

Python v3.2 documentation

Welcome! This is the documentation for Python 3.2, last updated Feb 20, 2011.

Parts of the documentation:

What's new in Python 3.2? <i>or all "What's new" documents since 2.0</i>	Extending and Embedding <i>tutorial for C/C++ programmers</i>
Tutorial <i>start here</i>	Python/C API <i>reference for C/C++ programmers</i>
Library Reference <i>keep this under your pillow</i>	Installing Python Modules <i>information for installers & sys-admins</i>
Language Reference <i>describes syntax and language elements</i>	Distributing Python Modules <i>sharing modules with others</i>
Python Setup and Usage <i>how to use Python on different platforms</i>	Documenting Python <i>guide for documentation authors</i>
Python HOWTOs <i>in-depth documents on specific topics</i>	FAQs <i>frequently asked questions (with answers!)</i>

Indices and tables:

Global Module Index

quick access to all modules

General Index

[x](#) | [z](#)

<code>__</code>	
<code>__future__</code>	<i>Future statement definitions</i>
<code>__main__</code>	<i>The environment where the top-level script is run.</i>
<code>_dummy_thread</code>	<i>Drop-in replacement for the <code>_thread</code> module.</i>
<code>_thread</code>	<i>Low-level threading API.</i>
a	
<code>abc</code>	<i>Abstract base classes according to PEP 3119.</i>
<code>aifc</code>	<i>Read and write audio files in AIFF or AIFC format.</i>
<code>argparse</code>	<i>Command-line option and argument parsing library.</i>
<code>array</code>	<i>Space efficient arrays of uniformly typed numeric values.</i>
<code>ast</code>	<i>Abstract Syntax Tree classes and manipulation.</i>
<code>asynchat</code>	<i>Support for asynchronous command/response protocols.</i>
<code>asyncore</code>	<i>A base class for developing asynchronous socket handling services.</i>
<code>atexit</code>	<i>Register and execute cleanup functions.</i>
<code>audioop</code>	<i>Manipulate raw audio data.</i>
b	

base64	<i>RFC 3548: Base16, Base32, Base64 Data Encodings</i>
bdb	<i>Debugger framework.</i>
binascii	<i>Tools for converting between binary and various ASCII-encoded binary representations.</i>
binhex	<i>Encode and decode files in binhex4 format.</i>
bisect	<i>Array bisection algorithms for binary searching.</i>
builtins	<i>The module that provides the built-in namespace.</i>
bz2	<i>Interface to compression and decompression routines compatible with bzip2.</i>

C	
calendar	<i>Functions for working with calendars, including some emulation of the Unix cal program.</i>
cgi	<i>Helpers for running Python scripts via the Common Gateway Interface.</i>
cgitb	<i>Configurable traceback handler for CGI scripts.</i>
chunk	<i>Module to read IFF chunks.</i>
cmath	<i>Mathematical functions for complex numbers.</i>
cmd	<i>Build line-oriented command interpreters.</i>
code	<i>Facilities to implement read-eval-print loops.</i>
codecs	<i>Encode and decode data and streams.</i>

<code>codeop</code>	<i>Compile (possibly incomplete) Python code.</i>
<code>collections</code>	<i>Container datatypes</i>
<code>colorsys</code>	<i>Conversion functions between RGB and other color systems.</i>
<code>compileall</code>	<i>Tools for byte-compiling all Python source files in a directory tree.</i>
<code>concurrent</code>	
<code>concurrent.futures</code>	<i>Execute computations concurrently using threads or processes.</i>
<code>configparser</code>	<i>Configuration file parser.</i>
<code>contextlib</code>	<i>Utilities for with-statement contexts.</i>
<code>copy</code>	<i>Shallow and deep copy operations.</i>
<code>copyreg</code>	<i>Register pickle support functions.</i>
<code>cProfile</code>	<i>Python profiler</i>
<code>crypt (Unix)</code>	<i>The crypt() function used to check Unix passwords.</i>
<code>csv</code>	<i>Write and read tabular data to and from delimited files.</i>
<code>ctypes</code>	<i>A foreign function library for Python.</i>
<code>curses (Unix)</code>	<i>An interface to the curses library, providing portable terminal handling.</i>
<code>curses.ascii</code>	<i>Constants and set-membership functions for ASCII characters.</i>
<code>curses.panel</code>	<i>A panel stack extension that adds depth to curses windows.</i>
<code>curses.textpad</code>	<i>Emacs-like input editing in a curses window.</i>

`curses.wrapper`

Terminal configuration wrapper for curses programs.

d

`datetime`

Basic date and time types.

`dbm`

Interfaces to various Unix "database" formats.

`dbm.dumb`

Portable implementation of the simple DBM interface.

`dbm.gnu (Unix)`

GNU's reinterpretation of dbm.

`dbm.ndbm (Unix)`

The standard "database" interface, based on ndbm.

`decimal`

Implementation of the General Decimal Arithmetic Specification.

`difflib`

Helpers for computing differences between objects.

`dis`

Disassembler for Python bytecode.

`distutils`

Support for building and installing Python modules into an existing Python installation.

`distutils.archive_util`

Utility functions for creating archive files (tarballs, zip files, ...)

`distutils.bcpcppcompiler`

`distutils.ccompiler`

`distutils.cmd`

Abstract CCompiler class

This module provides the abstract base class Command. This class is subclassed by the modules in the `distutils.command` subpackage.

`distutils.command`

This subpackage contains one module for each standard

<code>distutils.command.bdist</code>	<i>Distutils command. Build a binary installer for a package</i>
<code>distutils.command.bdist_dumb</code>	<i>Build a "dumb" installer - a simple archive of files</i>
<code>distutils.command.bdist_msi</code>	<i>Build a binary distribution as a Windows MSI file</i>
<code>distutils.command.bdist_packager</code>	<i>Abstract base class for packagers</i>
<code>distutils.command.bdist_rpm</code>	<i>Build a binary distribution as a Redhat RPM and SRPM</i>
<code>distutils.command.bdist_wininst</code>	<i>Build a Windows installer</i>
<code>distutils.command.build</code>	<i>Build all files of a package</i>
<code>distutils.command.build_clib</code>	<i>Build any C libraries in a package</i>
<code>distutils.command.build_ext</code>	<i>Build any extensions in a package</i>
<code>distutils.command.build_py</code>	<i>Build the .py/.pyc files of a package</i>
<code>distutils.command.build_scripts</code>	<i>Build the scripts of a package</i>
<code>distutils.command.check</code>	<i>Check the metadata of a package</i>
<code>distutils.command.clean</code>	<i>Clean a package build area</i>
<code>distutils.command.config</code>	<i>Perform package configuration</i>
<code>distutils.command.install</code>	<i>Install a package</i>
<code>distutils.command.install_data</code>	<i>Install data files from a package</i>
<code>distutils.command.install_headers</code>	<i>Install C/C++ header files from a package</i>
<code>distutils.command.install_lib</code>	<i>Install library files from a package</i>
<code>distutils.command.install_scripts</code>	<i>Install script files from a package</i>
<code>distutils.command.register</code>	<i>Register a module with the</i>

	<i>Python Package Index</i>
<code>distutils.command.sdist</code>	<i>Build a source distribution</i>
<code>distutils.core</code>	<i>The core Distutils functionality</i>
<code>distutils.cygwinccompiler</code>	
<code>distutils.debug</code>	<i>Provides the debug flag for distutils</i>
<code>distutils.dep_util</code>	<i>Utility functions for simple dependency checking</i>
<code>distutils.dir_util</code>	<i>Utility functions for operating on directories and directory trees</i>
<code>distutils.dist</code>	<i>Provides the Distribution class, which represents the module distribution being built/installed/distributed</i>
<code>distutils.emxccompiler</code>	<i>OS/2 EMX Compiler support</i>
<code>distutils.errors</code>	<i>Provides standard distutils exceptions</i>
<code>distutils.extension</code>	<i>Provides the Extension class, used to describe C/C++ extension modules in setup scripts</i>
<code>distutils.fancy_getopt</code>	<i>Additional getopt functionality</i>
<code>distutils.file_util</code>	<i>Utility functions for operating on single files</i>
<code>distutils.filelist</code>	<i>The FileList class, used for poking about the file system and building lists of files.</i>
<code>distutils.log</code>	<i>A simple logging mechanism, 282-style</i>
<code>distutils.msvccompiler</code>	<i>Microsoft Compiler</i>
<code>distutils.spawn</code>	<i>Provides the spawn() function</i>
<code>distutils.sysconfig</code>	<i>Low-level access to configuration information of the Python interpreter.</i>

<code>distutils.text_file</code>	<i>provides the <code>TextFile</code> class, a simple interface to text files</i>
<code>distutils.unixccompiler</code>	<i>UNIX C Compiler</i>
<code>distutils.util</code>	<i>Miscellaneous other utility functions</i>
<code>distutils.version</code>	<i>implements classes that represent module version numbers.</i>
<code>doctest</code>	<i>Test pieces of code within docstrings.</i>
<code>dummy_threading</code>	<i>Drop-in replacement for the threading module.</i>
e	
<code>email</code>	<i>Package supporting the parsing, manipulating, and generating email messages, including MIME documents.</i>
<code>email.charset</code>	<i>Character Sets</i>
<code>email.encoders</code>	<i>Encoders for email message payloads.</i>
<code>email.errors</code>	<i>The exception classes used by the email package.</i>
<code>email.generator</code>	<i>Generate flat text email messages from a message structure.</i>
<code>email.header</code>	<i>Representing non-ASCII headers</i>
<code>email.iterators</code>	<i>Iterate over a message object tree.</i>
<code>email.message</code>	<i>The base class representing email messages.</i>
<code>email.mime</code>	<i>Build MIME messages.</i>
<code>email.parser</code>	<i>Parse flat text email messages to produce a message object</i>

<code>email.utils</code>	<i>Miscellaneous email package utilities.</i>
encodings	
<code>encodings.idna</code>	<i>Internationalized Domain Names implementation</i>
<code>encodings.mbcs</code>	<i>Windows ANSI codepage</i>
<code>encodings.utf_8_sig</code>	<i>UTF-8 codec with BOM signature</i>
errno	<i>Standard errno system symbols.</i>
f	
<code>fcntl (Unix)</code>	<i>The <code>fcntl()</code> and <code>ioctl()</code> system calls.</i>
<code>filecmp</code>	<i>Compare files efficiently.</i>
<code>fileinput</code>	<i>Loop over standard input or a list of files.</i>
<code>fnmatch</code>	<i>Unix shell style filename pattern matching.</i>
<code>formatter</code>	<i>Generic output formatter and device interface.</i>
<code>fpectl (Unix)</code>	<i>Provide control for floating point exception handling.</i>
<code>fractions</code>	<i>Rational numbers.</i>
<code>ftplib</code>	<i>FTP protocol client (requires sockets).</i>
<code>functools</code>	<i>Higher order functions and operations on callable objects.</i>
g	
<code>gc</code>	<i>Interface to the cycle-detecting garbage collector.</i>
<code>getopt</code>	<i>Portable parser for command</i>

<code>getpass</code>	<i>Portable reading of passwords and retrieval of the userid.</i>
<code>gettext</code>	<i>Multilingual internationalization services.</i>
<code>glob</code>	<i>Unix shell style pathname pattern expansion.</i>
<code>grp (Unix)</code>	<i>The group database (getgrnam() and friends).</i>
<code>gzip</code>	<i>Interfaces for gzip compression and decompression using file objects.</i>
h	
<code>hashlib</code>	<i>Secure hash and message digest algorithms.</i>
<code>heapq</code>	<i>Heap queue algorithm (a.k.a. priority queue).</i>
<code>hmac</code>	<i>Keyed-Hashing for Message Authentication (HMAC) implementation for Python.</i>
<code>html</code>	<i>Helpers for manipulating HTML.</i>
<code>html.entities</code>	<i>Definitions of HTML general entities.</i>
<code>html.parser</code>	<i>A simple parser that can handle HTML and XHTML.</i>
<code>http</code>	
<code>http.client</code>	<i>HTTP and HTTPS protocol client (requires sockets).</i>
<code>http.cookiejar</code>	<i>Classes for automatic handling of HTTP cookies.</i>
<code>http.cookies</code>	<i>Support for HTTP state management (cookies).</i>

<code>http.server</code>	<i>HTTP server and request handlers.</i>
i	
<code>imaplib</code>	<i>IMAP4 protocol client (requires sockets).</i>
<code>imghdr</code>	<i>Determine the type of image contained in a file or byte stream.</i>
<code>imp</code>	<i>Access the implementation of the import statement.</i>
<code>importlib</code>	<i>An implementation of the import machinery.</i>
<code>importlib.abc</code>	<i>Abstract base classes related to import</i>
<code>importlib.machinery</code>	<i>Importers and path hooks</i>
<code>importlib.util</code>	<i>Importers and path hooks</i>
<code>inspect</code>	<i>Extract information and source code from live objects.</i>
<code>io</code>	<i>Core tools for working with streams.</i>
<code>itertools</code>	<i>Functions creating iterators for efficient looping.</i>
j	
<code>json</code>	<i>Encode and decode the JSON format.</i>
k	
<code>keyword</code>	<i>Test whether a string is a keyword in Python.</i>
l	
<code>lib2to3</code>	<i>the 2to3 library</i>

<code>linecache</code>	<i>This module provides random access to individual lines from text files.</i>
<code>locale</code>	<i>Internationalization services.</i>
<code>logging</code>	<i>Flexible event logging system for applications.</i>
<code>logging.config</code>	<i>Configuration of the logging module.</i>
<code>logging.handlers</code>	<i>Handlers for the logging module.</i>

m	
<code>macpath</code>	<i>Mac OS 9 path manipulation functions.</i>
<code>mailbox</code>	<i>Manipulate mailboxes in various formats</i>
<code>mailcap</code>	<i>Mailcap file handling.</i>
<code>marshal</code>	<i>Convert Python objects to streams of bytes and back (with different constraints).</i>
<code>math</code>	<i>Mathematical functions (sin() etc.).</i>
<code>mimetypes</code>	<i>Mapping of filename extensions to MIME types.</i>
<code>mmap</code>	<i>Interface to memory-mapped files for Unix and Windows.</i>
<code>modulefinder</code>	<i>Find modules used by a script.</i>
<code>msilib (Windows)</code>	<i>Creation of Microsoft Installer files, and CAB files.</i>
<code>msvcrt (Windows)</code>	<i>Miscellaneous useful routines from the MS VC++ runtime.</i>
<code>multiprocessing</code>	<i>Process-based parallelism.</i>
<code>multiprocessing.connection</code>	<i>API for dealing with sockets.</i>
<code>multiprocessing.dummy</code>	<i>Dumb wrapper around threading.</i>

`multiprocessing.managers`

Share data between process with shared objects.

`multiprocessing.pool`

Create pools of processes.

`multiprocessing.sharedctypes`

Allocate ctypes objects from shared memory.

n

`netrc`

Loading of .netrc files.

`nis (Unix)`

Interface to Sun's NIS (Yellow Pages) library.

`nntplib`

NNTP protocol client (requires sockets).

`numbers`

Numeric abstract base classes (Complex, Real, Integral, etc.).

o

`operator`

Functions corresponding to the standard operators.

`optparse`

Deprecated: *Command-line option parsing library.*

`os`

Miscellaneous operating system interfaces.

`os.path`

Operations on pathnames.

`ossaudiodev (Linux, FreeBSD)`

Access to OSS-compatible audio devices.

p

`parser`

Access parse trees for Python source code.

`pdb`

The Python debugger for interactive interpreters.

`pickle`

Convert Python objects to streams of bytes and back.

