module are usually more low-level than is comfortable, so I'm not going to describe the `codecs` module here. If you need to implement a completely new encoding, you'll need to learn about the `codecs` module interfaces, but implementing encodings is a specialized task that also won't be covered here. Consult the Python documentation to learn more about this module.

Unicode Literals in Python Source Code

In Python source code, specific Unicode code points can be written using the `\u` escape sequence, which is followed by four hex digits giving the code point. The `\U` escape sequence is similar, but

expects eight hex digits, not four:

```
>>> s = "\xac\u1234\u20ac\u00008000"
      ^^^^ two-digit hex escape
      ^^^^^ four-digit Unicode escape
      ^^^^^^^^^^^ eight-digit Unicode escape
>>> for c in s: print(ord(c), end=" ")
...
97 172 4660 8364 32768
```

Using escape sequences for code points greater than 127 is fine in small doses, but becomes an annoyance if you're using many accented characters, as you would in a program with messages in French or some other accent-using language. You can also assemble strings using the `chr()` built-in function, but this is even more tedious.

Ideally, you'd want to be able to write literals in your language's natural encoding. You could then edit Python source code with your favorite editor which would display the accented characters naturally, and have the right characters used at runtime.

Python supports writing source code in UTF-8 by default, but you can use almost any encoding if you declare the encoding being used. This is done by including a special comment as either the first or second line of the source file:

```
#!/usr/bin/env python
# -*- coding: latin-1 -*-

u = 'abcdé'
print(ord(u[-1]))
```

The syntax is inspired by Emacs's notation for specifying variables local to a file. Emacs supports many different variables, but Python only supports 'coding'. The `-*-` symbols indicate to Emacs that the comment is special; they have no significance to Python but are a

convention. Python looks for `coding: name` or `coding=name` in the comment.

If you don't include such a comment, the default encoding used will be UTF-8 as already mentioned.

Unicode Properties

The Unicode specification includes a database of information about code points. For each code point that's defined, the information includes the character's name, its category, the numeric value if applicable (Unicode has characters representing the Roman numerals and fractions such as one-third and four-fifths). There are also properties related to the code point's use in bidirectional text and other display-related properties.

The following program displays some information about several characters, and prints the numeric value of one particular character:

```
import unicodedata

u = chr(233) + chr(0x0bf2) + chr(3972) + chr(6000) + chr(13231)

for i, c in enumerate(u):
    print(i, '%04x' % ord(c), unicodedata.category(c), end=" ")
    print(unicodedata.name(c))

# Get numeric value of second character
print(unicodedata.numeric(u[1]))
```

When run, this prints:

```
0 00e9 Ll LATIN SMALL LETTER E WITH ACUTE
1 0bf2 No TAMIL NUMBER ONE THOUSAND
2 0f84 Mn TIBETAN MARK HALANTA
3 1770 Lo TAGBANWA LETTER SA
4 33af So SQUARE RAD OVER S SQUARED
1000.0
```

The category codes are abbreviations describing the nature of the character. These are grouped into categories such as “Letter”, “Number”, “Punctuation”, or “Symbol”, which in turn are broken up into subcategories. To take the codes from the above output, `'Ll'` means ‘Letter, lowercase’, `'No'` means “Number, other”, `'Mn'` is “Mark, nonspacing”, and `'So'` is “Symbol, other”. See http://www.unicode.org/reports/tr44/#General_Category_Values for a list of category codes.

References

The `str` type is described in the Python library reference at *Sequence Types — str, bytes, bytearray, list, tuple, range*.

The documentation for the `unicodedata` module.

The documentation for the `codecs` module.

Marc-André Lemburg gave a presentation at EuroPython 2002 titled “Python and Unicode”. A PDF version of his slides is available at <http://downloads.egenix.com/python/Unicode-EPC2002-Talk.pdf>, and is an excellent overview of the design of Python’s Unicode features (based on Python 2, where the Unicode string type is called `unicode` and literals start with `u`).

Reading and Writing Unicode Data

Once you've written some code that works with Unicode data, the next problem is input/output. How do you get Unicode strings into your program, and how do you convert Unicode into a form suitable for storage or transmission?

It's possible that you may not need to do anything depending on your input sources and output destinations; you should check whether the libraries used in your application support Unicode natively. XML parsers often return Unicode data, for example. Many relational databases also support Unicode-valued columns and can return Unicode values from an SQL query.

Unicode data is usually converted to a particular encoding before it gets written to disk or sent over a socket. It's possible to do all the work yourself: open a file, read an 8-bit byte string from it, and convert the string with `str(bytes, encoding)`. However, the manual approach is not recommended.

One problem is the multi-byte nature of encodings; one Unicode character can be represented by several bytes. If you want to read the file in arbitrary-sized chunks (say, 1K or 4K), you need to write error-handling code to catch the case where only part of the bytes encoding a single Unicode character are read at the end of a chunk. One solution would be to read the entire file into memory and then perform the decoding, but that prevents you from working with files that are extremely large; if you need to read a 2Gb file, you need 2Gb of RAM. (More, really, since for at least a moment you'd need to have both the encoded string and its Unicode version in memory.)

The solution would be to use the low-level decoding interface to catch the case of partial coding sequences. The work of implementing this has already been done for you: the built-in `open()`

function can return a file-like object that assumes the file's contents are in a specified encoding and accepts Unicode parameters for methods such as `.read()` and `.write()`. This works through `open()`'s *encoding* and *errors* parameters which are interpreted just like those in string objects' `encode()` and `decode()` methods.

Reading Unicode from a file is therefore simple:

```
with open('unicode.rst', encoding='utf-8') as f:
    for line in f:
        print(repr(line))
```

It's also possible to open files in update mode, allowing both reading and writing:

```
with open('test', encoding='utf-8', mode='w+') as f:
    f.write('\u4500 blah blah blah\n')
    f.seek(0)
    print(repr(f.readline()[:1]))
```

The Unicode character U+FEFF is used as a byte-order mark (BOM), and is often written as the first character of a file in order to assist with autodetection of the file's byte ordering. Some encodings, such as UTF-16, expect a BOM to be present at the start of a file; when such an encoding is used, the BOM will be automatically written as the first character and will be silently dropped when the file is read. There are variants of these encodings, such as 'utf-16-le' and 'utf-16-be' for little-endian and big-endian encodings, that specify one particular byte ordering and don't skip the BOM.

In some areas, it is also convention to use a "BOM" at the start of UTF-8 encoded files; the name is misleading since UTF-8 is not byte-order dependent. The mark simply announces that the file is encoded in UTF-8. Use the 'utf-8-sig' codec to automatically skip the mark if present for reading such files.

Unicode filenames

Most of the operating systems in common use today support filenames that contain arbitrary Unicode characters. Usually this is implemented by converting the Unicode string into some encoding that varies depending on the system. For example, Mac OS X uses UTF-8 while Windows uses a configurable encoding; on Windows, Python uses the name “mbcs” to refer to whatever the currently configured encoding is. On Unix systems, there will only be a filesystem encoding if you’ve set the `LANG` or `LC_CTYPE` environment variables; if you haven’t, the default encoding is ASCII.

The `sys.getfilesystemencoding()` function returns the encoding to use on your current system, in case you want to do the encoding manually, but there’s not much reason to bother. When opening a file for reading or writing, you can usually just provide the Unicode string as the filename, and it will be automatically converted to the right encoding for you:

```
filename = 'filename\u4500abc'  
with open(filename, 'w') as f:  
    f.write('blah\n')
```

Functions in the `os` module such as `os.stat()` will also accept Unicode filenames.

Function `os.listdir()`, which returns filenames, raises an issue: should it return the Unicode version of filenames, or should it return byte strings containing the encoded versions? `os.listdir()` will do both, depending on whether you provided the directory path as a byte string or a Unicode string. If you pass a Unicode string as the path, filenames will be decoded using the filesystem’s encoding and a list of Unicode strings will be returned, while passing a byte path will return the byte string versions of the filenames. For example, assuming the default filesystem encoding is UTF-8, running the

following program:

```
fn = 'filename\u4500abc'  
f = open(fn, 'w')  
f.close()  
  
import os  
print(os.listdir(b'.'))  
print(os.listdir('.'))
```

will produce the following output:

```
amk:~$ python t.py  
[b'.svn', b'filename\xe4\x94\x80abc', ...]  
['.svn', 'filename\u4500abc', ...]
```

The first list contains UTF-8-encoded filenames, and the second list contains the Unicode versions.

Note that in most occasions, the Unicode APIs should be used. The bytes APIs should only be used on systems where undecodable file names can be present, i.e. Unix systems.

Tips for Writing Unicode-aware Programs

This section provides some suggestions on writing software that deals with Unicode.

The most important tip is:

Software should only work with Unicode strings internally, converting to a particular encoding on output.

If you attempt to write processing functions that accept both Unicode and byte strings, you will find your program vulnerable to bugs wherever you combine the two different kinds of strings. There is no automatic encoding or decoding if you do e.g. `str + bytes`, a `TypeError` is raised for this expression.

When using data coming from a web browser or some other untrusted source, a common technique is to check for illegal characters in a string before using the string in a generated command line or storing it in a database. If you're doing this, be careful to check the string once it's in the form that will be used or stored; it's possible for encodings to be used to disguise characters. This is especially true if the input data also specifies the encoding; many encodings leave the commonly checked-for characters alone, but Python includes some encodings such as 'base64' that modify every single character.

For example, let's say you have a content management system that takes a Unicode filename, and you want to disallow paths with a '/' character. You might write this code:

```
def read_file(filename, encoding):
    if '/' in filename:
        raise ValueError("'/' not allowed in filenames")
    unicode_name = filename.decode(encoding)
    with open(unicode_name, 'r') as f:
        # ... return contents of file ...
```

However, if an attacker could specify the 'base64' encoding, they could pass 'L2V0Yy9wYXNzd2Q=', which is the base-64 encoded form of the string '/etc/passwd', to read a system file. The above code looks for '/' characters in the encoded form and misses the dangerous character in the resulting decoded form.

HOWTO Fetch Internet Resources Using The urllib Package

Author: Michael Foord

Note: There is a French translation of an earlier revision of this HOWTO, available at [urllib2 - Le Manuel manquant](#).

Introduction

`urllib.request` is a [Python](#) module for fetching URLs (Uniform Resource Locators). It offers a very simple interface, in the form of the *urlopen* function. This is capable of fetching URLs using a variety of different protocols. It also offers a slightly more complex interface for handling common situations - like basic authentication, cookies, proxies and so on. These are provided by objects called handlers and openers.

`urllib.request` supports fetching URLs for many “URL schemes” (identified by the string before the “:” in URL - for example “ftp” is the URL scheme of “<ftp://python.org/>”) using their associated network protocols (e.g. FTP, HTTP). This tutorial focuses on the most common case, HTTP.

For straightforward situations *urlopen* is very easy to use. But as soon as you encounter errors or non-trivial cases when opening HTTP URLs, you will need some understanding of the HyperText Transfer Protocol. The most comprehensive and authoritative reference to HTTP is [RFC 2616](#). This is a technical document and not intended to be easy to read. This HOWTO aims to illustrate using *urllib*, with enough detail about HTTP to help you through. It is not intended to replace the `urllib.request` docs, but is supplementary to them.

You may also find useful the following article on fetching web resources with Python:

- [Basic Authentication](#)

A tutorial on *Basic Authentication*, with examples in Python.

Fetching URLs

The simplest way to use `urllib.request` is as follows:

```
import urllib.request
response = urllib.request.urlopen('http://python.org/')
html = response.read()
```

Many uses of `urllib` will be that simple (note that instead of an 'http:' URL we could have used an URL starting with 'ftp:', 'file:', etc.). However, it's the purpose of this tutorial to explain the more complicated cases, concentrating on HTTP.

HTTP is based on requests and responses - the client makes requests and servers send responses. `urllib.request` mirrors this with a `Request` object which represents the HTTP request you are making. In its simplest form you create a `Request` object that specifies the URL you want to fetch. Calling `urlopen` with this `Request` object returns a response object for the URL requested. This response is a file-like object, which means you can for example call `.read()` on the response:

```
import urllib.request

req = urllib.request.Request('http://www.voidspace.org.uk')
response = urllib.request.urlopen(req)
the_page = response.read()
```

Note that `urllib.request` makes use of the same `Request` interface to handle all URL schemes. For example, you can make an FTP request like so:

```
req = urllib.request.Request('ftp://example.com/')
```

In the case of HTTP, there are two extra things that `Request` objects

allow you to do: First, you can pass data to be sent to the server. Second, you can pass extra information (“metadata”) *about* the data or the about request itself, to the server - this information is sent as HTTP “headers”. Let’s look at each of these in turn.

Data

Sometimes you want to send data to a URL (often the URL will refer to a CGI (Common Gateway Interface) script [1] or other web application). With HTTP, this is often done using what’s known as a **POST** request. This is often what your browser does when you submit a HTML form that you filled in on the web. Not all POSTs have to come from forms: you can use a POST to transmit arbitrary data to your own application. In the common case of HTML forms, the data needs to be encoded in a standard way, and then passed to the Request object as the `data` argument. The encoding is done using a function from the `urllib.parse` library.

```
import urllib.parse
import urllib.request

url = 'http://www.someserver.com/cgi-bin/register.cgi'
values = {'name' : 'Michael Foord',
          'location' : 'Northampton',
          'language' : 'Python' }

data = urllib.parse.urlencode(values)
req = urllib.request.Request(url, data)
response = urllib.request.urlopen(req)
the_page = response.read()
```

Note that other encodings are sometimes required (e.g. for file upload from HTML forms - see [HTML Specification, Form Submission](#) for more details).

If you do not pass the `data` argument, `urllib` uses a **GET** request. One way in which GET and POST requests differ is that POST

requests often have “side-effects”: they change the state of the system in some way (for example by placing an order with the website for a hundredweight of tinned spam to be delivered to your door). Though the HTTP standard makes it clear that POSTs are intended to *always* cause side-effects, and GET requests *never* to cause side-effects, nothing prevents a GET request from having side-effects, nor a POST requests from having no side-effects. Data can also be passed in an HTTP GET request by encoding it in the URL itself.

This is done as follows:

```
>>> import urllib.request
>>> import urllib.parse
>>> data = {}
>>> data['name'] = 'Somebody Here'
>>> data['location'] = 'Northampton'
>>> data['language'] = 'Python'
>>> url_values = urllib.parse.urlencode(data)
>>> print(url_values)
name=Somebody+Here&language=Python&location=Northampton
>>> url = 'http://www.example.com/example.cgi'
>>> full_url = url + '?' + url_values
>>> data = urllib.request.open(full_url)
```

Notice that the full URL is created by adding a `?` to the URL, followed by the encoded values.

Headers

We'll discuss here one particular HTTP header, to illustrate how to add headers to your HTTP request.

Some websites [2] dislike being browsed by programs, or send different versions to different browsers [3]. By default urllib identifies itself as `Python-urllib/x.y` (where `x` and `y` are the major and minor version numbers of the Python release, e.g. `Python-urllib/2.5`),

which may confuse the site, or just plain not work. The way a browser identifies itself is through the `User-Agent` header [4]. When you create a Request object you can pass a dictionary of headers in. The following example makes the same request as above, but identifies itself as a version of Internet Explorer [5].

```
import urllib.parse
import urllib.request

url = 'http://www.someserver.com/cgi-bin/register.cgi'
user_agent = 'Mozilla/4.0 (compatible; MSIE 5.5; Windows NT)'
values = {'name' : 'Michael Foord',
          'location' : 'Northampton',
          'language' : 'Python' }
headers = { 'User-Agent' : user_agent }

data = urllib.parse.urlencode(values)
req = urllib.request.Request(url, data, headers)
response = urllib.request.urlopen(req)
the_page = response.read()
```

The response also has two useful methods. See the section on [info](#) and [geturl](#) which comes after we have a look at what happens when things go wrong.

Handling Exceptions

`urlopen` raises `URLError` when it cannot handle a response (though as usual with Python APIs, built-in exceptions such as `ValueError`, `TypeError` etc. may also be raised).

`HTTPError` is the subclass of `URLError` raised in the specific case of HTTP URLs.

The exception classes are exported from the `urllib.error` module.

URLError

Often, `URLError` is raised because there is no network connection (no route to the specified server), or the specified server doesn't exist. In this case, the exception raised will have a 'reason' attribute, which is a tuple containing an error code and a text error message.

e.g.

```
>>> req = urllib.request.Request('http://www.pretend_server.org')
>>> try: urllib.request.urlopen(req)
>>> except urllib.error.URLError as e:
>>>     print(e.reason)
>>>
(4, 'getaddrinfo failed')
```

HTTPError

Every HTTP response from the server contains a numeric “status code”. Sometimes the status code indicates that the server is unable to fulfil the request. The default handlers will handle some of these responses for you (for example, if the response is a “redirection” that requests the client fetch the document from a different URL, `urllib` will

handle that for you). For those it can't handle, `urlopen` will raise an `HTTPError`. Typical errors include '404' (page not found), '403' (request forbidden), and '401' (authentication required).

See section 10 of RFC 2616 for a reference on all the HTTP error codes.

The `HTTPError` instance raised will have an integer 'code' attribute, which corresponds to the error sent by the server.

Error Codes

Because the default handlers handle redirects (codes in the 300 range), and codes in the 100-299 range indicate success, you will usually only see error codes in the 400-599 range.

`http.server.BaseHTTPRequestHandler.responses` is a useful dictionary of response codes in that shows all the response codes used by RFC 2616. The dictionary is reproduced here for convenience

```
# Table mapping response codes to messages; entries have the
# form {code: (shortmessage, longmessage)}.
responses = {
    100: ('Continue', 'Request received, please continue'),
    101: ('Switching Protocols',
         'Switching to new protocol; obey Upgrade header'),

    200: ('OK', 'Request fulfilled, document follows'),
    201: ('Created', 'Document created, URL follows'),
    202: ('Accepted',
         'Request accepted, processing continues off-line'),
    203: ('Non-Authoritative Information', 'Request fulfilled f
    204: ('No Content', 'Request fulfilled, nothing follows'),
    205: ('Reset Content', 'Clear input form for further input.
    206: ('Partial Content', 'Partial content follows.'),

    300: ('Multiple Choices',
         'Object has several resources -- see URI list'),
    301: ('Moved Permanently', 'Object moved permanently -- see
```

```
302: ('Found', 'Object moved temporarily -- see URI list'),
303: ('See Other', 'Object moved -- see Method and URL list'),
304: ('Not Modified',
     'Document has not changed since given time'),
305: ('Use Proxy',
     'You must use proxy specified in Location to access t
     'resource.'),
307: ('Temporary Redirect',
     'Object moved temporarily -- see URI list'),

400: ('Bad Request',
     'Bad request syntax or unsupported method'),
401: ('Unauthorized',
     'No permission -- see authorization schemes'),
402: ('Payment Required',
     'No payment -- see charging schemes'),
403: ('Forbidden',
     'Request forbidden -- authorization will not help'),
404: ('Not Found', 'Nothing matches the given URI'),
405: ('Method Not Allowed',
     'Specified method is invalid for this server.'),
406: ('Not Acceptable', 'URI not available in preferred for
407: ('Proxy Authentication Required', 'You must authentica
     'this proxy before proceeding.'),
408: ('Request Timeout', 'Request timed out; try again late
409: ('Conflict', 'Request conflict.'),
410: ('Gone',
     'URI no longer exists and has been permanently remove
411: ('Length Required', 'Client must specify Content-Lengt
412: ('Precondition Failed', 'Precondition in headers is fa
413: ('Request Entity Too Large', 'Entity is too large.'),
414: ('Request-URI Too Long', 'URI is too long.'),
415: ('Unsupported Media Type', 'Entity body in unsupported
416: ('Requested Range Not Satisfiable',
     'Cannot satisfy request range.'),
417: ('Expectation Failed',
     'Expect condition could not be satisfied.'),

500: ('Internal Server Error', 'Server got itself in troubl
501: ('Not Implemented',
     'Server does not support this operation'),
502: ('Bad Gateway', 'Invalid responses from another server
503: ('Service Unavailable',
     'The server cannot process the request due to a high
504: ('Gateway Timeout',
     'The gateway server did not receive a timely response
505: ('HTTP Version Not Supported', 'Cannot fulfill request
```

```
}
```

When an error is raised the server responds by returning an HTTP error code *and* an error page. You can use the `HTTPError` instance as a response on the page returned. This means that as well as the `code` attribute, it also has `read`, `geturl`, and `info`, methods as returned by the `urllib.response` module:

```
>>> req = urllib.request.Request('http://www.python.org/fish.ht
>>> try:
>>>     urllib.request.urlopen(req)
>>> except urllib.error.HTTPError as e:
>>>     print(e.code)
>>>     print(e.read())
>>>
404
<!DOCTYPE html PUBLIC "-//W3C//DTD HTML 4.01 Transitional//EN"
    "http://www.w3.org/TR/html4/loose.dtd">
<?xml-stylesheet href="./css/ht2html.css"
    type="text/css"?>
<html><head><title>Error 404: File Not Found</title>
..... etc...
```

Wrapping it Up

So if you want to be prepared for `HTTPError` *or* `URLError` there are two basic approaches. I prefer the second approach.

Number 1

```
from urllib.request import Request, urlopen
from urllib.error import URLError, HTTPError
req = Request(someurl)
try:
    response = urlopen(req)
except HTTPError as e:
    print('The server couldn\'t fulfill the request.')
    print('Error code: ', e.code)
except URLError as e:
```

```
print('We failed to reach a server.')
print('Reason: ', e.reason)
else:
    # everything is fine
```

Note: The except `HTTPError` *must* come first, otherwise except `URLError` will *also* catch an `HTTPError`.

Number 2

```
from urllib.request import Request, urlopen
from urllib.error import URLError
req = Request(someurl)
try:
    response = urlopen(req)
except URLError as e:
    if hasattr(e, 'reason'):
        print('We failed to reach a server.')
        print('Reason: ', e.reason)
    elif hasattr(e, 'code'):
        print('The server couldn\'t fulfill the request.')
        print('Error code: ', e.code)
else:
    # everything is fine
```

info and geturl

The response returned by `urlopen` (or the `HTTPError` instance) has two useful methods `info()` and `geturl()` and is defined in the module `urllib.response`.

geturl - this returns the real URL of the page fetched. This is useful because `urlopen` (or the opener object used) may have followed a redirect. The URL of the page fetched may not be the same as the URL requested.

info - this returns a dictionary-like object that describes the page fetched, particularly the headers sent by the server. It is currently an `http.client.HTTPMessage` instance.

Typical headers include 'Content-length', 'Content-type', and so on. See the [Quick Reference to HTTP Headers](#) for a useful listing of HTTP headers with brief explanations of their meaning and use.

Openers and Handlers

When you fetch a URL you use an opener (an instance of the perhaps confusingly-named `urllib.request.OpenerDirector`). Normally we have been using the default opener - via `urlopen` - but you can create custom openers. Openers use handlers. All the “heavy lifting” is done by the handlers. Each handler knows how to open URLs for a particular URL scheme (http, ftp, etc.), or how to handle an aspect of URL opening, for example HTTP redirections or HTTP cookies.

You will want to create openers if you want to fetch URLs with specific handlers installed, for example to get an opener that handles cookies, or to get an opener that does not handle redirections.

To create an opener, instantiate an `OpenerDirector`, and then call `.add_handler(some_handler_instance)` repeatedly.

Alternatively, you can use `build_opener`, which is a convenience function for creating opener objects with a single function call. `build_opener` adds several handlers by default, but provides a quick way to add more and/or override the default handlers.

Other sorts of handlers you might want to can handle proxies, authentication, and other common but slightly specialised situations.

`install_opener` can be used to make an `opener` object the (global) default opener. This means that calls to `urlopen` will use the opener you have installed.

Opener objects have an `open` method, which can be called directly to fetch urls in the same way as the `urlopen` function: there’s no need to call `install_opener`, except as a convenience.

Basic Authentication

To illustrate creating and installing a handler we will use the `HTTPBasicAuthHandler`. For a more detailed discussion of this subject – including an explanation of how Basic Authentication works - see the [Basic Authentication Tutorial](#).

When authentication is required, the server sends a header (as well as the 401 error code) requesting authentication. This specifies the authentication scheme and a 'realm'. The header looks like : `www-authenticate: SCHEME realm="REALM"`.

e.g.

```
www-authenticate: Basic realm="cPanel Users"
```

The client should then retry the request with the appropriate name and password for the realm included as a header in the request. This is 'basic authentication'. In order to simplify this process we can create an instance of `HTTPBasicAuthHandler` and an opener to use this handler.

The `HTTPBasicAuthHandler` uses an object called a password manager to handle the mapping of URLs and realms to passwords and usernames. If you know what the realm is (from the authentication header sent by the server), then you can use a `HTTPPasswordMgr`. Frequently one doesn't care what the realm is. In that case, it is convenient to use `HTTPPasswordMgrWithDefaultRealm`. This allows you to specify a default username and password for a URL. This will be supplied in the absence of you providing an alternative combination for a specific realm. We indicate this by providing `None` as the realm argument to the `add_password` method.

The top-level URL is the first URL that requires authentication. URLs “deeper” than the URL you pass to `.add_password()` will also match.

```
# create a password manager
password_mgr = urllib.request.HTTPPasswordMgrWithDefaultRealm()

# Add the username and password.
# If we knew the realm, we could use it instead of None.
top_level_url = "http://example.com/foo/"
password_mgr.add_password(None, top_level_url, username, passwo

handler = urllib.request.HTTPBasicAuthHandler(password_mgr)

# create "opener" (OpenerDirector instance)
opener = urllib.request.build_opener(handler)

# use the opener to fetch a URL
opener.open(a_url)

# Install the opener.
# Now all calls to urllib.request.urlopen use our opener.
urllib.request.install_opener(opener)
```

Note: In the above example we only supplied our `HTTPBasicAuthHandler` to `build_opener`. By default openers have the handlers for normal situations – `ProxyHandler`, `UnknownHandler`, `HTTPHandler`, `HTTPDefaultErrorHandler`, `HTTPRedirectHandler`, `FTPHandler`, `FileHandler`, `HTTPErrorProcessor`.

`top_level_url` is in fact *either* a full URL (including the ‘http:’ scheme component and the hostname and optionally the port number) e.g. “`http://example.com/`” or an “authority” (i.e. the hostname, optionally including the port number) e.g. “`example.com`” or “`example.com:8080`” (the latter example includes a port number). The authority, if present, must NOT contain the “userinfo” component - for example “`joe@password:example.com`” is not correct.

Proxies

urllib will auto-detect your proxy settings and use those. This is through the `ProxyHandler` which is part of the normal handler chain. Normally that's a good thing, but there are occasions when it may not be helpful [6]. One way to do this is to setup our own `ProxyHandler`, with no proxies defined. This is done using similar steps to setting up a [Basic Authentication](#) handler :

```
>>> proxy_support = urllib.request.ProxyHandler({})
>>> opener = urllib.request.build_opener(proxy_support)
>>> urllib.request.install_opener(opener)
```

Note: Currently `urllib.request` *does not* support fetching of `https` locations through a proxy. However, this can be enabled by extending `urllib.request` as shown in the recipe [7].

Sockets and Layers

The Python support for fetching resources from the web is layered. `urllib` uses the `http.client` library, which in turn uses the socket library.

As of Python 2.3 you can specify how long a socket should wait for a response before timing out. This can be useful in applications which have to fetch web pages. By default the socket module has *no timeout* and can hang. Currently, the socket timeout is not exposed at the `http.client` or `urllib.request` levels. However, you can set the default timeout globally for all sockets using

```
import socket
import urllib.request

# timeout in seconds
timeout = 10
socket.setdefaulttimeout(timeout)

# this call to urllib.request.urlopen now uses the default time
# we have set in the socket module
req = urllib.request.Request('http://www.voidspace.org.uk')
response = urllib.request.urlopen(req)
```

Footnotes

This document was reviewed and revised by John Lee.

- [1] For an introduction to the CGI protocol see [Writing Web Applications in Python](#).
Like Google for example. The *proper* way to use google from a
- [2] program is to use [PyGoogle](#) of course. See [Voidspace Google](#) for some examples of using the Google API.
Browser sniffing is a very bad practise for website design - building sites using web standards is much more sensible.
- [3] Unfortunately a lot of sites still send different versions to different browsers.
- [4] The user agent for MSIE 6 is *'Mozilla/4.0 (compatible; MSIE 6.0; Windows NT 5.1; SV1; .NET CLR 1.1.4322)'*
- [5] For details of more HTTP request headers, see [Quick Reference to HTTP Headers](#).
In my case I have to use a proxy to access the internet at work. If you attempt to fetch *localhost* URLs through this proxy it
- [6] blocks them. IE is set to use the proxy, which urllib picks up on. In order to test scripts with a localhost server, I have to prevent urllib from using the proxy.

HOWTO Use Python in the web

Author: Marek Kubica

Abstract

This document shows how Python fits into the web. It presents some ways to integrate Python with a web server, and general practices useful for developing web sites.

Programming for the Web has become a hot topic since the rise of “Web 2.0”, which focuses on user-generated content on web sites. It has always been possible to use Python for creating web sites, but it was a rather tedious task. Therefore, many frameworks and helper tools have been created to assist developers in creating faster and more robust sites. This HOWTO describes some of the methods used to combine Python with a web server to create dynamic content. It is not meant as a complete introduction, as this topic is far too broad to be covered in one single document. However, a short overview of the most popular libraries is provided.

See also: While this HOWTO tries to give an overview of Python in the web, it cannot always be as up to date as desired. Web development in Python is rapidly moving forward, so the wiki page on [Web Programming](#) may be more in sync with recent development.

The Low-Level View

When a user enters a web site, their browser makes a connection to the site's web server (this is called the *request*). The server looks up the file in the file system and sends it back to the user's browser, which displays it (this is the *response*). This is roughly how the underlying protocol, HTTP, works.

Dynamic web sites are not based on files in the file system, but rather on programs which are run by the web server when a request comes in, and which *generate* the content that is returned to the user. They can do all sorts of useful things, like display the postings of a bulletin board, show your email, configure software, or just display the current time. These programs can be written in any programming language the server supports. Since most servers support Python, it is easy to use Python to create dynamic web sites.

Most HTTP servers are written in C or C++, so they cannot execute Python code directly – a bridge is needed between the server and the program. These bridges, or rather interfaces, define how programs interact with the server. There have been numerous attempts to create the best possible interface, but there are only a few worth mentioning.

Not every web server supports every interface. Many web servers only support old, now-obsolete interfaces; however, they can often be extended using third-party modules to support newer ones.

Common Gateway Interface

This interface, most commonly referred to as “CGI”, is the oldest, and is supported by nearly every web server out of the box. Programs using CGI to communicate with their web server need to

be started by the server for every request. So, every request starts a new Python interpreter – which takes some time to start up – thus making the whole interface only usable for low load situations.

The upside of CGI is that it is simple – writing a Python program which uses CGI is a matter of about three lines of code. This simplicity comes at a price: it does very few things to help the developer.

Writing CGI programs, while still possible, is no longer recommended. With [WSGI](#), a topic covered later in this document, it is possible to write programs that emulate CGI, so they can be run as CGI if no better option is available.

See also: The Python standard library includes some modules that are helpful for creating plain CGI programs:

- [cgi](#) – Handling of user input in CGI scripts
- [cgi.tb](#) – Displays nice tracebacks when errors happen in CGI applications, instead of presenting a “500 Internal Server Error” message

The Python wiki features a page on [CGI scripts](#) with some additional information about CGI in Python.

Simple script for testing CGI

To test whether your web server works with CGI, you can use this short and simple CGI program:

```
#!/usr/bin/env python
# -*- coding: UTF-8 -*-

# enable debugging
import cgi.tb
cgi.tb.enable()
```

```
print("Content-Type: text/plain;charset=utf-8")
print()

print("Hello World!")
```

Depending on your web server configuration, you may need to save this code with a `.py` or `.cgi` extension. Additionally, this file may also need to be in a `cgi-bin` folder, for security reasons.

You might wonder what the `cgitb` line is about. This line makes it possible to display a nice traceback instead of just crashing and displaying an “Internal Server Error” in the user’s browser. This is useful for debugging, but it might risk exposing some confidential data to the user. You should not use `cgitb` in production code for this reason. You should *always* catch exceptions, and display proper error pages – end-users don’t like to see nondescript “Internal Server Errors” in their browsers.

Setting up CGI on your own server

If you don’t have your own web server, this does not apply to you. You can check whether it works as-is, and if not you will need to talk to the administrator of your web server. If it is a big host, you can try filing a ticket asking for Python support.

If you are your own administrator or want to set up CGI for testing purposes on your own computers, you have to configure it by yourself. There is no single way to configure CGI, as there are many web servers with different configuration options. Currently the most widely used free web server is [Apache HTTPd](#), or Apache for short. Apache can be easily installed on nearly every system using the system’s package management tool. [lighttpd](#) is another alternative and is said to have better performance. On many systems this server can also be installed using the package management tool, so manually compiling the web server may not be needed.

- On Apache you can take a look at the [Dynamic Content with CGI](#) tutorial, where everything is described. Most of the time it is enough just to set `+ExecCGI`. The tutorial also describes the most common gotchas that might arise.
- On lighttpd you need to use the [CGI module](#), which can be configured in a straightforward way. It boils down to setting `cgi.assign` properly.

Common problems with CGI scripts

Using CGI sometimes leads to small annoyances while trying to get these scripts to run. Sometimes a seemingly correct script does not work as expected, the cause being some small hidden problem that's difficult to spot.

Some of these potential problems are:

- The Python script is not marked as executable. When CGI scripts are not executable most web servers will let the user download it, instead of running it and sending the output to the user. For CGI scripts to run properly on Unix-like operating systems, the `+x` bit needs to be set. Using `chmod a+x your_script.py` may solve this problem.
- On a Unix-like system, The line endings in the program file must be Unix style line endings. This is important because the web server checks the first line of the script (called shebang) and tries to run the program specified there. It gets easily confused by Windows line endings (Carriage Return & Line Feed, also called CRLF), so you have to convert the file to Unix line endings (only Line Feed, LF). This can be done automatically by uploading the file via FTP in text mode instead of binary mode, but the preferred way is just telling your editor to save the files with Unix line endings. Most editors support this.
- Your web server must be able to read the file, and you need to

make sure the permissions are correct. On unix-like systems, the server often runs as user and group `www-data`, so it might be worth a try to change the file ownership, or making the file world readable by using `chmod a+r your_script.py`.

- The web server must know that the file you're trying to access is a CGI script. Check the configuration of your web server, as it may be configured to expect a specific file extension for CGI scripts.
- On Unix-like systems, the path to the interpreter in the shebang (`#!/usr/bin/env python`) must be correct. This line calls `/usr/bin/env` to find Python, but it will fail if there is no `/usr/bin/env`, or if Python is not in the web server's path. If you know where your Python is installed, you can also use that full path. The commands `whereis python` and `type -p python` could help you find where it is installed. Once you know the path, you can change the shebang accordingly: `#!/usr/bin/python`.
- The file must not contain a BOM (Byte Order Mark). The BOM is meant for determining the byte order of UTF-16 and UTF-32 encodings, but some editors write this also into UTF-8 files. The BOM interferes with the shebang line, so be sure to tell your editor not to write the BOM.
- If the web server is using `mod_python`, `mod_python` may be having problems. `mod_python` is able to handle CGI scripts by itself, but it can also be a source of issues.

mod_python

People coming from PHP often find it hard to grasp how to use Python in the web. Their first thought is mostly `mod_python`, because they think that this is the equivalent to `mod_php`. Actually, there are many differences. What `mod_python` does is embed the interpreter into the Apache process, thus speeding up requests by not having to start a Python interpreter for each request. On the

other hand, it is not “Python intermixed with HTML” in the way that PHP is often intermixed with HTML. The Python equivalent of that is a template engine. `mod_python` itself is much more powerful and provides more access to Apache internals. It can emulate CGI, work in a “Python Server Pages” mode (similar to JSP) which is “HTML intermingled with Python”, and it has a “Publisher” which designates one file to accept all requests and decide what to do with them.

`mod_python` does have some problems. Unlike the PHP interpreter, the Python interpreter uses caching when executing files, so changes to a file will require the web server to be restarted. Another problem is the basic concept – Apache starts child processes to handle the requests, and unfortunately every child process needs to load the whole Python interpreter even if it does not use it. This makes the whole web server slower. Another problem is that, because `mod_python` is linked against a specific version of `libpython`, it is not possible to switch from an older version to a newer (e.g. 2.4 to 2.5) without recompiling `mod_python`. `mod_python` is also bound to the Apache web server, so programs written for `mod_python` cannot easily run on other web servers.

These are the reasons why `mod_python` should be avoided when writing new programs. In some circumstances it still might be a good idea to use `mod_python` for deployment, but WSGI makes it possible to run WSGI programs under `mod_python` as well.

FastCGI and SCGI

FastCGI and SCGI try to solve the performance problem of CGI in another way. Instead of embedding the interpreter into the web server, they create long-running background processes. There is still a module in the web server which makes it possible for the web server to “speak” with the background process. As the background process is independent of the server, it can be written in any

language, including Python. The language just needs to have a library which handles the communication with the webserver.

The difference between FastCGI and SCGI is very small, as SCGI is essentially just a “simpler FastCGI”. As the web server support for SCGI is limited, most people use FastCGI instead, which works the same way. Almost everything that applies to SCGI also applies to FastCGI as well, so we’ll only cover the latter.

These days, FastCGI is never used directly. Just like `mod_python`, it is only used for the deployment of WSGI applications.

See also:

- [FastCGI, SCGI, and Apache: Background and Future](#) is a discussion on why the concept of FastCGI and SCGI is better than that of `mod_python`.

Setting up FastCGI

Each web server requires a specific module.

- Apache has both `mod_fastcgi` and `mod_fcgid`. `mod_fastcgi` is the original one, but it has some licensing issues, which is why it is sometimes considered non-free. `mod_fcgid` is a smaller, compatible alternative. One of these modules needs to be loaded by Apache.
- `lighttpd` ships its own [FastCGI module](#) as well as an [SCGI module](#).
- `nginx` also supports [FastCGI](#).

Once you have installed and configured the module, you can test it with the following WSGI-application:

```
#!/usr/bin/env python
```

```
# -*- coding: UTF-8 -*-

import sys, os
from html import escape
from flup.server.fcgi import WSGIServer

def app(environ, start_response):
    start_response('200 OK', [('Content-Type', 'text/html')])

    yield '<h1>FastCGI Environment</h1>'
    yield '<table>'
    for k, v in sorted(environ.items()):
        yield '<tr><th>{0}</th><td>{1}</td></tr>'.format(
            escape(k), escape(v))
    yield '</table>'

WSGIServer(app).run()
```

This is a simple WSGI application, but you need to install [flup](#) first, as flup handles the low level FastCGI access.

See also: There is some documentation on [setting up Django with FastCGI](#), most of which can be reused for other WSGI-compliant frameworks and libraries. Only the `manage.py` part has to be changed, the example used here can be used instead. Django does more or less the exact same thing.

mod_wsgi

`mod_wsgi` is an attempt to get rid of the low level gateways. Given that FastCGI, SCGI, and `mod_python` are mostly used to deploy WSGI applications, `mod_wsgi` was started to directly embed WSGI applications into the Apache web server. `mod_wsgi` is specifically designed to host WSGI applications. It makes the deployment of WSGI applications much easier than deployment using other low level methods, which need glue code. The downside is that `mod_wsgi` is limited to the Apache web server; other servers would need their own implementations of `mod_wsgi`.

`mod_wsgi` supports two modes: embedded mode, in which it integrates with the Apache process, and daemon mode, which is more FastCGI-like. Unlike FastCGI, `mod_wsgi` handles the worker-processes by itself, which makes administration easier.

Step back: WSGI

WSGI has already been mentioned several times, so it has to be something important. In fact it really is, and now it is time to explain it.

The *Web Server Gateway Interface*, or WSGI for short, is defined in [PEP 333](#) and is currently the best way to do Python web programming. While it is great for programmers writing frameworks, a normal web developer does not need to get in direct contact with it. When choosing a framework for web development it is a good idea to choose one which supports WSGI.