`pickletools`

Contains extensive comments

<code>pipes</code> (Unix)	<i>about the pickle protocols and pickle-machine opcodes, as well as some useful functions. A Python interface to Unix shell pipelines.</i>
<code>pkgutil</code>	<i>Utilities for the import system.</i>
<code>platform</code>	<i>Retrieves as much platform identifying data as possible.</i>
<code>plistlib</code>	<i>Generate and parse Mac OS X plist files.</i>
<code>poplib</code>	<i>POP3 protocol client (requires sockets).</i>
<code>posix</code> (Unix)	<i>The most common POSIX system calls (normally used via module <code>os</code>).</i>
<code>pprint</code>	<i>Data pretty printer.</i>
<code>profile</code>	<i>Python source profiler.</i>
<code>pstats</code>	<i>Statistics object for use with the profiler.</i>
<code>pty</code> (Linux)	<i>Pseudo-Terminal Handling for Linux.</i>
<code>pwd</code> (Unix)	<i>The password database (<code>getpwnam()</code> and friends).</i>
<code>py_compile</code>	<i>Generate byte-code files from Python source files.</i>
<code>pyclbr</code>	<i>Supports information extraction for a Python class browser.</i>
<code>pydoc</code>	<i>Documentation generator and online help system.</i>

q

<code>queue</code>	<i>A synchronized queue class.</i>
<code>quopri</code>	<i>Encode and decode files using the MIME quoted-printable encoding.</i>

r	
random	<i>Generate pseudo-random numbers with various common distributions.</i>
re	<i>Regular expression operations.</i>
readline (Unix)	<i>GNU readline support for Python.</i>
reprlib	<i>Alternate repr() implementation with size limits.</i>
resource (Unix)	<i>An interface to provide resource usage information on the current process.</i>
rlcompleter	<i>Python identifier completion, suitable for the GNU readline library.</i>
runpy	<i>Locate and run Python modules without importing them first.</i>

S	
sched	<i>General purpose event scheduler.</i>
select	<i>Wait for I/O completion on multiple streams.</i>
shelve	<i>Python object persistence.</i>
shlex	<i>Simple lexical analysis for Unix shell-like languages.</i>
shutil	<i>High-level file operations, including copying.</i>
signal	<i>Set handlers for asynchronous events.</i>
site	<i>A standard way to reference site-specific modules.</i>
smtpd	<i>A SMTP server implementation</i>

<code>smtplib</code>	<i>in Python. SMTP protocol client (requires sockets).</i>
<code>sndhdr</code>	<i>Determine type of a sound file.</i>
<code>socket</code>	<i>Low-level networking interface.</i>
<code>socketserver</code>	<i>A framework for network servers.</i>
<code>spwd (Unix)</code>	<i>The shadow password database (getspnam()) and friends).</i>
<code>sqlite3</code>	<i>A DB-API 2.0 implementation using SQLite 3.x.</i>
<code>ssl</code>	<i>TLS/SSL wrapper for socket objects</i>
<code>stat</code>	<i>Utilities for interpreting the results of os.stat(), os.lstat() and os.fstat().</i>
<code>string</code>	<i>Common string operations.</i>
<code>stringprep</code>	Deprecated: <i>String preparation, as per RFC 3453</i>
<code>struct</code>	<i>Interpret bytes as packed binary data.</i>
<code>subprocess</code>	<i>Subprocess management.</i>
<code>sunau</code>	<i>Provide an interface to the Sun AU sound format.</i>
<code>symbol</code>	<i>Constants representing internal nodes of the parse tree.</i>
<code>symtable</code>	<i>Interface to the compiler's internal symbol tables.</i>
<code>sys</code>	<i>Access system-specific parameters and functions.</i>
<code>sysconfig</code>	<i>Python's configuration information</i>
<code>syslog (Unix)</code>	<i>An interface to the Unix syslog</i>

library routines.

t	
tabnanny	<i>Tool for detecting white space related problems in Python source files in a directory tree.</i>
tarfile	<i>Read and write tar-format archive files.</i>
telnetlib	<i>Telnet client class.</i>
tempfile	<i>Generate temporary files and directories.</i>
termios (Unix)	<i>POSIX style tty control.</i>
test	<i>Regression tests package containing the testing suite for Python.</i>
test.support	<i>Support for Python regression tests.</i>
textwrap	<i>Text wrapping and filling</i>
threading	<i>Thread-based parallelism.</i>
time	<i>Time access and conversions.</i>
timeit	<i>Measure the execution time of small code snippets.</i>
tkinter	<i>Interface to Tcl/Tk for graphical user interfaces</i>
tkinter.scrolledtext (Tk)	<i>Text widget with a vertical scroll bar.</i>
tkinter.tix	<i>Tk Extension Widgets for Tkinter</i>
tkinter.ttk	<i>Tk themed widget set</i>
token	<i>Constants representing terminal nodes of the parse tree.</i>
tokenize	<i>Lexical scanner for Python source code.</i>
trace	<i>Trace or track Python</i>

<code>traceback</code>	<i>statement execution. Print or retrieve a stack traceback.</i>
<code>tty (Unix)</code>	<i>Utility functions that perform common terminal control operations.</i>
<code>turtle</code>	<i>An educational framework for simple graphics applications</i>
<code>types</code>	<i>Names for built-in types.</i>
U	
<code>unicodedata</code>	<i>Access the Unicode Database.</i>
<code>unittest</code>	<i>Unit testing framework for Python.</i>
<code>urllib</code>	
<code>urllib.error</code>	<i>Exception classes raised by <code>urllib.request</code>.</i>
<code>urllib.parse</code>	<i>Parse URLs into or assemble them from components.</i>
<code>urllib.request</code>	<i>Next generation URL opening library.</i>
<code>urllib.response</code>	<i>Response classes used by <code>urllib</code>.</i>
<code>urllib.robotparser</code>	<i>Load a <code>robots.txt</code> file and answer questions about fetchability of other URLs.</i>
<code>uu</code>	<i>Encode and decode files in <code>uuencode</code> format.</i>
<code>uuid</code>	<i>UUID objects (universally unique identifiers) according to RFC 4122</i>
W	
<code>warnings</code>	<i>Issue warning messages and control their disposition.</i>

<code>wave</code>	<i>Provide an interface to the WAV sound format.</i>
<code>weakref</code>	<i>Support for weak references and weak dictionaries.</i>
<code>webbrowser</code>	<i>Easy-to-use controller for Web browsers.</i>
<code>winreg (Windows)</code>	<i>Routines and objects for manipulating the Windows registry.</i>
<code>winsound (Windows)</code>	<i>Access to the sound-playing machinery for Windows.</i>
<code>wsgiref</code>	<i>WSGI Utilities and Reference Implementation.</i>
<code>wsgiref.handlers</code>	<i>WSGI server/gateway base classes.</i>
<code>wsgiref.headers</code>	<i>WSGI response header tools.</i>
<code>wsgiref.simple_server</code>	<i>A simple WSGI HTTP server.</i>
<code>wsgiref.util</code>	<i>WSGI environment utilities.</i>
<code>wsgiref.validate</code>	<i>WSGI conformance checker.</i>

X	
<code>xdrlib</code>	<i>Encoders and decoders for the External Data Representation (XDR).</i>
<code>xml</code>	
<code>xml.dom</code>	<i>Document Object Model API for Python.</i>
<code>xml.dom.minidom</code>	<i>Lightweight Document Object Model (DOM) implementation.</i>
<code>xml.dom.pulldom</code>	<i>Support for building partial DOM trees from SAX events.</i>
<code>xml.etree.ElementTree</code>	<i>Implementation of the ElementTree API.</i>
<code>xml.parsers.expat</code>	<i>An interface to the Expat non-validating XML parser.</i>

<code>xml.parsers.expat.errors</code>	
<code>xml.parsers.expat.model</code>	
<code>xml.sax</code>	<i>Package containing SAX2 base classes and convenience functions.</i>
<code>xml.sax.handler</code>	<i>Base classes for SAX event handlers.</i>
<code>xml.sax.saxutils</code>	<i>Convenience functions and classes for use with SAX.</i>
<code>xml.sax.xmlreader</code>	<i>Interface which SAX-compliant XML parsers must implement.</i>
xmlrpc	
<code>xmlrpc.client</code>	<i>XML-RPC client access.</i>
<code>xmlrpc.server</code>	<i>Basic XML-RPC server implementations.</i>
Z	
<code>zipfile</code>	<i>Read and write ZIP-format archive files.</i>
<code>zipimport</code>	<i>support for importing Python modules from ZIP archives.</i>
<code>zlib</code>	<i>Low-level interface to compression and decompression routines compatible with gzip.</i>

What's New In Python 3.2

Author: Raymond Hettinger

Release: 3.2

Date: February 20, 2011

This article explains the new features in Python 3.2 as compared to 3.1. It focuses on a few highlights and gives a few examples. For full details, see the [Misc/NEWS](#) file.

See also: [PEP 392](#) - Python 3.2 Release Schedule

PEP 384: Defining a Stable ABI

In the past, extension modules built for one Python version were often not usable with other Python versions. Particularly on Windows, every feature release of Python required rebuilding all extension modules that one wanted to use. This requirement was the result of the free access to Python interpreter internals that extension modules could use.

With Python 3.2, an alternative approach becomes available: extension modules which restrict themselves to a limited API (by defining `Py_LIMITED_API`) cannot use many of the internals, but are constrained to a set of API functions that are promised to be stable for several releases. As a consequence, extension modules built for 3.2 in that mode will also work with 3.3, 3.4, and so on. Extension modules that make use of details of memory structures can still be built, but will need to be recompiled for every feature release.

[PEP 384 - Defining a Stable ABI](#)

PEP written by Martin von Löwis.

PEP 389: Argparse Command Line Parsing Module

A new module for command line parsing, `argparse`, was introduced to overcome the limitations of `optparse` which did not provide support for positional arguments (not just options), subcommands, required options and other common patterns of specifying and validating options.

This module has already had widespread success in the community as a third-party module. Being more fully featured than its predecessor, the `argparse` module is now the preferred module for command-line processing. The older module is still being kept available because of the substantial amount of legacy code that depends on it.

Here's an annotated example parser showing features like limiting results to a set of choices, specifying a *metavar* in the help screen, validating that one or more positional arguments is present, and making a required option:

```
import argparse
parser = argparse.ArgumentParser(
    description = 'Manage servers',           # main desc
    epilog = 'Tested on Solaris and Linux') # displayed
parser.add_argument('action',               # argument
    choices = ['deploy', 'start', 'stop'], # three all
    help = 'action on each target')        # help msg
parser.add_argument('targets',              # var name
    metavar = 'HOSTNAME',                  # require o
    nargs = '+',                           # help msg
    help = 'url for target machines')
parser.add_argument('-u', '--user',        # -u or --u
    required = True,                       # make it a
    help = 'login as user')
```

Example of calling the parser on a command string:

```
>>> cmd = 'deploy sneezy.example.com sleepy.example.com -u sky'
>>> result = parser.parse_args(cmd.split())
>>> result.action
'deploy'
>>> result.targets
['sneezy.example.com', 'sleepy.example.com']
>>> result.user
'skycaptain'
```

Example of the parser's automatically generated help:

```
>>> parser.parse_args('-h'.split())

usage: manage_cloud.py [-h] -u USER
                       {deploy,start,stop} HOSTNAME [HOSTNAME .

Manage servers

positional arguments:
  {deploy,start,stop}  action on each target
  HOSTNAME             url for target machines

optional arguments:
  -h, --help          show this help message and exit
  -u USER, --user USER login as user

Tested on Solaris and Linux
```

An especially nice `argparse` feature is the ability to define subparsers, each with their own argument patterns and help displays:

```
import argparse
parser = argparse.ArgumentParser(prog='HELM')
subparsers = parser.add_subparsers()

parser_1 = subparsers.add_parser('launch', help='Launch Control')
parser_1.add_argument('-m', '--missiles', action='store_true')
parser_1.add_argument('-t', '--torpedos', action='store_true')
```

```
parser_m = subparsers.add_parser('move', help='Move Vessel',
                                aliases=('steer', 'turn'))
parser_m.add_argument('-c', '--course', type=int, required=True)
parser_m.add_argument('-s', '--speed', type=int, default=0)
```

```
$ ./helm.py --help # top level help (la
$ ./helm.py launch --help # help for launch op
$ ./helm.py launch --missiles # set missiles=True
$ ./helm.py steer --course 180 --speed 5 # set movement param
```

PEP 389 - New Command Line Parsing Module

PEP written by Steven Bethard.

Upgrading optparse code for details on the differences from *optparse*.

PEP 391: Dictionary Based Configuration for Logging

The `logging` module provided two kinds of configuration, one style with function calls for each option or another style driven by an external file saved in a `configParser` format. Those options did not provide the flexibility to create configurations from JSON or YAML files, nor did they support incremental configuration, which is needed for specifying logger options from a command line.

To support a more flexible style, the module now offers `logging.config.dictConfig()` for specifying logging configuration with plain Python dictionaries. The configuration options include formatters, handlers, filters, and loggers. Here's a working example of a configuration dictionary:

```
{"version": 1,
 "formatters": {"brief": {"format": "%(levelname)-8s: %(name)-15s"},
                "full": {"format": "%(asctime)s %(name)-15s %(levelname)-8s"}},
 "handlers": {"console": {"class": "logging.StreamHandler",
                          "formatter": "brief",
                          "level": "INFO",
                          "stream": "ext://sys.stdout"},
              "console_priority": {"class": "logging.StreamHandler",
                                   "formatter": "full",
                                   "level": "ERROR",
                                   "stream": "ext://sys.stderr"}},
 "root": {"level": "DEBUG", "handlers": ["console", "console_pr
```

If that dictionary is stored in a file called `conf.json`, it can be loaded and called with code like this:

```
>>> import json, logging.config
>>> with open('conf.json') as f:
    conf = json.load(f)
>>> logging.config.dictConfig(conf)
>>> logging.info("Transaction completed normally")
INFO      : root      : Transaction completed normally
>>> logging.critical("Abnormal termination")
2011-02-17 11:14:36,694 root      CRITICAL Abnormal termi
```

PEP 391 - Dictionary Based Configuration for Logging

PEP written by Vinay Sajip.

PEP 3148: The `concurrent.futures` module

Code for creating and managing concurrency is being collected in a new top-level namespace, *concurrent*. Its first member is a *futures* package which provides a uniform high-level interface for managing threads and processes.

The design for `concurrent.futures` was inspired by *java.util.concurrent.package*. In that model, a running call and its result are represented by a **Future** object that abstracts features common to threads, processes, and remote procedure calls. That object supports status checks (running or done), timeouts, cancellations, adding callbacks, and access to results or exceptions.

The primary offering of the new module is a pair of executor classes for launching and managing calls. The goal of the executors is to make it easier to use existing tools for making parallel calls. They save the effort needed to setup a pool of resources, launch the calls, create a results queue, add time-out handling, and limit the total number of threads, processes, or remote procedure calls.

Ideally, each application should share a single executor across multiple components so that process and thread limits can be centrally managed. This solves the design challenge that arises when each component has its own competing strategy for resource management.

Both classes share a common interface with three methods: `submit()` for scheduling a callable and returning a **Future** object; `map()` for scheduling many asynchronous calls at a time, and `shutdown()` for freeing resources. The class is a *context manager* and can be used in a `with` statement to assure that resources are automatically released when currently pending futures are done

executing.

A simple of example of `ThreadPoolExecutor` is a launch of four parallel threads for copying files:

```
import concurrent.futures, shutil
with concurrent.futures.ThreadPoolExecutor(max_workers=4) as e:
    e.submit(shutil.copy, 'src1.txt', 'dest1.txt')
    e.submit(shutil.copy, 'src2.txt', 'dest2.txt')
    e.submit(shutil.copy, 'src3.txt', 'dest3.txt')
    e.submit(shutil.copy, 'src3.txt', 'dest4.txt')
```

Code for computing prime numbers in parallel, an example demonstrating `ProcessPoolExecutor`.

PEP 3147: PYC Repository Directories

Python's scheme for caching bytecode in `.pyc` files did not work well in environments with multiple Python interpreters. If one interpreter encountered a cached file created by another interpreter, it would recompile the source and overwrite the cached file, thus losing the benefits of caching.

The issue of “pyc fights” has become more pronounced as it has become commonplace for Linux distributions to ship with multiple versions of Python. These conflicts also arise with CPython alternatives such as Unladen Swallow.

To solve this problem, Python's import machinery has been extended to use distinct filenames for each interpreter. Instead of Python 3.2 and Python 3.3 and Unladen Swallow each competing for a file called “`mymodule.pyc`”, they will now look for “`mymodule.cpython-32.pyc`”, “`mymodule.cpython-33.pyc`”, and “`mymodule.unladen10.pyc`”. And to prevent all of these new files from cluttering source directories, the `pyc` files are now collected in a “`__pycache__`” directory stored under the package directory.

Aside from the filenames and target directories, the new scheme has a few aspects that are visible to the programmer:

- Imported modules now have a `__cached__` attribute which stores the name of the actual file that was imported:

```
>>> import collections
>>> collections.__cached__
'c:/py32/lib/__pycache__/collections.cpython-32.pyc'
```

- The tag that is unique to each interpreter is accessible from the `imp` module:
-

```
>>> import imp
>>> imp.get_tag()
'cpython-32'
```

- Scripts that try to deduce source filename from the imported file now need to be smarter. It is no longer sufficient to simply strip the “c” from a “.pyc” filename. Instead, use the new functions in the `imp` module:

```
>>> imp.source_from_cache('c:/py32/lib/__pycache__/collecti
'c:/py32/lib/collections.py'
>>> imp.cache_from_source('c:/py32/lib/collections.py')
'c:/py32/lib/__pycache__/collections.cpython-32.pyc'
```

- The `py_compile` and `compileall` modules have been updated to reflect the new naming convention and target directory. The command-line invocation of `compileall` has new options: `-i` for specifying a list of files and directories to compile and `-b` which causes bytecode files to be written to their legacy location rather than `__pycache__`.
- The `importlib.abc` module has been updated with new *abstract base classes* for loading bytecode files. The obsolete ABCs, `PyLoader` and `PyPycLoader`, have been deprecated (instructions on how to stay Python 3.1 compatible are included with the documentation).

See also:

PEP 3147 - PYC Repository Directories

PEP written by Barry Warsaw.

PEP 3149: ABI Version Tagged .so Files

The PYC repository directory allows multiple bytecode cache files to be co-located. This PEP implements a similar mechanism for shared object files by giving them a common directory and distinct names for each version.

The common directory is “pyshared” and the file names are made distinct by identifying the Python implementation (such as CPython, PyPy, Jython, etc.), the major and minor version numbers, and optional build flags (such as “d” for debug, “m” for pymalloc, “u” for wide-unicode). For an arbitrary package “foo”, you may see these files when the distribution package is installed:

```
/usr/share/pyshared/foo.cpython-32m.so  
/usr/share/pyshared/foo.cpython-33md.so
```

In Python itself, the tags are accessible from functions in the `sysconfig` module:

```
>>> import sysconfig  
>>> sysconfig.get_config_var('SOABI')      # find the version tag  
'cpython-32mu'  
>>> sysconfig.get_config_var('SO')        # find the full filename  
'./cpython-32mu.so'
```

See also:

[PEP 3149 - ABI Version Tagged .so Files](#)

PEP written by Barry Warsaw.

PEP 3333: Python Web Server Gateway Interface v1.0.1

This informational PEP clarifies how bytes/text issues are to be handled by the WSGI protocol. The challenge is that string handling in Python 3 is most conveniently handled with the `str` type even though the HTTP protocol is itself bytes oriented.

The PEP differentiates so-called *native strings* that are used for request/response headers and metadata versus *byte strings* which are used for the bodies of requests and responses.

The *native strings* are always of type `str` but are restricted to code points between `U+0000` through `U+00FF` which are translatable to bytes using *Latin-1* encoding. These strings are used for the keys and values in the environment dictionary and for response headers and statuses in the `start_response()` function. They must follow [RFC 2616](#) with respect to encoding. That is, they must either be *ISO-8859-1* characters or use [RFC 2047](#) MIME encoding.

For developers porting WSGI applications from Python 2, here are the salient points:

- If the app already used strings for headers in Python 2, no change is needed.
- If instead, the app encoded output headers or decoded input headers, then the headers will need to be re-encoded to Latin-1. For example, an output header encoded in utf-8 was using `h.encode('utf-8')` now needs to convert from bytes to native strings using `h.encode('utf-8').decode('latin-1')`.
- Values yielded by an application or sent using the `write()` method must be byte strings. The `start_response()` function

and `environ` must use native strings. The two cannot be mixed.

For server implementers writing CGI-to-WSGI pathways or other CGI-style protocols, the users must to be able access the environment using native strings even though the underlying platform may have a different convention. To bridge this gap, the `wsgiref` module has a new function, `wsgiref.handlers.read_environ()` for transcoding CGI variables from `os.environ` into native strings and returning a new dictionary.

See also:

PEP 3333 - Python Web Server Gateway Interface v1.0.1

PEP written by Phillip Eby.

Other Language Changes

Some smaller changes made to the core Python language are:

- String formatting for `format()` and `str.format()` gained new capabilities for the format character `#`. Previously, for integers in binary, octal, or hexadecimal, it caused the output to be prefixed with `'0b'`, `'0o'`, or `'0x'` respectively. Now it can also handle floats, complex, and Decimal, causing the output to always have a decimal point even when no digits follow it.

```
>>> format(20, '#o')
'0o24'
>>> format(12.34, '#5.0f')
' 12.'
```

(Suggested by Mark Dickinson and implemented by Eric Smith in [issue 7094](#).)

- There is also a new `str.format_map()` method that extends the capabilities of the existing `str.format()` method by accepting arbitrary *mapping* objects. This new method makes it possible to use string formatting with any of Python's many dictionary-like objects such as `defaultdict`, `Shelf`, `ConfigParser`, or `dbm`. It is also useful with custom `dict` subclasses that normalize keys before look-up or that supply a `__missing__()` method for unknown keys:

```
>>> import shelve
>>> d = shelve.open('tmp.sh1')
>>> 'The {project_name} status is {status} as of {date}'.fo
'The testing project status is green as of February 15, 201

>>> class LowerCasedDict(dict):
    def __getitem__(self, key):
        return dict.__getitem__(self, key.lower())
```

```

>>> lcd = LowerCasedDict(part='widgets', quantity=10)
>>> 'There are {QUANTITY} {Part} in stock'.format_map(lcd)
'There are 10 widgets in stock'

>>> class PlaceholderDict(dict):
        def __missing__(self, key):
            return '<{}>'.format(key)
>>> 'Hello {name}, welcome to {location}'.format_map(Placeh
'Hello <name>, welcome to <location>'

```

(Suggested by Raymond Hettinger and implemented by Eric Smith in [issue 6081](#).)

- The interpreter can now be started with a quiet option, `-q`, to prevent the copyright and version information from being displayed in the interactive mode. The option can be introspected using the `sys.flags` attribute:

```

$ python -q
>>> sys.flags
sys.flags(debug=0, division_warning=0, inspect=0, interacti
optimize=0, dont_write_bytecode=0, no_user_site=0, no_site=
ignore_environment=0, verbose=0, bytes_warning=0, quiet=1)

```

(Contributed by Marcin Wojdyr in [issue 1772833](#)).

- The `hasattr()` function works by calling `getattr()` and detecting whether an exception is raised. This technique allows it to detect methods created dynamically by `__getattr__()` or `__getattribute__()` which would otherwise be absent from the class dictionary. Formerly, `hasattr` would catch any exception, possibly masking genuine errors. Now, `hasattr` has been tightened to only catch `AttributeError` and let other exceptions pass through:

```

>>> class A:
        @property

```

```
def f(self):
    return 1 // 0

>>> a = A()
>>> hasattr(a, 'f')
Traceback (most recent call last):
...
ZeroDivisionError: integer division or modulo by zero
```

(Discovered by Yury Selivanov and fixed by Benjamin Peterson; issue 9666.)

- The `str()` of a float or complex number is now the same as its `repr()`. Previously, the `str()` form was shorter but that just caused confusion and is no longer needed now that the shortest possible `repr()` is displayed by default:

```
>>> import math
>>> repr(math.pi)
'3.141592653589793'
>>> str(math.pi)
'3.141592653589793'
```

(Proposed and implemented by Mark Dickinson; issue 9337.)

- `memoryview` objects now have a `release()` method and they also now support the context manager protocol. This allows timely release of any resources that were acquired when requesting a buffer from the original object.

```
>>> with memoryview(b'abcdefgh') as v:
    print(v.tolist())
[97, 98, 99, 100, 101, 102, 103, 104]
```

(Added by Antoine Pitrou; issue 9757.)

- Previously it was illegal to delete a name from the local namespace if it occurs as a free variable in a nested block:

```
def outer(x):
    def inner():
        return x
    inner()
    del x
```

This is now allowed. Remember that the target of an `except` clause is cleared, so this code which used to work with Python 2.6, raised a `SyntaxError` with Python 3.1 and now works again:

```
def f():
    def print_error():
        print(e)
    try:
        something
    except Exception as e:
        print_error()
        # implicit "del e" here
```

(See [issue 4617](#).)

- The internal `structsequence` tool now creates subclasses of `tuple`. This means that C structures like those returned by `os.stat()`, `time.gmtime()`, and `sys.version_info` now work like a *named tuple* and now work with functions and methods that expect a tuple as an argument. This is a big step forward in making the C structures as flexible as their pure Python counterparts:

```
>>> isinstance(sys.version_info, tuple)
True
>>> 'Version %d.%d.%d %s(%d)' % sys.version_info
'Version 3.2.0 final(0)'
```

(Suggested by Arfrever Frehtes Taifersar Arahesis and implemented by Benjamin Peterson in [issue 8413](#).)

- Warnings are now easier to control using the `PYTHONWARNINGS`

environment variable as an alternative to using `-w` at the command line:

```
$ export PYTHONWARNINGS='ignore::RuntimeWarning::,once::Uni
```

(Suggested by Barry Warsaw and implemented by Philip Jenvey in [issue 7301](#).)

- A new warning category, `ResourceWarning`, has been added. It is emitted when potential issues with resource consumption or cleanup are detected. It is silenced by default in normal release builds but can be enabled through the means provided by the `warnings` module, or on the command line.

A `ResourceWarning` is issued at interpreter shutdown if the `gc.garbage` list isn't empty, and if `gc.DEBUG_UNCOLLECTABLE` is set, all uncollectable objects are printed. This is meant to make the programmer aware that their code contains object finalization issues.

A `ResourceWarning` is also issued when a *file object* is destroyed without having been explicitly closed. While the deallocator for such object ensures it closes the underlying operating system resource (usually, a file descriptor), the delay in deallocating the object could produce various issues, especially under Windows. Here is an example of enabling the warning from the command line:

```
$ python -q -Wdefault
>>> f = open("foo", "wb")
>>> del f
__main__:1: ResourceWarning: unclosed file <_io.BufferedWri
```

(Added by Antoine Pitrou and Georg Brandl in [issue 10093](#) and

issue 477863.)

- `range` objects now support *index* and *count* methods. This is part of an effort to make more objects fully implement the `collections.Sequence` *abstract base class*. As a result, the language will have a more uniform API. In addition, `range` objects now support slicing and negative indices, even with values larger than `sys.maxsize`. This makes *range* more interoperable with lists:

```
>>> range(0, 100, 2).count(10)
1
>>> range(0, 100, 2).index(10)
5
>>> range(0, 100, 2)[5]
10
>>> range(0, 100, 2)[0:5]
range(0, 10, 2)
```

(Contributed by Daniel Stutzbach in [issue 9213](#), by Alexander Belopolsky in [issue 2690](#), and by Nick Coghlan in [issue 10889](#).)

- The `callable()` builtin function from Py2.x was resurrected. It provides a concise, readable alternative to using an *abstract base class* in an expression like `isinstance(x, collections.Callable)`:

```
>>> callable(max)
True
>>> callable(20)
False
```

(See [issue 10518](#).)

- Python's import mechanism can now load modules installed in directories with non-ASCII characters in the path name. This solved an aggravating problem with home directories for users

with non-ASCII characters in their usernames.

(Required extensive work by Victor Stinner in [issue 9425](#).)

New, Improved, and Deprecated Modules

Python's standard library has undergone significant maintenance efforts and quality improvements.

The biggest news for Python 3.2 is that the `email` package, `mailbox` module, and `nntplib` modules now work correctly with the bytes/text model in Python 3. For the first time, there is correct handling of messages with mixed encodings.

Throughout the standard library, there has been more careful attention to encodings and text versus bytes issues. In particular, interactions with the operating system are now better able to exchange non-ASCII data using the Windows MBCS encoding, locale-aware encodings, or UTF-8.

Another significant win is the addition of substantially better support for *SSL* connections and security certificates.

In addition, more classes now implement a *context manager* to support convenient and reliable resource clean-up using a `with` statement.

email

The usability of the `email` package in Python 3 has been mostly fixed by the extensive efforts of R. David Murray. The problem was that emails are typically read and stored in the form of `bytes` rather than `str` text, and they may contain multiple encodings within a single email. So, the email package had to be extended to parse and generate email messages in bytes format.

- New functions `message_from_bytes()` and

`message_from_binary_file()`, and new classes `BytesFeedParser` and `BytesParser` allow binary message data to be parsed into model objects.

- Given bytes input to the model, `get_payload()` will by default decode a message body that has a *Content-Transfer-Encoding* of *8bit* using the charset specified in the MIME headers and return the resulting string.
- Given bytes input to the model, `Generator` will convert message bodies that have a *Content-Transfer-Encoding* of *8bit* to instead have a *7bit Content-Transfer-Encoding*.

Headers with unencoded non-ASCII bytes are deemed to be **RFC 2047**-encoded using the *unknown-8bit* character set.

- A new class `BytesGenerator` produces bytes as output, preserving any unchanged non-ASCII data that was present in the input used to build the model, including message bodies with a *Content-Transfer-Encoding* of *8bit*.
- The `smtpLib SMTP` class now accepts a byte string for the *msg* argument to the `sendmail()` method, and a new method, `send_message()` accepts a `Message` object and can optionally obtain the *from_addr* and *to_addrs* addresses directly from the object.

(Proposed and implemented by R. David Murray, [issue 4661](#) and [issue 10321](#).)

elementtree

The `xml.etree.ElementTree` package and its `xml.etree.cElementTree` counterpart have been updated to version 1.3.

Several new and useful functions and methods have been added:

- `xml.etree.ElementTree.fromstringlist()` which builds an XML document from a sequence of fragments
- `xml.etree.ElementTree.register_namespace()` for registering a global namespace prefix
- `xml.etree.ElementTree.tostringlist()` for string representation including all sublists
- `xml.etree.ElementTree.Element.extend()` for appending a sequence of zero or more elements
- `xml.etree.ElementTree.Element.iterfind()` searches an element and subelements
- `xml.etree.ElementTree.Element.itertext()` creates a text iterator over an element and its subelements
- `xml.etree.ElementTree.TreeBuilder.end()` closes the current element
- `xml.etree.ElementTree.TreeBuilder.doctype()` handles a doctype declaration

Two methods have been deprecated:

- `xml.etree.ElementTree.getchildren()` USE `list(elem)` instead.
- `xml.etree.ElementTree.getiterator()` USE `Element.iter` instead.

For details of the update, see [Introducing ElementTree](#) on Fredrik Lundh's website.

(Contributed by Florent Xicluna and Fredrik Lundh, [issue 6472](#).)

functools

- The `functools` module includes a new decorator for caching function calls. `functools.lru_cache()` can save repeated

queries to an external resource whenever the results are expected to be the same.

For example, adding a caching decorator to a database query function can save database accesses for popular searches:

```
>>> import functools
>>> @functools.lru_cache(maxsize=300)
>>> def get_phone_number(name):
    c = conn.cursor()
    c.execute('SELECT phonenumber FROM phonenumber WHERE
    return c.fetchone()[0]
```

```
>>> for name in user_requests:
    get_phone_number(name)           # cached lookup
```

To help with choosing an effective cache size, the wrapped function is instrumented for tracking cache statistics:

```
>>> get_phone_number.cache_info()
CacheInfo(hits=4805, misses=980, maxsize=300, currsize=300)
```

If the phonenumber table gets updated, the outdated contents of the cache can be cleared with:

```
>>> get_phone_number.cache_clear()
```

(Contributed by Raymond Hettinger and incorporating design ideas from Jim Baker, Miki Tebeka, and Nick Coghlan; see [recipe 498245](#), [recipe 577479](#), [issue 10586](#), and [issue 10593](#).)

- The `functools.wraps()` decorator now adds a `__wrapped__` attribute pointing to the original callable function. This allows wrapped functions to be introspected. It also copies `__annotations__` if defined. And now it also gracefully skips over missing attributes such as `__doc__` which might not be defined

for the wrapped callable.

In the above example, the cache can be removed by recovering the original function:

```
>>> get_phone_number = get_phone_number.__wrapped__ # un
```

(By Nick Coghlan and Terrence Cole; [issue 9567](#), [issue 3445](#), and [issue 8814](#).)

- To help write classes with rich comparison methods, a new decorator `functools.total_ordering()` will use a existing equality and inequality methods to fill in the remaining methods.

For example, supplying `__eq__` and `__lt__` will enable `total_ordering()` to fill-in `__le__`, `__gt__` and `__ge__`:

```
@total_ordering
class Student:
    def __eq__(self, other):
        return ((self.lastname.lower(), self.firstname.lower()
                (other.lastname.lower(), other.firstname.lo
    def __lt__(self, other):
        return ((self.lastname.lower(), self.firstname.lower()
                (other.lastname.lower(), other.firstname.lo
```

With the `total_ordering` decorator, the remaining comparison methods are filled in automatically.

(Contributed by Raymond Hettinger.)