The big benefit of WSGI is the unification of the application programming interface. When your program is compatible with WSGI – which at the outer level means that the framework you are using has support for WSGI – your program can be deployed via any web server interface for which there are WSGI wrappers. You do not need to care about whether the application user uses `mod_python` or `FastCGI` or `mod_wsgi` – with WSGI your application will work on any gateway interface. The Python standard library contains its own WSGI server, [wsgiref](#), which is a small web server that can be used for testing.

A really great WSGI feature is middleware. Middleware is a layer around your program which can add various functionality to it. There is quite a bit of [middleware](#) already available. For example, instead of writing your own session management (HTTP is a stateless protocol, so to associate multiple HTTP requests with a single user your application must create and manage such state via a session), you can just download middleware which does that, plug it in, and get on with coding the unique parts of your application. The same thing with compression – there is existing middleware which handles

compressing your HTML using gzip to save on your server's bandwidth. Authentication is another a problem easily solved using existing middleware.

Although WSGI may seem complex, the initial phase of learning can be very rewarding because WSGI and the associated middleware already have solutions to many problems that might arise while developing web sites.

WSGI Servers

The code that is used to connect to various low level gateways like CGI or `mod_python` is called a *WSGI server*. One of these servers is `flup`, which supports FastCGI and SCGI, as well as [AJP](#). Some of these servers are written in Python, as `flup` is, but there also exist others which are written in C and can be used as drop-in replacements.

There are many servers already available, so a Python web application can be deployed nearly anywhere. This is one big advantage that Python has compared with other web technologies.

See also: A good overview of WSGI-related code can be found in the [WSGI wiki](#), which contains an extensive list of [WSGI servers](#) which can be used by *any* application supporting WSGI.

You might be interested in some WSGI-supporting modules already contained in the standard library, namely:

- [wsgiref](#) – some tiny utilities and servers for WSGI

Case study: MoinMoin

What does WSGI give the web application developer? Let's take a

look at an application that's been around for a while, which was written in Python without using WSGI.

One of the most widely used wiki software packages is [MoinMoin](#). It was created in 2000, so it predates WSGI by about three years. Older versions needed separate code to run on CGI, mod_python, FastCGI and standalone.

It now includes support for WSGI. Using WSGI, it is possible to deploy MoinMoin on any WSGI compliant server, with no additional glue code. Unlike the pre-WSGI versions, this could include WSGI servers that the authors of MoinMoin know nothing about.

Model-View-Controller

The term *MVC* is often encountered in statements such as “framework *foo* supports MVC”. MVC is more about the overall organization of code, rather than any particular API. Many web frameworks use this model to help the developer bring structure to their program. Bigger web applications can have lots of code, so it is a good idea to have an effective structure right from the beginning. That way, even users of other frameworks (or even other languages, since MVC is not Python-specific) can easily understand the code, given that they are already familiar with the MVC structure.

MVC stands for three components:

- The *model*. This is the data that will be displayed and modified. In Python frameworks, this component is often represented by the classes used by an object-relational mapper.
- The *view*. This component’s job is to display the data of the model to the user. Typically this component is implemented via templates.
- The *controller*. This is the layer between the user and the model. The controller reacts to user actions (like opening some specific URL), tells the model to modify the data if necessary, and tells the view code what to display,

While one might think that MVC is a complex design pattern, in fact it is not. It is used in Python because it has turned out to be useful for creating clean, maintainable web sites.

Note: While not all Python frameworks explicitly support MVC, it is often trivial to create a web site which uses the MVC pattern by separating the data logic (the model) from the user interaction logic (the controller) and the templates (the view). That’s why it is

important not to write unnecessary Python code in the templates – it works against the MVC model and creates chaos in the code base, making it harder to understand and modify.

See also: The English Wikipedia has an article about the [Model-View-Controller pattern](#). It includes a long list of web frameworks for various programming languages.

Ingredients for Websites

Websites are complex constructs, so tools have been created to help web developers make their code easier to write and more maintainable. Tools like these exist for all web frameworks in all languages. Developers are not forced to use these tools, and often there is no “best” tool. It is worth learning about the available tools because they can greatly simplify the process of developing a web site.

See also: There are far more components than can be presented here. The Python wiki has a page about these components, called [Web Components](#).

Templates

Mixing of HTML and Python code is made possible by a few libraries. While convenient at first, it leads to horribly unmaintainable code. That’s why templates exist. Templates are, in the simplest case, just HTML files with placeholders. The HTML is sent to the user’s browser after filling in the placeholders.

Python already includes a way to build simple templates:

```
# a simple template
template = "<html><body><h1>Hello {who}!</h1></body></html>"
print(template.format(who="Reader"))
```

To generate complex HTML based on non-trivial model data, conditional and looping constructs like Python’s *for* and *if* are generally needed. *Template engines* support templates of this complexity.

There are a lot of template engines available for Python which can

be used with or without a [framework](#). Some of these define a plain-text programming language which is easy to learn, partly because it is limited in scope. Others use XML, and the template output is guaranteed to be always be valid XML. There are many other variations.

Some [frameworks](#) ship their own template engine or recommend one in particular. In the absence of a reason to use a different template engine, using the one provided by or recommended by the framework is a good idea.

Popular template engines include:

- [Mako](#)
- [Genshi](#)
- [Jinja](#)

See also: There are many template engines competing for attention, because it is pretty easy to create them in Python. The page [Templating](#) in the wiki lists a big, ever-growing number of these. The three listed above are considered “second generation” template engines and are a good place to start.

Data persistence

Data persistence, while sounding very complicated, is just about storing data. This data might be the text of blog entries, the postings on a bulletin board or the text of a wiki page. There are, of course, a number of different ways to store information on a web server.

Often, relational database engines like [MySQL](#) or [PostgreSQL](#) are used because of their good performance when handling very large databases consisting of millions of entries. There is also a small database engine called [SQLite](#), which is bundled with Python in the

`sqlite3` module, and which uses only one file. It has no other dependencies. For smaller sites SQLite is just enough.

Relational databases are *queried* using a language called [SQL](#). Python programmers in general do not like SQL too much, as they prefer to work with objects. It is possible to save Python objects into a database using a technology called [ORM](#) (Object Relational Mapping). ORM translates all object-oriented access into SQL code under the hood, so the developer does not need to think about it. Most [frameworks](#) use ORMs, and it works quite well.

A second possibility is storing data in normal, plain text files (some times called “flat files”). This is very easy for simple sites, but can be difficult to get right if the web site is performing many updates to the stored data.

A third possibility are object oriented databases (also called “object databases”). These databases store the object data in a form that closely parallels the way the objects are structured in memory during program execution. (By contrast, ORMs store the object data as rows of data in tables and relations between those rows.) Storing the objects directly has the advantage that nearly all objects can be saved in a straightforward way, unlike in relational databases where some objects are very hard to represent.

[Frameworks](#) often give hints on which data storage method to choose. It is usually a good idea to stick to the data store recommended by the framework unless the application has special requirements better satisfied by an alternate storage mechanism.

See also:

- [Persistence Tools](#) lists possibilities on how to save data in the file system. Some of these modules are part of the standard library

- [Database Programming](#) helps with choosing a method for saving data
- [SQLAlchemy](#), the most powerful OR-Mapper for Python, and [Elixir](#), which makes SQLAlchemy easier to use
- [SQLObject](#), another popular OR-Mapper
- [ZODB](#) and [Durus](#), two object oriented databases

Frameworks

The process of creating code to run web sites involves writing code to provide various services. The code to provide a particular service often works the same way regardless of the complexity or purpose of the web site in question. Abstracting these common solutions into reusable code produces what are called “frameworks” for web development. Perhaps the most well-known framework for web development is Ruby on Rails, but Python has its own frameworks. Some of these were partly inspired by Rails, or borrowed ideas from Rails, but many existed a long time before Rails.

Originally Python web frameworks tended to incorporate all of the services needed to develop web sites as a giant, integrated set of tools. No two web frameworks were interoperable: a program developed for one could not be deployed on a different one without considerable re-engineering work. This led to the development of “minimalist” web frameworks that provided just the tools to communicate between the Python code and the http protocol, with all other services to be added on top via separate components. Some ad hoc standards were developed that allowed for limited interoperability between frameworks, such as a standard that allowed different template engines to be used interchangeably.

Since the advent of WSGI, the Python web framework world has been evolving toward interoperability based on the WSGI standard. Now many web frameworks, whether “full stack” (providing all the tools one needs to deploy the most complex web sites) or minimalist, or anything in between, are built from collections of reusable components that can be used with more than one framework.

The majority of users will probably want to select a “full stack” framework that has an active community. These frameworks tend to be well documented, and provide the easiest path to producing a

fully functional web site in minimal time.

Some notable frameworks

There are an incredible number of frameworks, so they cannot all be covered here. Instead we will briefly touch on some of the most popular.

Django

[Django](#) is a framework consisting of several tightly coupled elements which were written from scratch and work together very well. It includes an ORM which is quite powerful while being simple to use, and has a great online administration interface which makes it possible to edit the data in the database with a browser. The template engine is text-based and is designed to be usable for page designers who cannot write Python. It supports template inheritance and filters (which work like Unix pipes). Django has many handy features bundled, such as creation of RSS feeds or generic views, which make it possible to create web sites almost without writing any Python code.

It has a big, international community, the members of which have created many web sites. There are also a lot of add-on projects which extend Django's normal functionality. This is partly due to Django's well written [online documentation](#) and the [Django book](#).

Note: Although Django is an MVC-style framework, it names the elements differently, which is described in the [Django FAQ](#).

TurboGears

Another popular web framework for Python is [TurboGears](#). TurboGears takes the approach of using already existing

components and combining them with glue code to create a seamless experience. TurboGears gives the user flexibility in choosing components. For example the ORM and template engine can be changed to use packages different from those used by default.

The documentation can be found in the [TurboGears wiki](#), where links to screencasts can be found. TurboGears has also an active user community which can respond to most related questions. There is also a [TurboGears book](#) published, which is a good starting point.

The newest version of TurboGears, version 2.0, moves even further in direction of WSGI support and a component-based architecture. TurboGears 2 is based on the WSGI stack of another popular component-based web framework, [Pylons](#).

Zope

The Zope framework is one of the “old original” frameworks. Its current incarnation in Zope2 is a tightly integrated full-stack framework. One of its most interesting feature is its tight integration with a powerful object database called the [ZODB](#) (Zope Object Database). Because of its highly integrated nature, Zope wound up in a somewhat isolated ecosystem: code written for Zope wasn’t very usable outside of Zope, and vice-versa. To solve this problem the Zope 3 effort was started. Zope 3 re-engineers Zope as a set of more cleanly isolated components. This effort was started before the advent of the WSGI standard, but there is WSGI support for Zope 3 from the [Repoze](#) project. Zope components have many years of production use behind them, and the Zope 3 project gives access to these components to the wider Python community. There is even a separate framework based on the Zope components: [Grok](#).

Zope is also the infrastructure used by the [Plone](#) content management system, one of the most powerful and popular content

management systems available.

Other notable frameworks

Of course these are not the only frameworks that are available. There are many other frameworks worth mentioning.

Another framework that's already been mentioned is [Pylons](#). Pylons is much like TurboGears, but with an even stronger emphasis on flexibility, which comes at the cost of being more difficult to use. Nearly every component can be exchanged, which makes it necessary to use the documentation of every single component, of which there are many. Pylons builds upon [Paste](#), an extensive set of tools which are handy for WSGI.

And that's still not everything. The most up-to-date information can always be found in the Python wiki.

See also: The Python wiki contains an extensive list of [web frameworks](#).

Most frameworks also have their own mailing lists and IRC channels, look out for these on the projects' web sites. There is also a general "Python in the Web" IRC channel on freenode called [#python.web](#).

General Information

What is Python?

Python is an interpreted, interactive, object-oriented programming language. It incorporates modules, exceptions, dynamic typing, very high level dynamic data types, and classes. Python combines remarkable power with very clear syntax. It has interfaces to many system calls and libraries, as well as to various window systems, and is extensible in C or C++. It is also usable as an extension language for applications that need a programmable interface. Finally, Python is portable: it runs on many Unix variants, on the Mac, and on PCs under MS-DOS, Windows, Windows NT, and OS/2.

To find out more, start with *The Python Tutorial*. The [Beginner's Guide to Python](#) links to other introductory tutorials and resources for learning Python.

What is the Python Software Foundation?

The Python Software Foundation is an independent non-profit organization that holds the copyright on Python versions 2.1 and newer. The PSF's mission is to advance open source technology related to the Python programming language and to publicize the use of Python. The PSF's home page is at <http://www.python.org/psf/>.

Donations to the PSF are tax-exempt in the US. If you use Python and find it helpful, please contribute via [the PSF donation page](#).

Are there copyright restrictions on the use of Python?

You can do anything you want with the source, as long as you leave the copyrights in and display those copyrights in any documentation about Python that you produce. If you honor the copyright rules, it's OK to use Python for commercial use, to sell copies of Python in source or binary form (modified or unmodified), or to sell products that incorporate Python in some form. We would still like to know about all commercial use of Python, of course.

See [the PSF license page](#) to find further explanations and a link to the full text of the license.

The Python logo is trademarked, and in certain cases permission is required to use it. Consult [the Trademark Usage Policy](#) for more information.

Why was Python created in the first place?

Here's a *very* brief summary of what started it all, written by Guido van Rossum:

I had extensive experience with implementing an interpreted language in the ABC group at CWI, and from working with this group I had learned a lot about language design. This is the origin of many Python features, including the use of indentation for statement grouping and the inclusion of very-high-level data types (although the details are all different in Python).

I had a number of gripes about the ABC language, but also liked many of its features. It was impossible to extend the ABC language (or its implementation) to remedy my complaints – in fact its lack of extensibility was one of its biggest problems. I had some experience with using Modula-2+ and talked with the designers of Modula-3 and read the Modula-3 report. Modula-3 is the origin of the syntax and semantics used for exceptions, and some other Python features.

I was working in the Amoeba distributed operating system group at CWI. We needed a better way to do system administration than by writing either C programs or Bourne shell scripts, since Amoeba had its own system call interface which wasn't easily accessible from the Bourne shell. My experience with error handling in Amoeba made me acutely aware of the importance of exceptions as a programming language feature.

It occurred to me that a scripting language with a syntax like ABC but with access to the Amoeba system calls would fill the need. I realized that it would be foolish to write an Amoeba-specific language, so I decided that I needed a language that was generally extensible.

During the 1989 Christmas holidays, I had a lot of time on my hand, so I decided to give it a try. During the next year, while still mostly working on it in my own time, Python was used in the Amoeba project with increasing success, and the feedback from colleagues made me add many early improvements.

In February 1991, after just over a year of development, I decided to post to USENET. The rest is in the [Misc/HISTORY](#) file.

What is Python good for?

Python is a high-level general-purpose programming language that can be applied to many different classes of problems.

The language comes with a large standard library that covers areas such as string processing (regular expressions, Unicode, calculating differences between files), Internet protocols (HTTP, FTP, SMTP, XML-RPC, POP, IMAP, CGI programming), software engineering (unit testing, logging, profiling, parsing Python code), and operating system interfaces (system calls, filesystems, TCP/IP sockets). Look at the table of contents for [The Python Standard Library](#) to get an

idea of what's available. A wide variety of third-party extensions are also available. Consult [the Python Package Index](#) to find packages of interest to you.

How does the Python version numbering scheme work?

Python versions are numbered A.B.C or A.B. A is the major version number – it is only incremented for really major changes in the language. B is the minor version number, incremented for less earth-shattering changes. C is the micro-level – it is incremented for each bugfix release. See [PEP 6](#) for more information about bugfix releases.

Not all releases are bugfix releases. In the run-up to a new major release, a series of development releases are made, denoted as alpha, beta, or release candidate. Alphas are early releases in which interfaces aren't yet finalized; it's not unexpected to see an interface change between two alpha releases. Betas are more stable, preserving existing interfaces but possibly adding new modules, and release candidates are frozen, making no changes except as needed to fix critical bugs.

Alpha, beta and release candidate versions have an additional suffix. The suffix for an alpha version is "aN" for some small number N, the suffix for a beta version is "bN" for some small number N, and the suffix for a release candidate version is "cN" for some small number N. In other words, all versions labeled 2.0aN precede the versions labeled 2.0bN, which precede versions labeled 2.0cN, and *those* precede 2.0.

You may also find version numbers with a "+" suffix, e.g. "2.2+". These are unreleased versions, built directly from the Subversion trunk. In practice, after a final minor release is made, the Subversion

trunk is incremented to the next minor version, which becomes the “a0” version, e.g. “2.4a0”.

See also the documentation for `sys.version`, `sys.hexversion`, and `sys.version_info`.

How do I obtain a copy of the Python source?

The latest Python source distribution is always available from python.org, at <http://www.python.org/download/>. The latest development sources can be obtained via anonymous Subversion at <http://svn.python.org/projects/python/trunk>.

The source distribution is a gzipped tar file containing the complete C source, Sphinx-formatted documentation, Python library modules, example programs, and several useful pieces of freely distributable software. The source will compile and run out of the box on most UNIX platforms.

Consult the [Developer FAQ](#) for more information on getting the source code and compiling it.

How do I get documentation on Python?

The standard documentation for the current stable version of Python is available at <http://docs.python.org/>. PDF, plain text, and downloadable HTML versions are also available at <http://docs.python.org/download.html>.

The documentation is written in reStructuredText and processed by the [Sphinx documentation tool](#). The reStructuredText source for the documentation is part of the Python source distribution.

I've never programmed before. Is there a Python

tutorial?

There are numerous tutorials and books available. The standard documentation includes *The Python Tutorial*.

Consult the [Beginner's Guide](#) to find information for beginning Python programmers, including lists of tutorials.

Is there a newsgroup or mailing list devoted to Python?

There is a newsgroup, *comp.lang.python*, and a mailing list, [python-list](#). The newsgroup and mailing list are gatewayed into each other – if you can read news it's unnecessary to subscribe to the mailing list. *comp.lang.python* is high-traffic, receiving hundreds of postings every day, and Usenet readers are often more able to cope with this volume.

Announcements of new software releases and events can be found in *comp.lang.python.announce*, a low-traffic moderated list that receives about five postings per day. It's available as the [python-announce mailing list](#).

More info about other mailing lists and newsgroups can be found at <http://www.python.org/community/lists/>.

How do I get a beta test version of Python?

Alpha and beta releases are available from <http://www.python.org/download/>. All releases are announced on the *comp.lang.python* and *comp.lang.python.announce* newsgroups and on the Python home page at <http://www.python.org/>; an RSS feed of news is available.

You can also access the development version of Python through Subversion. See <http://www.python.org/dev/faq/> for details.

How do I submit bug reports and patches for Python?

To report a bug or submit a patch, please use the Roundup installation at <http://bugs.python.org/>.

You must have a Roundup account to report bugs; this makes it possible for us to contact you if we have follow-up questions. It will also enable Roundup to send you updates as we act on your bug. If you had previously used SourceForge to report bugs to Python, you can obtain your Roundup password through Roundup's [password reset procedure](#).

For more information on how Python is developed, consult [the Python Developer's Guide](#).

Are there any published articles about Python that I can reference?

It's probably best to cite your favorite book about Python.

The very first article about Python was written in 1991 and is now quite outdated.

Guido van Rossum and Jelke de Boer, "Interactively Testing Remote Servers Using the Python Programming Language", CWI Quarterly, Volume 4, Issue 4 (December 1991), Amsterdam, pp 283-303.

Are there any books on Python?

Yes, there are many, and more are being published. See the

python.org wiki at <http://wiki.python.org/moin/PythonBooks> for a list.

You can also search online bookstores for “Python” and filter out the Monty Python references; or perhaps search for “Python” and “language”.

Where in the world is www.python.org located?

It's currently in Amsterdam, graciously hosted by [XS4ALL](#). Thanks to Thomas Wouters for his work in arranging python.org's hosting.

Why is it called Python?

When he began implementing Python, Guido van Rossum was also reading the published scripts from “[Monty Python's Flying Circus](#)”, a BBC comedy series from the 1970s. Van Rossum thought he needed a name that was short, unique, and slightly mysterious, so he decided to call the language Python.

Do I have to like “Monty Python's Flying Circus”?

No, but it helps. :)

Python in the real world

How stable is Python?

Very stable. New, stable releases have been coming out roughly every 6 to 18 months since 1991, and this seems likely to continue. Currently there are usually around 18 months between major releases.

The developers issue “bugfix” releases of older versions, so the stability of existing releases gradually improves. Bugfix releases, indicated by a third component of the version number (e.g. 2.5.3, 2.6.2), are managed for stability; only fixes for known problems are included in a bugfix release, and it’s guaranteed that interfaces will remain the same throughout a series of bugfix releases.

The latest stable releases can always be found on the [Python download page](#). There are two recommended production-ready versions at this point in time, because at the moment there are two branches of stable releases: 2.x and 3.x. Python 3.x may be less useful than 2.x, since currently there is more third party software available for Python 2 than for Python 3. Python 2 code will generally not run unchanged in Python 3.

How many people are using Python?

There are probably tens of thousands of users, though it’s difficult to obtain an exact count.

Python is available for free download, so there are no sales figures, and it’s available from many different sites and packaged with many Linux distributions, so download statistics don’t tell the whole story either.

The `comp.lang.python` newsgroup is very active, but not all Python users post to the group or even read it.

Have any significant projects been done in Python?

See <http://python.org/about/success> for a list of projects that use Python. Consulting the proceedings for [past Python conferences](#) will reveal contributions from many different companies and organizations.

High-profile Python projects include the [Mailman mailing list manager](#) and the [Zope application server](#). Several Linux distributions, most notably [Red Hat](#), have written part or all of their installer and system administration software in Python. Companies that use Python internally include Google, Yahoo, and Lucasfilm Ltd.

What new developments are expected for Python in the future?

See <http://www.python.org/dev/peps/> for the Python Enhancement Proposals (PEPs). PEPs are design documents describing a suggested new feature for Python, providing a concise technical specification and a rationale. Look for a PEP titled “Python X.Y Release Schedule”, where X.Y is a version that hasn’t been publicly released yet.

New development is discussed on the [python-dev mailing list](#).

Is it reasonable to propose incompatible changes to Python?

In general, no. There are already millions of lines of Python code around the world, so any change in the language that invalidates more than a very small fraction of existing programs has to be

frowned upon. Even if you can provide a conversion program, there's still the problem of updating all documentation; many books have been written about Python, and we don't want to invalidate them all at a single stroke.

Providing a gradual upgrade path is necessary if a feature has to be changed. **PEP 5** describes the procedure followed for introducing backward-incompatible changes while minimizing disruption for users.

Is Python Y2K (Year 2000) Compliant?

As of August, 2003 no major problems have been reported and Y2K compliance seems to be a non-issue.

Python does very few date calculations and for those it does perform relies on the C library functions. Python generally represents times either as seconds since 1970 or as a (year, month, day, ...) tuple where the year is expressed with four digits, which makes Y2K bugs unlikely. So as long as your C library is okay, Python should be okay. Of course, it's possible that a particular application written in Python makes assumptions about 2-digit years.

Because Python is available free of charge, there are no absolute guarantees. If there *are* unforeseen problems, liability is the user's problem rather than the developers', and there is nobody you can sue for damages. The Python copyright notice contains the following disclaimer:

4. PSF is making Python 2.3 available to Licensee on an "AS IS" basis. PSF MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT LIMITATION, PSF MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR

PURPOSE OR THAT THE USE OF PYTHON 2.3 WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.

5. PSF SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS OF PYTHON 2.3 FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF MODIFYING, DISTRIBUTING, OR OTHERWISE USING PYTHON 2.3, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.

The good news is that *if* you encounter a problem, you have full source available to track it down and fix it. This is one advantage of an open source programming environment.

Is Python a good language for beginning programmers?

Yes.

It is still common to start students with a procedural and statically typed language such as Pascal, C, or a subset of C++ or Java. Students may be better served by learning Python as their first language. Python has a very simple and consistent syntax and a large standard library and, most importantly, using Python in a beginning programming course lets students concentrate on important programming skills such as problem decomposition and data type design. With Python, students can be quickly introduced to basic concepts such as loops and procedures. They can probably even work with user-defined objects in their very first course.

For a student who has never programmed before, using a statically typed language seems unnatural. It presents additional complexity that the student must master and slows the pace of the course. The students are trying to learn to think like a computer, decompose problems, design consistent interfaces, and encapsulate data. While

learning to use a statically typed language is important in the long term, it is not necessarily the best topic to address in the students' first programming course.

Many other aspects of Python make it a good first language. Like Java, Python has a large standard library so that students can be assigned programming projects very early in the course that *do* something. Assignments aren't restricted to the standard four-function calculator and check balancing programs. By using the standard library, students can gain the satisfaction of working on realistic applications as they learn the fundamentals of programming. Using the standard library also teaches students about code reuse. Third-party modules such as PyGame are also helpful in extending the students' reach.

Python's interactive interpreter enables students to test language features while they're programming. They can keep a window with the interpreter running while they enter their program's source in another window. If they can't remember the methods for a list, they can do something like this:

```
>>> L = []
>>> dir(L)
['append', 'count', 'extend', 'index', 'insert', 'pop', 'remove',
'reverse', 'sort']
>>> help(L.append)
Help on built-in function append:

append(...)
    L.append(object) -- append object to end
>>> L.append(1)
>>> L
[1]
```

With the interpreter, documentation is never far from the student as he's programming.

There are also good IDEs for Python. IDLE is a cross-platform IDE for Python that is written in Python using Tkinter. PythonWin is a Windows-specific IDE. Emacs users will be happy to know that there is a very good Python mode for Emacs. All of these programming environments provide syntax highlighting, auto-indenting, and access to the interactive interpreter while coding. Consult <http://www.python.org/editors/> for a full list of Python editing environments.

If you want to discuss Python's use in education, you may be interested in joining [the edu-sig mailing list](#).

Upgrading Python

What is this bsddb185 module my application keeps complaining about?

Starting with Python2.3, the distribution includes the *PyBSDDDB package* <<http://pybsddb.sf.net/>> as a replacement for the old bsddb module. It includes functions which provide backward compatibility at the API level, but requires a newer version of the underlying [Berkeley DB](#) library. Files created with the older bsddb module can't be opened directly using the new module.

Using your old version of Python and a pair of scripts which are part of Python 2.3 (db2pickle.py and pickle2db.py, in the Tools/scripts directory) you can convert your old database files to the new format. Using your old Python version, run the db2pickle.py script to convert it to a pickle, e.g.:

```
python2.2 <pathto>/db2pickley.py database.db database.pck
```

Rename your database file:

```
mv database.db olddatabase.db
```

Now convert the pickle file to a new format database:

```
python <pathto>/pickle2db.py database.db database.pck
```

The precise commands you use will vary depending on the particulars of your installation. For full details about operation of these two scripts check the doc string at the start of each one.

 - `__import__('x.y.z')` returns `<module 'x'>`; how do I get `z`?
 - When I edit an imported module and reimport it, the changes don't show up. Why does this happen?

General Questions

Is there a source code level debugger with breakpoints, single-stepping, etc.?

Yes.

The `pdb` module is a simple but adequate console-mode debugger for Python. It is part of the standard Python library, and is **documented in the Library Reference Manual**. You can also write your own debugger by using the code for `pdb` as an example.

The IDLE interactive development environment, which is part of the standard Python distribution (normally available as `Tools/scripts/idle`), includes a graphical debugger. There is documentation for the IDLE debugger at <http://www.python.org/idle/doc/idle2.html#Debugger>.

PythonWin is a Python IDE that includes a GUI debugger based on `pdb`. The Pythonwin debugger colors breakpoints and has quite a few cool features such as debugging non-Pythonwin programs. Pythonwin is available as part of the [Python for Windows Extensions](#) project and as a part of the ActivePython distribution (see <http://www.activestate.com/Products/ActivePython/index.html>).

[Boa Constructor](#) is an IDE and GUI builder that uses `wxWidgets`. It offers visual frame creation and manipulation, an object inspector, many views on the source like object browsers, inheritance hierarchies, doc string generated html documentation, an advanced debugger, integrated help, and Zope support.

[Eric](#) is an IDE built on `PyQt` and the `Scintilla` editing component.

Pydb is a version of the standard Python debugger pdb, modified for use with DDD (Data Display Debugger), a popular graphical debugger front end. Pydb can be found at <http://bashdb.sourceforge.net/pydb/> and DDD can be found at <http://www.gnu.org/software/ddd>.

There are a number of commercial Python IDEs that include graphical debuggers. They include:

- Wing IDE (<http://wingware.com/>)
- Komodo IDE (<http://www.activestate.com/Products/Komodo>)

Is there a tool to help find bugs or perform static analysis?

Yes.

PyChecker is a static analysis tool that finds bugs in Python source code and warns about code complexity and style. You can get PyChecker from <http://pychecker.sf.net>.

Pylint is another tool that checks if a module satisfies a coding standard, and also makes it possible to write plug-ins to add a custom feature. In addition to the bug checking that PyChecker performs, Pylint offers some additional features such as checking line length, whether variable names are well-formed according to your coding standard, whether declared interfaces are fully implemented, and more. http://www.logilab.org/card/pylint_manual provides a full list of Pylint's features.

How can I create a stand-alone binary from a Python script?

You don't need the ability to compile Python to C code if all you want

is a stand-alone program that users can download and run without having to install the Python distribution first. There are a number of tools that determine the set of modules required by a program and bind these modules together with a Python binary to produce a single executable.

One is to use the freeze tool, which is included in the Python source tree as `Tools/freeze`. It converts Python byte code to C arrays; a C compiler you can embed all your modules into a new program, which is then linked with the standard Python modules.

It works by scanning your source recursively for import statements (in both forms) and looking for the modules in the standard Python path as well as in the source directory (for built-in modules). It then turns the bytecode for modules written in Python into C code (array initializers that can be turned into code objects using the marshal module) and creates a custom-made config file that only contains those built-in modules which are actually used in the program. It then compiles the generated C code and links it with the rest of the Python interpreter to form a self-contained binary which acts exactly like your script.

Obviously, freeze requires a C compiler. There are several other utilities which don't. One is Thomas Heller's py2exe (Windows only) at

<http://www.py2exe.org/>

Another is Christian Tismer's `SQFREEZE` which appends the byte code to a specially-prepared Python interpreter that can find the byte code in the executable.

Other tools include Fredrik Lundh's `Squeeze` and Anthony Tuininga's `cx_Freeze`.

Are there coding standards or a style guide for Python programs?

Yes. The coding style required for standard library modules is documented as [PEP 8](#).

My program is too slow. How do I speed it up?

That's a tough one, in general. There are many tricks to speed up Python code; consider rewriting parts in C as a last resort.

In some cases it's possible to automatically translate Python to C or x86 assembly language, meaning that you don't have to modify your code to gain increased speed.

[Cython](#) and [Pyrex](#) can compile a slightly modified version of Python code into a C extension, and can be used on many different platforms.

[Psyco](#) is a just-in-time compiler that translates Python code into x86 assembly language. If you can use it, Psyco can provide dramatic speedups for critical functions.

The rest of this answer will discuss various tricks for squeezing a bit more speed out of Python code. *Never* apply any optimization tricks unless you know you need them, after profiling has indicated that a particular function is the heavily executed hot spot in the code. Optimizations almost always make the code less clear, and you shouldn't pay the costs of reduced clarity (increased development time, greater likelihood of bugs) unless the resulting performance benefit is worth it.

There is a page on the wiki devoted to [performance tips](#).

Guido van Rossum has written up an anecdote related to

optimization at <http://www.python.org/doc/essays/list2str.html>.

One thing to notice is that function and (especially) method calls are rather expensive; if you have designed a purely OO interface with lots of tiny functions that don't do much more than get or set an instance variable or call another method, you might consider using a more direct way such as directly accessing instance variables. Also see the standard module `profile` which makes it possible to find out where your program is spending most of its time (if you have some patience – the profiling itself can slow your program down by an order of magnitude).

Remember that many standard optimization heuristics you may know from other programming experience may well apply to Python. For example it may be faster to send output to output devices using larger writes rather than smaller ones in order to reduce the overhead of kernel system calls. Thus CGI scripts that write all output in “one shot” may be faster than those that write lots of small pieces of output.

Also, be sure to use Python's core features where appropriate. For example, slicing allows programs to chop up lists and other sequence objects in a single tick of the interpreter's mainloop using highly optimized C implementations. Thus to get the same effect as:

```
L2 = []
for i in range(3):
    L2.append(L1[i])
```

it is much shorter and far faster to use

```
L2 = list(L1[:3]) # "list" is redundant if L1 is a list.
```

Note that the functionally-oriented built-in functions such as `map()`, `zip()`, and friends can be a convenient accelerator for loops that perform a single task. For example to pair the elements of two lists

together:

```
>>> list(zip([1, 2, 3], [4, 5, 6]))
[(1, 4), (2, 5), (3, 6)]
```

or to compute a number of sines:

```
>>> list(map(math.sin, (1, 2, 3, 4)))
[0.841470984808, 0.909297426826, 0.14112000806, -0.756802495308]
```

The operation completes very quickly in such cases.

Other examples include the `join()` and `split()` *methods of string objects*.

For example if `s1..s7` are large (10K+) strings then `"".join([s1, s2, s3, s4, s5, s6, s7])` may be far faster than the more obvious `s1+s2+s3+s4+s5+s6+s7`, since the “summation” will compute many subexpressions, whereas `join()` does all the copying in one pass. For manipulating strings, use the `replace()` and the `format()` *methods on string objects*. Use regular expressions only when you’re not dealing with constant string patterns.

Be sure to use the `list.sort()` built-in method to do sorting, and see the [sorting mini-HOWTO](#) for examples of moderately advanced usage. `list.sort()` beats other techniques for sorting in all but the most extreme circumstances.

Another common trick is to “push loops into functions or methods.” For example suppose you have a program that runs slowly and you use the profiler to determine that a Python function `ff()` is being called lots of times. If you notice that `ff()`:

```
def ff(x):
    ... # do something with x computing result...
```

```
return result
```

tends to be called in loops like:

```
list = map(ff, oldlist)
```

or:

```
for x in sequence:  
    value = ff(x)  
    ... # do something with value...
```

then you can often eliminate function call overhead by rewriting `ff()` to:

```
def ffseq(seq):  
    resultseq = []  
    for x in seq:  
        ... # do something with x computing result...  
        resultseq.append(result)  
    return resultseq
```

and rewrite the two examples to `list = ffseq(oldlist)` and to:

```
for value in ffseq(sequence):  
    ... # do something with value...
```

Single calls to `ff(x)` translate to `ffseq([x])[0]` with little penalty. Of course this technique is not always appropriate and there are other variants which you can figure out.

You can gain some performance by explicitly storing the results of a function or method lookup into a local variable. A loop like:

```
for key in token:  
    dict[key] = dict.get(key, 0) + 1
```

resolves `dict.get` every iteration. If the method isn't going to

change, a slightly faster implementation is:

```
dict_get = dict.get # look up the method once
for key in token:
    dict[key] = dict_get(key, 0) + 1
```

Default arguments can be used to determine values once, at compile time instead of at run time. This can only be done for functions or objects which will not be changed during program execution, such as replacing

```
def degree_sin(deg):
    return math.sin(deg * math.pi / 180.0)
```

with

```
def degree_sin(deg, factor=math.pi/180.0, sin=math.sin):
    return sin(deg * factor)
```

Because this trick uses default arguments for terms which should not be changed, it should only be used when you are not concerned with presenting a possibly confusing API to your users.

Core Language

Why am I getting an UnboundLocalError when the variable has a value?

It can be a surprise to get the `UnboundLocalError` in previously working code when it is modified by adding an assignment statement somewhere in the body of a function.

This code:

```
>>> x = 10
>>> def bar():
...     print(x)
>>> bar()
10
```

works, but this code:

```
>>> x = 10
>>> def foo():
...     print(x)
...     x += 1
```

results in an `UnboundLocalError`:

```
>>> foo()
Traceback (most recent call last):
...
UnboundLocalError: local variable 'x' referenced before assignment
```

This is because when you make an assignment to a variable in a scope, that variable becomes local to that scope and shadows any similarly named variable in the outer scope. Since the last statement in `foo` assigns a new value to `x`, the compiler recognizes it as a local

variable. Consequently when the earlier `print(x)` attempts to print the uninitialized local variable and an error results.

In the example above you can access the outer scope variable by declaring it global:

```
>>> x = 10
>>> def foobar():
...     global x
...     print(x)
...     x += 1
>>> foobar()
10
```

This explicit declaration is required in order to remind you that (unlike the superficially analogous situation with class and instance variables) you are actually modifying the value of the variable in the outer scope:

```
>>> print(x)
11
```

You can do a similar thing in a nested scope using the `nonlocal` keyword:

```
>>> def foo():
...     x = 10
...     def bar():
...         nonlocal x
...         print(x)
...         x += 1
...     bar()
...     print(x)
>>> foo()
10
11
```

What are the rules for local and global variables in Python?

In Python, variables that are only referenced inside a function are implicitly global. If a variable is assigned a new value anywhere within the function's body, it's assumed to be a local. If a variable is ever assigned a new value inside the function, the variable is implicitly local, and you need to explicitly declare it as 'global'.

Though a bit surprising at first, a moment's consideration explains this. On one hand, requiring `global` for assigned variables provides a bar against unintended side-effects. On the other hand, if `global` was required for all global references, you'd be using `global` all the time. You'd have to declare as global every reference to a built-in function or to a component of an imported module. This clutter would defeat the usefulness of the `global` declaration for identifying side-effects.

How do I share global variables across modules?

The canonical way to share information across modules within a single program is to create a special module (often called config or cfg). Just import the config module in all modules of your application; the module then becomes available as a global name. Because there is only one instance of each module, any changes made to the module object get reflected everywhere. For example:

config.py:

```
x = 0 # Default value of the 'x' configuration setting
```

mod.py:

```
import config
config.x = 1
```

main.py:

```
import config
import mod
print(config.x)
```

Note that using a module is also the basis for implementing the Singleton design pattern, for the same reason.

What are the “best practices” for using import in a module?

In general, don't use `from modulename import *`. Doing so clutters the importer's namespace. Some people avoid this idiom even with the few modules that were designed to be imported in this manner. Modules designed in this manner include `tkinter`, and `threading`.

Import modules at the top of a file. Doing so makes it clear what other modules your code requires and avoids questions of whether the module name is in scope. Using one import per line makes it easy to add and delete module imports, but using multiple imports per line uses less screen space.

It's good practice if you import modules in the following order:

1. standard library modules – e.g. `sys`, `os`, `getopt`, `re`
2. third-party library modules (anything installed in Python's site-packages directory) – e.g. `mx.DateTime`, `ZODB`, `PIL.Image`, etc.
3. locally-developed modules

Never use relative package imports. If you're writing code that's in the `package.sub.m1` module and want to import `package.sub.m2`, do not just write `from . import m2`, even though it's legal. Write `from package.sub import m2` instead. See [PEP 328](#) for details.

It is sometimes necessary to move imports to a function or class to avoid problems with circular imports. Gordon McMillan says:

Circular imports are fine where both modules use the “import <module>” form of import. They fail when the 2nd module wants to grab a name out of the first (“from module import name”) and the import is at the top level. That’s because names in the 1st are not yet available, because the first module is busy importing the 2nd.

In this case, if the second module is only used in one function, then the import can easily be moved into that function. By the time the import is called, the first module will have finished initializing, and the second module can do its import.

It may also be necessary to move imports out of the top level of code if some of the modules are platform-specific. In that case, it may not even be possible to import all of the modules at the top of the file. In this case, importing the correct modules in the corresponding platform-specific code is a good option.

Only move imports into a local scope, such as inside a function definition, if it’s necessary to solve a problem such as avoiding a circular import or are trying to reduce the initialization time of a module. This technique is especially helpful if many of the imports are unnecessary depending on how the program executes. You may also want to move imports into a function if the modules are only ever used in that function. Note that loading a module the first time may be expensive because of the one time initialization of the module, but loading a module multiple times is virtually free, costing only a couple of dictionary lookups. Even if the module name has gone out of scope, the module is probably available in `sys.modules`.