- To aid in porting programs from Python 2, the `functools.cmp_to_key()` function converts an old-style comparison function to modern *key function*:

```
>>> # locale-aware sort order
>>> sorted(iterable, key=cmp_to_key(locale.strcoll))
```

For sorting examples and a brief sorting tutorial, see the [Sorting HowTo](#) tutorial.

(Contributed by Raymond Hettinger.)

itertools

- The `itertools` module has a new `accumulate()` function modeled on APL's *scan* operator and Numpy's *accumulate* function:

```
>>> from itertools import accumulate
>>> list(accumulate([8, 2, 50]))
[8, 10, 60]
```

```
>>> prob_dist = [0.1, 0.4, 0.2, 0.3]
>>> list(accumulate(prob_dist))      # cumulative probabili
[0.1, 0.5, 0.7, 1.0]
```

For an example using `accumulate()`, see the [examples for the random module](#).

(Contributed by Raymond Hettinger and incorporating design suggestions from Mark Dickinson.)

collections

- The `collections.Counter` class now has two forms of in-place subtraction, the existing `-=` operator for [saturating subtraction](#) and the new `subtract()` method for regular subtraction. The former is suitable for [multisets](#) which only have positive counts, and the latter is more suitable for use cases that allow negative counts:

```
>>> tally = Counter(dogs=5, cat=3)
>>> tally -= Counter(dogs=2, cats=8)    # saturating subtra
>>> tally
Counter({'dogs': 3})
```

```
>>> tally = Counter(dogs=5, cats=3)
>>> tally.subtract(dogs=2, cats=8)    # regular subtracti
>>> tally
Counter({'dogs': 3, 'cats': -5})
```

(Contributed by Raymond Hettinger.)

- The `collections.OrderedDict` class has a new method `move_to_end()` which takes an existing key and moves it to either the first or last position in the ordered sequence.

The default is to move an item to the last position. This is equivalent of renewing an entry with `od[k] = od.pop(k)`.

A fast move-to-end operation is useful for resequencing entries. For example, an ordered dictionary can be used to track order of access by aging entries from the oldest to the most recently accessed.

```
>>> d = OrderedDict.fromkeys(['a', 'b', 'X', 'd', 'e'])
>>> list(d)
['a', 'b', 'X', 'd', 'e']
>>> d.move_to_end('X')
>>> list(d)
['a', 'b', 'd', 'e', 'X']
```

(Contributed by Raymond Hettinger.)

- The `collections.deque` class grew two new methods `count()` and `reverse()` that make them more substitutable for `list` objects:

```
>>> d = deque('simsalabim')
>>> d.count('s')
2
>>> d.reverse()
>>> d
deque(['m', 'i', 'b', 'a', 'l', 'a', 's', 'm', 'i', 's'])
```

(Contributed by Raymond Hettinger.)

threading

The `threading` module has a new `Barrier` synchronization class for making multiple threads wait until all of them have reached a common barrier point. Barriers are useful for making sure that a task with multiple preconditions does not run until all of the predecessor tasks are complete.

Barriers can work with an arbitrary number of threads. This is a generalization of a `Rendezvous` which is defined for only two threads.

Implemented as a two-phase cyclic barrier, `Barrier` objects are suitable for use in loops. The separate *filling* and *draining* phases assure that all threads get released (drained) before any one of them can loop back and re-enter the barrier. The barrier fully resets after each cycle.

Example of using barriers:

```
from threading import Barrier, Thread

def get_votes(site):
    ballots = conduct_election(site)
    all_polls_closed.wait()          # do not count until all poll
    totals = summarize(ballots)
    publish(site, totals)

all_polls_closed = Barrier(len(sites))
for site in sites:
```

```
Thread(target=get_votes, args=(site,)).start()
```

In this example, the barrier enforces a rule that votes cannot be counted at any polling site until all polls are closed. Notice how a solution with a barrier is similar to one with `threading.Thread.join()`, but the threads stay alive and continue to do work (summarizing ballots) after the barrier point is crossed.

If any of the predecessor tasks can hang or be delayed, a barrier can be created with an optional *timeout* parameter. Then if the timeout period elapses before all the predecessor tasks reach the barrier point, all waiting threads are released and a `BrokenBarrierError` exception is raised:

```
def get_votes(site):
    ballots = conduct_election(site)
    try:
        all_polls_closed.wait(timeout = midnight - time.now())
    except BrokenBarrierError:
        lockbox = seal_ballots(ballots)
        queue.put(lockbox)
    else:
        totals = summarize(ballots)
        publish(site, totals)
```

In this example, the barrier enforces a more robust rule. If some election sites do not finish before midnight, the barrier times-out and the ballots are sealed and deposited in a queue for later handling.

See [Barrier Synchronization Patterns](#) for more examples of how barriers can be used in parallel computing. Also, there is a simple but thorough explanation of barriers in [The Little Book of Semaphores](#), *section 3.6*.

(Contributed by Kristján Valur Jónsson with an API review by Jeffrey Yasskin in [issue 8777](#).)

datetime and time

- The `datetime` module has a new type `timezone` that implements the `tzinfo` interface by returning a fixed UTC offset and timezone name. This makes it easier to create timezone-aware datetime objects:

```
>>> from datetime import datetime, timezone

>>> datetime.now(timezone.utc)
datetime.datetime(2010, 12, 8, 21, 4, 2, 923754, tzinfo=dat

>>> datetime.strptime("01/01/2000 12:00 +0000", "%m/%d/%Y %
datetime.datetime(2000, 1, 1, 12, 0, tzinfo=datetime.timezo
```

- Also, `timedelta` objects can now be multiplied by `float` and divided by `float` and `int` objects. And `timedelta` objects can now divide one another.
- The `datetime.date.strptime()` method is no longer restricted to years after 1900. The new supported year range is from 1000 to 9999 inclusive.
- Whenever a two-digit year is used in a time tuple, the interpretation has been governed by `time.accept2dyear`. The default is `True` which means that for a two-digit year, the century is guessed according to the POSIX rules governing the `%y` `strptime` format.

Starting with Py3.2, use of the century guessing heuristic will emit a `DeprecationWarning`. Instead, it is recommended that `time.accept2dyear` be set to `False` so that large date ranges can be used without guesswork:

```
>>> import time, warnings
```

```

>>> warnings.resetwarnings()           # remove the default warn
>>> time.accept2dyear = True           # guess whether 11 means
>>> time.asctime((11, 1, 1, 12, 34, 56, 4, 1, 0))
Warning (from warnings module):
...
DeprecationWarning: Century info guessed for a 2-digit year
'Fri Jan  1 12:34:56 2011'

>>> time.accept2dyear = False         # use the full range of a
>>> time.asctime((11, 1, 1, 12, 34, 56, 4, 1, 0))
'Fri Jan  1 12:34:56 11'

```

Several functions now have significantly expanded date ranges. When `time.accept2dyear` is false, the `time.asctime()` function will accept any year that fits in a C int, while the `time.mktime()` and `time.strptime()` functions will accept the full range supported by the corresponding operating system functions.

(Contributed by Alexander Belopolsky and Victor Stinner in [issue 1289118](#), [issue 5094](#), [issue 6641](#), [issue 2706](#), [issue 1777412](#), [issue 8013](#), and [issue 10827](#).)

math

The `math` module has been updated with six new functions inspired by the C99 standard.

The `isfinite()` function provides a reliable and fast way to detect special values. It returns *True* for regular numbers and *False* for *Nan* or *Infinity*:

```

>>> [isfinite(x) for x in (123, 4.56, float('Nan'), float('Inf'))]
[True, True, False, False]

```

The `expm1()` function computes e^{x-1} for small values of x without

incurring the loss of precision that usually accompanies the subtraction of nearly equal quantities:

```
>>> expm1(0.013671875) # more accurate way to compute e**x-1
0.013765762467652909
```

The `erf()` function computes a probability integral or Gaussian error function. The complementary error function, `erfc()`, is `1 - erf(x)`:

```
>>> erf(1.0/sqrt(2.0)) # portion of normal distribution withi
0.682689492137086
>>> erfc(1.0/sqrt(2.0)) # portion of normal distribution outsi
0.31731050786291404
>>> erf(1.0/sqrt(2.0)) + erfc(1.0/sqrt(2.0))
1.0
```

The `gamma()` function is a continuous extension of the factorial function. See http://en.wikipedia.org/wiki/Gamma_function for details. Because the function is related to factorials, it grows large even for small values of x , so there is also a `lgamma()` function for computing the natural logarithm of the gamma function:

```
>>> gamma(7.0) # six factorial
720.0
>>> lgamma(801.0) # log(800 factorial)
4551.950730698041
```

(Contributed by Mark Dickinson.)

abc

The `abc` module now supports `abstractclassmethod()` and `abstractstaticmethod()`.

These tools make it possible to define an *abstract base class* that

requires a particular `classmethod()` or `staticmethod()` to be implemented:

```
class Temperature(metaclass=abc.ABCMeta):
    @abc.abstractclassmethod
    def from_fahrenheit(cls, t):
        ...
    @abc.abstractclassmethod
    def from_celsius(cls, t):
        ...
```

(Patch submitted by Daniel Urban; [issue 5867](#).)

io

The `io.BytesIO` has a new method, `getbuffer()`, which provides functionality similar to `memoryview()`. It creates an editable view of the data without making a copy. The buffer's random access and support for slice notation are well-suited to in-place editing:

```
>>> REC_LEN, LOC_START, LOC_LEN = 34, 7, 11

>>> def change_location(buffer, record_number, location):
    start = record_number * REC_LEN + LOC_START
    buffer[start: start+LOC_LEN] = location

>>> import io

>>> byte_stream = io.BytesIO(
    b'G3805 storeroom Main chassis   '
    b'X7899 shipping  Reserve cog    '
    b'L6988 receiving Primary sprocket'
)
>>> buffer = byte_stream.getbuffer()
>>> change_location(buffer, 1, b'warehouse ')
>>> change_location(buffer, 0, b'showroom ')
>>> print(byte_stream.getvalue())
b'G3805 showroom Main chassis   '
b'X7899 warehouse Reserve cog   '
b'L6988 receiving Primary sprocket'
```

(Contributed by Antoine Pitrou in [issue 5506](#).)

reprlib

When writing a `__repr__()` method for a custom container, it is easy to forget to handle the case where a member refers back to the container itself. Python's builtin objects such as `list` and `set` handle self-reference by displaying `"..."` in the recursive part of the representation string.

To help write such `__repr__()` methods, the `reprlib` module has a new decorator, `recursive_repr()`, for detecting recursive calls to `__repr__()` and substituting a placeholder string instead:

```
>>> class MyList(list):
    @recursive_repr()
    def __repr__(self):
        return '<' + '|'.join(map(repr, self)) + '>'

>>> m = MyList('abc')
>>> m.append(m)
>>> m.append('x')
>>> print(m)
<'a'|'b'|'c'|...|'x'>
```

(Contributed by Raymond Hettinger in [issue 9826](#) and [issue 9840](#).)

logging

In addition to dictionary-based configuration described above, the `logging` package has many other improvements.

The logging documentation has been augmented by a *basic tutorial*, an *advanced tutorial*, and a *cookbook* of logging recipes. These documents are the fastest way to learn about logging.

The `logging.basicConfig()` set-up function gained a `style` argument

to support three different types of string formatting. It defaults to “%” for traditional %-formatting, can be set to “{” for the new `str.format()` style, or can be set to “\$” for the shell-style formatting provided by `string.Template`. The following three configurations are equivalent:

```
>>> from logging import basicConfig
>>> basicConfig(style='%', format="%%(name)s -> %(levelname)s: %
>>> basicConfig(style='{', format="{name} -> {levelname} {messa
>>> basicConfig(style='$', format="$name -> $levelname: $messag
```

If no configuration is set-up before a logging event occurs, there is now a default configuration using a `StreamHandler` directed to `sys.stderr` for events of `WARNING` level or higher. Formerly, an event occurring before a configuration was set-up would either raise an exception or silently drop the event depending on the value of `logging.raiseExceptions`. The new default handler is stored in `logging.lastResort`.

The use of filters has been simplified. Instead of creating a `Filter` object, the predicate can be any Python callable that returns `True` or `False`.

There were a number of other improvements that add flexibility and simplify configuration. See the module documentation for a full listing of changes in Python 3.2.

CSV

The `csv` module now supports a new dialect, `unix_dialect`, which applies quoting for all fields and a traditional Unix style with `'\n'` as the line terminator. The registered dialect name is `unix`.

The `csv.DictWriter` has a new method, `writeheader()` for writing-out

an initial row to document the field names:

```
>>> import csv, sys
>>> w = csv.DictWriter(sys.stdout, ['name', 'dept'], dialect='u
>>> w.writeheader()
"name","dept"
>>> w.writerows([
    {'name': 'tom', 'dept': 'accounting'},
    {'name': 'susan', 'dept': 'Sales1'}])
"tom","accounting"
"susan","sales"
```

(New dialect suggested by Jay Talbot in [issue 5975](#), and the new method suggested by Ed Abraham in [issue 1537721](#).)

contextlib

There is a new and slightly mind-blowing tool `ContextDecorator` that is helpful for creating a *context manager* that does double duty as a function decorator.

As a convenience, this new functionality is used by `contextmanager()` so that no extra effort is needed to support both roles.

The basic idea is that both context managers and function decorators can be used for pre-action and post-action wrappers. Context managers wrap a group of statements using a `with` statement, and function decorators wrap a group of statements enclosed in a function. So, occasionally there is a need to write a pre-action or post-action wrapper that can be used in either role.

For example, it is sometimes useful to wrap functions or groups of statements with a logger that can track the time of entry and time of exit. Rather than writing both a function decorator and a context manager for the task, the `contextmanager()` provides both capabilities in a single definition:

```

from contextlib import contextmanager
import logging

logging.basicConfig(level=logging.INFO)

@contextmanager
def track_entry_and_exit(name):
    logging.info('Entering: {}'.format(name))
    yield
    logging.info('Exiting: {}'.format(name))

```

Formerly, this would have only been usable as a context manager:

```

with track_entry_and_exit('widget loader'):
    print('Some time consuming activity goes here')
    load_widget()

```

Now, it can be used as a decorator as well:

```

@track_entry_and_exit('widget loader')
def activity():
    print('Some time consuming activity goes here')
    load_widget()

```

Trying to fulfill two roles at once places some limitations on the technique. Context managers normally have the flexibility to return an argument usable by a `with` statement, but there is no parallel for function decorators.

In the above example, there is not a clean way for the `track_entry_and_exit` context manager to return a logging instance for use in the body of enclosed statements.

(Contributed by Michael Foord in [issue 9110](#).)

decimal and fractions

Mark Dickinson crafted an elegant and efficient scheme for assuring that different numeric datatypes will have the same hash value

whenever their actual values are equal ([issue 8188](#)):

```
assert hash(Fraction(3, 2)) == hash(1.5) == \
       hash(Decimal("1.5")) == hash(complex(1.5, 0))
```

Some of the hashing details are exposed through a new attribute, `sys.hash_info`, which describes the bit width of the hash value, the prime modulus, the hash values for *infinity* and *nan*, and the multiplier used for the imaginary part of a number:

```
>>> sys.hash_info
sys.hash_info(width=64, modulus=2305843009213693951, inf=314159
```

An early decision to limit the inter-operability of various numeric types has been relaxed. It is still unsupported (and ill-advised) to have implicit mixing in arithmetic expressions such as `Decimal('1.1') + float('1.1')` because the latter loses information in the process of constructing the binary float. However, since existing floating point value can be converted losslessly to either a decimal or rational representation, it makes sense to add them to the constructor and to support mixed-type comparisons.

- The `decimal.Decimal` constructor now accepts `float` objects directly so there is no longer a need to use the `from_float()` method ([issue 8257](#)).
- Mixed type comparisons are now fully supported so that `Decimal` objects can be directly compared with `float` and `fractions.Fraction` ([issue 2531](#) and [issue 8188](#)).

Similar changes were made to `fractions.Fraction` so that the `from_float()` and `from_decimal()` methods are no longer needed ([issue 8294](#)):

```
>>> Decimal(1.1)
Decimal('1.1000000000000000088817841970012523233890533447265625')
```

```
>>> Fraction(1.1)
Fraction(2476979795053773, 2251799813685248)
```

Another useful change for the `decimal` module is that the `Context.clamp` attribute is now public. This is useful in creating contexts that correspond to the decimal interchange formats specified in IEEE 754 (see [issue 8540](#)).