If only instances of a specific class use a module, then it is reasonable to import the module in the class’s `__init__` method and then assign the module to an instance variable so that the module is always available (via that instance variable) during the life of the object. Note that to delay an import until the class is instantiated, the import must be inside a method. Putting the import inside the class

but outside of any method still causes the import to occur when the module is initialized.

How can I pass optional or keyword parameters from one function to another?

Collect the arguments using the `*` and `**` specifiers in the function's parameter list; this gives you the positional arguments as a tuple and the keyword arguments as a dictionary. You can then pass these arguments when calling another function by using `*` and `**`:

```
def f(x, *args, **kwargs):  
    ...  
    kwargs['width'] = '14.3c'  
    ...  
    g(x, *args, **kwargs)
```

In the unlikely case that you care about Python versions older than 2.0, use `apply()`:

```
def f(x, *args, **kwargs):  
    ...  
    kwargs['width'] = '14.3c'  
    ...  
    apply(g, (x,)+args, kwargs)
```

How do I write a function with output parameters (call by reference)?

Remember that arguments are passed by assignment in Python. Since assignment just creates references to objects, there's no alias between an argument name in the caller and callee, and so no call-by-reference per se. You can achieve the desired effect in a number of ways.

1. By returning a tuple of the results:

```

def func2(a, b):
    a = 'new-value'           # a and b are local names
    b = b + 1                 # assigned to new objects
    return a, b              # return new values

x, y = 'old-value', 99
x, y = func2(x, y)
print(x, y)                  # output: new-value 100

```

This is almost always the clearest solution.

2. By using global variables. This isn't thread-safe, and is not recommended.
3. By passing a mutable (changeable in-place) object:

```

def func1(a):
    a[0] = 'new-value'       # 'a' references a mutable list
    a[1] = a[1] + 1          # changes a shared object

args = ['old-value', 99]
func1(args)
print(args[0], args[1])    # output: new-value 100

```

4. By passing in a dictionary that gets mutated:

```

def func3(args):
    args['a'] = 'new-value'   # args is a mutable dictionary
    args['b'] = args['b'] + 1 # change it in-place

args = {'a': 'old-value', 'b': 99}
func3(args)
print(args['a'], args['b'])

```

5. Or bundle up values in a class instance:

```

class callByRef:
    def __init__(self, **args):
        for (key, value) in args.items():
            setattr(self, key, value)

def func4(args):

```

```
args.a = 'new-value'           # args is a mutable callByR
args.b = args.b + 1           # change object in-place

args = callByRef(a='old-value', b=99)
func4(args)
print(args.a, args.b)
```

There's almost never a good reason to get this complicated.

Your best choice is to return a tuple containing the multiple results.

How do you make a higher order function in Python?

You have two choices: you can use nested scopes or you can use callable objects. For example, suppose you wanted to define `linear(a,b)` which returns a function `f(x)` that computes the value `a*x+b`. Using nested scopes:

```
def linear(a, b):
    def result(x):
        return a * x + b
    return result
```

Or using a callable object:

```
class linear:

    def __init__(self, a, b):
        self.a, self.b = a, b

    def __call__(self, x):
        return self.a * x + self.b
```

In both cases,

```
taxes = linear(0.3, 2)
```

gives a callable object where `taxes(10e6) == 0.3 * 10e6 + 2`.

The callable object approach has the disadvantage that it is a bit slower and results in slightly longer code. However, note that a collection of callables can share their signature via inheritance:

```
class exponential(linear):
    # __init__ inherited
    def __call__(self, x):
        return self.a * (x ** self.b)
```

Object can encapsulate state for several methods:

```
class counter:
    value = 0

    def set(self, x):
        self.value = x

    def up(self):
        self.value = self.value + 1

    def down(self):
        self.value = self.value - 1

count = counter()
inc, dec, reset = count.up, count.down, count.set
```

Here `inc()`, `dec()` and `reset()` act like functions which share the same counting variable.

How do I copy an object in Python?

In general, try `copy.copy()` or `copy.deepcopy()` for the general case. Not all objects can be copied, but most can.

Some objects can be copied more easily. Dictionaries have a `copy()` method:

```
newdict = olddict.copy()
```

Sequences can be copied by slicing:

```
new_l = l[:]
```

How can I find the methods or attributes of an object?

For an instance `x` of a user-defined class, `dir(x)` returns an alphabetized list of the names containing the instance attributes and methods and attributes defined by its class.

How can my code discover the name of an object?

Generally speaking, it can't, because objects don't really have names. Essentially, assignment always binds a name to a value; The same is true of `def` and `class` statements, but in that case the value is a callable. Consider the following code:

```
class A:
    pass

B = A

a = B()
b = a
print(b)
<__main__.A object at 0x16D07CC>
print(a)
<__main__.A object at 0x16D07CC>
```

Arguably the class has a name: even though it is bound to two names and invoked through the name `B` the created instance is still reported as an instance of class `A`. However, it is impossible to say whether the instance's name is `a` or `b`, since both names are bound to the same value.

Generally speaking it should not be necessary for your code to “know the names” of particular values. Unless you are deliberately writing introspective programs, this is usually an indication that a change of approach might be beneficial.

In comp.lang.python, Fredrik Lundh once gave an excellent analogy in answer to this question:

The same way as you get the name of that cat you found on your porch: the cat (object) itself cannot tell you its name, and it doesn't really care – so the only way to find out what it's called is to ask all your neighbours (namespaces) if it's their cat (object)...

...and don't be surprised if you'll find that it's known by many names, or no name at all!

What's up with the comma operator's precedence?

Comma is not an operator in Python. Consider this session:

```
>>> "a" in "b", "a"
(False, 'a')
```

Since the comma is not an operator, but a separator between expressions the above is evaluated as if you had entered:

```
>>> ("a" in "b"), "a"
```

not:

```
>>> "a" in ("b", "a")
```

The same is true of the various assignment operators (`=`, `+=` etc). They are not truly operators but syntactic delimiters in assignment

statements.

Is there an equivalent of C's "?:" ternary operator?

Yes, this feature was added in Python 2.5. The syntax would be as follows:

```
[on_true] if [expression] else [on_false]

x, y = 50, 25

small = x if x < y else y
```

For versions previous to 2.5 the answer would be 'No'.

In many cases you can mimic `a ? b : c` with `a and b or c`, but there's a flaw: if `b` is zero (or empty, or `None` – anything that tests false) then `c` will be selected instead. In many cases you can prove by looking at the code that this can't happen (e.g. because `b` is a constant or has a type that can never be false), but in general this can be a problem.

Tim Peters (who wishes it was Steve Majewski) suggested the following solution: `(a and [b] or [c])[0]`. Because `[b]` is a singleton list it is never false, so the wrong path is never taken; then applying `[0]` to the whole thing gets the `b` or `c` that you really wanted. Ugly, but it gets you there in the rare cases where it is really inconvenient to rewrite your code using 'if'.

The best course is usually to write a simple `if...else` statement. Another solution is to implement the `?:` operator as a function:

```
def q(cond, on_true, on_false):
    if cond:
        if not isfunction(on_true):
            return on_true
        else:
```

```

        return on_true()
    else:
        if not isfunction(on_false):
            return on_false
        else:
            return on_false()

```

In most cases you'll pass `b` and `c` directly: `q(a, b, c)`. To avoid evaluating `b` or `c` when they shouldn't be, encapsulate them within a lambda function, e.g.: `q(a, lambda: b, lambda: c)`.

It has been asked *why* Python has no if-then-else expression. There are several answers: many languages do just fine without one; it can easily lead to less readable code; no sufficiently "Pythonic" syntax has been discovered; a search of the standard library found remarkably few places where using an if-then-else expression would make the code more understandable.

In 2002, **PEP 308** was written proposing several possible syntaxes and the community was asked to vote on the issue. The vote was inconclusive. Most people liked one of the syntaxes, but also hated other syntaxes; many votes implied that people preferred no ternary operator rather than having a syntax they hated.

Is it possible to write obfuscated one-liners in Python?

Yes. Usually this is done by nesting `lambda` within `lambda`. See the following three examples, due to Ulf Bartelt:

```

from functools import reduce

# Primes < 1000
print(list(filter(None, map(lambda y:y*reduce(lambda x,y:x*y!=0,
map(lambda x,y:y:y%x, range(2, int(pow(y, 0.5)+1))), 1), range(2, 100

# First 10 Fibonacci numbers
print(list(map(lambda x, f=lambda x, f:(f(x-1, f))+f(x-2, f)) if x>1

```

```
f(x, f), range(10))))  
  
# Mandelbrot set  
print((lambda Ru, Ro, Iu, Io, IM, Sx, Sy: reduce(lambda x, y: x+y, map(lambda Iu=Iu, Io=Io, Ru=Ru, Ro=Ro, Sy=Sy, L=lambda yc, Iu=Iu, Io=Io, Ru=Ru, Ro=Ro, Sx=Sx, Sy=Sy: reduce(lambda x, y: x+y, map(lambda x, xc=Ru, yc=yc, Ru=Ru, Ro=Ro, Iu=Iu, Io=Io, Sx=Sx, F=lambda xc, yc, x, y, k, f=lambda xc, yc, x, y, k, f: (k<=0) or >=4.0) or 1+f(xc, yc, x*x-y*y+xc, 2.0*x*y+yc, k-1, f): f(xc, yc, x, y, k, 64+F(Ru+x*(Ro-Ru)/Sx, yc, 0, 0, i)), range(Sx))), range(Sy)): L(Iu+y*(Io-Iu)/Sy, Iu+Ro*(Io-Iu)/Sy, Io+Ro*(Io-Iu)/Sy, Io+Ro*(Io-Iu)/Sy)))(-2.1, 0.7, -1.2, 1.2, 30, 80, 24))  
#      \_____/ \_____/ | | | lines on screen  
#          V          V | | | columns on screen  
#          |          | | | maximum of "iterations"  
#          |          | | | range on y axis  
#          |          | | | range on x axis
```

Don't try this at home, kids!

Numbers and strings

How do I specify hexadecimal and octal integers?

To specify an octal digit, precede the octal value with a zero, and then a lower or uppercase “o”. For example, to set the variable “a” to the octal value “10” (8 in decimal), type:

```
>>> a = 0o10
>>> a
8
```

Hexadecimal is just as easy. Simply precede the hexadecimal number with a zero, and then a lower or uppercase “x”. Hexadecimal digits can be specified in lower or uppercase. For example, in the Python interpreter:

```
>>> a = 0xa5
>>> a
165
>>> b = 0xB2
>>> b
178
```

Why does `-22 // 10` return `-3`?

It's primarily driven by the desire that `i % j` have the same sign as `j`. If you want that, and also want:

```
i == (i // j) * j + (i % j)
```

then integer division has to return the floor. C also requires that identity to hold, and then compilers that truncate `i // j` need to make `i % j` have the same sign as `i`.

There are few real use cases for `i % j` when `j` is negative. When `j` is positive, there are many, and in virtually all of them it's more useful for `i % j` to be `>= 0`. If the clock says 10 now, what did it say 200 hours ago? `-190 % 12 == 2` is useful; `-190 % 12 == -10` is a bug waiting to bite.

How do I convert a string to a number?

For integers, use the built-in `int()` type constructor, e.g. `int('144') == 144`. Similarly, `float()` converts to floating-point, e.g. `float('144') == 144.0`.

By default, these interpret the number as decimal, so that `int('0144') == 144` and `int('0x144')` raises `ValueError`. `int(string, base)` takes the base to convert from as a second optional argument, so `int('0x144', 16) == 324`. If the base is specified as 0, the number is interpreted using Python's rules: a leading '0' indicates octal, and '0x' indicates a hex number.

Do not use the built-in function `eval()` if all you need is to convert strings to numbers. `eval()` will be significantly slower and it presents a security risk: someone could pass you a Python expression that might have unwanted side effects. For example, someone could pass `__import__('os').system("rm -rf $HOME")` which would erase your home directory.

`eval()` also has the effect of interpreting numbers as Python expressions, so that e.g. `eval('09')` gives a syntax error because Python does not allow leading '0' in a decimal number (except '0').

How do I convert a number to a string?

To convert, e.g., the number 144 to the string '144', use the built-in

type constructor `str()`. If you want a hexadecimal or octal representation, use the built-in functions `hex()` or `oct()`. For fancy formatting, see the *String Formatting* section, e.g. `"{:04d}".format(144)` yields `'0144'` and `"{: .3f}".format(1/3)` yields `'0.333'`.

How do I modify a string in place?

You can't, because strings are immutable. If you need an object with this ability, try converting the string to a list or use the array module:

```
>>> s = "Hello, world"
>>> a = list(s)
>>> print(a)
['H', 'e', 'l', 'l', 'o', ',', ' ', 'w', 'o', 'r', 'l', 'd']
>>> a[7:] = list("there!")
>>> ''.join(a)
'Hello, there!'

>>> import array
>>> a = array.array('u', s)
>>> print(a)
array('u', 'Hello, world')
>>> a[0] = 'y'
>>> print(a)
array('u', 'yello world')
>>> a.tounicode()
'yello, world'
```

How do I use strings to call functions/methods?

There are various techniques.

- The best is to use a dictionary that maps strings to functions. The primary advantage of this technique is that the strings do not need to match the names of the functions. This is also the primary technique used to emulate a case construct:

```
def a():
    pass

def b():
    pass

dispatch = {'go': a, 'stop': b} # Note lack of parens for
dispatch[get_input]() # Note trailing parens to call fun
```

- Use the built-in function `getattr()`:

```
import foo
getattr(foo, 'bar')()
```

Note that `getattr()` works on any object, including classes, class instances, modules, and so on.

This is used in several places in the standard library, like this:

```
class Foo:
    def do_foo(self):
        ...

    def do_bar(self):
        ...

f = getattr(foo_instance, 'do_' + opname)
f()
```

- Use `locals()` or `eval()` to resolve the function name:

```
def myFunc():
    print("hello")

fname = "myFunc"

f = locals()[fname]
f()

f = eval(fname)
f()
```

Note: Using `eval()` is slow and dangerous. If you don't have absolute control over the contents of the string, someone could pass a string that resulted in an arbitrary function being executed.

Is there an equivalent to Perl's `chomp()` for removing trailing newlines from strings?

Starting with Python 2.2, you can use `s.rstrip("\r\n")` to remove all occurrences of any line terminator from the end of the string `s` without removing other trailing whitespace. If the string `s` represents more than one line, with several empty lines at the end, the line terminators for all the blank lines will be removed:

```
>>> lines = ("line 1 \r\n"
...         "\r\n"
...         "\r\n")
>>> lines.rstrip("\n\r")
'line 1 '
```

Since this is typically only desired when reading text one line at a time, using `s.rstrip()` this way works well.

For older versions of Python, there are two partial substitutes:

- If you want to remove all trailing whitespace, use the `rstrip()` method of string objects. This removes all trailing whitespace, not just a single newline.
- Otherwise, if there is only one line in the string `s`, use `s.splitlines()[0]`.

Is there a `scanf()` or `sscanf()` equivalent?

Not as such.

For simple input parsing, the easiest approach is usually to split the line into whitespace-delimited words using the `split()` method of string objects and then convert decimal strings to numeric values using `int()` or `float()`. `split()` supports an optional “sep” parameter which is useful if the line uses something other than whitespace as a separator.

For more complicated input parsing, regular expressions are more powerful than C’s `scanf()` and better suited for the task.

What does ‘UnicodeDecodeError’ or ‘UnicodeEncodeError’ error mean?

See the *Unicode HOWTO*.

Sequences (Tuples/Lists)

How do I convert between tuples and lists?

The type constructor `tuple(seq)` converts any sequence (actually, any iterable) into a tuple with the same items in the same order.

For example, `tuple([1, 2, 3])` yields `(1, 2, 3)` and `tuple('abc')` yields `('a', 'b', 'c')`. If the argument is a tuple, it does not make a copy but returns the same object, so it is cheap to call `tuple()` when you aren't sure that an object is already a tuple.

The type constructor `list(seq)` converts any sequence or iterable into a list with the same items in the same order. For example, `list((1, 2, 3))` yields `[1, 2, 3]` and `list('abc')` yields `['a', 'b', 'c']`. If the argument is a list, it makes a copy just like `seq[:]` would.

What's a negative index?

Python sequences are indexed with positive numbers and negative numbers. For positive numbers 0 is the first index 1 is the second index and so forth. For negative indices -1 is the last index and -2 is the penultimate (next to last) index and so forth. Think of `seq[-n]` as the same as `seq[len(seq)-n]`.

Using negative indices can be very convenient. For example `s[:-1]` is all of the string except for its last character, which is useful for removing the trailing newline from a string.

How do I iterate over a sequence in reverse order?

Use the `reversed()` built-in function, which is new in Python 2.4:

```
for x in reversed(sequence):  
    ... # do something with x...
```

This won't touch your original sequence, but build a new copy with reversed order to iterate over.

With Python 2.3, you can use an extended slice syntax:

```
for x in sequence[::-1]:  
    ... # do something with x...
```

How do you remove duplicates from a list?

See the Python Cookbook for a long discussion of many ways to do this:

<http://aspn.activestate.com/ASPN/Cookbook/Python/Recipe/52560>

If you don't mind reordering the list, sort it and then scan from the end of the list, deleting duplicates as you go:

```
if mylist:  
    mylist.sort()  
    last = mylist[-1]  
    for i in range(len(mylist)-2, -1, -1):  
        if last == mylist[i]:  
            del mylist[i]  
        else:  
            last = mylist[i]
```

If all elements of the list may be used as dictionary keys (i.e. they are all hashable) this is often faster

```
d = {}  
for x in mylist:  
    d[x] = 1  
mylist = list(d.keys())
```

In Python 2.5 and later, the following is possible instead:

```
mylist = list(set(mylist))
```

This converts the list into a set, thereby removing duplicates, and then back into a list.

How do you make an array in Python?

Use a list:

```
["this", 1, "is", "an", "array"]
```

Lists are equivalent to C or Pascal arrays in their time complexity; the primary difference is that a Python list can contain objects of many different types.

The `array` module also provides methods for creating arrays of fixed types with compact representations, but they are slower to index than lists. Also note that the Numeric extensions and others define array-like structures with various characteristics as well.

To get Lisp-style linked lists, you can emulate cons cells using tuples:

```
lisp_list = ("like", ("this", ("example", None) ) )
```

If mutability is desired, you could use lists instead of tuples. Here the analogue of lisp car is `lisp_list[0]` and the analogue of cdr is `lisp_list[1]`. Only do this if you're sure you really need to, because it's usually a lot slower than using Python lists.

How do I create a multidimensional list?

You probably tried to make a multidimensional array like this:

```
A = [[None] * 2] * 3
```

This looks correct if you print it:

```
>>> A
[[None, None], [None, None], [None, None]]
```

But when you assign a value, it shows up in multiple places:

```
>>> A[0][0] = 5
>>> A
[[5, None], [5, None], [5, None]]
```

The reason is that replicating a list with `*` doesn't create copies, it only creates references to the existing objects. The `*3` creates a list containing 3 references to the same list of length two. Changes to one row will show in all rows, which is almost certainly not what you want.

The suggested approach is to create a list of the desired length first and then fill in each element with a newly created list:

```
A = [None] * 3
for i in range(3):
    A[i] = [None] * 2
```

This generates a list containing 3 different lists of length two. You can also use a list comprehension:

```
w, h = 2, 3
A = [[None] * w for i in range(h)]
```

Or, you can use an extension that provides a matrix datatype; [Numeric Python](#) is the best known.

How do I apply a method to a sequence of objects?

Use a list comprehension:

```
result = [obj.method() for obj in mylist]
```

Dictionaries

How can I get a dictionary to display its keys in a consistent order?

You can't. Dictionaries store their keys in an unpredictable order, so the display order of a dictionary's elements will be similarly unpredictable.

This can be frustrating if you want to save a printable version to a file, make some changes and then compare it with some other printed dictionary. In this case, use the `pprint` module to pretty-print the dictionary; the items will be presented in order sorted by the key.

A more complicated solution is to subclass `dict` to create a `SortedDict` class that prints itself in a predictable order. Here's one simpleminded implementation of such a class:

```
class SortedDict(dict):
    def __repr__(self):
        keys = sorted(self.keys())
        result = ("{!r}: {!r}".format(k, self[k]) for k in keys)
        return "{{{}}}".format(", ".join(result))

    __str__ = __repr__
```

This will work for many common situations you might encounter, though it's far from a perfect solution. The largest flaw is that if some values in the dictionary are also dictionaries, their values won't be presented in any particular order.

I want to do a complicated sort: can you do a Schwartzian Transform in Python?

The technique, attributed to Randal Schwartz of the Perl community, sorts the elements of a list by a metric which maps each element to its “sort value”. In Python, just use the `key` argument for the `sort()` method:

```
Isorted = L[:]
Isorted.sort(key=lambda s: int(s[10:15]))
```

The `key` argument is new in Python 2.4, for older versions this kind of sorting is quite simple to do with list comprehensions. To sort a list of strings by their uppercase values:

```
tmp1 = [(x.upper(), x) for x in L] # Schwartzian transform
tmp1.sort()
Isorted = [x[1] for x in tmp1]
```

To sort by the integer value of a subfield extending from positions 10-15 in each string:

```
tmp2 = [(int(s[10:15]), s) for s in L] # Schwartzian transform
tmp2.sort()
Isorted = [x[1] for x in tmp2]
```

For versions prior to 3.0, `Isorted` may also be computed by

```
def intfield(s):
    return int(s[10:15])

def Icmp(s1, s2):
    return cmp(intfield(s1), intfield(s2))

Isorted = L[:]
Isorted.sort(Icmp)
```

but since this method calls `intfield()` many times for each element of `L`, it is slower than the Schwartzian Transform.

How can I sort one list by values from another list?

Merge them into an iterator of tuples, sort the resulting list, and then pick out the element you want.

```
>>> list1 = ["what", "I'm", "sorting", "by"]
>>> list2 = ["something", "else", "to", "sort"]
>>> pairs = zip(list1, list2)
>>> pairs = sorted(pairs)
>>> pairs
[("I'm", 'else'), ('by', 'sort'), ('sorting', 'to'), ('what', '
>>> result = [x[1] for x in pairs]
>>> result
['else', 'sort', 'to', 'something']
```

An alternative for the last step is:

```
>>> result = []
>>> for p in pairs: result.append(p[1])
```

If you find this more legible, you might prefer to use this instead of the final list comprehension. However, it is almost twice as slow for long lists. Why? First, the `append()` operation has to reallocate memory, and while it uses some tricks to avoid doing that each time, it still has to do it occasionally, and that costs quite a bit. Second, the expression “`result.append`” requires an extra attribute lookup, and third, there’s a speed reduction from having to make all those function calls.

Objects

What is a class?

A class is the particular object type created by executing a class statement. Class objects are used as templates to create instance objects, which embody both the data (attributes) and code (methods) specific to a datatype.

A class can be based on one or more other classes, called its base class(es). It then inherits the attributes and methods of its base classes. This allows an object model to be successively refined by inheritance. You might have a generic `Mailbox` class that provides basic accessor methods for a mailbox, and subclasses such as `MboxMailbox`, `MaildirMailbox`, `OutlookMailbox` that handle various specific mailbox formats.

What is a method?

A method is a function on some object `x` that you normally call as `x.name(arguments...)`. Methods are defined as functions inside the class definition:

```
class C:  
    def meth (self, arg):  
        return arg * 2 + self.attribute
```

What is self?

Self is merely a conventional name for the first argument of a method. A method defined as `meth(self, a, b, c)` should be called as `x.meth(a, b, c)` for some instance `x` of the class in which the

definition occurs; the called method will think it is called as `meth(x, a, b, c)`.

See also *Why must 'self' be used explicitly in method definitions and calls?*.

How do I check if an object is an instance of a given class or of a subclass of it?

Use the built-in function `isinstance(obj, cls)`. You can check if an object is an instance of any of a number of classes by providing a tuple instead of a single class, e.g. `isinstance(obj, (class1, class2, ...))`, and can also check whether an object is one of Python's built-in types, e.g. `isinstance(obj, str)` or `isinstance(obj, (int, float, complex))`.

Note that most programs do not use `isinstance()` on user-defined classes very often. If you are developing the classes yourself, a more proper object-oriented style is to define methods on the classes that encapsulate a particular behaviour, instead of checking the object's class and doing a different thing based on what class it is. For example, if you have a function that does something:

```
def search(obj):
    if isinstance(obj, Mailbox):
        # ... code to search a mailbox
    elif isinstance(obj, Document):
        # ... code to search a document
    elif ...
```

A better approach is to define a `search()` method on all the classes and just call it:

```
class Mailbox:
    def search(self):
        # ... code to search a mailbox
```

```
class Document:
    def search(self):
        # ... code to search a document

obj.search()
```

What is delegation?

Delegation is an object oriented technique (also called a design pattern). Let's say you have an object `x` and want to change the behaviour of just one of its methods. You can create a new class that provides a new implementation of the method you're interested in changing and delegates all other methods to the corresponding method of `x`.

Python programmers can easily implement delegation. For example, the following class implements a class that behaves like a file but converts all written data to uppercase:

```
class UpperOut:

    def __init__(self, outfile):
        self._outfile = outfile

    def write(self, s):
        self._outfile.write(s.upper())

    def __getattr__(self, name):
        return getattr(self._outfile, name)
```

Here the `UpperOut` class redefines the `write()` method to convert the argument string to uppercase before calling the underlying `self._outfile.write()` method. All other methods are delegated to the underlying `self._outfile` object. The delegation is accomplished via the `__getattr__` method; consult [the language reference](#) for more information about controlling attribute access.

Note that for more general cases delegation can get trickier. When attributes must be set as well as retrieved, the class must define a `__setattr__()` method too, and it must do so carefully. The basic implementation of `__setattr__()` is roughly equivalent to the following:

```
class X:
    ...
    def __setattr__(self, name, value):
        self.__dict__[name] = value
    ...
```

Most `__setattr__()` implementations must modify `self.__dict__` to store local state for self without causing an infinite recursion.

How do I call a method defined in a base class from a derived class that overrides it?

Use the built-in `super()` function:

```
class Derived(Base):
    def meth(self):
        super(Derived, self).meth()
```

For version prior to 3.0, you may be using classic classes: For a class definition such as `class Derived(Base): ...` you can call method `meth()` defined in `Base` (or one of `Base`'s base classes) as `Base.meth(self, arguments...)`. Here, `Base.meth` is an unbound method, so you need to provide the `self` argument.

How can I organize my code to make it easier to change the base class?

You could define an alias for the base class, assign the real base class to it before your class definition, and use the alias throughout

your class. Then all you have to change is the value assigned to the alias. Incidentally, this trick is also handy if you want to decide dynamically (e.g. depending on availability of resources) which base class to use. Example:

```
BaseAlias = <real base class>

class Derived(BaseAlias):
    def meth(self):
        BaseAlias.meth(self)
    ...
```

How do I create static class data and static class methods?

Both static data and static methods (in the sense of C++ or Java) are supported in Python.

For static data, simply define a class attribute. To assign a new value to the attribute, you have to explicitly use the class name in the assignment:

```
class C:
    count = 0 # number of times C.__init__ called

    def __init__(self):
        C.count = C.count + 1

    def getcount(self):
        return C.count # or return self.count
```

`c.count` also refers to `C.count` for any `c` such that `isinstance(c, C)` holds, unless overridden by `c` itself or by some class on the base-class search path from `c.__class__` back to `C`.

Caution: within a method of `C`, an assignment like `self.count = 42` creates a new and unrelated instance named “count” in `self`’s own

dict. Rebinding of a class-static data name must always specify the class whether inside a method or not:

```
C.count = 314
```

Static methods are possible since Python 2.2:

```
class C:
    def static(arg1, arg2, arg3):
        # No 'self' parameter!
        ...
    static = staticmethod(static)
```

With Python 2.4's decorators, this can also be written as

```
class C:
    @staticmethod
    def static(arg1, arg2, arg3):
        # No 'self' parameter!
        ...
```

However, a far more straightforward way to get the effect of a static method is via a simple module-level function:

```
def getcount():
    return C.count
```

If your code is structured so as to define one class (or tightly related class hierarchy) per module, this supplies the desired encapsulation.

How can I overload constructors (or methods) in Python?

This answer actually applies to all methods, but the question usually comes up first in the context of constructors.

In C++ you'd write

```
class C {
    C() { cout << "No arguments\n"; }
    C(int i) { cout << "Argument is " << i << "\n"; }
}
```

In Python you have to write a single constructor that catches all cases using default arguments. For example:

```
class C:
    def __init__(self, i=None):
        if i is None:
            print("No arguments")
        else:
            print("Argument is", i)
```

This is not entirely equivalent, but close enough in practice.

You could also try a variable-length argument list, e.g.

```
def __init__(self, *args):
    ...
```

The same approach works for all method definitions.

I try to use `__spam` and I get an error about `__SomeClassName__spam`.

Variable names with double leading underscores are “mangled” to provide a simple but effective way to define class private variables. Any identifier of the form `__spam` (at least two leading underscores, at most one trailing underscore) is textually replaced with `__classname__spam`, where `classname` is the current class name with any leading underscores stripped.

This doesn’t guarantee privacy: an outside user can still deliberately access the `__classname__spam` attribute, and private values are visible in the object’s `__dict__`. Many Python programmers never

bother to use private variable names at all.

My class defines `__del__` but it is not called when I delete the object.

There are several possible reasons for this.

The `del` statement does not necessarily call `__del__()` – it simply decrements the object's reference count, and if this reaches zero `__del__()` is called.

If your data structures contain circular links (e.g. a tree where each child has a parent reference and each parent has a list of children) the reference counts will never go back to zero. Once in a while Python runs an algorithm to detect such cycles, but the garbage collector might run some time after the last reference to your data structure vanishes, so your `__del__()` method may be called at an inconvenient and random time. This is inconvenient if you're trying to reproduce a problem. Worse, the order in which object's `__del__()` methods are executed is arbitrary. You can run `gc.collect()` to force a collection, but there are pathological cases where objects will never be collected.

Despite the cycle collector, it's still a good idea to define an explicit `close()` method on objects to be called whenever you're done with them. The `close()` method can then remove attributes that refer to subobjects. Don't call `__del__()` directly – `__del__()` should call `close()` and `close()` should make sure that it can be called more than once for the same object.

Another way to avoid cyclical references is to use the `weakref` module, which allows you to point to objects without incrementing their reference count. Tree data structures, for instance, should use weak references for their parent and sibling references (if they need

them!).

Finally, if your `__del__()` method raises an exception, a warning message is printed to `sys.stderr`.

How do I get a list of all instances of a given class?

Python does not keep track of all instances of a class (or of a built-in type). You can program the class's constructor to keep track of all instances by keeping a list of weak references to each instance.

Modules

How do I create a .pyc file?

When a module is imported for the first time (or when the source is more recent than the current compiled file) a `.pyc` file containing the compiled code should be created in the same directory as the `.py` file.

One reason that a `.pyc` file may not be created is permissions problems with the directory. This can happen, for example, if you develop as one user but run as another, such as if you are testing with a web server. Creation of a `.pyc` file is automatic if you're importing a module and Python has the ability (permissions, free space, etc...) to write the compiled module back to the directory.

Running Python on a top level script is not considered an import and no `.pyc` will be created. For example, if you have a top-level module `abc.py` that imports another module `xyz.py`, when you run `abc.py`, `xyz.pyc` will be created since `xyz` is imported, but no `abc.pyc` file will be created since `abc.py` isn't being imported.

If you need to create `abc.pyc` – that is, to create a `.pyc` file for a module that is not imported – you can, using the `py_compile` and `compileall` modules.

The `py_compile` module can manually compile any module. One way is to use the `compile()` function in that module interactively:

```
>>> import py_compile
>>> py_compile.compile('abc.py')
```

This will write the `.pyc` to the same location as `abc.py` (or you can

override that with the optional parameter `cfile`).

You can also automatically compile all files in a directory or directories using the `compileall` module. You can do it from the shell prompt by running `compileall.py` and providing the path of a directory containing Python files to compile:

```
python -m compileall .
```

How do I find the current module name?

A module can find out its own module name by looking at the predefined global variable `__name__`. If this has the value `'__main__'`, the program is running as a script. Many modules that are usually used by importing them also provide a command-line interface or a self-test, and only execute this code after checking `__name__`:

```
def main():
    print('Running test...')
    ...

if __name__ == '__main__':
    main()
```

How can I have modules that mutually import each other?

Suppose you have the following modules:

foo.py:

```
from bar import bar_var
foo_var = 1
```

bar.py:

```
from foo import foo_var
bar_var = 2
```

The problem is that the interpreter will perform the following steps:

- main imports foo
- Empty globals for foo are created
- foo is compiled and starts executing
- foo imports bar
- Empty globals for bar are created
- bar is compiled and starts executing
- bar imports foo (which is a no-op since there already is a module named foo)
- `bar.foo_var = foo.foo_var`

The last step fails, because Python isn't done with interpreting `foo` yet and the global symbol dictionary for `foo` is still empty.

The same thing happens when you use `import foo`, and then try to access `foo.foo_var` in global code.

There are (at least) three possible workarounds for this problem.

Guido van Rossum recommends avoiding all uses of `from <module> import ...`, and placing all code inside functions. Initializations of global variables and class variables should use constants or built-in functions only. This means everything from an imported module is referenced as `<module>.<name>`.

Jim Roskind suggests performing steps in the following order in each module:

- exports (globals, functions, and classes that don't need imported base classes)
- `import` statements

- active code (including globals that are initialized from imported values).

van Rossum doesn't like this approach much because the imports appear in a strange place, but it does work.

Matthias Urlichs recommends restructuring your code so that the recursive import is not necessary in the first place.

These solutions are not mutually exclusive.

`__import__('x.y.z')` returns `<module 'x'>`; how do I get `z`?

Try:

```
__import__('x.y.z').y.z
```

For more realistic situations, you may have to do something like

```
m = __import__(s)
for i in s.split(".")[1:]:
    m = getattr(m, i)
```

See `importlib` for a convenience function called `import_module()`.

When I edit an imported module and reimport it, the changes don't show up. Why does this happen?

For reasons of efficiency as well as consistency, Python only reads the module file on the first time a module is imported. If it didn't, in a program consisting of many modules where each one imports the same basic module, the basic module would be parsed and re-parsed many times. To force rereading of a changed module, do this:

```
import imp
import modname
imp.reload(modname)
```

Warning: this technique is not 100% fool-proof. In particular, modules containing statements like

```
from modname import some_objects
```

will continue to work with the old version of the imported objects. If the module contains class definitions, existing class instances will *not* be updated to use the new class definition. This can result in the following paradoxical behaviour:

```
>>> import imp
>>> import cls
>>> c = cls.C()           # Create an instance of C
>>> imp.reload(cls)
<module 'cls' from 'cls.py'>
>>> isinstance(c, cls.C) # isinstance is false?!?
False
```

The nature of the problem is made clear if you print out the “identity” of the class objects:

```
>>> hex(id(c.__class__))
'0x7352a0'
>>> hex(id(cls.C))
'0x4198d0'
```

Design and History FAQ

Why does Python use indentation for grouping of statements?

Guido van Rossum believes that using indentation for grouping is extremely elegant and contributes a lot to the clarity of the average Python program. Most people learn to love this feature after a while.

Since there are no begin/end brackets there cannot be a disagreement between grouping perceived by the parser and the human reader. Occasionally C programmers will encounter a fragment of code like this:

```
if (x <= y)
    x++;
    y--;
z++;
```

Only the `x++` statement is executed if the condition is true, but the indentation leads you to believe otherwise. Even experienced C programmers will sometimes stare at it a long time wondering why `y` is being decremented even for `x > y`.

Because there are no begin/end brackets, Python is much less prone to coding-style conflicts. In C there are many different ways to place the braces. If you're used to reading and writing code that uses one style, you will feel at least slightly uneasy when reading (or being required to write) another style.

Many coding styles place begin/end brackets on a line by themselves. This makes programs considerably longer and wastes valuable screen space, making it harder to get a good overview of a program. Ideally, a function should fit on one screen (say, 20-30 lines). 20 lines of Python can do a lot more work than 20 lines of C. This is not solely due to the lack of begin/end brackets – the lack of

declarations and the high-level data types are also responsible – but the indentation-based syntax certainly helps.

Why am I getting strange results with simple arithmetic operations?

See the next question.

Why are floating point calculations so inaccurate?

People are often very surprised by results like this:

```
>>> 1.2 - 1.0  
0.19999999999999996
```

and think it is a bug in Python. It's not. This has nothing to do with Python, but with how the underlying C platform handles floating point numbers, and ultimately with the inaccuracies introduced when writing down numbers as a string of a fixed number of digits.

The internal representation of floating point numbers uses a fixed number of binary digits to represent a decimal number. Some decimal numbers can't be represented exactly in binary, resulting in small roundoff errors.

In decimal math, there are many numbers that can't be represented with a fixed number of decimal digits, e.g. $1/3 = 0.3333333333\dots$

In base 2, $1/2 = 0.1$, $1/4 = 0.01$, $1/8 = 0.001$, etc. $.2$ equals $2/10$ equals $1/5$, resulting in the binary fractional number $0.001100110011001\dots$

Floating point numbers only have 32 or 64 bits of precision, so the digits are cut off at some point, and the resulting number is 0.19999999999999996 in decimal, not 0.2 .

A floating point number's `repr()` function prints as many digits are necessary to make `eval(repr(f)) == f` true for any float `f`. The `str()` function prints fewer digits and this often results in the more sensible number that was probably intended:

```
>>> 1.1 - 0.9
0.20000000000000007
>>> print(1.1 - 0.9)
0.2
```

One of the consequences of this is that it is error-prone to compare the result of some computation to a float with `==`. Tiny inaccuracies may mean that `==` fails. Instead, you have to check that the difference between the two numbers is less than a certain threshold:

```
epsilon = 0.00000000000001 # Tiny allowed error
expected_result = 0.4

if expected_result-epsilon <= computation() <= expected_result+
    ...
```

Please see the chapter on *floating point arithmetic* in the Python tutorial for more information.

Why are Python strings immutable?

There are several advantages.

One is performance: knowing that a string is immutable means we can allocate space for it at creation time, and the storage requirements are fixed and unchanging. This is also one of the reasons for the distinction between tuples and lists.

Another advantage is that strings in Python are considered as “elemental” as numbers. No amount of activity will change the value 8 to anything else, and in Python, no amount of activity will change the string “eight” to anything else.

Why must 'self' be used explicitly in method definitions and calls?

The idea was borrowed from Modula-3. It turns out to be very useful, for a variety of reasons.

First, it's more obvious that you are using a method or instance attribute instead of a local variable. Reading `self.x` or `self.meth()` makes it absolutely clear that an instance variable or method is used even if you don't know the class definition by heart. In C++, you can sort of tell by the lack of a local variable declaration (assuming globals are rare or easily recognizable) – but in Python, there are no local variable declarations, so you'd have to look up the class definition to be sure. Some C++ and Java coding standards call for instance attributes to have an `m_` prefix, so this explicitness is still useful in those languages, too.

Second, it means that no special syntax is necessary if you want to explicitly reference or call the method from a particular class. In C++, if you want to use a method from a base class which is overridden in a derived class, you have to use the `::` operator – in Python you can write `baseclass.methodname(self, <argument list>)`. This is particularly useful for `__init__()` methods, and in general in cases where a derived class method wants to extend the base class method of the same name and thus has to call the base class method somehow.

Finally, for instance variables it solves a syntactic problem with assignment: since local variables in Python are (by definition!) those variables to which a value is assigned in a function body (and that aren't explicitly declared global), there has to be some way to tell the interpreter that an assignment was meant to assign to an instance

variable instead of to a local variable, and it should preferably be syntactic (for efficiency reasons). C++ does this through declarations, but Python doesn't have declarations and it would be a pity having to introduce them just for this purpose. Using the explicit `self.var` solves this nicely. Similarly, for using instance variables, having to write `self.var` means that references to unqualified names inside a method don't have to search the instance's directories. To put it another way, local variables and instance variables live in two different namespaces, and you need to tell Python which namespace to use.

Why can't I use an assignment in an expression?

Many people used to C or Perl complain that they want to use this C idiom:

```
while (line = readline(f)) {  
    // do something with line  
}
```

where in Python you're forced to write this:

```
while True:  
    line = f.readline()  
    if not line:  
        break  
    ... # do something with line
```

The reason for not allowing assignment in Python expressions is a common, hard-to-find bug in those other languages, caused by this construct:

```
if (x = 0) {  
    // error handling  
}  
else {  
    // code that only works for nonzero x  
}
```

The error is a simple typo: `x = 0`, which assigns 0 to the variable `x`, was written while the comparison `x == 0` is certainly what was intended.

Many alternatives have been proposed. Most are hacks that save some typing but use arbitrary or cryptic syntax or keywords, and fail the simple criterion for language change proposals: it should

intuitively suggest the proper meaning to a human reader who has not yet been introduced to the construct.

An interesting phenomenon is that most experienced Python programmers recognize the `while True` idiom and don't seem to be missing the assignment in expression construct much; it's only newcomers who express a strong desire to add this to the language.

There's an alternative way of spelling this that seems attractive but is generally less robust than the "while True" solution:

```
line = f.readline()
while line:
    ... # do something with line...
    line = f.readline()
```

The problem with this is that if you change your mind about exactly how you get the next line (e.g. you want to change it into `sys.stdin.readline()`) you have to remember to change two places in your program – the second occurrence is hidden at the bottom of the loop.

The best approach is to use iterators, making it possible to loop through objects using the `for` statement. For example, *file objects* support the iterator protocol, so you can write simply:

```
for line in f:
    ... # do something with line...
```

Why does Python use methods for some functionality (e.g. `list.index()`) but functions for other (e.g. `len(list)`)?

The major reason is history. Functions were used for those operations that were generic for a group of types and which were intended to work even for objects that didn't have methods at all (e.g. tuples). It is also convenient to have a function that can readily be applied to an amorphous collection of objects when you use the functional features of Python (`map()`, `apply()` et al).

In fact, implementing `len()`, `max()`, `min()` as a built-in function is actually less code than implementing them as methods for each type. One can quibble about individual cases but it's a part of Python, and it's too late to make such fundamental changes now. The functions have to remain to avoid massive code breakage.

Note: For string operations, Python has moved from external functions (the `string` module) to methods. However, `len()` is still a function.

Why is `join()` a string method instead of a list or tuple method?

Strings became much more like other standard types starting in Python 1.6, when methods were added which give the same functionality that has always been available using the functions of the `string` module. Most of these new methods have been widely accepted, but the one which appears to make some programmers feel uncomfortable is:

```
",".join(['1', '2', '4', '8', '16'])
```

which gives the result:

```
"1, 2, 4, 8, 16"
```

There are two common arguments against this usage.

The first runs along the lines of: “It looks really ugly using a method of a string literal (string constant)”, to which the answer is that it might, but a string literal is just a fixed value. If the methods are to be allowed on names bound to strings there is no logical reason to make them unavailable on literals.

The second objection is typically cast as: “I am really telling a sequence to join its members together with a string constant”. Sadly, you aren’t. For some reason there seems to be much less difficulty with having `split()` as a string method, since in that case it is easy to see that

```
"1, 2, 4, 8, 16".split(", ")
```

is an instruction to a string literal to return the substrings delimited by

the given separator (or, by default, arbitrary runs of white space).

`join()` is a string method because in using it you are telling the separator string to iterate over a sequence of strings and insert itself between adjacent elements. This method can be used with any argument which obeys the rules for sequence objects, including any new classes you might define yourself. Similar methods exist for bytes and bytearray objects.

How fast are exceptions?

A try/except block is extremely efficient. Actually catching an exception is expensive. In versions of Python prior to 2.0 it was common to use this idiom:

```
try:
    value = mydict[key]
except KeyError:
    mydict[key] = getvalue(key)
    value = mydict[key]
```

This only made sense when you expected the dict to have the key almost all the time. If that wasn't the case, you coded it like this:

```
if mydict.has_key(key):
    value = mydict[key]
else:
    mydict[key] = getvalue(key)
    value = mydict[key]
```

For this specific case, you could also use `value = dict.setdefault(key, getvalue(key))`, but only if the `getvalue()` call is cheap enough because it is evaluated in all cases.

Why isn't there a switch or case statement in Python?

You can do this easily enough with a sequence of `if... elif... elif... else`. There have been some proposals for switch statement syntax, but there is no consensus (yet) on whether and how to do range tests. See [PEP 275](#) for complete details and the current status.

For cases where you need to choose from a very large number of possibilities, you can create a dictionary mapping case values to functions to call. For example:

```
def function_1(...):
    ...

functions = {'a': function_1,
            'b': function_2,
            'c': self.method_1, ...}

func = functions[value]
func()
```

For calling methods on objects, you can simplify yet further by using the `getattr()` built-in to retrieve methods with a particular name:

```
def visit_a(self, ...):
    ...

...

def dispatch(self, value):
    method_name = 'visit_' + str(value)
    method = getattr(self, method_name)
    method()
```

It's suggested that you use a prefix for the method names, such as `visit_` in this example. Without such a prefix, if values are coming

from an untrusted source, an attacker would be able to call any method on your object.

Can't you emulate threads in the interpreter instead of relying on an OS-specific thread implementation?

Answer 1: Unfortunately, the interpreter pushes at least one C stack frame for each Python stack frame. Also, extensions can call back into Python at almost random moments. Therefore, a complete threads implementation requires thread support for C.

Answer 2: Fortunately, there is [Stackless Python](#), which has a completely redesigned interpreter loop that avoids the C stack. It's still experimental but looks very promising. Although it is binary compatible with standard Python, it's still unclear whether Stackless will make it into the core – maybe it's just too revolutionary.

Why can't lambda forms contain statements?

Python lambda forms cannot contain statements because Python's syntactic framework can't handle statements nested inside expressions. However, in Python, this is not a serious problem. Unlike lambda forms in other languages, where they add functionality, Python lambdas are only a shorthand notation if you're too lazy to define a function.

Functions are already first class objects in Python, and can be declared in a local scope. Therefore the only advantage of using a lambda form instead of a locally-defined function is that you don't need to invent a name for the function – but that's just a local variable to which the function object (which is exactly the same type of object that a lambda form yields) is assigned!

Can Python be compiled to machine code, C or some other language?

Not easily. Python's high level data types, dynamic typing of objects and run-time invocation of the interpreter (using `eval()` or `exec()`) together mean that a "compiled" Python program would probably consist mostly of calls into the Python run-time system, even for seemingly simple operations like `x+1`.

Several projects described in the Python newsgroup or at past [Python conferences](#) have shown that this approach is feasible, although the speedups reached so far are only modest (e.g. 2x). Jython uses the same strategy for compiling to Java bytecode. (Jim Hugunin has demonstrated that in combination with whole-program analysis, speedups of 1000x are feasible for small demo programs. See the proceedings from the [1997 Python conference](#) for more information.)

Internally, Python source code is always translated into a bytecode representation, and this bytecode is then executed by the Python virtual machine. In order to avoid the overhead of repeatedly parsing and translating modules that rarely change, this byte code is written into a file whose name ends in ".pyc" whenever a module is parsed. When the corresponding .py file is changed, it is parsed and translated again and the .pyc file is rewritten.

There is no performance difference once the .pyc file has been loaded, as the bytecode read from the .pyc file is exactly the same as the bytecode created by direct translation. The only difference is that loading code from a .pyc file is faster than parsing and translating a .py file, so the presence of precompiled .pyc files improves the start-up time of Python scripts. If desired, the `Lib/compileall.py` module can be used to create valid .pyc files for a

given set of modules.

Note that the main script executed by Python, even if its filename ends in `.py`, is not compiled to a `.pyc` file. It is compiled to bytecode, but the bytecode is not saved to a file. Usually main scripts are quite short, so this doesn't cost much speed.

There are also several programs which make it easier to intermingle Python and C code in various ways to increase performance. See, for example, [Cython](#), [Pyrex](#) and [Weave](#).

How does Python manage memory?

The details of Python memory management depend on the implementation. The standard C implementation of Python uses reference counting to detect inaccessible objects, and another mechanism to collect reference cycles, periodically executing a cycle detection algorithm which looks for inaccessible cycles and deletes the objects involved. The `gc` module provides functions to perform a garbage collection, obtain debugging statistics, and tune the collector's parameters.

Jython relies on the Java runtime so the JVM's garbage collector is used. This difference can cause some subtle porting problems if your Python code depends on the behavior of the reference counting implementation.

In the absence of circularities, Python programs do not need to manage memory explicitly.

Why doesn't Python use a more traditional garbage collection scheme? For one thing, this is not a C standard feature and hence it's not portable. (Yes, we know about the Boehm GC library. It has bits of assembler code for *most* common platforms, not for all of them, and although it is mostly transparent, it isn't completely transparent; patches are required to get Python to work with it.)

Traditional GC also becomes a problem when Python is embedded into other applications. While in a standalone Python it's fine to replace the standard `malloc()` and `free()` with versions provided by the GC library, an application embedding Python may want to have its *own* substitute for `malloc()` and `free()`, and may not want Python's. Right now, Python works with anything that implements `malloc()` and `free()` properly.

In Jython, the following code (which is fine in CPython) will probably run out of file descriptors long before it runs out of memory:

```
for file in very_long_list_of_files:  
    f = open(file)  
    c = f.read(1)
```

Using the current reference counting and destructor scheme, each new assignment to `f` closes the previous file. Using GC, this is not guaranteed. If you want to write code that will work with any Python implementation, you should explicitly close the file or use the `with` statement; this will work regardless of GC:

```
for file in very_long_list_of_files:  
    with open(file) as f:  
        c = f.read(1)
```

Why isn't all memory freed when Python exits?

Objects referenced from the global namespaces of Python modules are not always deallocated when Python exits. This may happen if there are circular references. There are also certain bits of memory that are allocated by the C library that are impossible to free (e.g. a tool like Purify will complain about these). Python is, however, aggressive about cleaning up memory on exit and does try to destroy every single object.

If you want to force Python to delete certain things on deallocation use the `atexit` module to run a function that will force those deletions.

Why are there separate tuple and list data types?

Lists and tuples, while similar in many respects, are generally used in fundamentally different ways. Tuples can be thought of as being similar to Pascal records or C structs; they're small collections of related data which may be of different types which are operated on as a group. For example, a Cartesian coordinate is appropriately represented as a tuple of two or three numbers.

Lists, on the other hand, are more like arrays in other languages. They tend to hold a varying number of objects all of which have the same type and which are operated on one-by-one. For example, `os.listdir('.')` returns a list of strings representing the files in the current directory. Functions which operate on this output would generally not break if you added another file or two to the directory.

Tuples are immutable, meaning that once a tuple has been created, you can't replace any of its elements with a new value. Lists are mutable, meaning that you can always change a list's elements. Only immutable elements can be used as dictionary keys, and hence only tuples and not lists can be used as keys.

How are lists implemented?

Python's lists are really variable-length arrays, not Lisp-style linked lists. The implementation uses a contiguous array of references to other objects, and keeps a pointer to this array and the array's length in a list head structure.

This makes indexing a list `a[i]` an operation whose cost is independent of the size of the list or the value of the index.

When items are appended or inserted, the array of references is resized. Some cleverness is applied to improve the performance of appending items repeatedly; when the array must be grown, some extra space is allocated so the next few times don't require an actual resize.

How are dictionaries implemented?

Python's dictionaries are implemented as resizable hash tables. Compared to B-trees, this gives better performance for lookup (the most common operation by far) under most circumstances, and the implementation is simpler.

Dictionaries work by computing a hash code for each key stored in the dictionary using the `hash()` built-in function. The hash code varies widely depending on the key; for example, "Python" hashes to -539294296 while "python", a string that differs by a single bit, hashes to 1142331976. The hash code is then used to calculate a location in an internal array where the value will be stored. Assuming that you're storing keys that all have different hash values, this means that dictionaries take constant time – $O(1)$, in computer science notation – to retrieve a key. It also means that no sorted order of the keys is maintained, and traversing the array as the `.keys()` and `.items()` do will output the dictionary's content in some arbitrary jumbled order.

Why must dictionary keys be immutable?

The hash table implementation of dictionaries uses a hash value calculated from the key value to find the key. If the key were a mutable object, its value could change, and thus its hash could also change. But since whoever changes the key object can't tell that it was being used as a dictionary key, it can't move the entry around in the dictionary. Then, when you try to look up the same object in the dictionary it won't be found because its hash value is different. If you tried to look up the old value it wouldn't be found either, because the value of the object found in that hash bin would be different.

If you want a dictionary indexed with a list, simply convert the list to a tuple first; the function `tuple(L)` creates a tuple with the same entries as the list `L`. Tuples are immutable and can therefore be used as dictionary keys.

Some unacceptable solutions that have been proposed:

- Hash lists by their address (object ID). This doesn't work because if you construct a new list with the same value it won't be found; e.g.:

```
mydict = {[1, 2]: '12'}  
print(mydict[[1, 2]])
```

would raise a `KeyError` exception because the id of the `[1, 2]` used in the second line differs from that in the first line. In other words, dictionary keys should be compared using `==`, not using `is`.

- Make a copy when using a list as a key. This doesn't work because the list, being a mutable object, could contain a reference to itself, and then the copying code would run into an

infinite loop.

- Allow lists as keys but tell the user not to modify them. This would allow a class of hard-to-track bugs in programs when you forgot or modified a list by accident. It also invalidates an important invariant of dictionaries: every value in `d.keys()` is usable as a key of the dictionary.
- Mark lists as read-only once they are used as a dictionary key. The problem is that it's not just the top-level object that could change its value; you could use a tuple containing a list as a key. Entering anything as a key into a dictionary would require marking all objects reachable from there as read-only – and again, self-referential objects could cause an infinite loop.

There is a trick to get around this if you need to, but use it at your own risk: You can wrap a mutable structure inside a class instance which has both a `__eq__()` and a `__hash__()` method. You must then make sure that the hash value for all such wrapper objects that reside in a dictionary (or other hash based structure), remain fixed while the object is in the dictionary (or other structure).

```
class ListWrapper:
    def __init__(self, the_list):
        self.the_list = the_list
    def __eq__(self, other):
        return self.the_list == other.the_list
    def __hash__(self):
        l = self.the_list
        result = 98767 - len(l)*555
        for i, el in enumerate(l):
            try:
                result = result + (hash(el) % 9999999) * 1001 +
            except Exception:
                result = (result % 7777777) + i * 333
        return result
```

Note that the hash computation is complicated by the possibility that

some members of the list may be unhashable and also by the possibility of arithmetic overflow.

Furthermore it must always be the case that if `o1 == o2` (ie `o1.__eq__(o2)` is `True`) then `hash(o1) == hash(o2)` (ie, `o1.__hash__() == o2.__hash__()`), regardless of whether the object is in a dictionary or not. If you fail to meet these restrictions dictionaries and other hash based structures will misbehave.

In the case of `ListWrapper`, whenever the wrapper object is in a dictionary the wrapped list must not change to avoid anomalies. Don't do this unless you are prepared to think hard about the requirements and the consequences of not meeting them correctly. Consider yourself warned.

Why doesn't `list.sort()` return the sorted list?

In situations where performance matters, making a copy of the list just to sort it would be wasteful. Therefore, `list.sort()` sorts the list in place. In order to remind you of that fact, it does not return the sorted list. This way, you won't be fooled into accidentally overwriting a list when you need a sorted copy but also need to keep the unsorted version around.

In Python 2.4 a new built-in function – `sorted()` – has been added. This function creates a new list from a provided iterable, sorts it and returns it. For example, here's how to iterate over the keys of a dictionary in sorted order:

```
for key in sorted(mydict):  
    ... # do whatever with mydict[key]...
```

How do you specify and enforce an interface spec in Python?

An interface specification for a module as provided by languages such as C++ and Java describes the prototypes for the methods and functions of the module. Many feel that compile-time enforcement of interface specifications helps in the construction of large programs.

Python 2.6 adds an `abc` module that lets you define Abstract Base Classes (ABCs). You can then use `isinstance()` and `issubclass()` to check whether an instance or a class implements a particular ABC. The `collections` module defines a set of useful ABCs such as `Iterable`, `Container`, and `MutableMapping`.

For Python, many of the advantages of interface specifications can be obtained by an appropriate test discipline for components. There is also a tool, PyChecker, which can be used to find problems due to subclassing.

A good test suite for a module can both provide a regression test and serve as a module interface specification and a set of examples. Many Python modules can be run as a script to provide a simple “self test.” Even modules which use complex external interfaces can often be tested in isolation using trivial “stub” emulations of the external interface. The `doctest` and `unittest` modules or third-party test frameworks can be used to construct exhaustive test suites that exercise every line of code in a module.

An appropriate testing discipline can help build large complex applications in Python as well as having interface specifications would. In fact, it can be better because an interface specification cannot test certain properties of a program. For example, the `append()` method is expected to add new elements to the end of

some internal list; an interface specification cannot test that your `append()` implementation will actually do this correctly, but it's trivial to check this property in a test suite.

Writing test suites is very helpful, and you might want to design your code with an eye to making it easily tested. One increasingly popular technique, test-directed development, calls for writing parts of the test suite first, before you write any of the actual code. Of course Python allows you to be sloppy and not write test cases at all.

Why are default values shared between objects?

This type of bug commonly bites neophyte programmers. Consider this function:

```
def foo(mydict={}): # Danger: shared reference to one dict for
    ... compute something ...
    mydict[key] = value
    return mydict
```

The first time you call this function, `mydict` contains a single item. The second time, `mydict` contains two items because when `foo()` begins executing, `mydict` starts out with an item already in it.

It is often expected that a function call creates new objects for default values. This is not what happens. Default values are created exactly once, when the function is defined. If that object is changed, like the dictionary in this example, subsequent calls to the function will refer to this changed object.

By definition, immutable objects such as numbers, strings, tuples, and `None`, are safe from change. Changes to mutable objects such as dictionaries, lists, and class instances can lead to confusion.

Because of this feature, it is good programming practice to not use mutable objects as default values. Instead, use `None` as the default value and inside the function, check if the parameter is `None` and create a new list/dictionary/whatever if it is. For example, don't write:

```
def foo(mydict={}):
    ...
```

but:

```
def foo(mydict=None):  
    if mydict is None:  
        mydict = {} # create a new dict for local namespace
```

This feature can be useful. When you have a function that's time-consuming to compute, a common technique is to cache the parameters and the resulting value of each call to the function, and return the cached value if the same value is requested again. This is called "memoizing", and can be implemented like this:

```
# Callers will never provide a third parameter for this function  
def expensive (arg1, arg2, _cache={}):  
    if (arg1, arg2) in _cache:  
        return _cache[(arg1, arg2)]  
  
    # Calculate the value  
    result = ... expensive computation ...  
    _cache[(arg1, arg2)] = result # Store result in t  
    return result
```

You could use a global variable containing a dictionary instead of the default value; it's a matter of taste.

Why is there no goto?

You can use exceptions to provide a “structured goto” that even works across function calls. Many feel that exceptions can conveniently emulate all reasonable uses of the “go” or “goto” constructs of C, Fortran, and other languages. For example:

```
class label: pass # declare a label

try:
    ...
    if (condition): raise label() # goto label
    ...
except label: # where to goto
    pass
...
```

This doesn't allow you to jump into the middle of a loop, but that's usually considered an abuse of goto anyway. Use sparingly.

Why can't raw strings (r-strings) end with a backslash?

More precisely, they can't end with an odd number of backslashes: the unpaired backslash at the end escapes the closing quote character, leaving an unterminated string.

Raw strings were designed to ease creating input for processors (chiefly regular expression engines) that want to do their own backslash escape processing. Such processors consider an unmatched trailing backslash to be an error anyway, so raw strings disallow that. In return, they allow you to pass on the string quote character by escaping it with a backslash. These rules work well when r-strings are used for their intended purpose.

If you're trying to build Windows pathnames, note that all Windows system calls accept forward slashes too:

```
f = open("/mydir/file.txt") # works fine!
```

If you're trying to build a pathname for a DOS command, try e.g. one of

```
dir = r"\this\is\my\dos\dir" "\\ "  
dir = r"\this\is\my\dos\dir\" "[:-1]"  
dir = "\\this\\is\\my\\dos\\dir\\"
```

Why doesn't Python have a “with” statement for attribute assignments?

Python has a ‘with’ statement that wraps the execution of a block, calling code on the entrance and exit from the block. Some language have a construct that looks like this:

```
with obj:
    a = 1                # equivalent to obj.a = 1
    total = total + 1   # obj.total = obj.total + 1
```

In Python, such a construct would be ambiguous.

Other languages, such as Object Pascal, Delphi, and C++, use static types, so it's possible to know, in an unambiguous way, what member is being assigned to. This is the main point of static typing – the compiler *always* knows the scope of every variable at compile time.

Python uses dynamic types. It is impossible to know in advance which attribute will be referenced at runtime. Member attributes may be added or removed from objects on the fly. This makes it impossible to know, from a simple reading, what attribute is being referenced: a local one, a global one, or a member attribute?

For instance, take the following incomplete snippet:

```
def foo(a):
    with a:
        print(x)
```

The snippet assumes that “a” must have a member attribute called “x”. However, there is nothing in Python that tells the interpreter this. What should happen if “a” is, let us say, an integer? If there is a global variable named “x”, will it be used inside the with block? As

you see, the dynamic nature of Python makes such choices much harder.

The primary benefit of “with” and similar language features (reduction of code volume) can, however, easily be achieved in Python by assignment. Instead of:

```
function(args).mydict[index][index].a = 21  
function(args).mydict[index][index].b = 42  
function(args).mydict[index][index].c = 63
```

write this:

```
ref = function(args).mydict[index][index]  
ref.a = 21  
ref.b = 42  
ref.c = 63
```

This also has the side-effect of increasing execution speed because name bindings are resolved at run-time in Python, and the second version only needs to perform the resolution once.

Why are colons required for the if/while/def/class statements?

The colon is required primarily to enhance readability (one of the results of the experimental ABC language). Consider this:

```
if a == b
    print(a)
```

versus

```
if a == b:
    print(a)
```

Notice how the second one is slightly easier to read. Notice further how a colon sets off the example in this FAQ answer; it's a standard usage in English.

Another minor reason is that the colon makes it easier for editors with syntax highlighting; they can look for colons to decide when indentation needs to be increased instead of having to do a more elaborate parsing of the program text.

Why does Python allow commas at the end of lists and tuples?

Python lets you add a trailing comma at the end of lists, tuples, and dictionaries:

```
[1, 2, 3,]
('a', 'b', 'c',)
d = {
    "A": [1, 5],
    "B": [6, 7], # last trailing comma is optional but good st
}
```

There are several reasons to allow this.

When you have a literal value for a list, tuple, or dictionary spread across multiple lines, it's easier to add more elements because you don't have to remember to add a comma to the previous line. The lines can also be sorted in your editor without creating a syntax error.

Accidentally omitting the comma can lead to errors that are hard to diagnose. For example:

```
x = [
    "fee",
    "fie",
    "foo",
    "fum"
]
```

This list looks like it has four elements, but it actually contains three: “fee”, “fiefoo” and “fum”. Always adding the comma avoids this source of error.

Allowing the trailing comma may also make programmatic code generation easier.

General Library Questions

How do I find a module or application to perform task X?

Check *the Library Reference* to see if there's a relevant standard library module. (Eventually you'll learn what's in the standard library and will be able to skip this step.)

For third-party packages, search the [Python Package Index](#) or try [Google](#) or another Web search engine. Searching for "Python" plus a keyword or two for your topic of interest will usually find something helpful.

Where is the math.py (socket.py, regex.py, etc.) source file?

If you can't find a source file for a module it may be a built-in or dynamically loaded module implemented in C, C++ or other compiled language. In this case you may not have the source file or it may be something like `mathmodule.c`, somewhere in a C source directory (not on the Python Path).

There are (at least) three kinds of modules in Python:

1. modules written in Python (.py);
2. modules written in C and dynamically loaded (.dll, .pyd, .so, .sl, etc);
3. modules written in C and linked with the interpreter; to get a list of these, type:

```
import sys
print(sys.builtin_module_names)
```

How do I make a Python script executable on Unix?

You need to do two things: the script file's mode must be executable and the first line must begin with `#!` followed by the path of the Python interpreter.

The first is done by executing `chmod +x scriptfile` or perhaps `chmod 755 scriptfile`.

The second can be done in a number of ways. The most straightforward way is to write

```
#!/usr/local/bin/python
```

as the very first line of your file, using the pathname for where the Python interpreter is installed on your platform.

If you would like the script to be independent of where the Python interpreter lives, you can use the “env” program. Almost all Unix variants support the following, assuming the Python interpreter is in a directory on the user's \$PATH:

```
#!/usr/bin/env python
```

Don't do this for CGI scripts. The \$PATH variable for CGI scripts is often very minimal, so you need to use the actual absolute pathname of the interpreter.

Occasionally, a user's environment is so full that the `/usr/bin/env` program fails; or there's no env program at all. In that case, you can try the following hack (due to Alex Rezinsky):

```
#!/bin/sh
"""
exec python $0 ${1+"$@"}
"""
```

The minor disadvantage is that this defines the script's `__doc__` string. However, you can fix that by adding

```
__doc__ = """...Whatever..."""
```

Is there a curses/termcap package for Python?

For Unix variants: The standard Python source distribution comes with a `curses` module in the `Modules/` subdirectory, though it's not compiled by default (note that this is not available in the Windows distribution – there is no `curses` module for Windows).

The `curses` module supports basic curses features as well as many additional functions from `ncurses` and `SVSV curses` such as colour, alternative character set support, pads, and mouse support. This means the module isn't compatible with operating systems that only have BSD `curses`, but there don't seem to be any currently maintained OSes that fall into this category.

For Windows: use [the consolelib module](#).

Is there an equivalent to C's `onexit()` in Python?

The `atexit` module provides a `register` function that is similar to C's `onexit`.

Why don't my signal handlers work?

The most common problem is that the signal handler is declared with the wrong argument list. It is called as

```
handler(signum, frame)
```

so it should be declared with two arguments:

```
def handler(signum, frame):  
    ...
```

Common tasks

How do I test a Python program or component?

Python comes with two testing frameworks. The `doctest` module finds examples in the docstrings for a module and runs them, comparing the output with the expected output given in the docstring.

The `unittest` module is a fancier testing framework modelled on Java and Smalltalk testing frameworks.

For testing, it helps to write the program so that it may be easily tested by using good modular design. Your program should have almost all functionality encapsulated in either functions or class methods – and this sometimes has the surprising and delightful effect of making the program run faster (because local variable accesses are faster than global accesses). Furthermore the program should avoid depending on mutating global variables, since this makes testing much more difficult to do.

The “global main logic” of your program may be as simple as

```
if __name__ == "__main__":  
    main_logic()
```

at the bottom of the main module of your program.

Once your program is organized as a tractable collection of functions and class behaviours you should write test functions that exercise the behaviours. A test suite can be associated with each module which automates a sequence of tests. This sounds like a lot of work, but since Python is so terse and flexible it's surprisingly easy. You can make coding much more pleasant and fun by writing your test functions in parallel with the “production code”, since this makes it

easy to find bugs and even design flaws earlier.

“Support modules” that are not intended to be the main module of a program may include a self-test of the module.

```
if __name__ == "__main__":  
    self_test()
```

Even programs that interact with complex external interfaces may be tested when the external interfaces are unavailable by using “fake” interfaces implemented in Python.

How do I create documentation from doc strings?

The `pydoc` module can create HTML from the doc strings in your Python source code. An alternative for creating API documentation purely from docstrings is `epydoc`. `Sphinx` can also include docstring content.

How do I get a single keypress at a time?

For Unix variants: There are several solutions. It's straightforward to do this using `curses`, but `curses` is a fairly large module to learn.

Threads

How do I program using threads?

Be sure to use the `threading` module and not the `_thread` module. The `threading` module builds convenient abstractions on top of the low-level primitives provided by the `_thread` module.

Aahz has a set of slides from his threading tutorial that are helpful; see <http://www.pythoncraft.com/OSCON2001/>.

None of my threads seem to run: why?

As soon as the main thread exits, all threads are killed. Your main thread is running too quickly, giving the threads no time to do any work.

A simple fix is to add a sleep to the end of the program that's long enough for all the threads to finish:

```
import threading, time

def thread_task(name, n):
    for i in range(n): print(name, i)

for i in range(10):
    T = threading.Thread(target=thread_task, args=(str(i), i))
    T.start()

time.sleep(10) # <-----! 
```

But now (on many platforms) the threads don't run in parallel, but appear to run sequentially, one at a time! The reason is that the OS thread scheduler doesn't start a new thread until the previous thread is blocked.

A simple fix is to add a tiny sleep to the start of the run function:

```
def thread_task(name, n):
    time.sleep(0.001) # <-----!
    for i in range(n): print(name, i)

for i in range(10):
    T = threading.Thread(target=thread_task, args=(str(i), i))
    T.start()

time.sleep(10)
```

Instead of trying to guess how long a `time.sleep()` delay will be enough, it's better to use some kind of semaphore mechanism. One idea is to use the `queue` module to create a queue object, let each thread append a token to the queue when it finishes, and let the main thread read as many tokens from the queue as there are threads.

How do I parcel out work among a bunch of worker threads?

The easiest way is to use the new `concurrent.futures` module, especially the `ThreadPoolExecutor` class.

Or, if you want fine control over the dispatching algorithm, you can write your own logic manually. Use the `queue` module to create a queue containing a list of jobs. The `Queue` class maintains a list of objects with `.put(obj)` to add an item to the queue and `.get()` to return an item. The class will take care of the locking necessary to ensure that each job is handed out exactly once.

Here's a trivial example:

```
import threading, queue, time

# The worker thread gets jobs off the queue. When the queue is
```

```

# assumes there will be no more work and exits.
# (Realistically workers will run until terminated.)
def worker ():
    print('Running worker')
    time.sleep(0.1)
    while True:
        try:
            arg = q.get(block=False)
        except queue.Empty:
            print('Worker', threading.currentThread(), end=' ')
            print('queue empty')
            break
        else:
            print('Worker', threading.currentThread(), end=' ')
            print('running with argument', arg)
            time.sleep(0.5)

# Create queue
q = queue.Queue()

# Start a pool of 5 workers
for i in range(5):
    t = threading.Thread(target=worker, name='worker %i' % (i+1))
    t.start()

# Begin adding work to the queue
for i in range(50):
    q.put(i)

# Give threads time to run
print('Main thread sleeping')
time.sleep(5)

```

When run, this will produce the following output:

```

Running worker
Running worker
Running worker
Running worker
Running worker
Main thread sleeping
Worker <Thread(worker 1, started 130283832797456)> running with
Worker <Thread(worker 2, started 130283824404752)> running with
Worker <Thread(worker 3, started 130283816012048)> running with
Worker <Thread(worker 4, started 130283807619344)> running with

```

```
Worker <Thread(worker 5, started 130283799226640)> running with  
Worker <Thread(worker 1, started 130283832797456)> running with  
...
```

Consult the module's documentation for more details; the `Queue` class provides a featureful interface.

What kinds of global value mutation are thread-safe?

A *global interpreter lock* (GIL) is used internally to ensure that only one thread runs in the Python VM at a time. In general, Python offers to switch among threads only between bytecode instructions; how frequently it switches can be set via `sys.setswitchinterval()`. Each bytecode instruction and therefore all the C implementation code reached from each instruction is therefore atomic from the point of view of a Python program.

In theory, this means an exact accounting requires an exact understanding of the PVM bytecode implementation. In practice, it means that operations on shared variables of built-in data types (ints, lists, dicts, etc) that “look atomic” really are.

For example, the following operations are all atomic (L, L1, L2 are lists, D, D1, D2 are dicts, x, y are objects, i, j are ints):

```
L.append(x)  
L1.extend(L2)  
x = L[i]  
x = L.pop()  
L1[i:j] = L2  
L.sort()  
x = y  
x.field = y  
D[x] = y  
D1.update(D2)  
D.keys()
```

These aren't:

```
i = i+1
L.append(L[-1])
L[i] = L[j]
D[x] = D[x] + 1
```

Operations that replace other objects may invoke those other objects' `__del__()` method when their reference count reaches zero, and that can affect things. This is especially true for the mass updates to dictionaries and lists. When in doubt, use a mutex!

Can't we get rid of the Global Interpreter Lock?

The *global interpreter lock* (GIL) is often seen as a hindrance to Python's deployment on high-end multiprocessor server machines, because a multi-threaded Python program effectively only uses one CPU, due to the insistence that (almost) all Python code can only run while the GIL is held.

Back in the days of Python 1.5, Greg Stein actually implemented a comprehensive patch set (the "free threading" patches) that removed the GIL and replaced it with fine-grained locking. Adam Olsen recently did a similar experiment in his [python-safethread](#) project. Unfortunately, both experiments exhibited a sharp drop in single-thread performance (at least 30% slower), due to the amount of fine-grained locking necessary to compensate for the removal of the GIL.

This doesn't mean that you can't make good use of Python on multi-CPU machines! You just have to be creative with dividing the work up between multiple *processes* rather than multiple *threads*. The `ProcessPoolExecutor` class in the new `concurrent.futures` module provides an easy way of doing so; the `multiprocessing` module provides a lower-level API in case you want more control over dispatching of tasks.

Judicious use of C extensions will also help; if you use a C extension to perform a time-consuming task, the extension can release the GIL while the thread of execution is in the C code and allow other threads to get some work done. Some standard library modules such as `zlib` and `hashlib` already do this.

It has been suggested that the GIL should be a per-interpreter-state lock rather than truly global; interpreters then wouldn't be able to share objects. Unfortunately, this isn't likely to happen either. It would be a tremendous amount of work, because many object implementations currently have global state. For example, small integers and short strings are cached; these caches would have to be moved to the interpreter state. Other object types have their own free list; these free lists would have to be moved to the interpreter state. And so on.

And I doubt that it can even be done in finite time, because the same problem exists for 3rd party extensions. It is likely that 3rd party extensions are being written at a faster rate than you can convert them to store all their global state in the interpreter state.

And finally, once you have multiple interpreters not sharing any state, what have you gained over running each interpreter in a separate process?

Input and Output

How do I delete a file? (And other file questions...)

Use `os.remove(filename)` or `os.unlink(filename)`; for documentation, see the `os` module. The two functions are identical; `unlink()` is simply the name of the Unix system call for this function.

To remove a directory, use `os.rmdir()`; use `os.mkdir()` to create one. `os.makedirs(path)` will create any intermediate directories in `path` that don't exist. `os.removedirs(path)` will remove intermediate directories as long as they're empty; if you want to delete an entire directory tree and its contents, use `shutil.rmtree()`.

To rename a file, use `os.rename(old_path, new_path)`.

To truncate a file, open it using `f = open(filename, "rb+")`, and use `f.truncate(offset)`; `offset` defaults to the current seek position. There's also `os.ftruncate(fd, offset)` for files opened with `os.open()`, where `fd` is the file descriptor (a small integer).

The `shutil` module also contains a number of functions to work on files including `copyfile()`, `copytree()`, and `rmtree()`.

How do I copy a file?

The `shutil` module contains a `copyfile()` function. Note that on MacOS 9 it doesn't copy the resource fork and Finder info.

How do I read (or write) binary data?

To read or write complex binary data formats, it's best to use the

`struct` module. It allows you to take a string containing binary data (usually numbers) and convert it to Python objects; and vice versa.

For example, the following code reads two 2-byte integers and one 4-byte integer in big-endian format from a file:

```
import struct

with open(filename, "rb") as f:
    s = f.read(8)
    x, y, z = struct.unpack(">hh1", s)
```

The `>` in the format string forces big-endian data; the letter `h` reads one “short integer” (2 bytes), and `l` reads one “long integer” (4 bytes) from the string.

For data that is more regular (e.g. a homogeneous list of ints or thefloats), you can also use the `array` module.

Note: To read and write binary data, it is mandatory to open the file in binary mode (here, passing `"rb"` to `open()`). If you use `"r"` instead (the default), the file will be open in text mode and `f.read()` will return `str` objects rather than `bytes` objects.

I can't seem to use `os.read()` on a pipe created with `os.popen()`; why?

`os.read()` is a low-level function which takes a file descriptor, a small integer representing the opened file. `os.popen()` creates a high-level file object, the same type returned by the built-in `open()` function. Thus, to read `n` bytes from a pipe `p` created with `os.popen()`, you need to use `p.read(n)`.

How do I access the serial (RS232) port?

For Win32, POSIX (Linux, BSD, etc.), Jython:

<http://pyserial.sourceforge.net>

For Unix, see a Usenet post by Mitch Chapman:

[http://groups.google.com/groups?
selm=34A04430.CF9@ohioee.com](http://groups.google.com/groups?selm=34A04430.CF9@ohioee.com)

Why doesn't closing `sys.stdout` (`stdin`, `stderr`) really close it?

Python *file objects* are a high-level layer of abstraction on low-level C file descriptors.

For most file objects you create in Python via the built-in `open()` function, `f.close()` marks the Python file object as being closed from Python's point of view, and also arranges to close the underlying C file descriptor. This also happens automatically in `f`'s destructor, when `f` becomes garbage.

But `stdin`, `stdout` and `stderr` are treated specially by Python, because of the special status also given to them by C. Running `sys.stdout.close()` marks the Python-level file object as being closed, but does *not* close the associated C file descriptor.

To close the underlying C file descriptor for one of these three, you should first be sure that's what you really want to do (e.g., you may confuse extension modules trying to do I/O). If it is, use `os.close()`:

```
os.close(stdin.fileno())
os.close(stdout.fileno())
os.close(stderr.fileno())
```

Or you can use the numeric constants 0, 1 and 2, respectively.

Network/Internet Programming

What WWW tools are there for Python?

See the chapters titled *Internet Protocols and Support* and *Internet Data Handling* in the Library Reference Manual. Python has many modules that will help you build server-side and client-side web systems.

A summary of available frameworks is maintained by Paul Boddie at <http://wiki.python.org/moin/WebProgramming> .

Cameron Laird maintains a useful set of pages about Python web technologies at http://phaseit.net/claird/comp.lang.python/web_python.

How can I mimic CGI form submission (METHOD=POST)?

I would like to retrieve web pages that are the result of POSTing a form. Is there existing code that would let me do this easily?

Yes. Here's a simple example that uses `urllib.request`:

```
#!/usr/local/bin/python

import urllib.request

### build the query string
qs = "First=Josephine&MI=Q&Last=Public"

### connect and send the server a path
req = urllib.request.urlopen('http://www.some-server.out-there'
                             '/cgi-bin/some-cgi-script', data=qs)
msg, hdrs = req.read(), req.info()
```

Note that in general for percent-encoded POST operations, query strings must be quoted using `urllib.parse.urlencode()`. For example to send `name="Guy Steele, Jr."`:

```
>>> import urllib.parse
>>> urllib.parse.urlencode({'name': 'Guy Steele, Jr.'})
'name=Guy+Steele%2C+Jr.'
```

See also: *HOWTO Fetch Internet Resources Using The urllib Package* for extensive examples.

What module should I use to help with generating HTML?

There are many different modules available:

- HTMLgen is a class library of objects corresponding to all the HTML 3.2 markup tags. It's used when you are writing in Python and wish to synthesize HTML pages for generating a web or for CGI forms, etc.
- DocumentTemplate and Zope Page Templates are two different systems that are part of Zope.
- Quixote's PTL uses Python syntax to assemble strings of text.

Consult the [Web Programming wiki pages](#) for more links.

How do I send mail from a Python script?

Use the standard library module `smtplib`.

Here's a very simple interactive mail sender that uses it. This method will work on any host that supports an SMTP listener.

```
import sys, smtplib
```

```

fromaddr = input("From: ")
toaddrs = input("To: ").split(',')
print("Enter message, end with ^D:")
msg = ''
while True:
    line = sys.stdin.readline()
    if not line:
        break
    msg += line

# The actual mail send
server = smtplib.SMTP('localhost')
server.sendmail(fromaddr, toaddrs, msg)
server.quit()

```

A Unix-only alternative uses `sendmail`. The location of the `sendmail` program varies between systems; sometimes it is `/usr/lib/sendmail`, sometime `/usr/sbin/sendmail`. The `sendmail` manual page will help you out. Here's some sample code:

```

SENDMAIL = "/usr/sbin/sendmail" # sendmail location
import os
p = os.popen("%s -t -i" % SENDMAIL, "w")
p.write("To: receiver@example.com\n")
p.write("Subject: test\n")
p.write("\n") # blank line separating headers from body
p.write("Some text\n")
p.write("some more text\n")
sts = p.close()
if sts != 0:
    print("Sendmail exit status", sts)

```

How do I avoid blocking in the `connect()` method of a socket?