(Contributed by Mark Dickinson and Raymond Hettinger.)

ftp

The `ftplib.FTP` class now supports the context manager protocol to unconditionally consume `socket.error` exceptions and to close the FTP connection when done:

```
>>> from ftplib import FTP
>>> with FTP("ftp1.at.proftpd.org") as ftp:
    ftp.login()
    ftp.dir()

'230 Anonymous login ok, restrictions apply.'
dr-xr-xr-x  9 ftp      ftp      154 May  6 10:43 .
dr-xr-xr-x  9 ftp      ftp      154 May  6 10:43 ..
dr-xr-xr-x  5 ftp      ftp      4096 May  6 10:43 CentOS
dr-xr-xr-x  3 ftp      ftp      18 Jul 10  2008 Fedora
```

Other file-like objects such as `mmap.mmap` and `fileinput.input()` also grew auto-closing context managers:

```
with fileinput.input(files=('log1.txt', 'log2.txt')) as f:
    for line in f:
        process(line)
```

(Contributed by Tarek Ziadé and Giampaolo Rodolà in [issue 4972](#), and by Georg Brandl in [issue 8046](#) and [issue 1286](#).)

The `FTP_TLS` class now accepts a *context* parameter, which is a `ssl.SSLContext` object allowing bundling SSL configuration options, certificates and private keys into a single (potentially long-lived) structure.

(Contributed by Giampaolo Rodolà; [issue 8806](#).)

popen

The `os.popen()` and `subprocess.Popen()` functions now support `with` statements for auto-closing of the file descriptors.

(Contributed by Antoine Pitrou and Brian Curtin in [issue 7461](#) and [issue 10554](#).)

select

The `select` module now exposes a new, constant attribute, `PIPE_BUF`, which gives the minimum number of bytes which are guaranteed not to block when `select.select()` says a pipe is ready for writing.

```
>>> import select
>>> select.PIPE_BUF
512
```

(Available on Unix systems. Patch by Sébastien Sablé in [issue 9862](#))

gzip and zipfile

`gzip.GzipFile` now implements the `io.BufferedIOBase` *abstract base class* (except for `truncate()`). It also has a `peek()` method and supports unseekable as well as zero-padded file objects.

The `gzip` module also gains the `compress()` and `decompress()` functions for easier in-memory compression and decompression. Keep in mind that text needs to be encoded as `bytes` before compressing and decompressing:

```
>>> s = 'Three shall be the number thou shalt count, '  
>>> s += 'and the number of the counting shall be three'  
>>> b = s.encode() # convert to utf-8  
>>> len(b)  
89  
>>> c = gzip.compress(b)  
>>> len(c)  
77  
>>> gzip.decompress(c).decode()[:42] # decompress and conv  
'Three shall be the number thou shalt count,'
```

(Contributed by Anand B. Pillai in [issue 3488](#); and by Antoine Pitrou, Nir Aides and Brian Curtin in [issue 9962](#), [issue 1675951](#), [issue 7471](#) and [issue 2846](#).)

Also, the `zipfile.ZipExtFile` class was reworked internally to represent files stored inside an archive. The new implementation is significantly faster and can be wrapped in a `io.BufferedReader` object for more speedups. It also solves an issue where interleaved calls to `read` and `readline` gave the wrong results.

(Patch submitted by Nir Aides in [issue 7610](#).)

tarfile

The `TarFile` class can now be used as a context manager. In addition, its `add()` method has a new option, `filter`, that controls which files are added to the archive and allows the file metadata to be edited.

The new `filter` option replaces the older, less flexible `exclude`

parameter which is now deprecated. If specified, the optional *filter* parameter needs to be a *keyword argument*. The user-supplied filter function accepts a `TarInfo` object and returns an updated `TarInfo` object, or if it wants the file to be excluded, the function can return `None`:

```
>>> import tarfile, glob

>>> def myfilter(tarinfo):
    if tarinfo.isfile():           # only save real files
        tarinfo.uname = 'monty'    # redact the user name
    return tarinfo

>>> with tarfile.open(name='myarchive.tar.gz', mode='w:gz') as
    for filename in glob.glob('*.txt'):
        tf.add(filename, filter=myfilter)
    tf.list()
-rw-r--r-- monty/501          902 2011-01-26 17:59:11 annotations
-rw-r--r-- monty/501          123 2011-01-26 17:59:11 general_que
-rw-r--r-- monty/501        3514 2011-01-26 17:59:11 prion.txt
-rw-r--r-- monty/501          124 2011-01-26 17:59:11 py_todo.txt
-rw-r--r-- monty/501        1399 2011-01-26 17:59:11 semaphore_n
```

(Proposed by Tarek Ziadé and implemented by Lars Gustäbel in [issue 6856](#).)

hashlib

The `hashlib` module has two new constant attributes listing the hashing algorithms guaranteed to be present in all implementations and those available on the current implementation:

```
>>> import hashlib

>>> hashlib.algorithms_guaranteed
{'sha1', 'sha224', 'sha384', 'sha256', 'sha512', 'md5'}

>>> hashlib.algorithms_available
{'md2', 'SHA256', 'SHA512', 'dsaWithSHA', 'mdc2', 'SHA224', 'MD',
'sha512', 'ripemd160', 'SHA1', 'MDC2', 'SHA', 'SHA384', 'MD2',
```

```
'ecdsa-with-SHA1', 'md4', 'md5', 'sha1', 'DSA-SHA', 'sha224',  
'dsaEncryption', 'DSA', 'RIPEMD160', 'sha', 'MD5', 'sha384'}
```

(Suggested by Carl Chenet in [issue 7418](#).)

ast

The `ast` module has a wonderful a general-purpose tool for safely evaluating expression strings using the Python literal syntax. The `ast.literal_eval()` function serves as a secure alternative to the builtin `eval()` function which is easily abused. Python 3.2 adds `bytes` and `set` literals to the list of supported types: strings, bytes, numbers, tuples, lists, dicts, sets, booleans, and None.

```
>>> from ast import literal_eval  
  
>>> request = '{"req": 3, "func": "pow", "args": (2, 0.5)}'  
>>> literal_eval(request)  
{'args': (2, 0.5), 'req': 3, 'func': 'pow'}  
  
>>> request = "os.system('do something harmful')"  
>>> literal_eval(request)  
Traceback (most recent call last):  
...  
ValueError: malformed node or string: <_ast.Call object at 0x10
```

(Implemented by Benjamin Peterson and Georg Brandl.)

OS

Different operating systems use various encodings for filenames and environment variables. The `os` module provides two new functions, `fsencode()` and `fsdecode()`, for encoding and decoding filenames:

```
>>> filename = 'Sehenswürdigkeiten'  
>>> os.fsencode(filename)
```

```
b'Sehensw\xc3\xbcrdigkeiten'
```

Some operating systems allow direct access to the unencoded bytes in the environment. If so, the `os.supports_bytes_environ` constant will be true.

For direct access to unencoded environment variables (if available), use the new `os.getenvb()` function or use `os.environb` which is a bytes version of `os.environ`.

(Contributed by Victor Stinner.)

shutil

The `shutil.copytree()` function has two new options:

- *ignore_dangling_symlinks*: when `symlinks=False` so that the function copies a file pointed to by a symlink, not the symlink itself. This option will silence the error raised if the file doesn't exist.
- *copy_function*: is a callable that will be used to copy files. `shutil.copy2()` is used by default.

(Contributed by Tarek Ziadé.)

In addition, the `shutil` module now supports *archiving operations* for zipfiles, uncompressed tarfiles, gzipped tarfiles, and bzipipped tarfiles. And there are functions for registering additional archiving file formats (such as xz compressed tarfiles or custom formats).

The principal functions are `make_archive()` and `unpack_archive()`. By default, both operate on the current directory (which can be set by `os.chdir()`) and on any sub-directories. The archive filename needs to be specified with a full pathname. The archiving step is non-destructive (the original files are left unchanged).

```

>>> import shutil, pprint

>>> os.chdir('mydata') # change t
>>> f = shutil.make_archive('/var/backup/mydata', # archive
                           'zip') # show the
>>> f # show the
'/var/backup/mydata.zip'
>>> os.chdir('tmp') # change t
>>> shutil.unpack_archive('/var/backup/mydata.zip') # recover

>>> pprint.pprint(shutil.get_archive_formats()) # display
[('bztar', "bzip2'ed tar-file"),
 ('gztar', "gzip'ed tar-file"),
 ('tar', 'uncompressed tar file'),
 ('zip', 'ZIP file')]

>>> shutil.register_archive_format( # register
    name = 'xz', # callable
    function = xz.compress, # argument
    extra_args = [('level', 8)],
    description = 'xz compression'
)

```

(Contributed by Tarek Ziadé.)

sqlite3

The `sqlite3` module was updated to `pysqlite` version 2.6.0. It has two new capabilities.

- The `sqlite3.Connection.in_transit` attribute is true if there is an active transaction for uncommitted changes.
- The `sqlite3.Connection.enable_load_extension()` and `sqlite3.Connection.load_extension()` methods allows you to load SQLite extensions from ".so" files. One well-known extension is the fulltext-search extension distributed with SQLite.

(Contributed by R. David Murray and Shashwat Anand; [issue 8845](#).)

html

A new `html` module was introduced with only a single function, `escape()`, which is used for escaping reserved characters from HTML markup:

```
>>> import html
>>> html.escape('x > 2 && x < 7')
'x &gt; 2 &amp;&amp; x &lt; 7'
```

socket

The `socket` module has two new improvements.

- Socket objects now have a `detach()` method which puts the socket into closed state without actually closing the underlying file descriptor. The latter can then be reused for other purposes. (Added by Antoine Pitrou; [issue 8524](#).)
- `socket.create_connection()` now supports the context manager protocol to unconditionally consume `socket.error` exceptions and to close the socket when done. (Contributed by Giampaolo Rodolà; [issue 9794](#).)

ssl

The `ssl` module added a number of features to satisfy common requirements for secure (encrypted, authenticated) internet connections:

- A new class, `SSLContext`, serves as a container for persistent SSL data, such as protocol settings, certificates, private keys, and various other options. It includes a `wrap_socket()` for creating an SSL socket from an SSL context.
- A new function, `ssl.match_hostname()`, supports server identity

verification for higher-level protocols by implementing the rules of HTTPS (from [RFC 2818](#)) which are also suitable for other protocols.

- The `ssl.wrap_socket()` constructor function now takes a *ciphers* argument. The *ciphers* string lists the allowed encryption algorithms using the format described in the [OpenSSL documentation](#).
- When linked against recent versions of OpenSSL, the `ssl` module now supports the Server Name Indication extension to the TLS protocol, allowing multiple “virtual hosts” using different certificates on a single IP port. This extension is only supported in client mode, and is activated by passing the *server_hostname* argument to `ssl.SSLContext.wrap_socket()`.
- Various options have been added to the `ssl` module, such as `OP_NO_SSLv2` which disables the insecure and obsolete SSLv2 protocol.
- The extension now loads all the OpenSSL ciphers and digest algorithms. If some SSL certificates cannot be verified, they are reported as an “unknown algorithm” error.
- The version of OpenSSL being used is now accessible using the module attributes `ssl.OPENSSSL_VERSION` (a string), `ssl.OPENSSSL_VERSION_INFO` (a 5-tuple), and `ssl.OPENSSSL_VERSION_NUMBER` (an integer).

(Contributed by Antoine Pitrou in [issue 8850](#), [issue 1589](#), [issue 8322](#), [issue 5639](#), [issue 4870](#), [issue 8484](#), and [issue 8321](#).)

nntp

The `nntplib` module has a revamped implementation with better bytes and text semantics as well as more practical APIs. These improvements break compatibility with the `nntplib` version in Python 3.1, which was partly dysfunctional in itself.

Support for secure connections through both implicit (using `ntplib.NNTP_SSL`) and explicit (using `ntplib.NNTP.starttls()`) TLS has also been added.

(Contributed by Antoine Pitrou in [issue 9360](#) and Andrew Vant in [issue 1926](#).)

certificates

`http.client.HTTPSConnection`, `urllib.request.HTTPSHandler` and `urllib.request.urlopen()` now take optional arguments to allow for server certificate checking against a set of Certificate Authorities, as recommended in public uses of HTTPS.

(Added by Antoine Pitrou, [issue 9003](#).)

imaplib

Support for explicit TLS on standard IMAP4 connections has been added through the new `imaplib.IMAP4.starttls` method.

(Contributed by Lorenzo M. Catucci and Antoine Pitrou, [issue 4471](#).)

http.client

There were a number of small API improvements in the `http.client` module. The old-style HTTP 0.9 simple responses are no longer supported and the `strict` parameter is deprecated in all classes.

The `HTTPConnection` and `HTTPSConnection` classes now have a `source_address` parameter for a (host, port) tuple indicating where the HTTP connection is made from.

Support for certificate checking and HTTPS virtual hosts were added

to `HTTPSConnection`.

The `request()` method on connection objects allowed an optional *body* argument so that a *file object* could be used to supply the content of the request. Conveniently, the *body* argument now also accepts an *iterable* object so long as it includes an explicit `Content-Length` header. This extended interface is much more flexible than before.

To establish an HTTPS connection through a proxy server, there is a new `set_tunnel()` method that sets the host and port for HTTP Connect tunneling.

To match the behavior of `http.server`, the HTTP client library now also encodes headers with ISO-8859-1 (Latin-1) encoding. It was already doing that for incoming headers, so now the behavior is consistent for both incoming and outgoing traffic. (See work by Armin Ronacher in [issue 10980](#).)

unittest

The `unittest` module has a number of improvements supporting test discovery for packages, easier experimentation at the interactive prompt, new testcase methods, improved diagnostic messages for test failures, and better method names.

- The command-line call `python -m unittest` can now accept file paths instead of module names for running specific tests ([issue 10620](#)). The new test discovery can find tests within packages, locating any test importable from the top-level directory. The top-level directory can be specified with the `-t` option, a pattern for matching files with `-p`, and a directory to start discovery with `-s`:

```
$ python -m unittest discover -s my_proj_dir -p _test.py
```

(Contributed by Michael Foord.)

- Experimentation at the interactive prompt is now easier because the `unittest.case.TestCase` class can now be instantiated without arguments:

```
>>> TestCase().assertEqual(pow(2, 3), 8)
```

(Contributed by Michael Foord.)

- The `unittest` module has two new methods, `assertWarns()` and `assertWarnsRegex()` to verify that a given warning type is triggered by the code under test:

```
with self.assertWarns(DeprecationWarning):  
    legacy_function('XYZ')
```

(Contributed by Antoine Pitrou, [issue 9754](#).)

Another new method, `assertCountEqual()` is used to compare two iterables to determine if their element counts are equal (whether the same elements are present with the same number of occurrences regardless of order):

```
def test_anagram(self):  
    self.assertEqual('algorithm', 'logarithm')
```

(Contributed by Raymond Hettinger.)

- A principal feature of the `unittest` module is an effort to produce meaningful diagnostics when a test fails. When possible, the failure is recorded along with a diff of the output. This is especially helpful for analyzing log files of failed test runs. However, since diffs can sometime be voluminous, there is a new `maxDiff` attribute that sets maximum length of diffs displayed.

- In addition, the method names in the module have undergone a number of clean-ups.

For example, `assertRegex()` is the new name for `assertRegexpMatches()` which was misnamed because the test uses `re.search()`, not `re.match()`. Other methods using regular expressions are now named using short form “Regex” in preference to “Regexp” – this matches the names used in other unittest implementations, matches Python’s old name for the `re` module, and it has unambiguous camel-casing.

(Contributed by Raymond Hettinger and implemented by Ezio Melotti.)

- To improve consistency, some long-standing method aliases are being deprecated in favor of the preferred names:

Old Name	Preferred Name
<code>assert_()</code>	<code>assertTrue()</code>
<code>assertEquals()</code>	<code>assertEqual()</code>
<code>assertNotEquals()</code>	<code>assertNotEqual()</code>
<code>assertAlmostEquals()</code>	<code>assertAlmostEqual()</code>
<code>assertNotAlmostEquals()</code>	<code>assertNotAlmostEqual()</code>

Likewise, the `TestCase.fail*` methods deprecated in Python 3.1 are expected to be removed in Python 3.3. Also see the *Deprecated aliases* section in the `unittest` documentation.

(Contributed by Ezio Melotti; [issue 9424](#).)

- The `assertDictContainsSubset()` method was deprecated because it was misimplemented with the arguments in the wrong order. This created hard-to-debug optical illusions where tests like `TestCase().assertDictContainsSubset({'a':1,`

`'b':2}, {'a':1})` would fail.

(Contributed by Raymond Hettinger.)

random

The integer methods in the `random` module now do a better job of producing uniform distributions. Previously, they computed selections with `int(n*random())` which had a slight bias whenever n was not a power of two. Now, multiple selections are made from a range up to the next power of two and a selection is kept only when it falls within the range $0 \leq x < n$. The functions and methods affected are `randrange()`, `randint()`, `choice()`, `shuffle()` and `sample()`.

(Contributed by Raymond Hettinger; [issue 9025](#).)

poplib

`POP3_SSL` class now accepts a `context` parameter, which is a `ssl.SSLContext` object allowing bundling SSL configuration options, certificates and private keys into a single (potentially long-lived) structure.

(Contributed by Giampaolo Rodolà; [issue 8807](#).)

asyncore

`asyncore.dispatcher` now provides a `handle_accepted()` method returning a `(sock, addr)` pair which is called when a connection has actually been established with a new remote endpoint. This is supposed to be used as a replacement for old `handle_accept()` and avoids the user to call `accept()` directly.

(Contributed by Giampaolo Rodolà; [issue 6706](#).)

tempfile

The `tempfile` module has a new context manager, `TemporaryDirectory` which provides easy deterministic cleanup of temporary directories:

```
with tempfile.TemporaryDirectory() as tmpdirname:
    print('created temporary dir:', tmpdirname)
```

(Contributed by Neil Schemenauer and Nick Coghlan; [issue 5178](#).)

inspect

- The `inspect` module has a new function `getgeneratorstate()` to easily identify the current state of a generator-iterator:

```
>>> from inspect import getgeneratorstate
>>> def gen():
>>>     yield 'demo'
>>> g = gen()
>>> getgeneratorstate(g)
'GEN_CREATED'
>>> next(g)
'demo'
>>> getgeneratorstate(g)
'GEN_SUSPENDED'
>>> next(g, None)
>>> getgeneratorstate(g)
'GEN_CLOSED'
```

(Contributed by Rodolpho Eckhardt and Nick Coghlan, [issue 10220](#).)

- To support lookups without the possibility of activating a dynamic attribute, the `inspect` module has a new function, `getattr_static()`. Unlike `hasattr()`, this is a true read-only

search, guaranteed not to change state while it is searching:

```
>>> class A:
    @property
    def f(self):
        print('Running')
        return 10

>>> a = A()
>>> getattr(a, 'f')
Running
10
>>> inspect.getattr_static(a, 'f')
<property object at 0x1022bd788>
```

(Contributed by Michael Foord.)

pydoc

The `pydoc` module now provides a much-improved Web server interface, as well as a new command-line option `-b` to automatically open a browser window to display that server:

```
$ pydoc3.2 -b
```

(Contributed by Ron Adam; [issue 2001](#).)

dis

The `dis` module gained two new functions for inspecting code, `code_info()` and `show_code()`. Both provide detailed code object information for the supplied function, method, source code string or code object. The former returns a string and the latter prints it:

```
>>> import dis, random
>>> dis.show_code(random.choice)
Name:                choice
Filename:            /Library/Frameworks/Python.framework/Version
```

```

Argument count:      2
Kw-only arguments:  0
Number of locals:   3
Stack size:         11
Flags:              OPTIMIZED, NEWLOCALS, NOFREE
Constants:
  0: 'Choose a random element from a non-empty sequence.'
  1: 'Cannot choose from an empty sequence'
Names:
  0: _randbelow
  1: len
  2: ValueError
  3: IndexError
Variable names:
  0: self
  1: seq
  2: i

```

In addition, the `dis()` function now accepts string arguments so that the common idiom `dis(compile(s, '', 'eval'))` can be shortened to `dis(s)`:

```

>>> dis('3*x+1 if x%2==1 else x//2')
1          0 LOAD_NAME           0 (x)
          3 LOAD_CONST          0 (2)
          6 BINARY_MODULO
          7 LOAD_CONST          1 (1)
         10 COMPARE_OP         2 (==)
         13 POP_JUMP_IF_FALSE  28
         16 LOAD_CONST          2 (3)
         19 LOAD_NAME           0 (x)
         22 BINARY_MULTIPLY
         23 LOAD_CONST          1 (1)
         26 BINARY_ADD
         27 RETURN_VALUE
>>        28 LOAD_NAME           0 (x)
         31 LOAD_CONST          0 (2)
         34 BINARY_FLOOR_DIVIDE
         35 RETURN_VALUE

```

Taken together, these improvements make it easier to explore how CPython is implemented and to see for yourself what the language

syntax does under-the-hood.

(Contributed by Nick Coghlan in [issue 9147](#).)

dbm

All database modules now support the `get()` and `setdefault()` methods.

(Suggested by Ray Allen in [issue 9523](#).)

ctypes

A new type, `ctypes.c_ssize_t` represents the C `ssize_t` datatype.

site

The `site` module has three new functions useful for reporting on the details of a given Python installation.

- `getsitepackages()` lists all global site-packages directories.
- `getuserbase()` reports on the user's base directory where data can be stored.
- `getusersitepackages()` reveals the user-specific site-packages directory path.

```
>>> import site
>>> site.getsitepackages()
['/Library/Frameworks/Python.framework/Versions/3.2/lib/python3
'/Library/Frameworks/Python.framework/Versions/3.2/lib/site-py
'/Library/Python/3.2/site-packages']
>>> site.getuserbase()
'/Users/raymondhettinger/Library/Python/3.2'
>>> site.getusersitepackages()
'/Users/raymondhettinger/Library/Python/3.2/lib/python/site-pac
```

Conveniently, some of site's functionality is accessible directly from the command-line:

```
$ python -m site --user-base
/Users/raymondhettinger/.local
$ python -m site --user-site
/Users/raymondhettinger/.local/lib/python3.2/site-packages
```

(Contributed by Tarek Ziadé in [issue 6693](#).)

sysconfig

The new `sysconfig` module makes it straightforward to discover installation paths and configuration variables that vary across platforms and installations.

The module offers access simple access functions for platform and version information:

- `get_platform()` returning values like *linux-i586* or *macosx-10.6-ppc*.
- `get_python_version()` returns a Python version string such as "3.2".

It also provides access to the paths and variables corresponding to one of seven named schemes used by `distutils`. Those include *posix_prefix*, *posix_home*, *posix_user*, *nt*, *nt_user*, *os2*, *os2_home*:

- `get_paths()` makes a dictionary containing installation paths for the current installation scheme.
- `get_config_vars()` returns a dictionary of platform specific variables.

There is also a convenient command-line interface:

```
C:\Python32>python -m sysconfig
```

```
Platform: "win32"
Python version: "3.2"
Current installation scheme: "nt"

Paths:
    data = "C:\Python32"
    include = "C:\Python32\Include"
    platinclude = "C:\Python32\Include"
    platlib = "C:\Python32\Lib\site-packages"
    platstdlib = "C:\Python32\Lib"
    purelib = "C:\Python32\Lib\site-packages"
    scripts = "C:\Python32\Scripts"
    stdlib = "C:\Python32\Lib"

Variables:
    BINDIR = "C:\Python32"
    BINLIBDEST = "C:\Python32\Lib"
    EXE = ".exe"
    INCLUDEPY = "C:\Python32\Include"
    LIBDEST = "C:\Python32\Lib"
    SO = ".pyd"
    VERSION = "32"
    abiflags = ""
    base = "C:\Python32"
    exec_prefix = "C:\Python32"
    platbase = "C:\Python32"
    prefix = "C:\Python32"
    projectbase = "C:\Python32"
    py_version = "3.2"
    py_version_nodot = "32"
    py_version_short = "3.2"
    srcdir = "C:\Python32"
    userbase = "C:\Documents and Settings\Raymond\Applicati
```

(Moved out of Distutils by Tarek Ziadé.)

pdb

The `pdb` debugger module gained a number of usability improvements:

- `pdb.py` now has a `-c` option that executes commands as given

in a `.pdbrc` script file.

- A `.pdbrc` script file can contain `continue` and `next` commands that continue debugging.
- The `Pdb` class constructor now accepts a `nosigint` argument.
- New commands: `l(list)`, `ll(long list)` and `source` for listing source code.
- New commands: `display` and `undisplay` for showing or hiding the value of an expression if it has changed.
- New command: `interact` for starting an interactive interpreter containing the global and local names found in the current scope.
- Breakpoints can be cleared by breakpoint number.

(Contributed by Georg Brandl, Antonio Cuni and Ilya Sandler.)

configparser

The `configparser` module was modified to improve usability and predictability of the default parser and its supported INI syntax. The old `ConfigParser` class was removed in favor of `SafeConfigParser` which has in turn been renamed to `ConfigParser`. Support for inline comments is now turned off by default and section or option duplicates are not allowed in a single configuration source.

Config parsers gained a new API based on the mapping protocol:

```
>>> parser = ConfigParser()
>>> parser.read_string("""
[DEFAULT]
location = upper left
visible = yes
editable = no
color = blue

[main]
title = Main Menu
```

```

color = green

[options]
title = Options
"""
>>> parser['main']['color']
'green'
>>> parser['main']['editable']
'no'
>>> section = parser['options']
>>> section['title']
'Options'
>>> section['title'] = 'Options (editable: %(editable)s)'
>>> section['title']
'Options (editable: no)'

```

The new API is implemented on top of the classical API, so custom parser subclasses should be able to use it without modifications.

The INI file structure accepted by config parsers can now be customized. Users can specify alternative option/value delimiters and comment prefixes, change the name of the *DEFAULT* section or switch the interpolation syntax.

There is support for pluggable interpolation including an additional interpolation handler **ExtendedInterpolation**:

```

>>> parser = ConfigParser(interpolation=ExtendedInterpolation())
>>> parser.read_dict({'buildout': {'directory': '/home/ambv/zop
                                'custom': {'prefix': '/usr/local'}}})
>>> parser.read_string("""
[buildout]
parts =
    zope9
    instance
find-links =
    ${buildout:directory}/downloads/dist

[zope9]
recipe = plone.recipe.zope9install
location = /opt/zope

[instance]

```

```
recipe = plone.recipe.zope9instance
zope9-location = ${zope9:location}
zope-conf = ${custom:prefix}/etc/zope.conf
"""
>>> parser['buildout']['find-links']
'\n/home/ambv/zope9/downloads/dist'
>>> parser['instance']['zope-conf']
'/usr/local/etc/zope.conf'
>>> instance = parser['instance']
>>> instance['zope-conf']
'/usr/local/etc/zope.conf'
>>> instance['zope9-location']
'/opt/zope'
```

A number of smaller features were also introduced, like support for specifying encoding in read operations, specifying fallback values for get-functions, or reading directly from dictionaries and strings.

(All changes contributed by Łukasz Langa.)

urllib.parse

A number of usability improvements were made for the `urllib.parse` module.

The `urlparse()` function now supports IPv6 addresses as described in [RFC 2732](#):

```
>>> import urllib.parse
>>> urllib.parse.urlparse('http://[dead:beef:cafe:5417:affe:8FA
ParseResult(scheme='http',
             netloc='[dead:beef:cafe:5417:affe:8FA3:deaf:feed]',
             path='/foo/',
             params='',
             query='',
             fragment='')
```

The `urldefrag()` function now returns a *named tuple*:

```
>>> r = urllib.parse.urldefrag('http://python.org/about/#target')
>>> r
DefragResult(url='http://python.org/about/', fragment='target')
>>> r[0]
'http://python.org/about/'
>>> r.fragment
'target'
```

And, the `urlencode()` function is now much more flexible, accepting either a string or bytes type for the *query* argument. If it is a string, then the *safe*, *encoding*, and *error* parameters are sent to `quote_plus()` for encoding:

```
>>> urllib.parse.urlencode([
    ('type', 'telenovela'),
    ('name', '¿Dónde Está Elisa?')],
    encoding='latin-1')
'type=telenovela&name=%BFD%F3nde+Est%E1+Elisa%3F'
```

As detailed in *Parsing ASCII Encoded Bytes*, all the `urllib.parse` functions now accept ASCII-encoded byte strings as input, so long as they are not mixed with regular strings. If ASCII-encoded byte strings are given as parameters, the return types will also be an ASCII-encoded byte strings:

```
>>> urllib.parse.urlparse(b'http://www.python.org:80/about/')
ParseResultBytes(scheme=b'http', netloc=b'www.python.org:80',
                 path=b'/about/', params=b'', query=b'', fragme
```

(Work by Nick Coghlan, Dan Mahn, and Senthil Kumaran in [issue 2987](#), [issue 5468](#), and [issue 9873](#).)

mailbox

Thanks to a concerted effort by R. David Murray, the `mailbox` module has been fixed for Python 3.2. The challenge was that mailbox had

been originally designed with a text interface, but email messages are best represented with `bytes` because various parts of a message may have different encodings.

The solution harnessed the `email` package's binary support for parsing arbitrary email messages. In addition, the solution required a number of API changes.

As expected, the `add()` method for `mailbox.Mailbox` objects now accepts binary input.

`StringIO` and text file input are deprecated. Also, string input will fail early if non-ASCII characters are used. Previously it would fail when the email was processed in a later step.

There is also support for binary output. The `get_file()` method now returns a file in the binary mode (where it used to incorrectly set the file to text-mode). There is also a new `get_bytes()` method that returns a `bytes` representation of a message corresponding to a given *key*.

It is still possible to get non-binary output using the old API's `get_string()` method, but that approach is not very useful. Instead, it is best to extract messages from a `Message` object or to load them from binary input.

(Contributed by R. David Murray, with efforts from Steffen Daode Nurpmeso and an initial patch by Victor Stinner in [issue 9124](#).)

turtledemo

The demonstration code for the `turtle` module was moved from the *Demo* directory to main library. It includes over a dozen sample scripts with lively displays. Being on `sys.path`, it can now be run

directly from the command-line:

```
$ python -m turtle demo
```

(Moved from the Demo directory by Alexander Belopolsky in [issue 10199](#).)

Multi-threading

- The mechanism for serializing execution of concurrently running Python threads (generally known as the *GIL* or *Global Interpreter Lock*) has been rewritten. Among the objectives were more predictable switching intervals and reduced overhead due to lock contention and the number of ensuing system calls. The notion of a “check interval” to allow thread switches has been abandoned and replaced by an absolute duration expressed in seconds. This parameter is tunable through `sys.setswitchinterval()`. It currently defaults to 5 milliseconds.

Additional details about the implementation can be read from a [python-dev mailing-list message](#) (however, “priority requests” as exposed in this message have not been kept for inclusion).

(Contributed by Antoine Pitrou.)

- Regular and recursive locks now accept an optional *timeout* argument to their `acquire()` method. (Contributed by Antoine Pitrou; [issue 7316](#).)
- Similarly, `threading.Semaphore.acquire()` also gained a *timeout* argument. (Contributed by Torsten Landschoff; [issue 850728](#).)
- Regular and recursive lock acquisitions can now be interrupted by signals on platforms using Pthreads. This means that Python programs that deadlock while acquiring locks can be successfully killed by repeatedly sending SIGINT to the process (by pressing `ctrl+c` in most shells). (Contributed by Reid Kleckner; [issue 8844](#).)

Optimizations

A number of small performance enhancements have been added:

- Python's peephole optimizer now recognizes patterns such `x in {1, 2, 3}` as being a test for membership in a set of constants. The optimizer recasts the `set` as a `frozenset` and stores the pre-built constant.

Now that the speed penalty is gone, it is practical to start writing membership tests using set-notation. This style is both semantically clear and operationally fast:

```
extension = name.rpartition('.')[2]
if extension in {'xml', 'html', 'xhtml', 'css'}:
    handle(name)
```

(Patch and additional tests contributed by Dave Malcolm; [issue 6690](#)).

- Serializing and unserializing data using the `pickle` module is now several times faster.

(Contributed by Alexandre Vassalotti, Antoine Pitrou and the Unladen Swallow team in [issue 9410](#) and [issue 3873](#).)

- The `Timsort` algorithm used in `list.sort()` and `sorted()` now runs faster and uses less memory when called with a *key function*. Previously, every element of a list was wrapped with a temporary object that remembered the key value associated with each element. Now, two arrays of keys and values are sorted in parallel. This saves the memory consumed by the sort wrappers, and it saves time lost to delegating comparisons.

(Patch by Daniel Stutzbach in [issue 9915](#).)

- JSON decoding performance is improved and memory consumption is reduced whenever the same string is repeated for multiple keys. Also, JSON encoding now uses the C speedups when the `sort_keys` argument is true.

(Contributed by Antoine Pitrou in [issue 7451](#) and by Raymond Hettinger and Antoine Pitrou in [issue 10314](#).)