The `select` module is commonly used to help with asynchronous I/O on sockets.

To prevent the TCP connect from blocking, you can set the socket to non-blocking mode. Then when you do the `connect()`, you will either

connect immediately (unlikely) or get an exception that contains the error number as `.errno`. `errno.EINPROGRESS` indicates that the connection is in progress, but hasn't finished yet. Different OSes will return different values, so you're going to have to check what's returned on your system.

You can use the `connect_ex()` method to avoid creating an exception. It will just return the `errno` value. To poll, you can call `connect_ex()` again later – `0` or `errno.EISCONN` indicate that you're connected – or you can pass this socket to `select` to check if it's writable.

Note: The `asyncore` module presents a framework-like approach to the problem of writing non-blocking networking code. The third-party `Twisted` library is a popular and feature-rich alternative.

Databases

Are there any interfaces to database packages in Python?

Yes.

Interfaces to disk-based hashes such as `DBM` and `GDBM` are also included with standard Python. There is also the `sqlite3` module, which provides a lightweight disk-based relational database.

Support for most relational databases is available. See the [DatabaseProgramming wiki page](#) for details.

How do you implement persistent objects in Python?

The `pickle` library module solves this in a very general way (though you still can't store things like open files, sockets or windows), and the `shelve` library module uses pickle and (g)dbm to create persistent mappings containing arbitrary Python objects.

A more awkward way of doing things is to use pickle's little sister, marshal. The `marshal` module provides very fast ways to store noncircular basic Python types to files and strings, and back again. Although marshal does not do fancy things like store instances or handle shared references properly, it does run extremely fast. For example loading a half megabyte of data may take less than a third of a second. This often beats doing something more complex and general such as using gdbm with pickle/shelve.

If my program crashes with a bsddb (or anydbm)

database open, it gets corrupted. How come?

Note: The bsddb module is now available as a standalone package [pybsddb](#).

Databases opened for write access with the bsddb module (and often by the anydbm module, since it will preferentially use bsddb) must explicitly be closed using the `.close()` method of the database. The underlying library caches database contents which need to be converted to on-disk form and written.

If you have initialized a new bsddb database but not written anything to it before the program crashes, you will often wind up with a zero-length file and encounter an exception the next time the file is opened.

I tried to open Berkeley DB file, but bsddb produces bsddb.error: (22, 'Invalid argument'). Help! How can I restore my data?

Note: The bsddb module is now available as a standalone package [pybsddb](#).

Don't panic! Your data is probably intact. The most frequent cause for the error is that you tried to open an earlier Berkeley DB file with a later version of the Berkeley DB library.

Many Linux systems now have all three versions of Berkeley DB available. If you are migrating from version 1 to a newer version use `db_dump185` to dump a plain text version of the database. If you are migrating from version 2 to version 3 use `db2_dump` to create a plain text version of the database. In either case, use `db_load` to create a new native database for the latest version installed on your computer. If you have version 3 of Berkeley DB installed, you should

be able to use `db2_load` to create a native version 2 database.

You should move away from Berkeley DB version 1 files because the hash file code contains known bugs that can corrupt your data.

Mathematics and Numerics

How do I generate random numbers in Python?

The standard module `random` implements a random number generator. Usage is simple:

```
import random
random.random()
```

This returns a random floating point number in the range `[0, 1)`.

There are also many other specialized generators in this module, such as:

- `randrange(a, b)` chooses an integer in the range `[a, b)`.
- `uniform(a, b)` chooses a floating point number in the range `[a, b)`.
- `normalvariate(mean, sdev)` samples the normal (Gaussian) distribution.

Some higher-level functions operate on sequences directly, such as:

- `choice(S)` chooses random element from a given sequence
- `shuffle(L)` shuffles a list in-place, i.e. permutes it randomly

There's also a `Random` class you can instantiate to create independent multiple random number generators.

 - How do I tell “incomplete input” from “invalid input”?
 - How do I find undefined g++ symbols `__builtin_new` or `__pure_virtual`?
 - Can I create an object class with some methods implemented in C and others in Python (e.g. through inheritance)?
 - When importing module X, why do I get “undefined

symbol: PyUnicodeUCS2*"?

Can I create my own functions in C?

Yes, you can create built-in modules containing functions, variables, exceptions and even new types in C. This is explained in the document *Extending and Embedding the Python Interpreter*.

Most intermediate or advanced Python books will also cover this topic.

Can I create my own functions in C++?

Yes, using the C compatibility features found in C++. Place `extern "C" { ... }` around the Python include files and put `extern "C"` before each function that is going to be called by the Python interpreter. Global or static C++ objects with constructors are probably not a good idea.

Writing C is hard; are there any alternatives?

There are a number of alternatives to writing your own C extensions, depending on what you're trying to do.

If you need more speed, [Psyco](#) generates x86 assembly code from Python bytecode. You can use Psyco to compile the most time-critical functions in your code, and gain a significant improvement with very little effort, as long as you're running on a machine with an x86-compatible processor.

[Cython](#) and its relative [Pyrex](#) are compilers that accept a slightly modified form of Python and generate the corresponding C code. Cython and Pyrex make it possible to write an extension without having to learn Python's C API.

If you need to interface to some C or C++ library for which no Python extension currently exists, you can try wrapping the library's data types and functions with a tool such as [SWIG](#). [SIP](#), [CXX Boost](#), or [Weave](#) are also alternatives for wrapping C++ libraries.

How can I execute arbitrary Python statements from C?

The highest-level function to do this is `PyRun_SimpleString()` which takes a single string argument to be executed in the context of the module `__main__` and returns 0 for success and -1 when an exception occurred (including `SyntaxError`). If you want more control, use `PyRun_String()`; see the source for `PyRun_SimpleString()` in `Python/pythonrun.c`.

How can I evaluate an arbitrary Python expression from C?

Call the function `PyRun_String()` from the previous question with the start symbol `Py_eval_input`; it parses an expression, evaluates it and returns its value.

How do I extract C values from a Python object?

That depends on the object's type. If it's a tuple, `PyTuple_Size()` returns its length and `PyTuple_GetItem()` returns the item at a specified index. Lists have similar functions, `PyList_Size()` and `PyList_GetItem()`.

For strings, `PyString_Size()` returns its length and `PyString_AsString()` a pointer to its value. Note that Python strings may contain null bytes so C's `strlen()` should not be used.

To test the type of an object, first make sure it isn't `NULL`, and then use `PyString_Check()`, `PyTuple_Check()`, `PyList_Check()`, etc.

There is also a high-level API to Python objects which is provided by the so-called 'abstract' interface – read `Include/abstract.h` for further details. It allows interfacing with any kind of Python sequence using calls like `PySequence_Length()`, `PySequence_GetItem()`, etc.) as well as many other useful protocols.

How do I use `Py_BuildValue()` to create a tuple of arbitrary length?

You can't. Use `t = PyTuple_New(n)` instead, and fill it with objects using `PyTuple_SetItem(t, i, o)` – note that this “eats” a reference count of `o`, so you have to `Py_INCREF()` it. Lists have similar functions `PyList_New(n)` and `PyList_SetItem(l, i, o)`. Note that you *must* set all the tuple items to some value before you pass the tuple to Python code – `PyTuple_New(n)` initializes them to NULL, which isn't a valid Python value.

How do I call an object's method from C?

The `PyObject_CallMethod()` function can be used to call an arbitrary method of an object. The parameters are the object, the name of the method to call, a format string like that used with `Py_BuildValue()`, and the argument values:

```
PyObject *
PyObject_CallMethod(PyObject *object, char *method_name,
                   char *arg_format, ...);
```

This works for any object that has methods – whether built-in or user-defined. You are responsible for eventually `Py_DECREF()`'ing the return value.

To call, e.g., a file object's "seek" method with arguments 10, 0 (assuming the file object pointer is "f"):

```
res = PyObject_CallMethod(f, "seek", "(ii)", 10, 0);
if (res == NULL) {
    ... an exception occurred ...
}
else {
    Py_DECREF(res);
}
```

Note that since `PyObject_CallObject()` *always* wants a tuple for the argument list, to call a function without arguments, pass "()" for the format, and to call a function with one argument, surround the argument in parentheses, e.g. "(i)".

How do I catch the output from `PyErr_Print()` (or anything that prints to `stdout/stderr`)?

In Python code, define an object that supports the `write()` method. Assign this object to `sys.stdout` and `sys.stderr`. Call `print_error`, or just allow the standard traceback mechanism to work. Then, the output will go wherever your `write()` method sends it.

The easiest way to do this is to use the `StringIO` class in the standard library.

Sample code and use for catching stdout:

```
>>> class StdoutCatcher:
...     def __init__(self):
...         self.data = ''
...     def write(self, stuff):
...         self.data = self.data + stuff
...
>>> import sys
>>> sys.stdout = StdoutCatcher()
>>> print('foo')
>>> print('hello world!')
>>> sys.stderr.write(sys.stdout.data)
foo
hello world!
```

How do I access a module written in Python from C?

You can get a pointer to the module object as follows:

```
module = PyImport_ImportModule("<modulename>");
```

If the module hasn't been imported yet (i.e. it is not yet present in `sys.modules`), this initializes the module; otherwise it simply returns the value of `sys.modules["<modulename>"]`. Note that it doesn't enter the module into any namespace – it only ensures it has been initialized and is stored in `sys.modules`.

You can then access the module's attributes (i.e. any name defined in the module) as follows:

```
attr = PyObject_GetAttrString(module, "<attrname>");
```

Calling `PyObject_SetAttrString()` to assign to variables in the module also works.

How do I interface to C++ objects from Python?

Depending on your requirements, there are many approaches. To do this manually, begin by reading *the “Extending and Embedding” document*. Realize that for the Python run-time system, there isn’t a whole lot of difference between C and C++ – so the strategy of building a new Python type around a C structure (pointer) type will also work for C++ objects.

For C++ libraries, see *Writing C is hard; are there any alternatives?*.

I added a module using the Setup file and the make fails; why?

Setup must end in a newline, if there is no newline there, the build process fails. (Fixing this requires some ugly shell script hackery, and this bug is so minor that it doesn't seem worth the effort.)

How do I debug an extension?

When using GDB with dynamically loaded extensions, you can't set a breakpoint in your extension until your extension is loaded.

In your `.gdbinit` file (or interactively), add the command:

```
br _PyImport_LoadDynamicModule
```

Then, when you run GDB:

```
$ gdb /local/bin/python
gdb) run myscript.py
gdb) continue # repeat until your extension is loaded
gdb) finish # so that your extension is loaded
gdb) br myfunction.c:50
gdb) continue
```

I want to compile a Python module on my Linux system, but some files are missing. Why?

Most packaged versions of Python don't include the `/usr/lib/python2.x/config/` directory, which contains various files required for compiling Python extensions.

For Red Hat, install the `python-devel` RPM to get the necessary files.

For Debian, run `apt-get install python-dev`.

What does “SystemError: _PyImport_FixupExtension: module yourmodule not loaded” mean?

This means that you have created an extension module named “yourmodule”, but your module init function does not initialize with that name.

Every module init function will have a line similar to:

```
module = Py_InitModule("yourmodule", yourmodule_functions);
```

If the string passed to this function is not the same name as your extension module, the `SystemError` exception will be raised.

How do I tell “incomplete input” from “invalid input”?

Sometimes you want to emulate the Python interactive interpreter’s behavior, where it gives you a continuation prompt when the input is incomplete (e.g. you typed the start of an “if” statement or you didn’t close your parentheses or triple string quotes), but it gives you a syntax error message immediately when the input is invalid.

In Python you can use the `codeop` module, which approximates the parser’s behavior sufficiently. IDLE uses this, for example.

The easiest way to do it in C is to call `PyRun_InteractiveLoop()` (perhaps in a separate thread) and let the Python interpreter handle the input for you. You can also set the `PyOS_ReadlineFunctionPointer()` to point at your custom input function. See `Modules/readline.c` and `Parser/myreadline.c` for more hints.

However sometimes you have to run the embedded Python interpreter in the same thread as your rest application and you can’t allow the `PyRun_InteractiveLoop()` to stop while waiting for user input. The one solution then is to call `PyParser_ParseString()` and test for `e.error` equal to `E_EOF`, which means the input is incomplete). Here’s a sample code fragment, untested, inspired by code from Alex Farber:

```
#include <Python.h>
#include <node.h>
#include <errcode.h>
#include <grammar.h>
#include <parsetok.h>
#include <compile.h>
```

```

int testcomplete(char *code)
    /* code should end in \n */
    /* return -1 for error, 0 for incomplete, 1 for complete */
{
    node *n;
    perrdetail e;

    n = PyParser_ParseString(code, &PyParser_Grammar,
                             Py_file_input, &e);

    if (n == NULL) {
        if (e.error == E_EOF)
            return 0;
        return -1;
    }

    PyNode_Free(n);
    return 1;
}

```

Another solution is trying to compile the received string with `PyCompileString()`. If it compiles without errors, try to execute the returned code object by calling `PyEval_EvalCode()`. Otherwise save the input for later. If the compilation fails, find out if it's an error or just more input is required - by extracting the message string from the exception tuple and comparing it to the string "unexpected EOF while parsing". Here is a complete example using the GNU readline library (you may want to ignore **SIGINT** while calling `readline()`):

```

#include <stdio.h>
#include <readline.h>

#include <Python.h>
#include <object.h>
#include <compile.h>
#include <eval.h>

int main (int argc, char* argv[])
{
    int i, j, done = 0;
    char ps1[] = ">>> ";
    char ps2[] = "... ";
    char *prompt = ps1;
    char *msg, *line, *code = NULL;

```

```

PyObject *src, *glb, *loc;
PyObject *exc, *val, *trb, *obj, *dum;

Py_Initialize ();
loc = PyDict_New ();
glb = PyDict_New ();
PyDict_SetItemString (glb, "__builtins__", PyEval_GetBuiltins);

while (!done)
{
    line = readline (prompt);

    if (NULL == line)                                /* CTRL-D presse
    {
        done = 1;
    }
    else
    {
        i = strlen (line);

        if (i > 0)                                    /* save non-empt
            add_history (line);

        if (NULL == code)                             /* nothing in co
            j = 0;
        else
            j = strlen (code);

        code = realloc (code, i + j + 2);
        if (NULL == code)                             /* out of memory
            exit (1);

        if (0 == j)                                   /* code was empt
            code[0] = '\0';                             /* keep strncat

        strncat (code, line, i);                       /* append line t
        code[i + j] = '\n';                             /* append '\n' t
        code[i + j + 1] = '\0';

        src = Py_CompileString (code, "<stdin>", Py_single_input);

        if (NULL != src)                               /* compiled just
        {
            if (ps1 == prompt ||                       /* ">>> " or */
                '\n' == code[i + j - 1])             /* "... " and do
            {                                           /* so e
                dum = PyEval_EvalCode (src, glb, loc);
            }
        }
    }
}

```

```

        Py_XDECREF (dum);
        Py_XDECREF (src);
        free (code);
        code = NULL;
        if (PyErr_Occurred ())
            PyErr_Print ();
        prompt = ps1;
    }
}
/* syntax error
else if (PyErr_ExceptionMatches (PyExc_SyntaxError))
{
    PyErr_Fetch (&exc, &val, &trb);
/* clears except

    if (PyArg_ParseTuple (val, "s0", &msg, &obj) &&
        !strcmp (msg, "unexpected EOF while parsing")) /* E
    {
        Py_XDECREF (exc);
        Py_XDECREF (val);
        Py_XDECREF (trb);
        prompt = ps2;
    }
    else
/* some other sy
    {
        PyErr_Restore (exc, val, trb);
        PyErr_Print ();
        free (code);
        code = NULL;
        prompt = ps1;
    }
}
else
/* some non-synt
{
    PyErr_Print ();
    free (code);
    code = NULL;
    prompt = ps1;
}

    free (line);
}
}

Py_XDECREF (glb);
Py_XDECREF (loc);
Py_Finalize ();
exit (0);
}

```

How do I find undefined g++ symbols `__builtin_new` or `__pure_virtual`?

To dynamically load g++ extension modules, you must recompile Python, relink it using g++ (change LINKCC in the Python Modules Makefile), and link your extension module using g++ (e.g., `g++ -shared -o mymodule.so mymodule.o`).

Can I create an object class with some methods implemented in C and others in Python (e.g. through inheritance)?

In Python 2.2, you can inherit from built-in classes such as `int`, `list`, `dict`, etc.

The Boost Python Library (BPL, <http://www.boost.org/libs/python/doc/index.html>) provides a way of doing this from C++ (i.e. you can inherit from an extension class written in C++ using the BPL).

When importing module X, why do I get “undefined symbol: PyUnicodeUCS2*”?

You are using a version of Python that uses a 4-byte representation for Unicode characters, but some C extension module you are importing was compiled using a Python that uses a 2-byte representation for Unicode characters (the default).

If instead the name of the undefined symbol starts with `PyUnicodeUCS4`, the problem is the reverse: Python was built using 2-byte Unicode characters, and the extension module was compiled using a Python with 4-byte Unicode characters.

This can easily occur when using pre-built extension packages. RedHat Linux 7.x, in particular, provided a “python2” binary that is compiled with 4-byte Unicode. This only causes the link failure if the extension uses any of the `PyUnicode_*` functions. It is also a problem if an extension uses any of the Unicode-related format specifiers for `Py_BuildValue()` (or similar) or parameter specifications for `PyArg_ParseTuple()`.

You can check the size of the Unicode character a Python interpreter is using by checking the value of `sys.maxunicode`:

```
>>> import sys
>>> if sys.maxunicode > 65535:
...     print('UCS4 build')
... else:
...     print('UCS2 build')
```

The only way to solve this problem is to use extension modules compiled with a Python binary built using the same size for Unicode characters.

How do I run a Python program under Windows?

This is not necessarily a straightforward question. If you are already familiar with running programs from the Windows command line then everything will seem obvious; otherwise, you might need a little more guidance. There are also differences between Windows 95, 98, NT, ME, 2000 and XP which can add to the confusion.

Unless you use some sort of integrated development environment, you will end up *typing* Windows commands into what is variously referred to as a “DOS window” or “Command prompt window”. Usually you can create such a window from your Start menu; under Windows 2000 the menu selection is *Start ▶ Programs ▶ Accessories ▶ Command Prompt*. You should be able to recognize when you have started such a window because you will see a Windows “command prompt”, which usually looks like this:

```
C:\>
```

The letter may be different, and there might be other things after it, so you might just as easily see something like:

```
D:\Steve\Projects\Python>
```

Python Development on XP

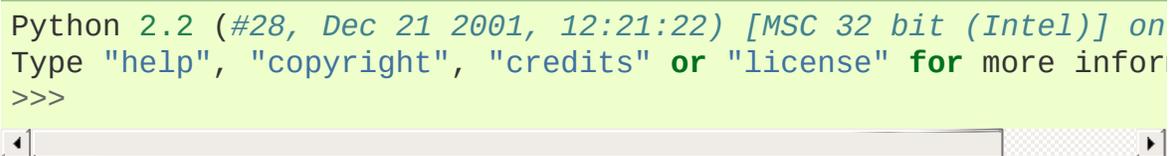

This series of screencasts aims to get you up and running with Python on Windows XP. The knowledge is distilled into 1.5 hours and will get you up and running with the right Python distribution, coding in your choice of IDE, and debugging and writing solid code with unit-tests.

depending on how your computer has been set up and what else you have recently done with it. Once you have started such a window, you are well on the way to running Python programs.

You need to realize that your Python scripts have to be processed by another program called the Python interpreter. The interpreter reads your script, compiles it into bytecodes, and then executes the bytecodes to run your program. So, how do you arrange for the interpreter to handle your Python?

First, you need to make sure that your command window recognises the word “python” as an instruction to start the interpreter. If you have opened a command window, you should try entering the command `python` and hitting return. You should then see something like:

```
Python 2.2 (#28, Dec 21 2001, 12:21:22) [MSC 32 bit (Intel)] on
Type "help", "copyright", "credits" or "license" for more infor
>>>
```

You have started the interpreter in “interactive mode”. That means you can enter Python statements or expressions interactively and have them executed or evaluated while you wait. This is one of Python’s strongest features. Check it by entering a few expressions of your choice and seeing the results:

```
>>> print("Hello")
Hello
>>> "Hello" * 3
HelloHelloHello
```

Many people use the interactive mode as a convenient yet highly programmable calculator. When you want to end your interactive Python session, hold the Ctrl key down while you enter a Z, then hit the “Enter” key to get back to your Windows command prompt.

You may also find that you have a Start-menu entry such as *Start ▶ Programs ▶ Python 2.2 ▶ Python (command line)* that results in you seeing the `>>>` prompt in a new window. If so, the window will disappear after you enter the Ctrl-Z character; Windows is running a single “python” command in the window, and closes it when you terminate the interpreter.

If the `python` command, instead of displaying the interpreter prompt `>>>`, gives you a message like:

```
'python' is not recognized as an internal or external command,  
operable program or batch file.
```

or:

```
Bad command or filename
```

then you need to make sure that your computer knows where to find the Python interpreter. To do this you will have to modify a setting called `PATH`, which is a list of directories where Windows will look for programs.

You should arrange for Python’s installation directory to be added to the `PATH` of every command window as it starts. If you installed Python fairly recently then the command

```
dir C:\py*
```

will probably tell you where it is installed; the usual location is something like `C:\Python23`. Otherwise you will be reduced to a

Adding Python to DOS Path

Python is not added to the DOS path by default. This screencast will walk you through the steps to add the correct entry to the *System Path*, allowing Python to be executed from the command-line by all users.

search of your whole disk ... use *Tools* ▶ *Find* or hit the *Search* button and look for “python.exe”. Supposing you discover that Python is installed in the `c:\Python23` directory (the default at the time of writing), you should make sure that entering the command

```
c:\Python23\python
```

starts up the interpreter as above (and don't forget you'll need a “CTRL-Z” and an “Enter” to get out of it). Once you have verified the directory, you need to add it to the start-up routines your computer goes through. For older versions of Windows the easiest way to do this is to edit the `c:\AUTOEXEC.BAT` file. You would want to add a line like the following to `AUTOEXEC.BAT`:

```
PATH C:\Python23;%PATH%
```

For Windows NT, 2000 and (I assume) XP, you will need to add a string such as

```
;C:\Python23
```

to the current setting for the PATH environment variable, which you will find in the properties window of “My Computer” under the “Advanced” tab. Note that if you have sufficient privilege you might get a choice of installing the settings either for the Current User or for System. The latter is preferred if you want everybody to be able to run Python on the machine.

If you aren't confident doing any of these manipulations yourself, ask for help! At this stage you may want to reboot your system to make absolutely sure the new setting has taken effect. You probably won't need to reboot for Windows NT, XP or 2000. You can also avoid it in earlier versions by editing the file `c:\WINDOWS\COMMAND\CMDINIT.BAT` instead of `AUTOEXEC.BAT`.

You should now be able to start a new command window, enter `python` at the `C:\>` (or whatever) prompt, and see the `>>>` prompt that indicates the Python interpreter is reading interactive commands.

Let's suppose you have a program called `pytest.py` in directory `C:\Steve\Projects\Python`. A session to run that program might look like this:

```
C:\> cd \Steve\Projects\Python
C:\Steve\Projects\Python> python pytest.py
```

Because you added a file name to the command to start the interpreter, when it starts up it reads the Python script in the named file, compiles it, executes it, and terminates, so you see another `C:\>` prompt. You might also have entered

```
C:\> python \Steve\Projects\Python\pytest.py
```

if you hadn't wanted to change your current directory.

Under NT, 2000 and XP you may well find that the installation process has also arranged that the command `pytest.py` (or, if the file isn't in the current directory, `C:\Steve\Projects\Python\pytest.py`) will automatically recognize the ".py" extension and run the Python interpreter on the named file. Using this feature is fine, but *some* versions of Windows have bugs which mean that this form isn't exactly equivalent to using the interpreter explicitly, so be careful.

The important things to remember are:

1. Start Python from the Start Menu, or make sure the PATH is set correctly so Windows can find the Python interpreter.

```
python
```

should give you a '>>>' prompt from the Python interpreter. Don't forget the CTRL-Z and ENTER to terminate the interpreter (and, if you started the window from the Start Menu, make the window disappear).

2. Once this works, you run programs with commands:

```
python {program-file}
```

3. When you know the commands to use you can build Windows shortcuts to run the Python interpreter on any of your scripts, naming particular working directories, and adding them to your menus. Take a look at

```
python --help
```

if your needs are complex.

4. Interactive mode (where you see the `>>>` prompt) is best used for checking that individual statements and expressions do what you think they will, and for developing code by experiment.

How do I make Python scripts executable?

On Windows 2000, the standard Python installer already associates the .py extension with a file type (Python.File) and gives that file type an open command that runs the interpreter (`D:\Program Files\Python\python.exe "%1" %*`). This is enough to make scripts executable from the command prompt as 'foo.py'. If you'd rather be able to execute the script by simple typing 'foo' with no extension you need to add .py to the PATHEXT environment variable.

On Windows NT, the steps taken by the installer as described above allow you to run a script with 'foo.py', but a longtime bug in the NT command processor prevents you from redirecting the input or output of any script executed in this way. This is often important.

The incantation for making a Python script executable under WinNT is to give the file an extension of .cmd and add the following as the first line:

```
@setlocal enableextensions & python -x %~f0 %* & goto :EOF
```

Why does Python sometimes take so long to start?

Usually Python starts very quickly on Windows, but occasionally there are bug reports that Python suddenly begins to take a long time to start up. This is made even more puzzling because Python will work fine on other Windows systems which appear to be configured identically.

The problem may be caused by a misconfiguration of virus checking software on the problem machine. Some virus scanners have been known to introduce startup overhead of two orders of magnitude when the scanner is configured to monitor all reads from the filesystem. Try checking the configuration of virus scanning software on your systems to ensure that they are indeed configured identically. McAfee, when configured to scan all file system read activity, is a particular offender.

Where is Freeze for Windows?

“Freeze” is a program that allows you to ship a Python program as a single stand-alone executable file. It is *not* a compiler; your programs don’t run any faster, but they are more easily distributable, at least to platforms with the same OS and CPU. Read the README file of the freeze program for more disclaimers.

You can use freeze on Windows, but you must download the source tree (see <http://www.python.org/download/source>). The freeze program is in the `Tools\freeze` subdirectory of the source tree.

You need the Microsoft VC++ compiler, and you probably need to build Python. The required project files are in the PCbuild directory.

Is a *.pyd file the same as a DLL?

Yes, .pyd files are dll's, but there are a few differences. If you have a DLL named `foo.pyd`, then it must have a function `initfoo()`. You can then write Python "import foo", and Python will search for `foo.pyd` (as well as `foo.py`, `foo.pyc`) and if it finds it, will attempt to call `initfoo()` to initialize it. You do not link your .exe with `foo.lib`, as that would cause Windows to require the DLL to be present.

Note that the search path for `foo.pyd` is `PYTHONPATH`, not the same as the path that Windows uses to search for `foo.dll`. Also, `foo.pyd` need not be present to run your program, whereas if you linked your program with a dll, the dll is required. Of course, `foo.pyd` is required if you want to say `import foo`. In a DLL, linkage is declared in the source code with `__declspec(dllexport)`. In a .pyd, linkage is defined in a list of available functions.

How can I embed Python into a Windows application?

Embedding the Python interpreter in a Windows app can be summarized as follows:

1. Do `_not_` build Python into your `.exe` file directly. On Windows, Python must be a DLL to handle importing modules that are themselves DLL's. (This is the first key undocumented fact.) Instead, link to `pythonNN.dll`; it is typically installed in `C:\Windows\System`. `NN` is the Python version, a number such as "23" for Python 2.3.

You can link to Python in two different ways. Load-time linking means linking against `pythonNN.lib`, while run-time linking means linking against `pythonNN.dll`. (General note: `pythonNN.lib` is the so-called "import lib" corresponding to `pythonNN.dll`. It merely defines symbols for the linker.)

Run-time linking greatly simplifies link options; everything happens at run time. Your code must load `pythonNN.dll` using the Windows `LoadLibraryEx()` routine. The code must also use access routines and data in `pythonNN.dll` (that is, Python's C API's) using pointers obtained by the Windows `GetProcAddress()` routine. Macros can make using these pointers transparent to any C code that calls routines in Python's C API.

Borland note: convert `pythonNN.lib` to OMF format using `Coff2Omf.exe` first.

2. If you use SWIG, it is easy to create a Python "extension

module” that will make the app’s data and methods available to Python. SWIG will handle just about all the grungy details for you. The result is C code that you link *into* your .exe file (!) You do not have to create a DLL file, and this also simplifies linking.

3. SWIG will create an init function (a C function) whose name depends on the name of the extension module. For example, if the name of the module is leo, the init function will be called initleo(). If you use SWIG shadow classes, as you should, the init function will be called initleoc(). This initializes a mostly hidden helper class used by the shadow class.

The reason you can link the C code in step 2 into your .exe file is that calling the initialization function is equivalent to importing the module into Python! (This is the second key undocumented fact.)

4. In short, you can use the following code to initialize the Python interpreter with your extension module.

```
#include "python.h"
...
Py_Initialize(); // Initialize Python.
initmyAppc(); // Initialize (import) the helper class.
PyRun_SimpleString("import myApp"); // Import the shadow
```

5. There are two problems with Python’s C API which will become apparent if you use a compiler other than MSVC, the compiler used to build pythonNN.dll.

Problem 1: The so-called “Very High Level” functions that take FILE * arguments will not work in a multi-compiler environment because each compiler’s notion of a struct FILE will be different. From an implementation standpoint these are very low level functions.

Problem 2: SWIG generates the following code when generating wrappers to void functions:

```
Py_INCREF(Py_None);  
_resultobj = Py_None;  
return _resultobj;
```

Alas, `Py_None` is a macro that expands to a reference to a complex data structure called `_Py_NoneStruct` inside `pythonNN.dll`. Again, this code will fail in a multi-compiler environment. Replace such code by:

```
return Py_BuildValue("");
```

It may be possible to use SWIG's `%typemap` command to make the change automatically, though I have not been able to get this to work (I'm a complete SWIG newbie).

6. Using a Python shell script to put up a Python interpreter window from inside your Windows app is not a good idea; the resulting window will be independent of your app's windowing system. Rather, you (or the `wxPythonWindow` class) should create a "native" interpreter window. It is easy to connect that window to the Python interpreter. You can redirect Python's i/o to `_any_` object that supports read and write, so all you need is a Python object (defined in your extension module) that contains `read()` and `write()` methods.

How do I use Python for CGI?

On the Microsoft IIS server or on the Win95 MS Personal Web Server you set up Python in the same way that you would set up any other scripting engine.

Run regedt32 and go to:

```
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\W3SVC\Para
```

and enter the following line (making any specific changes that your system may need):

```
.py :REG_SZ: c:\<path to python>\python.exe -u %s %s
```

This line will allow you to call your script with a simple reference like: `http://yourserver/scripts/yourscript.py` provided “scripts” is an “executable” directory for your server (which it usually is by default). The `-u` flag specifies unbuffered and binary mode for stdin - needed when working with binary data.

In addition, it is recommended that using “.py” may not be a good idea for the file extensions when used in this context (you might want to reserve *.py for support modules and use *.cgi or *.cgp for “main program” scripts).

In order to set up Internet Information Services 5 to use Python for CGI processing, please see the following links:

http://www.e-coli.net/pyiis_server.html (for Win2k Server)

<http://www.e-coli.net/pyiis.html> (for Win2k pro)

Configuring Apache is much simpler. In the Apache configuration file `httpd.conf`, add the following line at the end of the file:

ScriptInterpreterSource Registry

Then, give your Python CGI-scripts the extension `.py` and put them in the `cgi-bin` directory.

How do I keep editors from inserting tabs into my Python source?

The FAQ does not recommend using tabs, and the Python style guide, [PEP 8](#), recommends 4 spaces for distributed Python code; this is also the Emacs python-mode default.

Under any editor, mixing tabs and spaces is a bad idea. MSVC is no different in this respect, and is easily configured to use spaces: Take *Tools* ▶ *Options* ▶ *Tabs*, and for file type “Default” set “Tab size” and “Indent size” to 4, and select the “Insert spaces” radio button.

If you suspect mixed tabs and spaces are causing problems in leading whitespace, run Python with the `-t` switch or run `Tools/Scripts/tabnanny.py` to check a directory tree in batch mode.

How do I check for a keypress without blocking?

Use the `msvcrt` module. This is a standard Windows-specific extension module. It defines a function `kbhit()` which checks whether a keyboard hit is present, and `getch()` which gets one character without echoing it.

How do I emulate `os.kill()` in Windows?

Prior to Python 2.7 and 3.2, to terminate a process, you can use `ctypes`:

```
import ctypes

def kill(pid):
    """kill function for Win32"""
    kernel32 = ctypes.windll.kernel32
    handle = kernel32.OpenProcess(1, 0, pid)
    return (0 != kernel32.TerminateProcess(handle, 0))
```

In 2.7 and 3.2, `os.kill()` is implemented similar to the above function, with the additional feature of being able to send CTRL+C and CTRL+BREAK to console subprocesses which are designed to handle those signals. See `os.kill()` for further details.

Why does `os.path.isdir()` fail on NT shared directories?

The solution appears to be always append the “\” on the end of shared drives.

```
>>> import os
>>> os.path.isdir( '\\\\rorschach\\public')
0
>>> os.path.isdir( '\\\\rorschach\\public\\')
1
```

It helps to think of share points as being like drive letters. Example:

```
k: is not a directory
k:\ is a directory
k:\media is a directory
k:\media\ is not a directory
```

The same rules apply if you substitute “k:” with “\conkyfoo”:

```
\\conky\foo is not a directory
\\conky\foo\ is a directory
\\conky\foo\media is a directory
\\conky\foo\media\ is not a directory
```

cgi.py (or other CGI programming) doesn't work sometimes on NT or win95!

Be sure you have the latest python.exe, that you are using python.exe rather than a GUI version of Python and that you have configured the server to execute

```
"... \python.exe -u ..."
```

for the CGI execution. The *-u* (unbuffered) option on NT and Win95 prevents the interpreter from altering newlines in the standard input and output. Without it post/multipart requests will seem to have the wrong length and binary (e.g. GIF) responses may get garbled (resulting in broken images, PDF files, and other binary downloads failing).

Why doesn't os.popen() work in PythonWin on NT?

The reason that `os.popen()` doesn't work from within PythonWin is due to a bug in Microsoft's C Runtime Library (CRT). The CRT assumes you have a Win32 console attached to the process.

You should use the `win32pipe` module's `popen()` instead which doesn't depend on having an attached Win32 console.

Example:

```
import win32pipe
f = win32pipe.popen('dir /c c:\\')
print(f.readlines())
f.close()
```

Why doesn't `os.popen()/win32pipe.popen()` work on Win9x?

There is a bug in Win9x that prevents `os.popen/win32pipe.popen*` from working. The good news is there is a way to work around this problem. The Microsoft Knowledge Base article that you need to lookup is: Q150956. You will find links to the knowledge base at: <http://support.microsoft.com/>.

PyRun_SimpleFile() crashes on Windows but not on Unix; why?

This is very sensitive to the compiler vendor, version and (perhaps) even options. If the FILE* structure in your embedding program isn't the same as is assumed by the Python interpreter it won't work.

The Python 1.5.* DLLs (`python15.dll`) are all compiled with MS VC++ 5.0 and with multithreading-DLL options (`/MD`).

If you can't change compilers or flags, try using `Py_RunSimpleString()`. A trick to get it to run an arbitrary file is to construct a call to `execfile()` with the name of your file as argument.

Also note that you can not mix-and-match Debug and Release versions. If you wish to use the Debug Multithreaded DLL, then your module *must* have an “_d” appended to the base name.

Importing `_tkinter` fails on Windows 95/98: why?

Sometimes, the import of `_tkinter` fails on Windows 95 or 98, complaining with a message like the following:

```
ImportError: DLL load failed: One of the library files needed to run this application cannot be found.
```

It could be that you haven't installed Tcl/Tk, but if you did install Tcl/Tk, and the Wish application works correctly, the problem may be that its installer didn't manage to edit the `autoexec.bat` file correctly. It tries to add a statement that changes the `PATH` environment variable to include the Tcl/Tk 'bin' subdirectory, but sometimes this edit doesn't quite work. Opening it with notepad usually reveals what the problem is.

(One additional hint, noted by David Szafranski: you can't use long filenames here; e.g. use `C:\PROGRA~1\Tcl\bin` instead of `C:\Program Files\Tcl\bin`.)

How do I extract the downloaded documentation on Windows?

Sometimes, when you download the documentation package to a Windows machine using a web browser, the file extension of the saved file ends up being .EXE. This is a mistake; the extension should be .TGZ.

Simply rename the downloaded file to have the .TGZ extension, and WinZip will be able to handle it. (If your copy of WinZip doesn't, get a newer one from <http://www.winzip.com>.)

Missing cw3215mt.dll (or missing cw3215.dll)

Sometimes, when using Tkinter on Windows, you get an error that cw3215mt.dll or cw3215.dll is missing.

Cause: you have an old Tcl/Tk DLL built with cygwin in your path (probably `c:\windows`). You must use the Tcl/Tk DLLs from the standard Tcl/Tk installation (Python 1.5.2 comes with one).

Warning about CTL3D32 version from installer

The Python installer issues a warning like this:

```
This version uses CTL3D32.DLL which is not the correct version.  
This version is used for windows NT applications only.
```

Tim Peters:

This is a Microsoft DLL, and a notorious source of problems. The message means what it says: you have the wrong version of this DLL for your operating system. The Python installation did not cause this – something else you installed previous to this overwrote the DLL that came with your OS (probably older shareware of some sort, but there’s no way to tell now). If you search for “CTL3D32” using any search engine (AltaVista, for example), you’ll find hundreds and hundreds of web pages complaining about the same problem with all sorts of installation programs. They’ll point you to ways to get the correct version reinstalled on your system (since Python doesn’t cause this, we can’t fix it).

David A Burton has written a little program to fix this. Go to <http://www.burtonsys.com/downloads.html> and click on “ctl3dfix.zip”.

General GUI Questions

What platform-independent GUI toolkits exist for Python?

Depending on what platform(s) you are aiming at, there are several. Some of them haven't been ported to Python 3 yet. At least [Tkinter](#) and [Qt](#) are known to be Python 3-compatible.

Tkinter

Standard builds of Python include an object-oriented interface to the Tcl/Tk widget set, called *tkinter*. This is probably the easiest to install (since it comes included with most [binary distributions](#) of Python) and use. For more info about Tk, including pointers to the source, see the [Tcl/Tk home page](#). Tcl/Tk is fully portable to the MacOS, Windows, and Unix platforms.

wxWidgets

wxWidgets (<http://www.wxwidgets.org>) is a free, portable GUI class library written in C++ that provides a native look and feel on a number of platforms, with Windows, MacOS X, GTK, X11, all listed as current stable targets. Language bindings are available for a number of languages including Python, Perl, Ruby, etc.

wxPython (<http://www.wxpython.org>) is the Python binding for wxwidgets. While it often lags slightly behind the official wxWidgets releases, it also offers a number of features via pure Python extensions that are not available in other language bindings. There is an active wxPython user and developer community.

Both wxWidgets and wxPython are free, open source, software with permissive licences that allow their use in commercial products as well as in freeware or shareware.

Qt

There are bindings available for the Qt toolkit (using either [PyQt](#) or [PySide](#)) and for KDE ([PyKDE](#)). PyQt is currently more mature than PySide, but you must buy a PyQt license from [Riverbank Computing](#) if you want to write proprietary applications. PySide is free for all applications.