- Recursive locks (created with the `threading.RLock()` API) now benefit from a C implementation which makes them as fast as regular locks, and between 10x and 15x faster than their previous pure Python implementation.

(Contributed by Antoine Pitrou; [issue 3001](#).)

- The fast-search algorithm in stringlib is now used by the `split()`, `rsplit()`, `splitlines()` and `replace()` methods on `bytes`, `bytearray` and `str` objects. Likewise, the algorithm is also used by `rfind()`, `rindex()`, `rsplit()` and `rpartition()`.

(Patch by Florent Xicluna in [issue 7622](#) and [issue 7462](#).)

- String to integer conversions now work two “digits” at a time, reducing the number of division and modulo operations.

([issue 6713](#) by Gawain Bolton, Mark Dickinson, and Victor Stinner.)

There were several other minor optimizations. Set differencing now runs faster when one operand is much larger than the other (patch by Andress Bennetts in [issue 8685](#)). The `array.repeat()` method has a faster implementation ([issue 1569291](#) by Alexander Belopolsky). The `BaseHTTPRequestHandler` has more efficient

buffering ([issue 3709](#) by Andrew Schaaf). The multi-argument form of `operator.attrgetter()` function now runs slightly faster ([issue 10160](#) by Christos Georgiou). And `configParser` loads multi-line arguments a bit faster ([issue 7113](#) by Łukasz Langa).

Unicode

Python has been updated to [Unicode 6.0.0](#). The update to the standard adds over 2,000 new characters including [emoji](#) symbols which are important for mobile phones.

In addition, the updated standard has altered the character properties for two Kannada characters (U+0CF1, U+0CF2) and one New Tai Lue numeric character (U+19DA), making the former eligible for use in identifiers while disqualifying the latter. For more information, see [Unicode Character Database Changes](#).

Codecs

Support was added for `cp720` Arabic DOS encoding ([issue 1616979](#)).

MBCS encoding no longer ignores the error handler argument. In the default strict mode, it raises an `UnicodeDecodeError` when it encounters an undecodable byte sequence and an `UnicodeEncodeError` for an unencodable character.

The MBCS codec supports `'strict'` and `'ignore'` error handlers for decoding, and `'strict'` and `'replace'` for encoding.

To emulate Python3.1 MBCS encoding, select the `'ignore'` handler for decoding and the `'replace'` handler for encoding.

On Mac OS X, Python decodes command line arguments with `'utf-8'` rather than the locale encoding.

By default, `tarfile` uses `'utf-8'` encoding on Windows (instead of `'mbscs'`) and the `'surrogateescape'` error handler on all operating systems.

Documentation

The documentation continues to be improved.

- A table of quick links has been added to the top of lengthy sections such as *Built-in Functions*. In the case of `itertools`, the links are accompanied by tables of cheatsheet-style summaries to provide an overview and memory jog without having to read all of the docs.
- In some cases, the pure Python source code can be a helpful adjunct to the documentation, so now many modules now feature quick links to the latest version of the source code. For example, the `functools` module documentation has a quick link at the top labeled:

Source code [Lib/functools.py](#).

(Contributed by Raymond Hettinger; see [rationale](#).)

- The docs now contain more examples and recipes. In particular, `re` module has an extensive section, *Regular Expression Examples*. Likewise, the `itertools` module continues to be updated with new *Itertools Recipes*.
- The `datetime` module now has an auxiliary implementation in pure Python. No functionality was changed. This just provides an easier-to-read alternate implementation.

(Contributed by Alexander Belopolsky in [issue 9528](#).)

- The unmaintained `Demo` directory has been removed. Some demos were integrated into the documentation, some were moved to the `Tools/demo` directory, and others were removed

altogether.

(Contributed by Georg Brandl in [issue 7962](#).)

IDLE

- The format menu now has an option to clean source files by stripping trailing whitespace.

(Contributed by Raymond Hettinger; [issue 5150](#).)

- IDLE on Mac OS X now works with both Carbon AquaTk and Cocoa AquaTk.

(Contributed by Kevin Walzer, Ned Deily, and Ronald Oussoren; [issue 6075](#).)

Code Repository

In addition to the existing Subversion code repository at <http://svn.python.org> there is now a Mercurial repository at <http://hg.python.org/> .

After the 3.2 release, there are plans to switch to Mercurial as the primary repository. This distributed version control system should make it easier for members of the community to create and share external changesets. See [PEP 385](#) for details.

To learn to use the new version control system, see the [tutorial by Joel Spolsky](#) or the [Guide to Mercurial Workflows](#).

Build and C API Changes

Changes to Python's build process and to the C API include:

- The *idle*, *pydoc* and *2to3* scripts are now installed with a version-specific suffix on `make altinstall` ([issue 10679](#)).
- The C functions that access the Unicode Database now accept and return characters from the full Unicode range, even on narrow unicode builds (`Py_UNICODE_TOLOWER`, `Py_UNICODE_ISDECIMAL`, and others). A visible difference in Python is that `unicodedata.numeric()` now returns the correct value for large code points, and `repr()` may consider more characters as printable.

(Reported by Bupjoe Lee and fixed by Amaury Forgeot D'Arc; [issue 5127](#).)

- Computed gotos are now enabled by default on supported compilers (which are detected by the configure script). They can still be disabled selectively by specifying `--without-computed-gotos`.

(Contributed by Antoine Pitrou; [issue 9203](#).)

- The option `--with-wctype-functions` was removed. The built-in unicode database is now used for all functions.

(Contributed by Amaury Forgeot D'Arc; [issue 9210](#).)

- Hash values are now values of a new type, `Py_hash_t`, which is defined to be the same size as a pointer. Previously they were of type `long`, which on some 64-bit operating systems is still only 32 bits long. As a result of this fix, `set` and `dict` can now hold

more than `2**32` entries on builds with 64-bit pointers (previously, they could grow to that size but their performance degraded catastrophically).

(Suggested by Raymond Hettinger and implemented by Benjamin Peterson; [issue 9778](#).)

- A new macro `Py_VA_COPY` copies the state of the variable argument list. It is equivalent to C99 `va_copy` but available on all Python platforms ([issue 2443](#)).
- A new C API function `PySys_SetArgvEx()` allows an embedded interpreter to set `sys.argv` without also modifying `sys.path` ([issue 5753](#)).
- `PyEval_CallObject` is now only available in macro form. The function declaration, which was kept for backwards compatibility reasons, is now removed – the macro was introduced in 1997 ([issue 8276](#)).
- There is a new function `PyLong_AsLongLongAndOverflow()` which is analogous to `PyLong_AsLongAndOverflow()`. They both serve to convert Python `int` into a native fixed-width type while providing detection of cases where the conversion won't fit ([issue 7767](#)).
- The `PyUnicode_CompareWithASCIIString()` function now returns *not equal* if the Python string is `NUL` terminated.
- There is a new function `PyErr_NewExceptionWithDoc()` that is like `PyErr_NewException()` but allows a docstring to be specified. This lets C exceptions have the same self-documenting capabilities as their pure Python counterparts ([issue 7033](#)).
- When compiled with the `--with-valgrind` option, the `pymalloc` allocator will be automatically disabled when running under

Valgrind. This gives improved memory leak detection when running under Valgrind, while taking advantage of pymalloc at other times ([issue 2422](#)).

- Removed the `o?` format from the *PyArg_Parse* functions. The format is no longer used and it had never been documented ([issue 8837](#)).

There were a number of other small changes to the C-API. See the [Misc/NEWS](#) file for a complete list.

Also, there were a number of updates to the Mac OS X build, see [Mac/BuildScript/README.txt](#) for details. For users running a 32/64-bit build, there is a known problem with the default Tcl/Tk on Mac OS X 10.6. Accordingly, we recommend installing an updated alternative such as [ActiveState Tcl/Tk 8.5.9](#). See <http://www.python.org/download/mac/tcltk/> for additional details.

Porting to Python 3.2

This section lists previously described changes and other bugfixes that may require changes to your code:

- The `configparser` module has a number of clean-ups. The major change is to replace the old `ConfigParser` class with long-standing preferred alternative `SafeConfigParser`. In addition there are a number of smaller incompatibilities:
 - The interpolation syntax is now validated on `get()` and `set()` operations. In the default interpolation scheme, only two tokens with percent signs are valid: `%(name)s` and `%%`, the latter being an escaped percent sign.
 - The `set()` and `add_section()` methods now verify that values are actual strings. Formerly, unsupported types could be introduced unintentionally.
 - Duplicate sections or options from a single source now raise either `DuplicateSectionError` or `DuplicateOptionError`. Formerly, duplicates would silently overwrite a previous entry.
 - Inline comments are now disabled by default so now the `;` character can be safely used in values.
 - Comments now can be indented. Consequently, for `;` or `#` to appear at the start of a line in multiline values, it has to be interpolated. This keeps comment prefix characters in values from being mistaken as comments.
 - `""` is now a valid value and is no longer automatically converted to an empty string. For empty strings, use `"option ="` in a line.
- The `nntplib` module was reworked extensively, meaning that its APIs are often incompatible with the 3.1 APIs.

- `bytearray` objects can no longer be used as filenames; instead, they should be converted to `bytes`.
- The `array.tostring()` and `array.fromstring()` have been renamed to `array.tobytes()` and `array.frombytes()` for clarity. The old names have been deprecated. (See [issue 8990](#).)
- `PyArg_Parse*()` functions:
 - “t#” format has been removed: use “s#” or “s*” instead
 - “w” and “w#” formats has been removed: use “w*” instead
- The `PyObject` type, deprecated in 3.1, has been removed. To wrap opaque C pointers in Python objects, the `PyCapsule` API should be used instead; the new type has a well-defined interface for passing typing safety information and a less complicated signature for calling a destructor.
- The `sys.setfilesystemencoding()` function was removed because it had a flawed design.
- The `random.seed()` function and method now salt string seeds with an sha512 hash function. To access the previous version of `seed` in order to reproduce Python 3.1 sequences, set the `version` argument to `1`, `random.seed(s, version=1)`.
- The previously deprecated `string.maketrans()` function has been removed in favor of the static methods `bytes.maketrans()` and `bytearray.maketrans()`. This change solves the confusion around which types were supported by the `string` module. Now, `str`, `bytes`, and `bytearray` each have their own `maketrans` and `translate` methods with intermediate translation tables of the appropriate type.

(Contributed by Georg Brandl; [issue 5675](#).)

- The previously deprecated `contextlib.nested()` function has been removed in favor of a plain `with` statement which can accept multiple context managers. The latter technique is faster (because it is built-in), and it does a better job finalizing multiple context managers when one of them raises an exception:

```
with open('mylog.txt') as infile, open('a.out', 'w') as out:
    for line in infile:
        if '<critical>' in line:
            outfile.write(line)
```

(Contributed by Georg Brandl and Mattias Brändström; [appspot issue 53094](#).)

- `struct.pack()` now only allows bytes for the `s` string pack code. Formerly, it would accept text arguments and implicitly encode them to bytes using UTF-8. This was problematic because it made assumptions about the correct encoding and because a variable-length encoding can fail when writing to fixed length segment of a structure.

Code such as `struct.pack('<6sHHBBB', 'GIF87a', x, y)` should be rewritten to use bytes instead of text, `struct.pack('<6sHHBBB', b'GIF87a', x, y)`.

(Discovered by David Beazley and fixed by Victor Stinner; [issue 10783](#).)

- The `xml.etree.ElementTree` class now raises an `xml.etree.ElementTree.ParseError` when a parse fails. Previously it raised a `xml.parsers.expat.ExpatError`.
- The new, longer `str()` value on floats may break doctests which rely on the old output format.

- In `subprocess.Popen`, the default value for `close_fds` is now `True` under Unix; under Windows, it is `True` if the three standard streams are set to `None`, `False` otherwise. Previously, `close_fds` was always `False` by default, which produced difficult to solve bugs or race conditions when open file descriptors would leak into the child process.
- Support for legacy HTTP 0.9 has been removed from `urllib.request` and `http.client`. Such support is still present on the server side (in `http.server`).

(Contributed by Antoine Pitrou, [issue 10711](#).)

- SSL sockets in timeout mode now raise `socket.timeout` when a timeout occurs, rather than a generic `SSLERROR`.

(Contributed by Antoine Pitrou, [issue 10272](#).)

- The misleading functions `PyEval_AcquireLock()` and `PyEval_ReleaseLock()` have been officially deprecated. The thread-state aware APIs (such as `PyEval_SaveThread()` and `PyEval_RestoreThread()`) should be used instead.
- Due to security risks, `asyncore.handle_accept()` has been deprecated, and a new function, `asyncore.handle_accepted()`, was added to replace it.

(Contributed by Giampaolo Rodola in [issue 6706](#).)

What's New In Python 3.1

Author: Raymond Hettinger

Release: 3.2

Date: February 20, 2011

This article explains the new features in Python 3.1, compared to 3.0.

PEP 372: Ordered Dictionaries

Regular Python dictionaries iterate over key/value pairs in arbitrary order. Over the years, a number of authors have written alternative implementations that remember the order that the keys were originally inserted. Based on the experiences from those implementations, a new `collections.OrderedDict` class has been introduced.

The `OrderedDict` API is substantially the same as regular dictionaries but will iterate over keys and values in a guaranteed order depending on when a key was first inserted. If a new entry overwrites an existing entry, the original insertion position is left unchanged. Deleting an entry and reinserting it will move it to the end.

The standard library now supports use of ordered dictionaries in several modules. The `configparser` module uses them by default. This lets configuration files be read, modified, and then written back in their original order. The `_asdict()` method for `collections.namedtuple()` now returns an ordered dictionary with the values appearing in the same order as the underlying tuple indices. The `json` module is being built-out with an `object_pairs_hook` to allow `OrderedDicts` to be built by the decoder. Support was also added for third-party tools like `PyYAML`.

PEP 372 - Ordered Dictionaries

PEP written by Armin Ronacher and Raymond Hettinger.
Implementation written by Raymond Hettinger.

PEP 378: Format Specifier for Thousands Separator

The built-in `format()` function and the `str.format()` method use a mini-language that now includes a simple, non-locale aware way to format a number with a thousands separator. That provides a way to humanize a program's output, improving its professional appearance and readability:

```
>>> format(1234567, ',d')
'1,234,567'
>>> format(1234567.89, ',.2f')
'1,234,567.89'
>>> format(12345.6 + 8901234.12j, ',f')
'12,345.600000+8,901,234.120000j'
>>> format(Decimal('1234567.89'), ',f')
'1,234,567.89'
```

The supported types are `int`, `float`, `complex` and `decimal.Decimal`.

Discussions are underway about how to specify alternative separators like dots, spaces, apostrophes, or underscores. Locale-aware applications should use the existing `n` format specifier which already has some support for thousands separators.

PEP 378 - Format Specifier for Thousands Separator

PEP written by Raymond Hettinger and implemented by Eric Smith and Mark Dickinson.

Other Language Changes

Some smaller changes made to the core Python language are:

- Directories and zip archives containing a `__main__.py` file can now be executed directly by passing their name to the interpreter. The directory/zipfile is automatically inserted as the first entry in `sys.path`. (Suggestion and initial patch by Andy Chu; revised patch by Phillip J. Eby and Nick Coghlan; [issue 1739468](#).)
- The `int()` type gained a `bit_length` method that returns the number of bits necessary to represent its argument in binary:

```
>>> n = 37
>>> bin(37)
'0b100101'
>>> n.bit_length()
6
>>> n = 2**123-1
>>> n.bit_length()
123
>>> (n+1).bit_length()
124
```

(Contributed by Fredrik Johansson, Victor Stinner, Raymond Hettinger, and Mark Dickinson; [issue 3439](#).)

- The fields in `format()` strings can now be automatically numbered:

```
>>> 'Sir {} of {}'.format('Gallahad', 'Camelot')
'Sir Gallahad of Camelot'
```

Formerly, the string would have required numbered fields such as: `'Sir {0} of {1}'`.

(Contributed by Eric Smith; [issue 5237](#).)

- The `string.maketrans()` function is deprecated and is replaced by new static methods, `bytes.maketrans()` and `bytearray.maketrans()`. This change solves the confusion around which types were supported by the `string` module. Now, `str`, `bytes`, and `bytearray` each have their own **maketrans** and **translate** methods with intermediate translation tables of the appropriate type.

(Contributed by Georg Brandl; [issue 5675](#).)

- The syntax of the `with` statement now allows multiple context managers in a single statement:

```
>>> with open('mylog.txt') as infile, open('a.out', 'w') as
...     for line in infile:
...         if '<critical>' in line:
...             outfile.write(line)
```

With the new syntax, the `contextlib.nested()` function is no longer needed and is now deprecated.