Qt 4.5 upwards is licensed under the LGPL license; also, commercial licenses are available from [Nokia](#).

Gtk+

PyGtk bindings for the [Gtk+](#) toolkit have been implemented by James Henstridge; see <http://www.pygtk.org>.

FLTK

Python bindings for the [FLTK](#) toolkit, a simple yet powerful and mature cross-platform windowing system, are available from the [PyFLTK](#) project.

FOX

A wrapper for the [FOX](#) toolkit called [FXpy](#) is available. FOX supports both Unix variants and Windows.

OpenGL

For OpenGL bindings, see [PyOpenGL](#).

What platform-specific GUI toolkits exist for Python?

The [Mac port](#) by Jack Jansen has a rich and ever-growing set of modules that support the native Mac toolbox calls. The port supports MacOS X's Carbon libraries.

By installing the [PyObjc Objective-C bridge](#), Python programs can use MacOS X's Cocoa libraries. See the documentation that comes with the Mac port.

[Pythonwin](#) by Mark Hammond includes an interface to the Microsoft Foundation Classes and a Python programming environment that's written mostly in Python using the MFC classes.

Tkinter questions

How do I freeze Tkinter applications?

Freeze is a tool to create stand-alone applications. When freezing Tkinter applications, the applications will not be truly stand-alone, as the application will still need the Tcl and Tk libraries.

One solution is to ship the application with the Tcl and Tk libraries, and point to them at run-time using the `TCL_LIBRARY` and `TK_LIBRARY` environment variables.

To get truly stand-alone applications, the Tcl scripts that form the library have to be integrated into the application as well. One tool supporting that is SAM (stand-alone modules), which is part of the Tix distribution (<http://tix.sourceforge.net/>).

Build Tix with SAM enabled, perform the appropriate call to `Tclsam_init()`, etc. inside Python's `Modules/tkappinit.c`, and link with `libtclsam` and `libtkbam` (you might include the Tix libraries as well).

Can I have Tk events handled while waiting for I/O?

Yes, and you don't even need threads! But you'll have to restructure your I/O code a bit. Tk has the equivalent of Xt's `xtAddInput()` call, which allows you to register a callback function which will be called from the Tk mainloop when I/O is possible on a file descriptor. Here's what you need:

```
from Tkinter import tkinter
tkinter.createfilehandler(file, mask, callback)
```

The file may be a Python file or socket object (actually, anything with a `fileno()` method), or an integer file descriptor. The mask is one of the constants `tkinter.READABLE` or `tkinter.WRITABLE`. The callback is called as follows:

```
callback(file, mask)
```

You must unregister the callback when you're done, using

```
tkinter.deletefilehandler(file)
```

Note: since you don't know *how many bytes* are available for reading, you can't use the Python file object's `read` or `readline` methods, since these will insist on reading a predefined number of bytes. For sockets, the `recv()` or `recvfrom()` methods will work fine; for other files, use `os.read(file.fileno(), maxbytecount)`.

I can't get key bindings to work in Tkinter: why?

An often-heard complaint is that event handlers bound to events with the `bind()` method don't get handled even when the appropriate key is pressed.

The most common cause is that the widget to which the binding applies doesn't have "keyboard focus". Check out the Tk documentation for the `focus` command. Usually a widget is given the keyboard focus by clicking in it (but not for labels; see the `takefocus` option).

Questions »

“Why is Python Installed on my Computer?” FAQ

What is Python?

Python is a programming language. It's used for many different applications. It's used in some high schools and colleges as an introductory programming language because Python is easy to learn, but it's also used by professional software developers at places such as Google, NASA, and Lucasfilm Ltd.

If you wish to learn more about Python, start with the [Beginner's Guide to Python](#).

Why is Python installed on my machine?

If you find Python installed on your system but don't remember installing it, there are several possible ways it could have gotten there.

- Perhaps another user on the computer wanted to learn programming and installed it; you'll have to figure out who's been using the machine and might have installed it.
- A third-party application installed on the machine might have been written in Python and included a Python installation. There are many such applications, from GUI programs to network servers and administrative scripts.
- Some Windows machines also have Python installed. At this writing we're aware of computers from Hewlett-Packard and Compaq that include Python. Apparently some of HP/Compaq's administrative tools are written in Python.
- Many Unix-compatible operating systems, such as Mac OS X and some Linux distributions, have Python installed by default; it's included in the base installation.

Can I delete Python?

That depends on where Python came from.

If someone installed it deliberately, you can remove it without hurting anything. On Windows, use the Add/Remove Programs icon in the Control Panel.

If Python was installed by a third-party application, you can also remove it, but that application will no longer work. You should use that application's uninstaller rather than removing Python directly.

If Python came with your operating system, removing it is not recommended. If you remove it, whatever tools were written in Python will no longer run, and some of them might be important to you. Reinstalling the whole system would then be required to fix things again.

Glossary

`>>>`

The default Python prompt of the interactive shell. Often seen for code examples which can be executed interactively in the interpreter.

`...`

The default Python prompt of the interactive shell when entering code for an indented code block or within a pair of matching left and right delimiters (parentheses, square brackets or curly braces).

2to3

A tool that tries to convert Python 2.x code to Python 3.x code by handling most of the incompatibilities which can be detected by parsing the source and traversing the parse tree.

2to3 is available in the standard library as `lib2to3`; a standalone entry point is provided as `Tools/scripts/2to3`. See [2to3 - Automated Python 2 to 3 code translation](#).

abstract base class

ABCs - abstract base classes complement *duck-typing* by providing a way to define interfaces when other techniques like `hasattr()` would be clumsy. Python comes with many built-in ABCs for data structures (in the `collections` module), numbers (in the `numbers` module), and streams (in the `io` module). You can create your own ABC with the `abc` module.

argument

A value passed to a function or method, assigned to a named local variable in the function body. A function or method may have both positional arguments and keyword arguments in its definition. Positional and keyword arguments may be variable-

length: `*` accepts or passes (if in the function definition or call) several positional arguments in a list, while `**` does the same for keyword arguments in a dictionary.

Any expression may be used within the argument list, and the evaluated value is passed to the local variable.

attribute

A value associated with an object which is referenced by name using dotted expressions. For example, if an object `o` has an attribute `a` it would be referenced as `o.a`.

BDFL

Benevolent Dictator For Life, a.k.a. [Guido van Rossum](#), Python's creator.

bytecode

Python source code is compiled into bytecode, the internal representation of a Python program in the CPython interpreter. The bytecode is also cached in `.pyc` and `.pyo` files so that executing the same file is faster the second time (recompilation from source to bytecode can be avoided). This “intermediate language” is said to run on a *virtual machine* that executes the machine code corresponding to each bytecode. Do note that bytecodes are not expected to work between different Python virtual machines, nor to be stable between Python releases.

A list of bytecode instructions can be found in the documentation for [the `dis` module](#).

class

A template for creating user-defined objects. Class definitions normally contain method definitions which operate on instances of the class.

coercion

The implicit conversion of an instance of one type to another during an operation which involves two arguments of the same type. For example, `int(3.15)` converts the floating point number to the integer `3`, but in `3+4.5`, each argument is of a different type (one int, one float), and both must be converted to the same type before they can be added or it will raise a `TypeError`. Without coercion, all arguments of even compatible types would have to be normalized to the same value by the programmer, e.g., `float(3)+4.5` rather than just `3+4.5`.

complex number

An extension of the familiar real number system in which all numbers are expressed as a sum of a real part and an imaginary part. Imaginary numbers are real multiples of the imaginary unit (the square root of `-1`), often written `i` in mathematics or `j` in engineering. Python has built-in support for complex numbers, which are written with this latter notation; the imaginary part is written with a `j` suffix, e.g., `3+1j`. To get access to complex equivalents of the `math` module, use `cmath`. Use of complex numbers is a fairly advanced mathematical feature. If you're not aware of a need for them, it's almost certain you can safely ignore them.

context manager

An object which controls the environment seen in a `with` statement by defining `__enter__()` and `__exit__()` methods. See [PEP 343](#).

CPython

The canonical implementation of the Python programming language, as distributed on [python.org](#). The term "CPython" is used when necessary to distinguish this implementation from others such as Jython or IronPython.

decorator

A function returning another function, usually applied as a function transformation using the `@wrapper` syntax. Common examples for decorators are `classmethod()` and `staticmethod()`.

The decorator syntax is merely syntactic sugar, the following two function definitions are semantically equivalent:

```
def f(...):  
    ...  
f = staticmethod(f)  
  
@staticmethod  
def f(...):  
    ...
```

The same concept exists for classes, but is less commonly used there. See the documentation for [function definitions](#) and [class definitions](#) for more about decorators.

descriptor

Any object which defines the methods `__get__()`, `__set__()`, or `__delete__()`. When a class attribute is a descriptor, its special binding behavior is triggered upon attribute lookup. Normally, using `a.b` to get, set or delete an attribute looks up the object named `b` in the class dictionary for `a`, but if `b` is a descriptor, the respective descriptor method gets called. Understanding descriptors is a key to a deep understanding of Python because they are the basis for many features including functions, methods, properties, class methods, static methods, and reference to super classes.

For more information about descriptors' methods, see [Implementing Descriptors](#).

dictionary

An associative array, where arbitrary keys are mapped to values.

The keys can be any object with `__hash__()` function and `__eq__()` methods. Called a hash in Perl.

docstring

A string literal which appears as the first expression in a class, function or module. While ignored when the suite is executed, it is recognized by the compiler and put into the `__doc__` attribute of the enclosing class, function or module. Since it is available via introspection, it is the canonical place for documentation of the object.

duck-typing

A programming style which does not look at an object's type to determine if it has the right interface; instead, the method or attribute is simply called or used ("If it looks like a duck and quacks like a duck, it must be a duck.") By emphasizing interfaces rather than specific types, well-designed code improves its flexibility by allowing polymorphic substitution. Duck-typing avoids tests using `type()` or `isinstance()`. (Note, however, that duck-typing can be complemented with *abstract base classes*.) Instead, it typically employs `hasattr()` tests or *EAFP* programming.

EAFP

Easier to ask for forgiveness than permission. This common Python coding style assumes the existence of valid keys or attributes and catches exceptions if the assumption proves false. This clean and fast style is characterized by the presence of many `try` and `except` statements. The technique contrasts with the *LBYL* style common to many other languages such as C.

expression

A piece of syntax which can be evaluated to some value. In other words, an expression is an accumulation of expression elements like literals, names, attribute access, operators or function calls

which all return a value. In contrast to many other languages, not all language constructs are expressions. There are also *statements* which cannot be used as expressions, such as `if`. Assignments are also statements, not expressions.

extension module

A module written in C or C++, using Python's C API to interact with the core and with user code.

file object

An object exposing a file-oriented API (with methods such as `read()` or `write()`) to an underlying resource. Depending on the way it was created, a file object can mediate access to a real on-disk file or to another other type of storage or communication device (for example standard input/output, in-memory buffers, sockets, pipes, etc.). File objects are also called *file-like objects* or *streams*.

There are actually three categories of file objects: raw binary files, buffered binary files and text files. Their interfaces are defined in the `io` module. The canonical way to create a file object is by using the `open()` function.

file-like object

A synonym for *file object*.

finder

An object that tries to find the *loader* for a module. It must implement a method named `find_module()`. See [PEP 302](#) for details and `importlib.abc.Finder` for an *abstract base class*.

floor division

Mathematical division that rounds down to nearest integer. The floor division operator is `//`. For example, the expression `11 // 4` evaluates to `2` in contrast to the `2.75` returned by float true

division. Note that `(-11) // 4` is `-3` because that is `-2.75` rounded *downward*. See [PEP 238](#).

function

A series of statements which returns some value to a caller. It can also be passed zero or more arguments which may be used in the execution of the body. See also [argument](#) and [method](#).

`__future__`

A pseudo-module which programmers can use to enable new language features which are not compatible with the current interpreter.

By importing the `__future__` module and evaluating its variables, you can see when a new feature was first added to the language and when it becomes the default:

```
>>> import __future__
>>> __future__.division
_Feature((2, 2, 0, 'alpha', 2), (3, 0, 0, 'alpha', 0), 8192)
```

garbage collection

The process of freeing memory when it is not used anymore. Python performs garbage collection via reference counting and a cyclic garbage collector that is able to detect and break reference cycles.

generator

A function which returns an iterator. It looks like a normal function except that it contains `yield` statements for producing a series a values usable in a for-loop or that can be retrieved one at a time with the `next()` function. Each `yield` temporarily suspends processing, remembering the location execution state (including local variables and pending try-statements). When the generator resumes, it picks-up where it left-off (in contrast to functions

which start fresh on every invocation.

generator expression

An expression that returns an iterator. It looks like a normal expression followed by a `for` expression defining a loop variable, range, and an optional `if` expression. The combined expression generates values for an enclosing function:

```
>>> sum(i*i for i in range(10))           # sum of squares 0,
285
```

GIL

See [global interpreter lock](#).

global interpreter lock

The mechanism used by the *CPython* interpreter to assure that only one thread executes Python *bytecode* at a time. This simplifies the CPython implementation by making the object model (including critical built-in types such as `dict`) implicitly safe against concurrent access. Locking the entire interpreter makes it easier for the interpreter to be multi-threaded, at the expense of much of the parallelism afforded by multi-processor machines.

However, some extension modules, either standard or third-party, are designed so as to release the GIL when doing computationally-intensive tasks such as compression or hashing. Also, the GIL is always released when doing I/O.

Past efforts to create a “free-threaded” interpreter (one which locks shared data at a much finer granularity) have not been successful because performance suffered in the common single-processor case. It is believed that overcoming this performance issue would make the implementation much more complicated and therefore costlier to maintain.

hashable

An object is *hashable* if it has a hash value which never changes during its lifetime (it needs a `__hash__()` method), and can be compared to other objects (it needs an `__eq__()` method). Hashable objects which compare equal must have the same hash value.

Hashability makes an object usable as a dictionary key and a set member, because these data structures use the hash value internally.

All of Python's immutable built-in objects are hashable, while no mutable containers (such as lists or dictionaries) are. Objects which are instances of user-defined classes are hashable by default; they all compare unequal, and their hash value is their `id()`.

IDLE

An Integrated Development Environment for Python. IDLE is a basic editor and interpreter environment which ships with the standard distribution of Python.

immutable

An object with a fixed value. Immutable objects include numbers, strings and tuples. Such an object cannot be altered. A new object has to be created if a different value has to be stored. They play an important role in places where a constant hash value is needed, for example as a key in a dictionary.

importer

An object that both finds and loads a module; both a *finder* and *loader* object.

interactive

Python has an interactive interpreter which means you can enter statements and expressions at the interpreter prompt,

immediately execute them and see their results. Just launch `python` with no arguments (possibly by selecting it from your computer's main menu). It is a very powerful way to test out new ideas or inspect modules and packages (remember `help(x)`).

interpreted

Python is an interpreted language, as opposed to a compiled one, though the distinction can be blurry because of the presence of the bytecode compiler. This means that source files can be run directly without explicitly creating an executable which is then run. Interpreted languages typically have a shorter development/debug cycle than compiled ones, though their programs generally also run more slowly. See also *interactive*.

iterable

An object capable of returning its members one at a time. Examples of iterables include all sequence types (such as `list`, `str`, and `tuple`) and some non-sequence types like `dict` and `file` and objects of any classes you define with an `__iter__()` or `__getitem__()` method. Iterables can be used in a `for` loop and in many other places where a sequence is needed (`zip()`, `map()`, ...). When an iterable object is passed as an argument to the built-in function `iter()`, it returns an iterator for the object. This iterator is good for one pass over the set of values. When using iterables, it is usually not necessary to call `iter()` or deal with iterator objects yourself. The `for` statement does that automatically for you, creating a temporary unnamed variable to hold the iterator for the duration of the loop. See also *iterator*, *sequence*, and *generator*.

iterator

An object representing a stream of data. Repeated calls to the iterator's `__next__()` method (or passing it to the built-in function `next()`) return successive items in the stream. When no more

data are available a `StopIteration` exception is raised instead. At this point, the iterator object is exhausted and any further calls to its `__next__()` method just raise `StopIteration` again. Iterators are required to have an `__iter__()` method that returns the iterator object itself so every iterator is also iterable and may be used in most places where other iterables are accepted. One notable exception is code which attempts multiple iteration passes. A container object (such as a `list`) produces a fresh new iterator each time you pass it to the `iter()` function or use it in a `for` loop. Attempting this with an iterator will just return the same exhausted iterator object used in the previous iteration pass, making it appear like an empty container.

More information can be found in *Iterator Types*.

key function

A key function or collation function is a callable that returns a value used for sorting or ordering. For example, `locale.strxfrm()` is used to produce a sort key that is aware of locale specific sort conventions.

A number of tools in Python accept key functions to control how elements are ordered or grouped. They include `min()`, `max()`, `sorted()`, `list.sort()`, `heapq.nsmallest()`, `heapq.nlargest()`, and `itertools.groupby()`.

There are several ways to create a key function. For example, the `str.lower()` method can serve as a key function for case insensitive sorts. Alternatively, an ad-hoc key function can be built from a `lambda` expression such as `lambda r: (r[0], r[2])`. Also, the `operator` module provides three key function constructors: `attrgetter()`, `itemgetter()`, and `methodcaller()`. See the *Sorting HOW TO* for examples of how to create and use

key functions.

keyword argument

Arguments which are preceded with a `variable_name=` in the call. The variable name designates the local name in the function to which the value is assigned. `**` is used to accept or pass a dictionary of keyword arguments. See *argument*.

lambda

An anonymous inline function consisting of a single *expression* which is evaluated when the function is called. The syntax to create a lambda function is `lambda [arguments]: expression`

LBYL

Look before you leap. This coding style explicitly tests for pre-conditions before making calls or lookups. This style contrasts with the *EAFP* approach and is characterized by the presence of many `if` statements.

In a multi-threaded environment, the LBYL approach can risk introducing a race condition between “the looking” and “the leaping”. For example, the code, `if key in mapping: return mapping[key]` can fail if another thread removes *key* from *mapping* after the test, but before the lookup. This issue can be solved with locks or by using the EAFP approach.

list

A built-in Python *sequence*. Despite its name it is more akin to an array in other languages than to a linked list since access to elements are $O(1)$.

list comprehension

A compact way to process all or part of the elements in a sequence and return a list with the results. `result = ['{:#04x}'.format(x) for x in range(256) if x % 2 == 0]`

generates a list of strings containing even hex numbers (0x..) in the range from 0 to 255. The `if` clause is optional. If omitted, all elements in `range(256)` are processed.

loader

An object that loads a module. It must define a method named `load_module()`. A loader is typically returned by a *finder*. See [PEP 302](#) for details and `importlib.abc.Loader` for an *abstract base class*.

mapping

A container object that supports arbitrary key lookups and implements the methods specified in the `Mapping` or `MutableMapping` *abstract base classes*. Examples include `dict`, `collections.defaultdict`, `collections.OrderedDict` and `collections.Counter`.

metaclass

The class of a class. Class definitions create a class name, a class dictionary, and a list of base classes. The metaclass is responsible for taking those three arguments and creating the class. Most object oriented programming languages provide a default implementation. What makes Python special is that it is possible to create custom metaclasses. Most users never need this tool, but when the need arises, metaclasses can provide powerful, elegant solutions. They have been used for logging attribute access, adding thread-safety, tracking object creation, implementing singletons, and many other tasks.

More information can be found in [Customizing class creation](#).

method

A function which is defined inside a class body. If called as an attribute of an instance of that class, the method will get the instance object as its first *argument* (which is usually called

`self`). See *function* and *nested scope*.

method resolution order

Method Resolution Order is the order in which base classes are searched for a member during lookup. See [The Python 2.3 Method Resolution Order](#).

MRO

See *method resolution order*.

mutable

Mutable objects can change their value but keep their `id()`. See also *immutable*.

named tuple

Any tuple-like class whose indexable elements are also accessible using named attributes (for example, `time.localtime()` returns a tuple-like object where the *year* is accessible either with an index such as `t[0]` or with a named attribute like `t.tm_year`).

A named tuple can be a built-in type such as `time.struct_time`, or it can be created with a regular class definition. A full featured named tuple can also be created with the factory function `collections.namedtuple()`. The latter approach automatically provides extra features such as a self-documenting representation like `Employee(name='jones', title='programmer')`.

namespace

The place where a variable is stored. Namespaces are implemented as dictionaries. There are the local, global and built-in namespaces as well as nested namespaces in objects (in methods). Namespaces support modularity by preventing naming conflicts. For instance, the functions `builtins.open()` and `os.open()` are distinguished by their namespaces. Namespaces

also aid readability and maintainability by making it clear which module implements a function. For instance, writing `random.seed()` or `itertools.izip()` makes it clear that those functions are implemented by the `random` and `itertools` modules, respectively.

nested scope

The ability to refer to a variable in an enclosing definition. For instance, a function defined inside another function can refer to variables in the outer function. Note that nested scopes by default work only for reference and not for assignment. Local variables both read and write in the innermost scope. Likewise, global variables read and write to the global namespace. The `nonlocal` allows writing to outer scopes.

new-style class

Old name for the flavor of classes now used for all class objects. In earlier Python versions, only new-style classes could use Python's newer, versatile features like `__slots__`, descriptors, properties, `__getattr__()`, class methods, and static methods.

object

Any data with state (attributes or value) and defined behavior (methods). Also the ultimate base class of any *new-style class*.

positional argument

The arguments assigned to local names inside a function or method, determined by the order in which they were given in the call. `*` is used to either accept multiple positional arguments (when in the definition), or pass several arguments as a list to a function. See *argument*.

Python 3000

Nickname for the Python 3.x release line (coined long ago when the release of version 3 was something in the distant future.) This

is also abbreviated “Py3k”.

Pythonic

An idea or piece of code which closely follows the most common idioms of the Python language, rather than implementing code using concepts common to other languages. For example, a common idiom in Python is to loop over all elements of an iterable using a `for` statement. Many other languages don't have this type of construct, so people unfamiliar with Python sometimes use a numerical counter instead:

```
for i in range(len(food)):
    print(food[i])
```

As opposed to the cleaner, Pythonic method:

```
for piece in food:
    print(piece)
```

reference count

The number of references to an object. When the reference count of an object drops to zero, it is deallocated. Reference counting is generally not visible to Python code, but it is a key element of the *CPython* implementation. The `sys` module defines a `getrefcount()` function that programmers can call to return the reference count for a particular object.

slots

A declaration inside a class that saves memory by pre-declaring space for instance attributes and eliminating instance dictionaries. Though popular, the technique is somewhat tricky to get right and is best reserved for rare cases where there are large numbers of instances in a memory-critical application.

sequence

An *iterable* which supports efficient element access using integer

indices via the `__getitem__()` special method and defines a `len()` method that returns the length of the sequence. Some built-in sequence types are `list`, `str`, `tuple`, and `bytes`. Note that `dict` also supports `__getitem__()` and `__len__()`, but is considered a mapping rather than a sequence because the lookups use arbitrary *immutable* keys rather than integers.

slice

An object usually containing a portion of a *sequence*. A slice is created using the subscript notation, `[]` with colons between numbers when several are given, such as in `variable_name[1:3:5]`. The bracket (subscript) notation uses `slice` objects internally.

special method

A method that is called implicitly by Python to execute a certain operation on a type, such as addition. Such methods have names starting and ending with double underscores. Special methods are documented in *Special method names*.

statement

A statement is part of a suite (a “block” of code). A statement is either an *expression* or a one of several constructs with a keyword, such as `if`, `while` or `for`.

triple-quoted string

A string which is bound by three instances of either a quotation mark (") or an apostrophe ('). While they don't provide any functionality not available with single-quoted strings, they are useful for a number of reasons. They allow you to include unescaped single and double quotes within a string and they can span multiple lines without the use of the continuation character, making them especially useful when writing docstrings.

type

The type of a Python object determines what kind of object it is;

every object has a type. An object's type is accessible as its `__class__` attribute or can be retrieved with `type(obj)`.

view

The objects returned from `dict.keys()`, `dict.values()`, and `dict.items()` are called dictionary views. They are lazy sequences that will see changes in the underlying dictionary. To force the dictionary view to become a full list use `list(dictview)`. See *Dictionary view objects*.

virtual machine

A computer defined entirely in software. Python's virtual machine executes the *bytecode* emitted by the bytecode compiler.

Zen of Python

Listing of Python design principles and philosophies that are helpful in understanding and using the language. The listing can be found by typing "`import this`" at the interactive prompt.

About these documents

These documents are generated from [reStructuredText](#) sources by [Sphinx](#), a document processor specifically written for the Python documentation.

Development of the documentation and its toolchain takes place on the docs@python.org mailing list. We're always looking for volunteers wanting to help with the docs, so feel free to send a mail there!

Many thanks go to:

- Fred L. Drake, Jr., the creator of the original Python documentation toolset and writer of much of the content;
- the [Docutils](#) project for creating reStructuredText and the Docutils suite;
- Fredrik Lundh for his [Alternative Python Reference](#) project from which Sphinx got many good ideas.

See [Reporting Bugs](#) for information how to report bugs in this documentation, or Python itself.

Contributors to the Python Documentation

This section lists people who have contributed in some way to the Python documentation. It is probably not complete – if you feel that you or anyone else should be on this list, please let us know (send email to docs@python.org), and we'll be glad to correct the problem.

It is only with the input and contributions of the Python community that Python has such wonderful documentation – Thank You!

Reporting Bugs

Python is a mature programming language which has established a reputation for stability. In order to maintain this reputation, the developers would like to know of any deficiencies you find in Python.

Documentation bugs

If you find a bug in this documentation or would like to propose an improvement, please send an e-mail to docs@python.org describing the bug and where you found it. If you have a suggestion how to fix it, include that as well.

docs@python.org is a mailing list run by volunteers; your request will be noticed, even if it takes a while to be processed.

Of course, if you want a more persistent record of your issue, you can use the issue tracker for documentation bugs as well.

Using the Python issue tracker

Bug reports for Python itself should be submitted via the Python Bug Tracker (<http://bugs.python.org/>). The bug tracker offers a Web form which allows pertinent information to be entered and submitted to the developers.

The first step in filing a report is to determine whether the problem has already been reported. The advantage in doing so, aside from saving the developers time, is that you learn what has been done to fix it; it may be that the problem has already been fixed for the next release, or additional information is needed (in which case you are welcome to provide it if you can!). To do this, search the bug database using the search box on the top of the page.

If the problem you're reporting is not already in the bug tracker, go back to the Python Bug Tracker and log in. If you don't already have a tracker account, select the "Register" link or, if you use OpenID, one of the OpenID provider logos in the sidebar. It is not possible to submit a bug report anonymously.

Being now logged in, you can submit a bug. Select the "Create New" link in the sidebar to open the bug reporting form.

The submission form has a number of fields. For the "Title" field, enter a *very* short description of the problem; less than ten words is good. In the "Type" field, select the type of your problem; also select the "Component" and "Versions" to which the bug relates.

In the "Comment" field, describe the problem in detail, including what you expected to happen and what did happen. Be sure to include whether any extension modules were involved, and what hardware and software platform you were using (including version information as appropriate).

Each bug report will be assigned to a developer who will determine what needs to be done to correct the problem. You will receive an update each time action is taken on the bug. See <http://www.python.org/dev/workflow/> for a detailed description of the issue workflow.

History and License

History of the software

Python was created in the early 1990s by Guido van Rossum at Stichting Mathematisch Centrum (CWI, see <http://www.cwi.nl/>) in the Netherlands as a successor of a language called ABC. Guido remains Python's principal author, although it includes many contributions from others.

In 1995, Guido continued his work on Python at the Corporation for National Research Initiatives (CNRI, see <http://www.cnri.reston.va.us/>) in Reston, Virginia where he released several versions of the software.

In May 2000, Guido and the Python core development team moved to BeOpen.com to form the BeOpen PythonLabs team. In October of the same year, the PythonLabs team moved to Digital Creations (now Zope Corporation; see <http://www.zope.com/>). In 2001, the Python Software Foundation (PSF, see <http://www.python.org/psf/>) was formed, a non-profit organization created specifically to own Python-related Intellectual Property. Zope Corporation is a sponsoring member of the PSF.

All Python releases are Open Source (see <http://www.opensource.org/> for the Open Source Definition). Historically, most, but not all, Python releases have also been GPL-compatible; the table below summarizes the various releases.

Release	Derived from	Year	Owner	GPL compatible?
0.9.0 thru 1.2	n/a	1991-1995	CWI	yes
1.3 thru 1.5.2	1.2	1995-1999	CNRI	yes
1.6	1.5.2	2000	CNRI	no

2.0	1.6	2000	BeOpen.com	no
1.6.1	1.6	2001	CNRI	no
2.1	2.0+1.6.1	2001	PSF	no
2.0.1	2.0+1.6.1	2001	PSF	yes
2.1.1	2.1+2.0.1	2001	PSF	yes
2.2	2.1.1	2001	PSF	yes
2.1.2	2.1.1	2002	PSF	yes
2.1.3	2.1.2	2002	PSF	yes
2.2.1	2.2	2002	PSF	yes
2.2.2	2.2.1	2002	PSF	yes
2.2.3	2.2.2	2002- 2003	PSF	yes
2.3	2.2.2	2002- 2003	PSF	yes
2.3.1	2.3	2002- 2003	PSF	yes
2.3.2	2.3.1	2003	PSF	yes
2.3.3	2.3.2	2003	PSF	yes
2.3.4	2.3.3	2004	PSF	yes
2.3.5	2.3.4	2005	PSF	yes
2.4	2.3	2004	PSF	yes
2.4.1	2.4	2005	PSF	yes
2.4.2	2.4.1	2005	PSF	yes
2.4.3	2.4.2	2006	PSF	yes
2.4.4	2.4.3	2006	PSF	yes
2.5	2.4	2006	PSF	yes
2.5.1	2.5	2007	PSF	yes
2.6	2.5	2008	PSF	yes
2.6.1	2.6	2008	PSF	yes
2.6.2	2.6.1	2009	PSF	yes
2.6.3	2.6.2	2009	PSF	yes
2.6.4	2.6.3	2009	PSF	yes

3.0	2.6	2008	PSF	yes
3.0.1	3.0	2009	PSF	yes
3.1	3.0.1	2009	PSF	yes
3.1.1	3.1	2009	PSF	yes
3.1.2	3.1	2010	PSF	yes
3.2	3.1	2011	PSF	yes

Note: GPL-compatible doesn't mean that we're distributing Python under the GPL. All Python licenses, unlike the GPL, let you distribute a modified version without making your changes open source. The GPL-compatible licenses make it possible to combine Python with other software that is released under the GPL; the others don't.

Thanks to the many outside volunteers who have worked under Guido's direction to make these releases possible.

Terms and conditions for accessing or otherwise using Python

PSF LICENSE AGREEMENT FOR PYTHON 3.2

1. This LICENSE AGREEMENT is between the Python Software Foundation (“PSF”), and the Individual or Organization (“Licensee”) accessing and otherwise using Python 3.2 software in source or binary form and its associated documentation.
2. Subject to the terms and conditions of this License Agreement, PSF hereby grants Licensee a nonexclusive, royalty-free, world-wide license to reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use Python 3.2 alone or in any derivative version, provided, however, that PSF’s License Agreement and PSF’s notice of copyright, i.e., “Copyright © 2001-2011 Python Software Foundation; All Rights Reserved” are retained in Python 3.2 alone or in any derivative version prepared by Licensee.
3. In the event Licensee prepares a derivative work that is based on or incorporates Python 3.2 or any part thereof, and wants to make the derivative work available to others as provided herein, then Licensee hereby agrees to include in any such work a brief summary of the changes made to Python 3.2.
4. PSF is making Python 3.2 available to Licensee on an “AS IS” basis. PSF MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT LIMITATION, PSF MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF PYTHON 3.2 WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.
5. PSF SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER

USERS OF PYTHON 3.2 FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF MODIFYING, DISTRIBUTING, OR OTHERWISE USING PYTHON 3.2, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.

6. This License Agreement will automatically terminate upon a material breach of its terms and conditions.
7. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between PSF and Licensee. This License Agreement does not grant permission to use PSF trademarks or trade name in a trademark sense to endorse or promote products or services of Licensee, or any third party.
8. By copying, installing or otherwise using Python 3.2, Licensee agrees to be bound by the terms and conditions of this License Agreement.

BEOPEN.COM LICENSE AGREEMENT FOR PYTHON 2.0

BEOPEN PYTHON OPEN SOURCE LICENSE AGREEMENT VERSION 1

1. This LICENSE AGREEMENT is between BeOpen.com (“BeOpen”), having an office at 160 Saratoga Avenue, Santa Clara, CA 95051, and the Individual or Organization (“Licensee”) accessing and otherwise using this software in source or binary form and its associated documentation (“the Software”).
2. Subject to the terms and conditions of this BeOpen Python License Agreement, BeOpen hereby grants Licensee a non-exclusive, royalty-free, world-wide license to reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use the Software alone or in any derivative version, provided, however, that the BeOpen Python License is retained in the Software, alone or in any

derivative version prepared by Licensee.

3. BeOpen is making the Software available to Licensee on an “AS IS” basis. BEOPEN MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT LIMITATION, BEOPEN MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF THE SOFTWARE WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.
4. BEOPEN SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS OF THE SOFTWARE FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF USING, MODIFYING OR DISTRIBUTING THE SOFTWARE, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.
5. This License Agreement will automatically terminate upon a material breach of its terms and conditions.
6. This License Agreement shall be governed by and interpreted in all respects by the law of the State of California, excluding conflict of law provisions. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between BeOpen and Licensee. This License Agreement does not grant permission to use BeOpen trademarks or trade names in a trademark sense to endorse or promote products or services of Licensee, or any third party. As an exception, the “BeOpen Python” logos available at <http://www.pythonlabs.com/logos.html> may be used according to the permissions granted on that web page.
7. By copying, installing or otherwise using the software, Licensee agrees to be bound by the terms and conditions of this License Agreement.

CNRI LICENSE AGREEMENT FOR PYTHON 1.6.1

1. This LICENSE AGREEMENT is between the Corporation for National Research Initiatives, having an office at 1895 Preston White Drive, Reston, VA 20191 ("CNRI"), and the Individual or Organization ("Licensee") accessing and otherwise using Python 1.6.1 software in source or binary form and its associated documentation.
2. Subject to the terms and conditions of this License Agreement, CNRI hereby grants Licensee a nonexclusive, royalty-free, world-wide license to reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use Python 1.6.1 alone or in any derivative version, provided, however, that CNRI's License Agreement and CNRI's notice of copyright, i.e., "Copyright © 1995-2001 Corporation for National Research Initiatives; All Rights Reserved" are retained in Python 1.6.1 alone or in any derivative version prepared by Licensee. Alternately, in lieu of CNRI's License Agreement, Licensee may substitute the following text (omitting the quotes): "Python 1.6.1 is made available subject to the terms and conditions in CNRI's License Agreement. This Agreement together with Python 1.6.1 may be located on the Internet using the following unique, persistent identifier (known as a handle): 1895.22/1013. This Agreement may also be obtained from a proxy server on the Internet using the following URL: <http://hdl.handle.net/1895.22/1013>."
3. In the event Licensee prepares a derivative work that is based on or incorporates Python 1.6.1 or any part thereof, and wants to make the derivative work available to others as provided herein, then Licensee hereby agrees to include in any such work a brief summary of the changes made to Python 1.6.1.
4. CNRI is making Python 1.6.1 available to Licensee on an "AS IS" basis. CNRI MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT LIMITATION, CNRI MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF

MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF PYTHON 1.6.1 WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.

5. CNRI SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS OF PYTHON 1.6.1 FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF MODIFYING, DISTRIBUTING, OR OTHERWISE USING PYTHON 1.6.1, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.
6. This License Agreement will automatically terminate upon a material breach of its terms and conditions.
7. This License Agreement shall be governed by the federal intellectual property law of the United States, including without limitation the federal copyright law, and, to the extent such U.S. federal law does not apply, by the law of the Commonwealth of Virginia, excluding Virginia's conflict of law provisions. Notwithstanding the foregoing, with regard to derivative works based on Python 1.6.1 that incorporate non-separable material that was previously distributed under the GNU General Public License (GPL), the law of the Commonwealth of Virginia shall govern this License Agreement only as to issues arising under or with respect to Paragraphs 4, 5, and 7 of this License Agreement. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between CNRI and Licensee. This License Agreement does not grant permission to use CNRI trademarks or trade name in a trademark sense to endorse or promote products or services of Licensee, or any third party.
8. By clicking on the "ACCEPT" button where indicated, or by copying, installing or otherwise using Python 1.6.1, Licensee agrees to be bound by the terms and conditions of this License Agreement.

ACCEPT

CWI LICENSE AGREEMENT FOR PYTHON 0.9.0 THROUGH 1.2

ACTION OF CONTRACT, NEGLIGENCE OR OTHER TORTIOUS ACTION, ARISING
OF OR IN CONNECTION WITH THE USE OR PERFORMANCE OF THIS SOFTWARE
```

Modified by Jack Jansen, CWI, July 1995:

- Use `binascii` module to do the actual line-by-line conversion between `ascii` and `binary`. This results in a 1000-fold speedup version is still 5 times faster, though.
- Arguments more compliant with Python standard

XML Remote Procedure Calls

The `xmlrpc.client` module contains the following notice:

```
The XML-RPC client interface is
```

```

The Python Tutorial

Release: 3.2

Date: February 20, 2011

Python is an easy to learn, powerful programming language. It has efficient high-level data structures and a simple but effective approach to object-oriented programming. Python's elegant syntax and dynamic typing, together with its interpreted nature, make it an ideal language for scripting and rapid application development in many areas on most platforms.

The Python interpreter and the extensive standard library are freely available in source or binary form for all major platforms from the Python Web site, <http://www.python.org/>, and may be freely distributed. The same site also contains distributions of and pointers to many free third party Python modules, programs and tools, and additional documentation.

The Python interpreter is easily extended with new functions and data types implemented in C or C++ (or other languages callable from C). Python is also suitable as an extension language for customizable applications.

This tutorial introduces the reader informally to the basic concepts and features of the Python language and system. It helps to have a Python interpreter handy for hands-on experience, but all examples are self-contained, so the tutorial can be read off-line as well.

For a description of standard objects and modules, see *The Python Standard Library*. *The Python Language Reference* gives a more formal definition of the language. To write extensions in C or C++, read *Extending and Embedding the Python Interpreter* and *Python/C API Reference Manual*. There are also several books covering Python in depth.

This tutorial does not attempt to be comprehensive and cover every single feature, or even every commonly used feature. Instead, it introduces many of Python's most noteworthy features, and will give you a good idea of the language's flavor and style. After reading it, you will be able to read and write Python modules and programs, and you will be ready to learn more about the various Python library modules described in *The Python Standard Library*.

The *Glossary* is also worth going through.

- 1. Whetting Your Appetite
- 2. Using the Python Interpreter
 - 2.1. Invoking the Interpreter
 - 2.1.1. Argument Passing
 - 2.1.2. Interactive Mode
 - 2.2. The Interpreter and Its Environment
 - 2.2.1. Error Handling
 - 2.2.2. Executable Python Scripts
 - 2.2.3. Source Code Encoding
 - 2.2.4. The Interactive Startup File
- 3. An Informal Introduction to Python

The Python Standard Library

Release: 3.2

Date: February 20, 2011

While *The Python Language Reference* describes the exact syntax and semantics of the Python language, this library reference manual describes the standard library that is distributed with Python. It also describes some of the optional components that are commonly included in Python distributions.

Python's standard library is very extensive, offering a wide range of facilities as indicated by the long table of contents listed below. The library contains built-in modules (written in C) that provide access to system functionality such as file I/O that would otherwise be inaccessible to Python programmers, as well as modules written in Python that provide standardized solutions for many problems that occur in everyday programming. Some of these modules are explicitly designed to encourage and enhance the portability of Python programs by abstracting away platform-specifics into platform-neutral APIs.

The Python installers for the Windows platform usually includes the entire standard library and often also include many additional components. For Unix-like operating systems Python is normally provided as a collection of packages, so it may be necessary to use the packaging tools provided with the operating system to obtain some or all of the optional components.

In addition to the standard library, there is a growing collection of several thousand components (from individual programs and modules to packages and entire application development frameworks), available from the [Python Package Index](#).

- [1. Introduction](#)

- 2. Built-in Functions
- 3. Built-in Constants
 - 3.1. Constants added by the `site` module
- 4. Built-in Types
 - 4.1. Truth Value Testing
 - 4.2. Boolean Operations — `and`, `or`, `not`
 - 4.3. Comparisons
 - 4.4. Numeric Types — `int`, `float`, `complex`
 - 4.5. Iterator Types
 - 4.6. Sequence Types — `str`, `bytes`, `bytearray`, `list`, `tuple`, `range`
 - 4.7. Set Types — `set`, `frozenset`
 - 4.8. Mapping Types — `dict`
 - 4.9. `memoryview` type
 - 4.10. Context Manager Types
 - 4.11. Other Built-in Types
 - 4.12. Special Attributes
- 5. Built-in Exceptions
 - 5.1. Exception hierarchy
- 6. String Services
 - 6.1. `string` — Common string operations
 - 6.2. `re` — Regular expression operations
 - 6.3. `struct` — Interpret bytes as packed binary data
 - 6.4. `difflib` — Helpers for computing deltas
 - 6.5. `textwrap` — Text wrapping and filling
 - 6.6. `codecs` — Codec registry and base classes
 - 6.7. `unicodedata` — Unicode Database
 - 6.8. `stringprep` — Internet String Preparation
- 7. Data Types
 - 7.1. `datetime` — Basic date and time types
 - 7.2. `calendar` — General calendar-related functions
 - 7.3. `collections` — Container datatypes

- 7.4. `heapq` — Heap queue algorithm
- 7.5. `bisect` — Array bisection algorithm
- 7.6. `array` — Efficient arrays of numeric values
- 7.7. `sched` — Event scheduler
- 7.8. `queue` — A synchronized queue class
- 7.9. `weakref` — Weak references
- 7.10. `types` — Names for built-in types
- 7.11. `copy` — Shallow and deep copy operations
- 7.12. `pprint` — Data pretty printer
- 7.13. `reprlib` — Alternate `repr()` implementation
- 8. Numeric and Mathematical Modules
 - 8.1. `numbers` — Numeric abstract base classes
 - 8.2. `math` — Mathematical functions
 - 8.3. `cmath` — Mathematical functions for complex numbers
 - 8.4. `decimal` — Decimal fixed point and floating point arithmetic
 - 8.5. `fractions` — Rational numbers
 - 8.6. `random` — Generate pseudo-random numbers
- 9. Functional Programming Modules
 - 9.1. `itertools` — Functions creating iterators for efficient looping
 - 9.2. `functools` — Higher order functions and operations on callable objects
 - 9.3. `operator` — Standard operators as functions
 - 9.4. Inplace Operators
- 10. File and Directory Access
 - 10.1. `os.path` — Common pathname manipulations
 - 10.2. `fileinput` — Iterate over lines from multiple input streams
 - 10.3. `stat` — Interpreting `stat()` results
 - 10.4. `filecmp` — File and Directory Comparisons

- 10.5. `tempfile` — Generate temporary files and directories
- 10.6. `glob` — Unix style pathname pattern expansion
- 10.7. `fnmatch` — Unix filename pattern matching
- 10.8. `linecache` — Random access to text lines
- 10.9. `shutil` — High-level file operations
- 10.10. `macpath` — Mac OS 9 path manipulation functions
- 11. Data Persistence
 - 11.1. `pickle` — Python object serialization
 - 11.2. `copyreg` — Register `pickle` support functions
 - 11.3. `shelve` — Python object persistence
 - 11.4. `marshal` — Internal Python object serialization
 - 11.5. `dbm` — Interfaces to Unix “databases”
 - 11.6. `sqlite3` — DB-API 2.0 interface for SQLite databases
- 12. Data Compression and Archiving
 - 12.1. `zlib` — Compression compatible with `gzip`
 - 12.2. `gzip` — Support for `gzip` files
 - 12.3. `bz2` — Compression compatible with `bzip2`
 - 12.4. `zipfile` — Work with ZIP archives
 - 12.5. `tarfile` — Read and write tar archive files
- 13. File Formats
 - 13.1. `csv` — CSV File Reading and Writing
 - 13.2. `configparser` — Configuration file parser
 - 13.3. `netrc` — netrc file processing
 - 13.4. `xdrlib` — Encode and decode XDR data
 - 13.5. `plistlib` — Generate and parse Mac OS X `.plist` files
- 14. Cryptographic Services
 - 14.1. `hashlib` — Secure hashes and message digests
 - 14.2. `hmac` — Keyed-Hashing for Message Authentication
- 15. Generic Operating System Services
 - 15.1. `os` — Miscellaneous operating system interfaces

- 15.2. `io` — Core tools for working with streams
- 15.3. `time` — Time access and conversions
- 15.4. `argparse` — Parser for command line options, arguments and sub-commands
- 15.5. `optparse` — Parser for command line options
- 15.6. `getopt` — C-style parser for command line options
- 15.7. `logging` — Logging facility for Python
- 15.8. `logging.config` — Logging configuration
- 15.9. `logging.handlers` — Logging handlers
- 15.10. `getpass` — Portable password input
- 15.11. `curses` — Terminal handling for character-cell displays
- 15.12. `curses.textpad` — Text input widget for curses programs
- 15.13. `curses.wrapper` — Terminal handler for curses programs
- 15.14. `curses.ascii` — Utilities for ASCII characters
- 15.15. `curses.panel` — A panel stack extension for curses
- 15.16. `platform` — Access to underlying platform's identifying data
- 15.17. `errno` — Standard errno system symbols
- 15.18. `ctypes` — A foreign function library for Python
- 16. Optional Operating System Services
 - 16.1. `select` — Waiting for I/O completion
 - 16.2. `threading` — Thread-based parallelism
 - 16.3. `multiprocessing` — Process-based parallelism
 - 16.4. `concurrent.futures` — Launching parallel tasks
 - 16.5. `mmap` — Memory-mapped file support
 - 16.6. `readline` — GNU readline interface
 - 16.7. `rlcompleter` — Completion function for GNU readline
 - 16.8. `dummy_threading` — Drop-in replacement for the

`threading` module

- 16.9. `_thread` — Low-level threading API
- 16.10. `_dummy_thread` — Drop-in replacement for the `_thread` module
- 17. Interprocess Communication and Networking
 - 17.1. `subprocess` — Subprocess management
 - 17.2. `socket` — Low-level networking interface
 - 17.3. `ssl` — TLS/SSL wrapper for socket objects
 - 17.4. `signal` — Set handlers for asynchronous events
 - 17.5. `asyncore` — Asynchronous socket handler
 - 17.6. `asynchat` — Asynchronous socket command/response handler
- 18. Internet Data Handling
 - 18.1. `email` — An email and MIME handling package
 - 18.2. `json` — JSON encoder and decoder
 - 18.3. `mailcap` — Mailcap file handling
 - 18.4. `mailbox` — Manipulate mailboxes in various formats
 - 18.5. `mimetypes` — Map filenames to MIME types
 - 18.6. `base64` — RFC 3548: Base16, Base32, Base64 Data Encodings
 - 18.7. `binhex` — Encode and decode binhex4 files
 - 18.8. `binascii` — Convert between binary and ASCII
 - 18.9. `quopri` — Encode and decode MIME quoted-printable data
 - 18.10. `uu` — Encode and decode uuencode files
- 19. Structured Markup Processing Tools
 - 19.1. `html` — HyperText Markup Language support
 - 19.2. `html.parser` — Simple HTML and XHTML parser
 - 19.3. `html.entities` — Definitions of HTML general entities
 - 19.4. `xml.parsers.expat` — Fast XML parsing using Expat
 - 19.5. `xml.dom` — The Document Object Model API

- 19.6. `xml.dom.minidom` — Lightweight DOM implementation
- 19.7. `xml.dom.pulldom` — Support for building partial DOM trees
- 19.8. `xml.sax` — Support for SAX2 parsers
- 19.9. `xml.sax.handler` — Base classes for SAX handlers
- 19.10. `xml.sax.saxutils` — SAX Utilities
- 19.11. `xml.sax.xmlreader` — Interface for XML parsers
- 19.12. `xml.etree.ElementTree` — The ElementTree XML API
- 20. Internet Protocols and Support
 - 20.1. `webbrowser` — Convenient Web-browser controller
 - 20.2. `cgi` — Common Gateway Interface support
 - 20.3. `cgitb` — Traceback manager for CGI scripts
 - 20.4. `wsgiref` — WSGI Utilities and Reference Implementation
 - 20.5. `urllib.request` — Extensible library for opening URLs
 - 20.6. `urllib.response` — Response classes used by urllib
 - 20.7. `urllib.parse` — Parse URLs into components
 - 20.8. `urllib.error` — Exception classes raised by `urllib.request`
 - 20.9. `urllib.robotparser` — Parser for robots.txt
 - 20.10. `http.client` — HTTP protocol client
 - 20.11. `ftplib` — FTP protocol client
 - 20.12. `poplib` — POP3 protocol client
 - 20.13. `imaplib` — IMAP4 protocol client
 - 20.14. `nntplib` — NNTP protocol client
 - 20.15. `smtplib` — SMTP protocol client
 - 20.16. `smtpd` — SMTP Server
 - 20.17. `telnetlib` — Telnet client
 - 20.18. `uuid` — UUID objects according to RFC 4122

- 20.19. `socketserver` — A framework for network servers
- 20.20. `http.server` — HTTP servers
- 20.21. `http.cookies` — HTTP state management
- 20.22. `http.cookiejar` — Cookie handling for HTTP clients
- 20.23. `xmlrpc.client` — XML-RPC client access
- 20.24. `xmlrpc.server` — Basic XML-RPC servers
- 21. Multimedia Services
 - 21.1. `audioop` — Manipulate raw audio data
 - 21.2. `aifc` — Read and write AIFF and AIFC files
 - 21.3. `sunau` — Read and write Sun AU files
 - 21.4. `wave` — Read and write WAV files
 - 21.5. `chunk` — Read IFF chunked data
 - 21.6. `colorsys` — Conversions between color systems
 - 21.7. `imghdr` — Determine the type of an image
 - 21.8. `sndhdr` — Determine type of sound file
 - 21.9. `ossaudiodev` — Access to OSS-compatible audio devices
- 22. Internationalization
 - 22.1. `gettext` — Multilingual internationalization services
 - 22.2. `locale` — Internationalization services
- 23. Program Frameworks
 - 23.1. `turtle` — Turtle graphics
 - 23.2. `cmd` — Support for line-oriented command interpreters
 - 23.3. `shlex` — Simple lexical analysis
- 24. Graphical User Interfaces with Tk
 - 24.1. `tkinter` — Python interface to Tcl/Tk
 - 24.2. `tkinter.ttk` — Tk themed widgets
 - 24.3. `tkinter.tix` — Extension widgets for Tk
 - 24.4. `tkinter.scrolledtext` — Scrolled Text Widget
 - 24.5. IDLE
 - 24.6. Other Graphical User Interface Packages

- 25. Development Tools
 - 25.1. `pydoc` — Documentation generator and online help system
 - 25.2. `doctest` — Test interactive Python examples
 - 25.3. `unittest` — Unit testing framework
 - 25.4. `2to3` - Automated Python 2 to 3 code translation
 - 25.5. `test` — Regression tests package for Python
 - 25.6. `test.support` — Utility functions for tests
- 26. Debugging and Profiling
 - 26.1. `bdb` — Debugger framework
 - 26.2. `pdb` — The Python Debugger
 - 26.3. The Python Profilers
 - 26.4. `timeit` — Measure execution time of small code snippets
 - 26.5. `trace` — Trace or track Python statement execution
- 27. Python Runtime Services
 - 27.1. `sys` — System-specific parameters and functions
 - 27.2. `sysconfig` — Provide access to Python's configuration information
 - 27.3. `builtins` — Built-in objects
 - 27.4. `__main__` — Top-level script environment
 - 27.5. `warnings` — Warning control
 - 27.6. `contextlib` — Utilities for `with`-statement contexts
 - 27.7. `abc` — Abstract Base Classes
 - 27.8. `atexit` — Exit handlers
 - 27.9. `traceback` — Print or retrieve a stack traceback
 - 27.10. `__future__` — Future statement definitions
 - 27.11. `gc` — Garbage Collector interface
 - 27.12. `inspect` — Inspect live objects
 - 27.13. `site` — Site-specific configuration hook
 - 27.14. `fpect1` — Floating point exception control

- 27.15. `distutils` — Building and installing Python modules
- 28. Custom Python Interpreters
 - 28.1. `code` — Interpreter base classes
 - 28.2. `codeop` — Compile Python code
- 29. Importing Modules
 - 29.1. `imp` — Access the `import` internals
 - 29.2. `zipimport` — Import modules from Zip archives
 - 29.3. `pkgutil` — Package extension utility
 - 29.4. `modulefinder` — Find modules used by a script
 - 29.5. `runpy` — Locating and executing Python modules
 - 29.6. `importlib` — An implementation of `import`
- 30. Python Language Services
 - 30.1. `parser` — Access Python parse trees
 - 30.2. `ast` — Abstract Syntax Trees
 - 30.3. `symtable` — Access to the compiler's symbol tables
 - 30.4. `symbol` — Constants used with Python parse trees
 - 30.5. `token` — Constants used with Python parse trees
 - 30.6. `keyword` — Testing for Python keywords
 - 30.7. `tokenize` — Tokenizer for Python source
 - 30.8. `tabnanny` — Detection of ambiguous indentation
 - 30.9. `pyclbr` — Python class browser support
 - 30.10. `py_compile` — Compile Python source files
 - 30.11. `compileall` — Byte-compile Python libraries
 - 30.12. `dis` — Disassembler for Python bytecode
 - 30.13. `pickletools` — Tools for pickle developers
- 31. Miscellaneous Services
 - 31.1. `formatter` — Generic output formatting
- 32. MS Windows Specific Services
 - 32.1. `msilib` — Read and write Microsoft Installer files
 - 32.2. `msvcrt` — Useful routines from the MS VC++ runtime
 - 32.3. `winreg` — Windows registry access

- 32.4. `winsound` — Sound-playing interface for Windows
- 33. Unix Specific Services
 - 33.1. `posix` — The most common POSIX system calls
 - 33.2. `pwd` — The password database
 - 33.3. `spwd` — The shadow password database
 - 33.4. `grp` — The group database
 - 33.5. `crypt` — Function to check Unix passwords
 - 33.6. `termios` — POSIX style tty control
 - 33.7. `tty` — Terminal control functions
 - 33.8. `pty` — Pseudo-terminal utilities
 - 33.9. `fcntl` — The `fcntl()` and `ioctl()` system calls
 - 33.10. `pipes` — Interface to shell pipelines
 - 33.11. `resource` — Resource usage information
 - 33.12. `nis` — Interface to Sun's NIS (Yellow Pages)
 - 33.13. `syslog` — Unix syslog library routines
- 34. Undocumented Modules
 - 34.1. Platform specific modules

The Python Language Reference

Release: 3.2

Date: February 20, 2011

This reference manual describes the syntax and “core semantics” of the language. It is terse, but attempts to be exact and complete. The semantics of non-essential built-in object types and of the built-in functions and modules are described in *The Python Standard Library*. For an informal introduction to the language, see *The Python Tutorial*. For C or C++ programmers, two additional manuals exist: *Extending and Embedding the Python Interpreter* describes the high-level picture of how to write a Python extension module, and the *Python/C API Reference Manual* describes the interfaces available to C/C++ programmers in detail.

- 1. Introduction
 - 1.1. Alternate Implementations
 - 1.2. Notation
- 2. Lexical analysis
 - 2.1. Line structure
 - 2.2. Other tokens
 - 2.3. Identifiers and keywords
 - 2.4. Literals
 - 2.5. Operators
 - 2.6. Delimiters
- 3. Data model
 - 3.1. Objects, values and types
 - 3.2. The standard type hierarchy
 - 3.3. Special method names
- 4. Execution model
 - 4.1. Naming and binding
 - 4.2. Exceptions
- 5. Expressions

- 5.1. Arithmetic conversions
- 5.2. Atoms
- 5.3. Primaries
- 5.4. The power operator
- 5.5. Unary arithmetic and bitwise operations
- 5.6. Binary arithmetic operations
- 5.7. Shifting operations
- 5.8. Binary bitwise operations
- 5.9. Comparisons
- 5.10. Boolean operations
- 5.11. Conditional expressions
- 5.12. Lambdas
- 5.13. Expression lists
- 5.14. Evaluation order
- 5.15. Summary
- 6. Simple statements
 - 6.1. Expression statements
 - 6.2. Assignment statements
 - 6.3. The `assert` statement
 - 6.4. The `pass` statement
 - 6.5. The `del` statement
 - 6.6. The `return` statement
 - 6.7. The `yield` statement
 - 6.8. The `raise` statement
 - 6.9. The `break` statement
 - 6.10. The `continue` statement
 - 6.11. The `import` statement
 - 6.12. The `global` statement
 - 6.13. The `nonlocal` statement
- 7. Compound statements
 - 7.1. The `if` statement
 - 7.2. The `while` statement
 - 7.3. The `for` statement

- 7.4. The `try` statement
- 7.5. The `with` statement
- 7.6. Function definitions
- 7.7. Class definitions
- 8. Top-level components
 - 8.1. Complete Python programs
 - 8.2. File input
 - 8.3. Interactive input
 - 8.4. Expression input
- 9. Full Grammar specification

Python Setup and Usage

This part of the documentation is devoted to general information on the setup of the Python environment on different platform, the invocation of the interpreter and things that make working with Python easier.

- 1. Command line and environment
 - 1.1. Command line
 - 1.1.1. Interface options
 - 1.1.2. Generic options
 - 1.1.3. Miscellaneous options
 - 1.1.4. Options you shouldn't use
 - 1.2. Environment variables
 - 1.2.1. Debug-mode variables
- 2. Using Python on Unix platforms
 - 2.1. Getting and installing the latest version of Python
 - 2.1.1. On Linux
 - 2.1.2. On FreeBSD and OpenBSD
 - 2.1.3. On OpenSolaris
 - 2.2. Building Python
 - 2.3. Python-related paths and files
 - 2.4. Miscellaneous
 - 2.5. Editors
- 3. Using Python on Windows
 - 3.1. Installing Python
 - 3.2. Alternative bundles
 - 3.3. Configuring Python
 - 3.3.1. Excursus: Setting environment variables
 - 3.3.2. Finding the Python executable
 - 3.3.3. Finding modules
 - 3.3.4. Executing scripts
 - 3.4. Additional modules

- 3.4.1. PyWin32
 - 3.4.2. Py2exe
 - 3.4.3. WConio
 - 3.5. Compiling Python on Windows
 - 3.6. Other resources
- 4. Using Python on a Macintosh
 - 4.1. Getting and Installing MacPython
 - 4.1.1. How to run a Python script
 - 4.1.2. Running scripts with a GUI
 - 4.1.3. Configuration
 - 4.2. The IDE
 - 4.3. Installing Additional Python Packages
 - 4.4. GUI Programming on the Mac
 - 4.5. Distributing Python Applications on the Mac
 - 4.6. Application Scripting
 - 4.7. Other Resources

Python HOWTOs

Python HOWTOs are documents that cover a single, specific topic, and attempt to cover it fairly completely. Modelled on the Linux Documentation Project's HOWTO collection, this collection is an effort to foster documentation that's more detailed than the Python Library Reference.

Currently, the HOWTOs are:

- [Python Advocacy HOWTO](#)
- [Porting Python 2 Code to Python 3](#)
- [Porting Extension Modules to 3.0](#)
- [Curses Programming with Python](#)
- [Descriptor HowTo Guide](#)

Extending and Embedding the Python Interpreter

Release: 3.2

Date: February 20, 2011

This document describes how to write modules in C or C++ to extend the Python interpreter with new modules. Those modules can define new functions but also new object types and their methods. The document also describes how to embed the Python interpreter in another application, for use as an extension language. Finally, it shows how to compile and link extension modules so that they can be loaded dynamically (at run time) into the interpreter, if the underlying operating system supports this feature.

This document assumes basic knowledge about Python. For an informal introduction to the language, see *The Python Tutorial*. *The Python Language Reference* gives a more formal definition of the language. *The Python Standard Library* documents the existing object types, functions and modules (both built-in and written in Python) that give the language its wide application range.

For a detailed description of the whole Python/C API, see the separate *Python/C API Reference Manual*.

Installing Python Modules

Author:	Greg Ward
Release:	3.2
Date:	February 20, 2011

Abstract

This document describes the Python Distribution Utilities (“Distutils”) from the end-user’s point-of-view, describing how to extend the capabilities of a standard Python installation by building and installing third-party Python modules and extensions.

Introduction

Although Python's extensive standard library covers many programming needs, there often comes a time when you need to add some new functionality to your Python installation in the form of third-party modules. This might be necessary to support your own programming, or to support an application that you want to use and that happens to be written in Python.

In the past, there has been little support for adding third-party modules to an existing Python installation. With the introduction of the Python Distribution Utilities (Distutils for short) in Python 2.0, this changed.

This document is aimed primarily at the people who need to install third-party Python modules: end-users and system administrators who just need to get some Python application running, and existing Python programmers who want to add some new goodies to their toolbox. You don't need to know Python to read this document; there will be some brief forays into using Python's interactive mode to explore your installation, but that's it. If you're looking for information on how to distribute your own Python modules so that others may use them, see the [Distributing Python Modules](#) manual.

Best case: trivial installation

In the best case, someone will have prepared a special version of the module distribution you want to install that is targeted specifically at your platform and is installed just like any other software on your platform. For example, the module developer might make an executable installer available for Windows users, an RPM package for users of RPM-based Linux systems (Red Hat, SuSE, Mandrake, and many others), a Debian package for users of Debian-based

Linux systems, and so forth.

In that case, you would download the installer appropriate to your platform and do the obvious thing with it: run it if it's an executable installer, `rpm --install` it if it's an RPM, etc. You don't need to run Python or a setup script, you don't need to compile anything—you might not even need to read any instructions (although it's always a good idea to do so anyways).

Of course, things will not always be that easy. You might be interested in a module distribution that doesn't have an easy-to-use installer for your platform. In that case, you'll have to start with the source distribution released by the module's author/maintainer. Installing from a source distribution is not too hard, as long as the modules are packaged in the standard way. The bulk of this document is about building and installing modules from standard source distributions.

The new standard: Distutils

If you download a module source distribution, you can tell pretty quickly if it was packaged and distributed in the standard way, i.e. using the Distutils. First, the distribution's name and version number will be featured prominently in the name of the downloaded archive, e.g. `foo-1.0.tar.gz` or `widget-0.9.7.zip`. Next, the archive will unpack into a similarly-named directory: `foo-1.0` or `widget-0.9.7`. Additionally, the distribution will contain a setup script `setup.py`, and a file named `README.txt` or possibly just `README`, which should explain that building and installing the module distribution is a simple matter of running

```
python setup.py install
```

If all these things are true, then you already know how to build and

install the modules you've just downloaded: Run the command above. Unless you need to install things in a non-standard way or customize the build process, you don't really need this manual. Or rather, the above command is everything you need to get out of this manual.

Standard Build and Install

As described in section *The new standard: Distutils*, building and installing a module distribution using the Distutils is usually one simple command:

```
python setup.py install
```

On Unix, you'd run this command from a shell prompt; on Windows, you have to open a command prompt window ("DOS box") and do it there; on Mac OS X, you open a **Terminal** window to get a shell prompt.

Platform variations

You should always run the setup command from the distribution root directory, i.e. the top-level subdirectory that the module source distribution unpacks into. For example, if you've just downloaded a module source distribution `foo-1.0.tar.gz` onto a Unix system, the normal thing to do is:

```
gunzip -c foo-1.0.tar.gz | tar xf -      # unpacks into directory
cd foo-1.0
python setup.py install
```

On Windows, you'd probably download `foo-1.0.zip`. If you downloaded the archive file to `c:\Temp`, then it would unpack into `c:\Temp\foo-1.0`; you can use either a archive manipulator with a graphical user interface (such as WinZip) or a command-line tool (such as **unzip** or **pkunzip**) to unpack the archive. Then, open a command prompt window ("DOS box"), and run:

```
cd c:\Temp\foo-1.0
```

```
python setup.py install
```

Splitting the job up

Running `setup.py install` builds and installs all modules in one run. If you prefer to work incrementally—especially useful if you want to customize the build process, or if things are going wrong—you can use the setup script to do one thing at a time. This is particularly helpful when the build and install will be done by different users—for example, you might want to build a module distribution and hand it off to a system administrator for installation (or do it yourself, with super-user privileges).

For example, you can build everything in one step, and then install everything in a second step, by invoking the setup script twice:

```
python setup.py build  
python setup.py install
```

If you do this, you will notice that running the **install** command first runs the **build** command, which—in this case—quickly notices that it has nothing to do, since everything in the `build` directory is up-to-date.

You may not need this ability to break things down often if all you do is install modules downloaded off the ‘net, but it’s very handy for more advanced tasks. If you get into distributing your own Python modules and extensions, you’ll run lots of individual Distutils commands on their own.

How building works

As implied above, the **build** command is responsible for putting the files to install into a *build directory*. By default, this is `build` under the distribution root; if you’re excessively concerned with speed, or want

to keep the source tree pristine, you can change the build directory with the `--build-base` option. For example:

```
python setup.py build --build-base=/tmp/pybuild/foo-1.0
```

(Or you could do this permanently with a directive in your system or personal `Distutils` configuration file; see section [Distutils Configuration Files](#).) Normally, this isn't necessary.

The default layout for the build tree is as follows:

```
--- build/ --- lib/
or
--- build/ --- lib.<plat>/
                temp.<plat>/
```

where `<plat>` expands to a brief description of the current OS/hardware platform and Python version. The first form, with just a `lib` directory, is used for “pure module distributions”—that is, module distributions that include only pure Python modules. If a module distribution contains any extensions (modules written in C/C++), then the second form, with two `<plat>` directories, is used. In that case, the `temp.<plat>` directory holds temporary files generated by the compile/link process that don't actually get installed. In either case, the `lib` (or `lib.<plat>`) directory contains all Python modules (pure Python and extensions) that will be installed.

In the future, more directories will be added to handle Python scripts, documentation, binary executables, and whatever else is needed to handle the job of installing Python modules and applications.

How installation works

After the **build** command runs (whether you run it explicitly, or the **install** command does it for you), the work of the **install** command is

relatively simple: all it has to do is copy everything under `build/lib` (or `build/lib.plat`) to your chosen installation directory.

If you don't choose an installation directory—i.e., if you just run `setup.py install`—then the **install** command installs to the standard location for third-party Python modules. This location varies by platform and by how you built/installed Python itself. On Unix (and Mac OS X, which is also Unix-based), it also depends on whether the module distribution being installed is pure Python or contains extensions (“non-pure”):

Platform	Standard installation location	Default value
Unix (pure)	<code>prefix/lib/pythonX.Y/site-packages</code>	<code>/usr/local/lib/pythonX.Y/site-packages</code>
Unix (non-pure)	<code>exec-prefix/lib/pythonX.Y/site-packages</code>	<code>/usr/local/lib/pythonX.Y/site-packages</code>
Windows	<code>prefix</code>	<code>C:\Python</code>

Notes:

1. Most Linux distributions include Python as a standard part of the system, so `prefix` and `exec-prefix` are usually both `/usr` on Linux. If you build Python yourself on Linux (or any Unix-like system), the default `prefix` and `exec-prefix` are `/usr/local`.
2. The default installation directory on Windows was `C:\Program Files\Python` under Python 1.6a1, 1.5.2, and earlier.

`prefix` and `exec-prefix` stand for the directories that Python is installed to, and where it finds its libraries at run-time. They are always the same under Windows, and very often the same under Unix and Mac OS X. You can find out what your Python installation uses for `prefix` and `exec-prefix` by running Python in interactive

mode and typing a few simple commands. Under Unix, just type `python` at the shell prompt. Under Windows, choose *Start ▶ Programs ▶ Python X.Y ▶ Python (command line)*. Once the interpreter is started, you type Python code at the prompt. For example, on my Linux system, I type the three Python statements shown below, and get the output as shown, to find out my `prefix` and `exec-prefix`:

```
Python 2.4 (#26, Aug 7 2004, 17:19:02)
Type "help", "copyright", "credits" or "license" for more infor
>>> import sys
>>> sys.prefix
'/usr'
>>> sys.exec_prefix
'/usr'
```

If you don't want to install modules to the standard location, or if you don't have permission to write there, then you need to read about alternate installations in section [Alternate Installation](#). If you want to customize your installation directories more heavily, see section [Custom Installation](#) on custom installations.

Alternate Installation

Often, it is necessary or desirable to install modules to a location other than the standard location for third-party Python modules. For example, on a Unix system you might not have permission to write to the standard third-party module directory. Or you might wish to try out a module before making it a standard part of your local Python installation. This is especially true when upgrading a distribution already present: you want to make sure your existing base of scripts still works with the new version before actually upgrading.

The Distutils **install** command is designed to make installing module distributions to an alternate location simple and painless. The basic idea is that you supply a base directory for the installation, and the **install** command picks a set of directories (called an *installation scheme*) under this base directory in which to install files. The details differ across platforms, so read whichever of the following sections applies to you.

Alternate installation: the home scheme

The idea behind the “home scheme” is that you build and maintain a personal stash of Python modules. This scheme’s name is derived from the idea of a “home” directory on Unix, since it’s not unusual for a Unix user to make their home directory have a layout similar to `/usr/` or `/usr/local/`. This scheme can be used by anyone, regardless of the operating system they are installing for.

Installing a new module distribution is as simple as

```
python setup.py install --home=<dir>
```

where you can supply any directory you like for the `--home` option.

On Unix, lazy typists can just type a tilde (~); the **install** command will expand this to your home directory:

```
python setup.py install --home=~
```

The `--home` option defines the installation base directory. Files are installed to the following directories under the installation base as follows:

Type of file	Installation Directory	Override option
pure module distribution	<i>home/lib/python</i>	<i>--install-purelib</i>
non-pure module distribution	<i>home/lib/python</i>	<i>--install-platlib</i>
scripts	<i>home/bin</i>	<i>--install-scripts</i>
data	<i>home/share</i>	<i>--install-data</i>

Alternate installation: Unix (the prefix scheme)

The “prefix scheme” is useful when you wish to use one Python installation to perform the build/install (i.e., to run the setup script), but install modules into the third-party module directory of a different Python installation (or something that looks like a different Python installation). If this sounds a trifle unusual, it is—that’s why the “home scheme” comes first. However, there are at least two known cases where the prefix scheme will be useful.

First, consider that many Linux distributions put Python in `/usr`, rather than the more traditional `/usr/local`. This is entirely appropriate, since in those cases Python is part of “the system” rather than a local add-on. However, if you are installing Python modules from source, you probably want them to go in `/usr/local/lib/python2.X` rather than `/usr/lib/python2.X`. This can

be done with

```
/usr/bin/python setup.py install --prefix=/usr/local
```

Another possibility is a network filesystem where the name used to write to a remote directory is different from the name used to read it: for example, the Python interpreter accessed as `/usr/local/bin/python` might search for modules in `/usr/local/lib/python2.X`, but those modules would have to be installed to, say, `/mnt/@server/export/lib/python2.X`. This could be done with

```
/usr/local/bin/python setup.py install --prefix=/mnt/@server/ex
```

In either case, the `--prefix` option defines the installation base, and the `--exec-prefix` option defines the platform-specific installation base, which is used for platform-specific files. (Currently, this just means non-pure module distributions, but could be expanded to C libraries, binary executables, etc.) If `--exec-prefix` is not supplied, it defaults to `--prefix`. Files are installed as follows:

Type of file	Installation Directory	Override option
pure module distribution	<code>prefix/lib/pythonX.Y/site-packages</code>	<code>--install-purelib</code>
non-pure module distribution	<code>exec-prefix/lib/pythonX.Y/site-packages</code>	<code>--install-platlib</code>
scripts	<code>prefix/bin</code>	<code>--install-scripts</code>
data	<code>prefix/share</code>	<code>--install-data</code>

There is no requirement that `--prefix` or `--exec-prefix` actually point to an alternate Python installation; if the directories listed above do not already exist, they are created at installation time.

Incidentally, the real reason the prefix scheme is important is simply that a standard Unix installation uses the prefix scheme, but with `--prefix` and `--exec-prefix` supplied by Python itself as `sys.prefix` and `sys.exec_prefix`. Thus, you might think you'll never use the prefix scheme, but every time you run `python setup.py install` without any other options, you're using it.

Note that installing extensions to an alternate Python installation has no effect on how those extensions are built: in particular, the Python header files (`Python.h` and friends) installed with the Python interpreter used to run the setup script will be used in compiling extensions. It is your responsibility to ensure that the interpreter used to run extensions installed in this way is compatible with the interpreter used to build them. The best way to do this is to ensure that the two interpreters are the same version of Python (possibly different builds, or possibly copies of the same build). (Of course, if your `--prefix` and `--exec-prefix` don't even point to an alternate Python installation, this is immaterial.)

Alternate installation: Windows (the prefix scheme)

Windows has no concept of a user's home directory, and since the standard Python installation under Windows is simpler than under Unix, the `--prefix` option has traditionally been used to install additional packages in separate locations on Windows.

```
python setup.py install --prefix="\Temp\Python"
```

to install modules to the `\Temp\Python` directory on the current drive.

The installation base is defined by the `--prefix` option; the `--exec-prefix` option is not supported under Windows. Files are installed as follows:

Type of file	Installation Directory	Override option
pure module distribution	<i>prefix</i>	<i>--install-purelib</i>
non-pure module distribution	<i>prefix</i>	<i>--install-platlib</i>
scripts	<i>prefix\Scripts</i>	<i>--install-scripts</i>
data	<i>prefix\Data</i>	<i>--install-data</i>

Custom Installation

Sometimes, the alternate installation schemes described in section *Alternate Installation* just don't do what you want. You might want to tweak just one or two directories while keeping everything under the same base directory, or you might want to completely redefine the installation scheme. In either case, you're creating a *custom installation scheme*.

You probably noticed the column of “override options” in the tables describing the alternate installation schemes above. Those options are how you define a custom installation scheme. These override options can be relative, absolute, or explicitly defined in terms of one of the installation base directories. (There are two installation base directories, and they are normally the same— they only differ when you use the Unix “prefix scheme” and supply different `--prefix` and `--exec-prefix` options.)

For example, say you're installing a module distribution to your home directory under Unix—but you want scripts to go in `~/scripts` rather than `~/bin`. As you might expect, you can override this directory with the `--install-scripts` option; in this case, it makes most sense to supply a relative path, which will be interpreted relative to the installation base directory (your home directory, in this case):

```
python setup.py install --home=~ --install-scripts=scripts
```

Another Unix example: suppose your Python installation was built and installed with a prefix of `/usr/local/python`, so under a standard installation scripts will wind up in `/usr/local/python/bin`. If you want them in `/usr/local/bin` instead, you would supply this absolute directory for the `--install-scripts` option:

```
python setup.py install --install-scripts=/usr/local/bin
```

(This performs an installation using the “prefix scheme,” where the prefix is whatever your Python interpreter was installed with—`/usr/local/python` in this case.)

If you maintain Python on Windows, you might want third-party modules to live in a subdirectory of `prefix`, rather than right in `prefix` itself. This is almost as easy as customizing the script installation directory—you just have to remember that there are two types of modules to worry about, pure modules and non-pure modules (i.e., modules from a non-pure distribution). For example:

```
python setup.py install --install-purelib=Site --install-platli
```

The specified installation directories are relative to `prefix`. Of course, you also have to ensure that these directories are in Python’s module search path, such as by putting a `.pth` file in `prefix`. See section [Modifying Python’s Search Path](#) to find out how to modify Python’s search path.

If you want to define an entire installation scheme, you just have to supply all of the installation directory options. The recommended way to do this is to supply relative paths; for example, if you want to maintain all Python module-related files under `python` in your home directory, and you want a separate directory for each platform that you use your home directory from, you might define the following installation scheme:

```
python setup.py install --home=~ \  
    --install-purelib=python/lib \  
    --install-platlib=python/lib.$PLAT \  
    --install-scripts=python/scripts \  
    --install-data=python/data
```

or, equivalently,

```
python setup.py install --home=~/.python \  
                        --install-purelib=lib \  
                        --install-platlib='lib.$PLAT' \  
                        --install-scripts=scripts \  
                        --install-data=data
```

`$PLAT` is not (necessarily) an environment variable—it will be expanded by the Distutils as it parses your command line options, just as it does when parsing your configuration file(s).

Obviously, specifying the entire installation scheme every time you install a new module distribution would be very tedious. Thus, you can put these options into your Distutils config file (see section *Distutils Configuration Files*):

```
[install]  
install-base=$HOME  
install-purelib=python/lib  
install-platlib=python/lib.$PLAT  
install-scripts=python/scripts  
install-data=python/data
```

or, equivalently,

```
[install]  
install-base=$HOME/python  
install-purelib=lib  
install-platlib=lib.$PLAT  
install-scripts=scripts  
install-data=data
```

Note that these two are *not* equivalent if you supply a different installation base directory when you run the setup script. For example,

```
python setup.py install --install-base=/tmp
```

would install pure modules to `/tmp/python/lib` in the first case, and to `/tmp/lib` in the second case. (For the second case, you probably want to supply an installation base of `/tmp/python`.)

You probably noticed the use of `$HOME` and `$PLAT` in the sample configuration file input. These are Distutils configuration variables, which bear a strong resemblance to environment variables. In fact, you can use environment variables in config files on platforms that have such a notion but the Distutils additionally define a few extra variables that may not be in your environment, such as `$PLAT`. (And of course, on systems that don't have environment variables, such as Mac OS 9, the configuration variables supplied by the Distutils are the only ones you can use.) See section [Distutils Configuration Files](#) for details.

Modifying Python's Search Path

When the Python interpreter executes an `import` statement, it searches for both Python code and extension modules along a search path. A default value for the path is configured into the Python binary when the interpreter is built. You can determine the path by importing the `sys` module and printing the value of `sys.path`.

```
$ python
Python 2.2 (#11, Oct  3 2002, 13:31:27)
[GCC 2.96 20000731 (Red Hat Linux 7.3 2.96-112)] on linux2
Type "help", "copyright", "credits" or "license" for more infor
>>> import sys
>>> sys.path
['', '/usr/local/lib/python2.3', '/usr/local/lib/python2.3/plat
'/usr/local/lib/python2.3/lib-tk', '/usr/local/lib/python2.3/l
'/usr/local/lib/python2.3/site-packages']
>>>
```

The null string in `sys.path` represents the current working directory.

The expected convention for locally installed packages is to put them in the `.../site-packages/` directory, but you may want to install Python modules into some arbitrary directory. For example, your site may have a convention of keeping all software related to the web server under `/www`. Add-on Python modules might then belong in `/www/python`, and in order to import them, this directory must be added to `sys.path`. There are several different ways to add the directory.

The most convenient way is to add a path configuration file to a directory that's already on Python's path, usually to the `.../site-packages/` directory. Path configuration files have an extension of `.pth`, and each line must contain a single path that will be appended to `sys.path`. (Because the new paths are appended to `sys.path`, modules in the added directories will not override standard modules. This means you can't use this mechanism for installing fixed versions of standard modules.)

Paths can be absolute or relative, in which case they're relative to the directory containing the `.pth` file. See the documentation of the `site` module for more information.

A slightly less convenient way is to edit the `site.py` file in Python's standard library, and modify `sys.path`. `site.py` is automatically imported when the Python interpreter is executed, unless the `-S` switch is supplied to suppress this behaviour. So you could simply edit `site.py` and add two lines to it:

```
import sys
sys.path.append('/www/python/')
```

However, if you reinstall the same major version of Python (perhaps when upgrading from 2.2 to 2.2.2, for example) `site.py` will be overwritten by the stock version. You'd have to remember that it was

modified and save a copy before doing the installation.

There are two environment variables that can modify `sys.path`. `PYTHONHOME` sets an alternate value for the prefix of the Python installation. For example, if `PYTHONHOME` is set to `/www/python`, the search path will be set to `['', '/www/python/lib/pythonX.Y/', '/www/python/lib/pythonX.Y/plat-linux2', ...]`.

The `PYTHONPATH` variable can be set to a list of paths that will be added to the beginning of `sys.path`. For example, if `PYTHONPATH` is set to `/www/python:/opt/py`, the search path will begin with `['/www/python', '/opt/py']`. (Note that directories must exist in order to be added to `sys.path`; the `site` module removes paths that don't exist.)

Finally, `sys.path` is just a regular Python list, so any Python application can modify it by adding or removing entries.

Distutils Configuration Files

As mentioned above, you can use Distutils configuration files to record personal or site preferences for any Distutils options. That is, any option to any command can be stored in one of two or three (depending on your platform) configuration files, which will be consulted before the command-line is parsed. This means that configuration files will override default values, and the command-line will in turn override configuration files. Furthermore, if multiple configuration files apply, values from “earlier” files are overridden by “later” files.

Location and names of config files

The names and locations of the configuration files vary slightly across platforms. On Unix and Mac OS X, the three configuration files (in the order they are processed) are:

Type of file	Location and filename	Notes
system	<i>prefix</i> /lib/pythonver/distutils/distutils.cfg	(1)
personal	\$HOME/.pydistutils.cfg	(2)
local	setup.cfg	(3)

And on Windows, the configuration files are:

Type of file	Location and filename	Notes
system	<i>prefix</i> \Lib\distutils\distutils.cfg	(4)
personal	%HOME%\pydistutils.cfg	(5)
local	setup.cfg	(3)

On all platforms, the “personal” file can be temporarily disabled by passing the `-no-user-cfg` option.

Notes:

1. Strictly speaking, the system-wide configuration file lives in the directory where the Distutils are installed; under Python 1.6 and later on Unix, this is as shown. For Python 1.5.2, the Distutils will normally be installed to `prefix/lib/python1.5/site-packages/distutils`, so the system configuration file should be put there under Python 1.5.2.
2. On Unix, if the `HOME` environment variable is not defined, the user's home directory will be determined with the `getpwuid()` function from the standard `pwd` module. This is done by the `os.path.expanduser()` function used by Distutils.
3. I.e., in the current directory (usually the location of the setup script).
4. (See also note (1).) Under Python 1.6 and later, Python's default "installation prefix" is `C:\Python`, so the system configuration file is normally `C:\Python\Lib\distutils\distutils.cfg`. Under Python 1.5.2, the default prefix was `C:\Program Files\Python`, and the Distutils were not part of the standard library—so the system configuration file would be `C:\Program Files\Python\distutils\distutils.cfg` in a standard Python 1.5.2 installation under Windows.
5. On Windows, if the `HOME` environment variable is not defined, `USERPROFILE` then `HOMEDRIVE` and `HOMEPATH` will be tried. This is done by the `os.path.expanduser()` function used by Distutils.

Syntax of config files

The Distutils configuration files all have the same syntax. The config files are grouped into sections. There is one section for each Distutils command, plus a `global` section for global options that affect every command. Each section consists of one option per line, specified as

option=value.

For example, the following is a complete config file that just forces all commands to run quietly by default:

```
[global]
verbose=0
```

If this is installed as the system config file, it will affect all processing of any Python module distribution by any user on the current system. If it is installed as your personal config file (on systems that support them), it will affect only module distributions processed by you. And if it is used as the `setup.cfg` for a particular module distribution, it affects only that distribution.

You could override the default “build base” directory and make the **build*** commands always forcibly rebuild all files with the following:

```
[build]
build-base=blib
force=1
```

which corresponds to the command-line arguments

```
python setup.py build --build-base=blib --force
```

except that including the **build** command on the command-line means that command will be run. Including a particular command in config files has no such implication; it only means that if the command is run, the options in the config file will apply. (Or if other commands that derive values from it are run, they will use the values in the config file.)

You can find out the complete list of options for any command using the `--help` option, e.g.:

```
python setup.py build --help
```

and you can find out the complete list of global options by using `--help` without a command:

```
python setup.py --help
```

See also the “Reference” section of the “Distributing Python Modules” manual.

Building Extensions: Tips and Tricks

Whenever possible, the Distutils try to use the configuration information made available by the Python interpreter used to run the `setup.py` script. For example, the same compiler and linker flags used to compile Python will also be used for compiling extensions. Usually this will work well, but in complicated situations this might be inappropriate. This section discusses how to override the usual Distutils behaviour.

Tweaking compiler/linker flags

Compiling a Python extension written in C or C++ will sometimes require specifying custom flags for the compiler and linker in order to use a particular library or produce a special kind of object code. This is especially true if the extension hasn't been tested on your platform, or if you're trying to cross-compile Python.

In the most general case, the extension author might have foreseen that compiling the extensions would be complicated, and provided a `setup` file for you to edit. This will likely only be done if the module distribution contains many separate extension modules, or if they often require elaborate sets of compiler flags in order to work.

A `setup` file, if present, is parsed in order to get a list of extensions to build. Each line in a `setup` describes a single module. Lines have the following structure:

```
module ... [sourcefile ...] [cpparg ...] [library ...]
```

Let's examine each of the fields in turn.

- *module* is the name of the extension module to be built, and

should be a valid Python identifier. You can't just change this in order to rename a module (edits to the source code would also be needed), so this should be left alone.

- *sourcefile* is anything that's likely to be a source code file, at least judging by the filename. Filenames ending in `.c` are assumed to be written in C, filenames ending in `.c`, `.cc`, and `.c++` are assumed to be C++, and filenames ending in `.m` or `.mm` are assumed to be in Objective C.
- *cpparg* is an argument for the C preprocessor, and is anything starting with `-I`, `-D`, `-U` or `-C`.
- *library* is anything ending in `.a` or beginning with `-l` or `-L`.

If a particular platform requires a special library on your platform, you can add it by editing the `setup` file and running `python setup.py build`. For example, if the module defined by the line

```
foo foomodule.c
```

must be linked with the math library `libm.a` on your platform, simply add `-lm` to the line:

```
foo foomodule.c -lm
```

Arbitrary switches intended for the compiler or the linker can be supplied with the `-Xcompiler arg` and `-Xlinker arg` options:

```
foo foomodule.c -Xcompiler -o32 -Xlinker -shared -lm
```

The next option after `-Xcompiler` and `-Xlinker` will be appended to the proper command line, so in the above example the compiler will be passed the `-o32` option, and the linker will be passed `-shared`. If a compiler option requires an argument, you'll have to supply multiple `-Xcompiler` options; for example, to pass `-x c++` the `setup` file would have to contain `-Xcompiler -x -Xcompiler c++`.

Compiler flags can also be supplied through setting the `CFLAGS` environment variable. If set, the contents of `CFLAGS` will be added to the compiler flags specified in the `Setup` file.

Using non-Microsoft compilers on Windows

Borland/CodeGear C++

This subsection describes the necessary steps to use Distutils with the Borland C++ compiler version 5.5. First you have to know that Borland's object file format (OMF) is different from the format used by the Python version you can download from the Python or ActiveState Web site. (Python is built with Microsoft Visual C++, which uses COFF as the object file format.) For this reason you have to convert Python's library `python25.lib` into the Borland format. You can do this as follows:

```
coff2omf python25.lib python25_bcpp.lib
```

The `coff2omf` program comes with the Borland compiler. The file `python25.lib` is in the `Libs` directory of your Python installation. If your extension uses other libraries (zlib, ...) you have to convert them too.

The converted files have to reside in the same directories as the normal libraries.

How does Distutils manage to use these libraries with their changed names? If the extension needs a library (eg. `foo`) Distutils checks first if it finds a library with suffix `_bcpp` (eg. `foo_bcpp.lib`) and then uses this library. In the case it doesn't find such a special library it uses the default name (`foo.lib`.) [1]

To let Distutils compile your extension with Borland C++ you now

have to type:

```
python setup.py build --compiler=bcpp
```

If you want to use the Borland C++ compiler as the default, you could specify this in your personal or system-wide configuration file for Distutils (see section *Distutils Configuration Files*.)

See also:

C++Builder Compiler

Information about the free C++ compiler from Borland, including links to the download pages.

Creating Python Extensions Using Borland's Free Compiler

Document describing how to use Borland's free command-line C++ compiler to build Python.

GNU C / Cygwin / MinGW

This section describes the necessary steps to use Distutils with the GNU C/C++ compilers in their Cygwin and MinGW distributions. [2] For a Python interpreter that was built with Cygwin, everything should work without any of these following steps.

Not all extensions can be built with MinGW or Cygwin, but many can. Extensions most likely to not work are those that use C++ or depend on Microsoft Visual C extensions.

To let Distutils compile your extension with Cygwin you have to type:

```
python setup.py build --compiler=cygwin
```

and for Cygwin in no-cygwin mode [3] or for MinGW type:

```
python setup.py build --compiler=mingw32
```

If you want to use any of these options/compilers as default, you should consider writing it in your personal or system-wide configuration file for Distutils (see section *Distutils Configuration Files*.)

Older Versions of Python and MinGW

The following instructions only apply if you're using a version of Python inferior to 2.4.1 with a MinGW inferior to 3.0.0 (with binutils-2.13.90-20030111-1).

These compilers require some special libraries. This task is more complex than for Borland's C++, because there is no program to convert the library. First you have to create a list of symbols which the Python DLL exports. (You can find a good program for this task at http://www.emmestech.com/software/pexports-0.43/download_pexports.html).

```
pexports python25.dll >python25.def
```

The location of an installed `python25.dll` will depend on the installation options and the version and language of Windows. In a "just for me" installation, it will appear in the root of the installation directory. In a shared installation, it will be located in the system directory.

Then you can create from these information an import library for gcc.

```
/cygwin/bin/dlltool --dllname python25.dll --def python25.def -
```

The resulting library has to be placed in the same directory as `python25.lib`. (Should be the `libs` directory under your Python installation directory.)

If your extension uses other libraries (zlib,...) you might have to convert them too. The converted files have to reside in the same directories as the normal libraries do.

See also:

Building Python modules on MS Windows platform with MinGW

Information about building the required libraries for the MinGW environment.

Footnotes

- [1] This also means you could replace all existing COFF-libraries with OMF-libraries of the same name.
- [2] Check <http://sources.redhat.com/cygwin/> and <http://www.mingw.org/> for more information
- [3] Then you have no POSIX emulation available, but you also don't need `cygwin1.dll`.

Distributing Python Modules

Authors:	Greg Ward, Anthony Baxter
Email:	distutils-sig@python.org
Release:	3.2
Date:	February 20, 2011

This document describes the Python Distribution Utilities (“Distutils”) from the module developer’s point of view, describing how to use the Distutils to make Python modules and extensions easily available to a wider audience with very little overhead for build/release/install mechanics.

- 1. An Introduction to Distutils
 - 1.1. Concepts & Terminology
 - 1.2. A Simple Example
 - 1.3. General Python terminology
 - 1.4. Distutils-specific terminology
- 2. Writing the Setup Script
 - 2.1. Listing whole packages
 - 2.2. Listing individual modules
 - 2.3. Describing extension modules
 - 2.4. Relationships between Distributions and Packages
 - 2.5. Installing Scripts
 - 2.6. Installing Package Data
 - 2.7. Installing Additional Files
 - 2.8. Additional meta-data
 - 2.9. Debugging the setup script
- 3. Writing the Setup Configuration File
- 4. Creating a Source Distribution
 - 4.1. Specifying the files to distribute
 - 4.2. Manifest-related options
- 5. Creating Built Distributions
 - 5.1. Creating RPM packages

- 5.2. Creating Windows Installers
- 5.3. Cross-compiling on Windows
- 5.4. Vista User Access Control (UAC)
- 6. Registering with the Package Index
 - 6.1. The .pypirc file
- 7. Uploading Packages to the Package Index
 - 7.1. PyPI package display
- 8. Examples
 - 8.1. Pure Python distribution (by module)
 - 8.2. Pure Python distribution (by package)
 - 8.3. Single extension module
 - 8.4. Checking a package
- 9. Extending Distutils
 - 9.1. Integrating new commands
 - 9.2. Adding new distribution types
- 10. Command Reference
 - 10.1. Installing modules: the **install** command family
 - 10.2. Creating a source distribution: the **sdist** command
- 11. API Reference
 - 11.1. **distutils.core** — Core Distutils functionality
 - 11.2. **distutils.ccompiler** — CCompiler base class
 - 11.3. **distutils.unixccompiler** — Unix C Compiler
 - 11.4. **distutils.msvccompiler** — Microsoft Compiler
 - 11.5. **distutils.bcppcompiler** — Borland Compiler
 - 11.6. **distutils.cygwincompiler** — Cygwin Compiler
 - 11.7. **distutils.emxccompiler** — OS/2 EMX Compiler
 - 11.8. **distutils.archive_util** — Archiving utilities
 - 11.9. **distutils.dep_util** — Dependency checking
 - 11.10. **distutils.dir_util** — Directory tree operations
 - 11.11. **distutils.file_util** — Single file operations
 - 11.12. **distutils.util** — Miscellaneous other utility functions
 - 11.13. **distutils.dist** — The Distribution class

- 11.14. `distutils.extension` — The Extension class
- 11.15. `distutils.debug` — Distutils debug mode
- 11.16. `distutils.errors` — Distutils exceptions
- 11.17. `distutils.fancy_getopt` — Wrapper around the standard `getopt` module
- 11.18. `distutils.filelist` — The FileList class
- 11.19. `distutils.log` — Simple PEP 282-style logging
- 11.20. `distutils.spawn` — Spawn a sub-process
- 11.21. `distutils.sysconfig` — System configuration information
- 11.22. `distutils.text_file` — The TextFile class
- 11.23. `distutils.version` — Version number classes
- 11.24. `distutils.cmd` — Abstract base class for Distutils commands
- 11.25. `distutils.command` — Individual Distutils commands
- 11.26. `distutils.command.bdist` — Build a binary installer
- 11.27. `distutils.command.bdist_packager` — Abstract base class for packagers
- 11.28. `distutils.command.bdist_dumb` — Build a “dumb” installer
- 11.29. `distutils.command.bdist_msi` — Build a Microsoft Installer binary package
- 11.30. `distutils.command.bdist_rpm` — Build a binary distribution as a Redhat RPM and SRPM
- 11.31. `distutils.command.bdist_wininst` — Build a Windows installer
- 11.32. `distutils.command.sdist` — Build a source distribution
- 11.33. `distutils.command.build` — Build all files of a package
- 11.34. `distutils.command.build_clib` — Build any C libraries in a package

- `11.35. distutils.command.build_ext` — Build any extensions in a package
- `11.36. distutils.command.build_py` — Build the `.py/.pyc` files of a package
- `11.37. distutils.command.build_scripts` — Build the scripts of a package
- `11.38. distutils.command.clean` — Clean a package build area
- `11.39. distutils.command.config` — Perform package configuration
- `11.40. distutils.command.install` — Install a package
- `11.41. distutils.command.install_data` — Install data files from a package
- `11.42. distutils.command.install_headers` — Install C/C++ header files from a package
- `11.43. distutils.command.install_lib` — Install library files from a package
- `11.44. distutils.command.install_scripts` — Install script files from a package
- `11.45. distutils.command.register` — Register a module with the Python Package Index
- `11.46. distutils.command.check` — Check the meta-data of a package
- `11.47. Creating a new Distutils command`

Documenting Python

The Python language has a substantial body of documentation, much of it contributed by various authors. The markup used for the Python documentation is [reStructuredText](#), developed by the [docutils](#) project, amended by custom directives and using a toolset named [Sphinx](#) to postprocess the HTML output.

This document describes the style guide for our documentation as well as the custom reStructuredText markup introduced by Sphinx to support Python documentation and how it should be used.

Note: If you're interested in contributing to Python's documentation, there's no need to write reStructuredText if you're not so inclined; plain text contributions are more than welcome as well. Send an e-mail to docs@python.org or open an issue on the [tracker](#).

- 11.1.5. Pickling Class Instances
 - 11.1.5.1. Persistence of External Objects
 - 11.1.5.2. Handling Stateful Objects
- 11.1.6. Restricting Globals
- 11.1.7. Examples
- 11.2. `copyreg` — Register `pickle` support functions
- 11.3. `shelve` — Python object persistence
 - 11.3.1. Restrictions
 - 11.3.2. Example
- 11.4. `marshal` — Internal Python object serialization
- 11.5. `dbm` — Interfaces to Unix “databases”
 - 11.5.1. `dbm.gnu` — GNU’s reinterpretation of `dbm`
 - 11.5.2. `dbm.ndbm` — Interface based on `ndbm`
 - 11.5.3. `dbm.dumb` — Portable DBM implementation
- 11.6. `sqlite3` — DB-API 2.0 interface for SQLite databases
 - 11.6.1. Module functions and constants
 - 11.6.2. Connection Objects
 - 11.6.3. Cursor Objects
 - 11.6.4. Row Objects
 - 11.6.5. SQLite and Python types
 - 11.6.5.1. Introduction
 - 11.6.5.2. Using adapters to store additional Python types in SQLite databases
 - 11.6.5.2.1. Letting your object adapt itself
 - 11.6.5.2.2. Registering an adapter callable
 - 11.6.5.3. Converting SQLite values to custom Python types
 - 11.6.5.4. Default adapters and converters

- 11.6.6. Controlling Transactions
- 11.6.7. Using `sqlite3` efficiently
 - 11.6.7.1. Using shortcut methods
 - 11.6.7.2. Accessing columns by name instead of by index
 - 11.6.7.3. Using the connection as a context manager
- 11.6.8. Common issues
 - 11.6.8.1. Multithreading
- 12. Data Compression and Archiving
 - 12.1. `zlib` — Compression compatible with **gzip**
 - 12.2. `gzip` — Support for **gzip** files
 - 12.2.1. Examples of usage
 - 12.3. `bz2` — Compression compatible with **bzip2**
 - 12.3.1. (De)compression of files
 - 12.3.2. Sequential (de)compression
 - 12.3.3. One-shot (de)compression
 - 12.4. `zipfile` — Work with ZIP archives
 - 12.4.1. ZipFile Objects
 - 12.4.2. PyZipFile Objects
 - 12.4.3. ZipInfo Objects
 - 12.5. `tarfile` — Read and write tar archive files
 - 12.5.1. TarFile Objects
 - 12.5.2. TarInfo Objects
 - 12.5.3. Examples
 - 12.5.4. Supported tar formats
 - 12.5.5. Unicode issues
- 13. File Formats
 - 13.1. `csv` — CSV File Reading and Writing
 - 13.1.1. Module Contents
 - 13.1.2. Dialects and Formatting Parameters
 - 13.1.3. Reader Objects
 - 13.1.4. Writer Objects

- 13.1.5. Examples
- 13.2. **configparser** — Configuration file parser
 - 13.2.1. Quick Start
 - 13.2.2. Supported Datatypes
 - 13.2.3. Fallback Values
 - 13.2.4. Supported INI File Structure
 - 13.2.5. Interpolation of values
 - 13.2.6. Mapping Protocol Access
 - 13.2.7. Customizing Parser Behaviour
 - 13.2.8. Legacy API Examples
 - 13.2.9. ConfigParser Objects
 - 13.2.10. RawConfigParser Objects
 - 13.2.11. Exceptions
- 13.3. **netrc** — netrc file processing
 - 13.3.1. netrc Objects
- 13.4. **xdrlib** — Encode and decode XDR data
 - 13.4.1. Packer Objects
 - 13.4.2. Unpacker Objects
 - 13.4.3. Exceptions
- 13.5. **plistlib** — Generate and parse Mac OS X `.plist` files
 - 13.5.1. Examples
- 14. Cryptographic Services
 - 14.1. **hashlib** — Secure hashes and message digests
 - 14.2. **hmac** — Keyed-Hashing for Message Authentication
- 15. Generic Operating System Services
 - 15.1. **os** — Miscellaneous operating system interfaces
 - 15.1.1. File Names, Command Line Arguments, and Environment Variables
 - 15.1.2. Process Parameters
 - 15.1.3. File Object Creation
 - 15.1.4. File Descriptor Operations

- 16.3. multiprocessing — Process-based parallelism
 - 16.3.1. Introduction
 - 16.3.1.1. The `Process` class
 - 16.3.1.2. Exchanging objects between processes
 - 16.3.1.3. Synchronization between processes
 - 16.3.1.4. Sharing state between processes
 - 16.3.1.5. Using a pool of workers
 - 16.3.2. Reference
 - 16.3.2.1. `Process` and exceptions
 - 16.3.2.2. Pipes and Queues
 - 16.3.2.3. Miscellaneous
 - 16.3.2.4. Connection Objects
 - 16.3.2.5. Synchronization primitives
 - 16.3.2.6. Shared `ctypes` Objects
 - 16.3.2.6.1. `ctypes.LinuxDLL` The `multiprocessing.sharedctypes` module
 - 16.3.2.7. Managers
 - 16.3.2.7.1. Namespace objects
 - 16.3.2.7.2. Customized managers
 - 16.3.2.7.3. Using a remote manager
 - 16.3.2.8. Proxy Objects
 - 16.3.2.8.1. Cleanup
 - 16.3.2.9. Process Pools
 - 16.3.2.10. Listeners and Clients
 - 16.3.2.10.1. Address Formats
 - 16.3.2.11. Authentication keys
 - 16.3.2.12. Logging
 - 16.3.2.13. The `multiprocessing.dummy` module

- 16.3.3. Programming guidelines
 - 16.3.3.1. All platforms
 - 16.3.3.2. Windows
- 16.3.4. Examples
- 16.4. `concurrent.futures` — Launching parallel tasks
 - 16.4.1. Executor Objects
 - 16.4.2. `ThreadPoolExecutor`
 - 16.4.2.1. `ThreadPoolExecutor` Example
 - 16.4.3. `ProcessPoolExecutor`
 - 16.4.3.1. `ProcessPoolExecutor` Example
 - 16.4.4. Future Objects
 - 16.4.5. Module Functions
- 16.5. `mmap` — Memory-mapped file support
- 16.6. `readline` — GNU readline interface
 - 16.6.1. Example
- 16.7. `rlcompleter` — Completion function for GNU readline
 - 16.7.1. Completer Objects
- 16.8. `dummy_threading` — Drop-in replacement for the `threading` module
- 16.9. `_thread` — Low-level threading API
- 16.10. `_dummy_thread` — Drop-in replacement for the `_thread` module
- 17. Interprocess Communication and Networking
 - 17.1. `subprocess` — Subprocess management
 - 17.1.1. Using the `subprocess` Module
 - 17.1.1.1. Convenience Functions
 - 17.1.1.2. Exceptions
 - 17.1.1.3. Security
 - 17.1.2. `Popen` Objects
 - 17.1.3. Replacing Older Functions with the `subprocess` Module
 - 17.1.3.1. Replacing `/bin/sh` shell backquote

- 17.1.3.2. Replacing shell pipeline
- 17.1.3.3. Replacing `os.system()`
- 17.1.3.4. Replacing the `os.spawn` family
- 17.1.3.5. Replacing `os.popen()`, `os.popen2()`, `os.popen3()`
- 17.1.3.6. Replacing functions from the `popen2` module
- 17.2. `socket` — Low-level networking interface
 - 17.2.1. Socket families
 - 17.2.2. Module contents
 - 17.2.3. Socket Objects
 - 17.2.4. Notes on socket timeouts
 - 17.2.4.1. Timeouts and the `connect` method
 - 17.2.4.2. Timeouts and the `accept` method
 - 17.2.5. Example
- 17.3. `ssl` — TLS/SSL wrapper for socket objects
 - 17.3.1. Functions, Constants, and Exceptions
 - 17.3.1.1. Socket creation
 - 17.3.1.2. Random generation
 - 17.3.1.3. Certificate handling
 - 17.3.1.4. Constants
 - 17.3.2. SSL Sockets
 - 17.3.3. SSL Contexts
 - 17.3.4. Certificates
 - 17.3.4.1. Certificate chains
 - 17.3.4.2. CA certificates
 - 17.3.4.3. Combined key and certificate
 - 17.3.4.4. Self-signed certificates
 - 17.3.5. Examples
 - 17.3.5.1. Testing for SSL support
 - 17.3.5.2. Client-side operation
 - 17.3.5.3. Server-side operation
 - 17.3.6. Security considerations

- 17.3.6.1. Verifying certificates
 - 17.3.6.2. Protocol versions
 - 17.4. `signal` — Set handlers for asynchronous events
 - 17.4.1. Example
 - 17.5. `asyncore` — Asynchronous socket handler
 - 17.5.1. `asyncore` Example basic HTTP client
 - 17.5.2. `asyncore` Example basic echo server
 - 17.6. `asynchat` — Asynchronous socket command/response handler
 - 17.6.1. `asynchat` - Auxiliary Classes
 - 17.6.2. `asynchat` Example
- 18. Internet Data Handling
 - 18.1. `email` — An email and MIME handling package
 - 18.1.1. `email`: Representing an email message
 - 18.1.2. `email`: Parsing email messages
 - 18.1.2.1. FeedParser API
 - 18.1.2.2. Parser class API
 - 18.1.2.3. Additional notes
 - 18.1.3. `email`: Generating MIME documents
 - 18.1.4. `email`: Creating email and MIME objects from scratch
 - 18.1.5. `email`: Internationalized headers
 - 18.1.6. `email`: Representing character sets
 - 18.1.7. `email`: Encoders
 - 18.1.8. `email`: Exception and Defect classes
 - 18.1.9. `email`: Miscellaneous utilities
 - 18.1.10. `email`: Iterators
 - 18.1.11. `email`: Examples
 - 18.1.12. Package History
 - 18.1.13. Differences from `mimelib`
 - 18.2. `json` — JSON encoder and decoder
 - 18.2.1. Basic Usage

- 18.2.2. Encoders and decoders
 - 18.3. `mailcap` — Mailcap file handling
 - 18.4. `mailbox` — Manipulate mailboxes in various formats
 - 18.4.1. Mailbox objects
 - 18.4.1.1. `Maildir`
 - 18.4.1.2. `mbox`
 - 18.4.1.3. `MH`
 - 18.4.1.4. `Baby1`
 - 18.4.1.5. `M MDF`
 - 18.4.2. Message objects
 - 18.4.2.1. `MaildirMessage`
 - 18.4.2.2. `mboxMessage`
 - 18.4.2.3. `MHMessage`
 - 18.4.2.4. `Baby1Message`
 - 18.4.2.5. `M MDFMessage`
 - 18.4.3. Exceptions
 - 18.4.4. Examples
 - 18.5. `mimetypes` — Map filenames to MIME types
 - 18.5.1. `MimeTypes` Objects
 - 18.6. `base64` — RFC 3548: Base16, Base32, Base64 Data Encodings
 - 18.7. `binhex` — Encode and decode binhex4 files
 - 18.7.1. Notes
 - 18.8. `binascii` — Convert between binary and ASCII
 - 18.9. `quopri` — Encode and decode MIME quoted-printable data
 - 18.10. `uu` — Encode and decode uuencode files
- 19. Structured Markup Processing Tools
 - 19.1. `html` — HyperText Markup Language support
 - 19.2. `html.parser` — Simple HTML and XHTML parser
 - 19.2.1. Example HTML Parser Application

- 19.3. `html.entities` — Definitions of HTML general entities
- 19.4. `xml.parsers.expat` — Fast XML parsing using Expat
 - 19.4.1. XMLParser Objects
 - 19.4.2. ExpatError Exceptions
 - 19.4.3. Example
 - 19.4.4. Content Model Descriptions
 - 19.4.5. Expat error constants
- 19.5. `xml.dom` — The Document Object Model API
 - 19.5.1. Module Contents
 - 19.5.2. Objects in the DOM
 - 19.5.2.1. DOMImplementation Objects
 - 19.5.2.2. Node Objects
 - 19.5.2.3. NodeList Objects
 - 19.5.2.4. DocumentType Objects
 - 19.5.2.5. Document Objects
 - 19.5.2.6. Element Objects
 - 19.5.2.7. Attr Objects
 - 19.5.2.8. NamedNodeMap Objects
 - 19.5.2.9. Comment Objects
 - 19.5.2.10. Text and CDATASection Objects
 - 19.5.2.11. ProcessingInstruction Objects
 - 19.5.2.12. Exceptions
 - 19.5.3. Conformance
 - 19.5.3.1. Type Mapping
 - 19.5.3.2. Accessor Methods
- 19.6. `xml.dom.minidom` — Lightweight DOM implementation
 - 19.6.1. DOM Objects
 - 19.6.2. DOM Example
 - 19.6.3. minidom and the DOM standard
- 19.7. `xml.dom.pulldom` — Support for building partial DOM trees

- 19.7.1. DOMEventStream Objects
- 19.8. `xml.sax` — Support for SAX2 parsers
 - 19.8.1. SAXException Objects
- 19.9. `xml.sax.handler` — Base classes for SAX handlers
 - 19.9.1. ContentHandler Objects
 - 19.9.2. DTDHandler Objects
 - 19.9.3. EntityResolver Objects
 - 19.9.4. ErrorHandler Objects
- 19.10. `xml.sax.saxutils` — SAX Utilities
- 19.11. `xml.sax.xmlreader` — Interface for XML parsers
 - 19.11.1. XMLReader Objects
 - 19.11.2. IncrementalParser Objects
 - 19.11.3. Locator Objects
 - 19.11.4. InputSource Objects
 - 19.11.5. The `Attributes` Interface
 - 19.11.6. The `AttributesNS` Interface
- 19.12. `xml.etree.ElementTree` — The ElementTree XML API
 - 19.12.1. Functions
 - 19.12.2. Element Objects
 - 19.12.3. ElementTree Objects
 - 19.12.4. QName Objects
 - 19.12.5. TreeBuilder Objects
 - 19.12.6. XMLParser Objects
- 20. Internet Protocols and Support
 - 20.1. `webbrowser` — Convenient Web-browser controller
 - 20.1.1. Browser Controller Objects
 - 20.2. `cgi` — Common Gateway Interface support
 - 20.2.1. Introduction
 - 20.2.2. Using the `cgi` module
 - 20.2.3. Higher Level Interface

- 20.2.4. Functions
- 20.2.5. Caring about security
- 20.2.6. Installing your CGI script on a Unix system
- 20.2.7. Testing your CGI script
- 20.2.8. Debugging CGI scripts
- 20.2.9. Common problems and solutions
- 20.3. `cgitb` — Traceback manager for CGI scripts
- 20.4. `wsgiref` — WSGI Utilities and Reference Implementation
 - 20.4.1. `wsgiref.util` – WSGI environment utilities
 - 20.4.2. `wsgiref.headers` – WSGI response header tools
 - 20.4.3. `wsgiref.simple_server` – a simple WSGI HTTP server
 - 20.4.4. `wsgiref.validate` — WSGI conformance checker
 - 20.4.5. `wsgiref.handlers` – server/gateway base classes
 - 20.4.6. Examples
- 20.5. `urllib.request` — Extensible library for opening URLs
 - 20.5.1. Request Objects
 - 20.5.2. OpenerDirector Objects
 - 20.5.3. BaseHandler Objects
 - 20.5.4. HTTPRedirectHandler Objects
 - 20.5.5. HTTPCookieProcessor Objects
 - 20.5.6. ProxyHandler Objects
 - 20.5.7. HTTPPasswordMgr Objects
 - 20.5.8. AbstractBasicAuthHandler Objects
 - 20.5.9. HTTPBasicAuthHandler Objects
 - 20.5.10. ProxyBasicAuthHandler Objects
 - 20.5.11. AbstractDigestAuthHandler Objects
 - 20.5.12. HTTPDigestAuthHandler Objects

- 20.5.13. ProxyDigestAuthHandler Objects
- 20.5.14. HTTPHandler Objects
- 20.5.15. HTTPSHandler Objects
- 20.5.16. FileHandler Objects
- 20.5.17. FTPHandler Objects
- 20.5.18. CacheFTPHandler Objects
- 20.5.19. UnknownHandler Objects
- 20.5.20. HTTPErrorProcessor Objects
- 20.5.21. Examples
- 20.5.22. Legacy interface
- 20.5.23. `urllib.request` Restrictions
- 20.6. `urllib.response` — Response classes used by `urllib`
- 20.7. `urllib.parse` — Parse URLs into components
 - 20.7.1. URL Parsing
 - 20.7.2. Parsing ASCII Encoded Bytes
 - 20.7.3. Structured Parse Results
 - 20.7.4. URL Quoting
- 20.8. `urllib.error` — Exception classes raised by `urllib.request`
- 20.9. `urllib.robotparser` — Parser for robots.txt
- 20.10. `http.client` — HTTP protocol client
 - 20.10.1. HTTPConnection Objects
 - 20.10.2. HTTPResponse Objects
 - 20.10.3. Examples
 - 20.10.4. HTTPMessage Objects
- 20.11. `ftplib` — FTP protocol client
 - 20.11.1. FTP Objects
 - 20.11.2. FTP_TLS Objects
- 20.12. `poplib` — POP3 protocol client
 - 20.12.1. POP3 Objects
 - 20.12.2. POP3 Example
- 20.13. `imaplib` — IMAP4 protocol client

- 20.13.1. IMAP4 Objects
- 20.13.2. IMAP4 Example
- 20.14. `nntp1ib` — NNTP protocol client
 - 20.14.1. NNTP Objects
 - 20.14.1.1. Attributes
 - 20.14.1.2. Methods
 - 20.14.2. Utility functions
- 20.15. `smtp1ib` — SMTP protocol client
 - 20.15.1. SMTP Objects
 - 20.15.2. SMTP Example
- 20.16. `smtpd` — SMTP Server
 - 20.16.1. SMTPServer Objects
 - 20.16.2. DebuggingServer Objects
 - 20.16.3. PureProxy Objects
 - 20.16.4. MailmanProxy Objects
 - 20.16.5. SMTPChannel Objects
- 20.17. `telnet1ib` — Telnet client
 - 20.17.1. Telnet Objects
 - 20.17.2. Telnet Example
- 20.18. `uuid` — UUID objects according to RFC 4122
 - 20.18.1. Example
- 20.19. `socketserver` — A framework for network servers
 - 20.19.1. Server Creation Notes
 - 20.19.2. Server Objects
 - 20.19.3. RequestHandler Objects
 - 20.19.4. Examples
 - 20.19.4.1. `socketserver.TCPServer` Example
 - 20.19.4.2. `socketserver.UDPServer` Example
 - 20.19.4.3. Asynchronous Mixins
- 20.20. `http.server` — HTTP servers
- 20.21. `http.cookies` — HTTP state management
 - 20.21.1. Cookie Objects

- 20.21.2. Morsel Objects
- 20.21.3. Example
- 20.22. `http.cookiejar` — Cookie handling for HTTP clients
 - 20.22.1. CookieJar and FileCookieJar Objects
 - 20.22.2. FileCookieJar subclasses and co-operation with web browsers
 - 20.22.3. CookiePolicy Objects
 - 20.22.4. DefaultCookiePolicy Objects
 - 20.22.5. Cookie Objects
 - 20.22.6. Examples
- 20.23. `xmlrpc.client` — XML-RPC client access
 - 20.23.1. ServerProxy Objects
 - 20.23.2. DateTime Objects
 - 20.23.3. Binary Objects
 - 20.23.4. Fault Objects
 - 20.23.5. ProtocolError Objects
 - 20.23.6. MultiCall Objects
 - 20.23.7. Convenience Functions
 - 20.23.8. Example of Client Usage
 - 20.23.9. Example of Client and Server Usage
- 20.24. `xmlrpc.server` — Basic XML-RPC servers
 - 20.24.1. SimpleXMLRPCServer Objects
 - 20.24.1.1. SimpleXMLRPCServer Example
 - 20.24.2. CGIXMLRPCRequestHandler
 - 20.24.3. Documenting XMLRPC server
 - 20.24.4. DocXMLRPCServer Objects
 - 20.24.5. DocCGIXMLRPCRequestHandler
- 21. Multimedia Services
 - 21.1. `audioop` — Manipulate raw audio data
 - 21.2. `aifc` — Read and write AIFF and AIFC files
 - 21.3. `sunau` — Read and write Sun AU files
 - 21.3.1. AU_read Objects

- 21.3.2. `AU_write` Objects
- 21.4. `wave` — Read and write WAV files
 - 21.4.1. `Wave_read` Objects
 - 21.4.2. `Wave_write` Objects

- 11.8. `distutils.archive_util` — Archiving utilities
- 11.9. `distutils.dep_util` — Dependency checking
- 11.10. `distutils.dir_util` — Directory tree operations
- 11.11. `distutils.file_util` — Single file operations
- 11.12. `distutils.util` — Miscellaneous other utility functions
- 11.13. `distutils.dist` — The Distribution class
- 11.14. `distutils.extension` — The Extension class
- 11.15. `distutils.debug` — Distutils debug mode
- 11.16. `distutils.errors` — Distutils exceptions
- 11.17. `distutils.fancy_getopt` — Wrapper around the standard `getopt` module
- 11.18. `distutils.filelist` — The FileList class
- 11.19. `distutils.log` — Simple PEP 282-style logging
- 11.20. `distutils.spawn` — Spawn a sub-process
- 11.21. `distutils.sysconfig` — System configuration information
- 11.22. `distutils.text_file` — The TextFile class
- 11.23. `distutils.version` — Version number classes
- 11.24. `distutils.cmd` — Abstract base class for Distutils commands
- 11.25. `distutils.command` — Individual Distutils commands
- 11.26. `distutils.command.bdist` — Build a binary installer
- 11.27. `distutils.command.bdist_packager` — Abstract base class for packagers
- 11.28. `distutils.command.bdist_dumb` — Build a “dumb” installer

- 11.29. `distutils.command.bdist_msi` — Build a Microsoft Installer binary package
- 11.30. `distutils.command.bdist_rpm` — Build a binary distribution as a Redhat RPM and SRPM
- 11.31. `distutils.command.bdist_wininst` — Build a Windows installer
- 11.32. `distutils.command.sdist` — Build a source distribution
- 11.33. `distutils.command.build` — Build all files of a package
- 11.34. `distutils.command.build_clib` — Build any C libraries in a package
- 11.35. `distutils.command.build_ext` — Build any extensions in a package
- 11.36. `distutils.command.build_py` — Build the .py/.pyc files of a package
- 11.37. `distutils.command.build_scripts` — Build the scripts of a package
- 11.38. `distutils.command.clean` — Clean a package build area
- 11.39. `distutils.command.config` — Perform package configuration
- 11.40. `distutils.command.install` — Install a package
- 11.41. `distutils.command.install_data` — Install data files from a package
- 11.42. `distutils.command.install_headers` — Install C/C++ header files from a package
- 11.43. `distutils.command.install_lib` — Install library files from a package
- 11.44. `distutils.command.install_scripts` — Install script files from a package
- 11.45. `distutils.command.register` — Register a

- module with the Python Package Index
 - 11.46. `distutils.command.check` — Check the meta-data of a package

 - Why does Python use indentation for grouping of statements?
 - Why am I getting strange results with simple arithmetic operations?
 - Why are floating point calculations so inaccurate?
 - Why are Python strings immutable?
 - Why must 'self' be used explicitly in method definitions and calls?

- Why can't I use an assignment in an expression?
- Why does Python use methods for some functionality (e.g. `list.index()`) but functions for other (e.g. `len(list)`)?
- Why is `join()` a string method instead of a list or tuple method?
- How fast are exceptions?
- Why isn't there a switch or case statement in Python?
- Can't you emulate threads in the interpreter instead of relying on an OS-specific thread implementation?
- Why can't lambda forms contain statements?
- Can Python be compiled to machine code, C or some other language?
- How does Python manage memory?
- Why isn't all memory freed when Python exits?
- Why are there separate tuple and list data types?
- How are lists implemented?
- How are dictionaries implemented?
- Why must dictionary keys be immutable?
- Why doesn't `list.sort()` return the sorted list?
- How do you specify and enforce an interface spec in Python?
- Why are default values shared between objects?
- Why is there no `goto`?
- Why can't raw strings (r-strings) end with a backslash?
- Why doesn't Python have a "with" statement for attribute assignments?
- Why are colons required for the `if/while/def/class` statements?
- Why does Python allow commas at the end of lists and tuples?