(Contributed by Georg Brandl and Mattias Brändström; [appspot issue 53094](#).)

- `round(x, n)` now returns an integer if `x` is an integer. Previously it returned a float:

```
>>> round(1123, -2)
1100
```

(Contributed by Mark Dickinson; [issue 4707](#).)

- Python now uses David Gay's algorithm for finding the shortest floating point representation that doesn't change its value. This

should help mitigate some of the confusion surrounding binary floating point numbers.

The significance is easily seen with a number like `1.1` which does not have an exact equivalent in binary floating point. Since there is no exact equivalent, an expression like `float('1.1')` evaluates to the nearest representable value which is `0x1.199999999999ap+0` in hex or `1.100000000000000088817841970012523233890533447265625` in decimal. That nearest value was and still is used in subsequent floating point calculations.

What is new is how the number gets displayed. Formerly, Python used a simple approach. The value of `repr(1.1)` was computed as `format(1.1, '.17g')` which evaluated to `'1.1000000000000001'`. The advantage of using 17 digits was that it relied on IEEE-754 guarantees to assure that `eval(repr(1.1))` would round-trip exactly to its original value. The disadvantage is that many people found the output to be confusing (mistaking intrinsic limitations of binary floating point representation as being a problem with Python itself).

The new algorithm for `repr(1.1)` is smarter and returns `'1.1'`. Effectively, it searches all equivalent string representations (ones that get stored with the same underlying float value) and returns the shortest representation.

The new algorithm tends to emit cleaner representations when possible, but it does not change the underlying values. So, it is still the case that `1.1 + 2.2 != 3.3` even though the representations may suggest otherwise.

The new algorithm depends on certain features in the underlying floating point implementation. If the required features are not

found, the old algorithm will continue to be used. Also, the text pickle protocols assure cross-platform portability by using the old algorithm.

(Contributed by Eric Smith and Mark Dickinson; [issue 1580](#))

New, Improved, and Deprecated Modules

- Added a `collections.Counter` class to support convenient counting of unique items in a sequence or iterable:

```
>>> Counter(['red', 'blue', 'red', 'green', 'blue', 'blue'])
Counter({'blue': 3, 'red': 2, 'green': 1})
```

(Contributed by Raymond Hettinger; [issue 1696199](#).)

- Added a new module, `tkinter.ttk` for access to the Tk themed widget set. The basic idea of `ttk` is to separate, to the extent possible, the code implementing a widget's behavior from the code implementing its appearance.

(Contributed by Guilherme Polo; [issue 2983](#).)

- The `gzip.GzipFile` and `bz2.BZ2File` classes now support the context manager protocol:

```
>>> # Automatically close file after writing
>>> with gzip.GzipFile(filename, "wb") as f:
...     f.write(b"xxx")
```

(Contributed by Antoine Pitrou.)

- The `decimal` module now supports methods for creating a decimal object from a binary `float`. The conversion is exact but can sometimes be surprising:

```
>>> Decimal.from_float(1.1)
Decimal('1.100000000000000000088817841970012523233890533447265')
```

The long decimal result shows the actual binary fraction being

stored for *1.1*. The fraction has many digits because *1.1* cannot be exactly represented in binary.

(Contributed by Raymond Hettinger and Mark Dickinson.)

- The `itertools` module grew two new functions. The `itertools.combinations_with_replacement()` function is one of four for generating combinatorics including permutations and Cartesian products. The `itertools.compress()` function mimics its namesake from APL. Also, the existing `itertools.count()` function now has an optional `step` argument and can accept any type of counting sequence including `fractions.Fraction` and `decimal.Decimal`:

```
>>> [p+q for p,q in combinations_with_replacement('LOVE', 2)
      ['LL', 'LO', 'LV', 'LE', 'OO', 'OV', 'OE', 'VV', 'VE', 'EE']]
>>> list(compress(data=range(10), selectors=[0,0,1,1,0,1,0,
      [2, 3, 5, 7]))
>>> c = count(start=Fraction(1,2), step=Fraction(1,6))
>>> [next(c), next(c), next(c), next(c)]
[Fraction(1, 2), Fraction(2, 3), Fraction(5, 6), Fraction(1
```

(Contributed by Raymond Hettinger.)

- `collections.namedtuple()` now supports a keyword argument `rename` which lets invalid fieldnames be automatically converted to positional names in the form `_0`, `_1`, etc. This is useful when the field names are being created by an external source such as a CSV header, SQL field list, or user input:

```
>>> query = input()
SELECT region, dept, count(*) FROM main GROUPBY region, dept
>>> cursor.execute(query)
>>> query_fields = [desc[0] for desc in cursor.description]
```

```
>>> UserQuery = namedtuple('UserQuery', query_fields, renam
>>> pprint.pprint([UserQuery(*row) for row in cursor])
[UserQuery(region='South', dept='Shipping', _2=185),
 UserQuery(region='North', dept='Accounting', _2=37),
 UserQuery(region='West', dept='Sales', _2=419)]
```

(Contributed by Raymond Hettinger; [issue 1818](#).)

- The `re.sub()`, `re.subn()` and `re.split()` functions now accept a `flags` parameter.

(Contributed by Gregory Smith.)

- The `logging` module now implements a simple `logging.NullHandler` class for applications that are not using logging but are calling library code that does. Setting-up a null handler will suppress spurious warnings such as “No handlers could be found for logger foo”:

```
>>> h = logging.NullHandler()
>>> logging.getLogger("foo").addHandler(h)
```

(Contributed by Vinay Sajip; [issue 4384](#).)

- The `runpy` module which supports the `-m` command line switch now supports the execution of packages by looking for and executing a `__main__` submodule when a package name is supplied.

(Contributed by Andi Vajda; [issue 4195](#).)

- The `pdb` module can now access and display source code loaded via `zipimport` (or any other conformant [PEP 302](#) loader).

(Contributed by Alexander Belopolsky; [issue 4201](#).)

- `functools.partial` objects can now be pickled.

(Suggested by Antoine Pitrou and Jesse Noller. Implemented by Jack Diederich; [issue 5228](#).)

- Add `pydoc` help topics for symbols so that `help('@')` works as expected in the interactive environment.

(Contributed by David Laban; [issue 4739](#).)

- The `unittest` module now supports skipping individual tests or classes of tests. And it supports marking a test as a expected failure, a test that is known to be broken, but shouldn't be counted as a failure on a `TestResult`:

```
class TestGizmo(unittest.TestCase):  
  
    @unittest.skipUnless(sys.platform.startswith("win"), "r  
    def test_gizmo_on_windows(self):  
        ...  
  
    @unittest.expectedFailure  
    def test_gimzo_without_required_library(self):  
        ...
```

Also, tests for exceptions have been builtout to work with context managers using the `with` statement:

```
def test_division_by_zero(self):  
    with self.assertRaises(ZeroDivisionError):  
        x / 0
```

In addition, several new assertion methods were added including `assertSetEqual()`, `assertDictEqual()`, `assertDictContainsSubset()`, `assertListEqual()`, `assertTupleEqual()`, `assertSequenceEqual()`, `assertRaisesRegexp()`, `assertIsNone()`, and `assertIsNotNone()`.

(Contributed by Benjamin Peterson and Antoine Pitrou.)

- The `io` module has three new constants for the `seek()` method `SEEK_SET`, `SEEK_CUR`, and `SEEK_END`.
- The `sys.version_info` tuple is now a named tuple:

```
>>> sys.version_info
sys.version_info(major=3, minor=1, micro=0, releaselevel='a
```

(Contributed by Ross Light; [issue 4285](#).)

- The `nntplib` and `imaplib` modules now support IPv6.

(Contributed by Derek Morr; [issue 1655](#) and [issue 1664](#).)

- The `pickle` module has been adapted for better interoperability with Python 2.x when used with protocol 2 or lower. The reorganization of the standard library changed the formal reference for many objects. For example, `__builtin__.set` in Python 2 is called `builtins.set` in Python 3. This change confounded efforts to share data between different versions of Python. But now when protocol 2 or lower is selected, the pickler will automatically use the old Python 2 names for both loading and dumping. This remapping is turned-on by default but can be disabled with the `fix_imports` option:

```
>>> s = {1, 2, 3}
>>> pickle.dumps(s, protocol=0)
b'c__builtin__\nset\np0\n((lp1\nL1L\naL2L\naL3L\natp2\nRp3\
>>> pickle.dumps(s, protocol=0, fix_imports=False)
b'cbuiltins\nset\np0\n((lp1\nL1L\naL2L\naL3L\natp2\nRp3\n.'
```

An unfortunate but unavoidable side-effect of this change is that protocol 2 pickles produced by Python 3.1 won't be readable

with Python 3.0. The latest pickle protocol, protocol 3, should be used when migrating data between Python 3.x implementations, as it doesn't attempt to remain compatible with Python 2.x.

(Contributed by Alexandre Vassalotti and Antoine Pitrou, [issue 6137](#).)

- A new module, `importlib` was added. It provides a complete, portable, pure Python reference implementation of the `import` statement and its counterpart, the `__import__()` function. It represents a substantial step forward in documenting and defining the actions that take place during imports.

(Contributed by Brett Cannon.)

Optimizations

Major performance enhancements have been added:

- The new I/O library (as defined in [PEP 3116](#)) was mostly written in Python and quickly proved to be a problematic bottleneck in Python 3.0. In Python 3.1, the I/O library has been entirely rewritten in C and is 2 to 20 times faster depending on the task at hand. The pure Python version is still available for experimentation purposes through the `_pyio` module.

(Contributed by Amaury Forgeot d'Arc and Antoine Pitrou.)

- Added a heuristic so that tuples and dicts containing only untrackable objects are not tracked by the garbage collector. This can reduce the size of collections and therefore the garbage collection overhead on long-running programs, depending on their particular use of datatypes.

(Contributed by Antoine Pitrou, [issue 4688](#).)

- Enabling a configure option named `--with-computed-gotos` on compilers that support it (notably: gcc, SunPro, icc), the bytecode evaluation loop is compiled with a new dispatch mechanism which gives speedups of up to 20%, depending on the system, the compiler, and the benchmark.

(Contributed by Antoine Pitrou along with a number of other participants, [issue 4753](#)).

- The decoding of UTF-8, UTF-16 and LATIN-1 is now two to four times faster.

(Contributed by Antoine Pitrou and Amaury Forgeot d'Arc, [issue](#)

4868.)

- The `json` module now has a C extension to substantially improve its performance. In addition, the API was modified so that `json` works only with `str`, not with `bytes`. That change makes the module closely match the [JSON specification](#) which is defined in terms of Unicode.

(Contributed by Bob Ippolito and converted to Py3.1 by Antoine Pitrou and Benjamin Peterson; [issue 4136](#).)

- Unpickling now interns the attribute names of pickled objects. This saves memory and allows pickles to be smaller.

(Contributed by Jake McGuire and Antoine Pitrou; [issue 5084](#).)

IDLE

- IDLE's format menu now provides an option to strip trailing whitespace from a source file.

(Contributed by Roger D. Serwy; [issue 5150](#).)

Build and C API Changes

Changes to Python's build process and to the C API include:

- Integers are now stored internally either in base 2^{15} or in base 2^{30} , the base being determined at build time. Previously, they were always stored in base 2^{15} . Using base 2^{30} gives significant performance improvements on 64-bit machines, but benchmark results on 32-bit machines have been mixed. Therefore, the default is to use base 2^{30} on 64-bit machines and base 2^{15} on 32-bit machines; on Unix, there's a new configure option `--enable-big-digits` that can be used to override this default.

Apart from the performance improvements this change should be invisible to end users, with one exception: for testing and debugging purposes there's a new `sys.int_info` that provides information about the internal format, giving the number of bits per digit and the size in bytes of the C type used to store each digit:

```
>>> import sys
>>> sys.int_info
sys.int_info(bits_per_digit=30, sizeof_digit=4)
```

(Contributed by Mark Dickinson; [issue 4258](#).)

- The `PyLong_AsUnsignedLongLong()` function now handles a negative *pylong* by raising `OverflowError` instead of `TypeError`.

(Contributed by Mark Dickinson and Lisandro Dalcrin; [issue 5175](#).)

- Deprecated `PyNumber_Int()`. Use `PyNumber_Long()` instead.

(Contributed by Mark Dickinson; [issue 4910](#).)

- Added a new `PyOS_string_to_double()` function to replace the deprecated functions `PyOS_ascii_strtod()` and `PyOS_ascii_atof()`.

(Contributed by Mark Dickinson; [issue 5914](#).)

- Added `PyCapsule` as a replacement for the `PyObject` API. The principal difference is that the new type has a well defined interface for passing typing safety information and a less complicated signature for calling a destructor. The old type had a problematic API and is now deprecated.

(Contributed by Larry Hastings; [issue 5630](#).)

Porting to Python 3.1

This section lists previously described changes and other bugfixes that may require changes to your code:

- The new floating point string representations can break existing doctests. For example:

```
def e():
    '''Compute the base of natural logarithms.

    >>> e()
    2.7182818284590451

    '''
    return sum(1/math.factorial(x) for x in reversed(range(
doctest.testmod()

*****
Failed example:
  e()
Expected:
  2.7182818284590451
Got:
  2.718281828459045
*****
```

- The automatic name remapping in the pickle module for protocol 2 or lower can make Python 3.1 pickles unreadable in Python 3.0. One solution is to use protocol 3. Another solution is to set the `fix_imports` option to **False**. See the discussion above for more details.

What's New In Python 3.0

Author:	Guido van Rossum
Release:	3.2
Date:	February 20, 2011

This article explains the new features in Python 3.0, compared to 2.6. Python 3.0, also known as “Python 3000” or “Py3K”, is the first ever *intentionally backwards incompatible* Python release. There are more changes than in a typical release, and more that are important for all Python users. Nevertheless, after digesting the changes, you’ll find that Python really hasn’t changed all that much – by and large, we’re mostly fixing well-known annoyances and warts, and removing a lot of old cruft.

This article doesn’t attempt to provide a complete specification of all new features, but instead tries to give a convenient overview. For full details, you should refer to the documentation for Python 3.0, and/or the many PEPs referenced in the text. If you want to understand the complete implementation and design rationale for a particular feature, PEPs usually have more details than the regular documentation; but note that PEPs usually are not kept up-to-date once a feature has been fully implemented.

Due to time constraints this document is not as complete as it should have been. As always for a new release, the `Misc/NEWS` file in the source distribution contains a wealth of detailed information about every small thing that was changed.

Common Stumbling Blocks

This section lists those few changes that are most likely to trip you up if you're used to Python 2.5.

Print Is A Function

The `print` statement has been replaced with a `print()` function, with keyword arguments to replace most of the special syntax of the old `print` statement ([PEP 3105](#)). Examples:

```
Old: print "The answer is", 2*2
New: print("The answer is", 2*2)

Old: print x,           # Trailing comma suppresses newline
New: print(x, end=" ") # Appends a space instead of a newline

Old: print             # Prints a newline
New: print()          # You must call the function!

Old: print >>sys.stderr, "fatal error"
New: print("fatal error", file=sys.stderr)

Old: print (x, y)      # prints repr((x, y))
New: print((x, y))    # Not the same as print(x, y)!
```

You can also customize the separator between items, e.g.:

```
print("There are <", 2**32, "> possibilities!", sep="")
```

which produces:

```
There are <4294967296> possibilities!
```

Note:

- The `print()` function doesn't support the "softspace" feature of

the old `print` statement. For example, in Python 2.x, `print "A\n", "B"` would write `"A\nB\n"`; but in Python 3.0, `print("A\n", "B")` writes `"A\n B\n"`.

- Initially, you'll be finding yourself typing the old `print x` a lot in interactive mode. Time to retrain your fingers to type `print(x)` instead!
- When using the `2to3` source-to-source conversion tool, all `print` statements are automatically converted to `print()` function calls, so this is mostly a non-issue for larger projects.

Views And Iterators Instead Of Lists

Some well-known APIs no longer return lists:

- `dict` methods `dict.keys()`, `dict.items()` and `dict.values()` return "views" instead of lists. For example, this no longer works: `k = d.keys(); k.sort()`. Use `k = sorted(d)` instead (this works in Python 2.5 too and is just as efficient).
- Also, the `dict.iterkeys()`, `dict.iteritems()` and `dict.itervalues()` methods are no longer supported.
- `map()` and `filter()` return iterators. If you really need a list, a quick fix is e.g. `list(map(...))`, but a better fix is often to use a list comprehension (especially when the original code uses `lambda`), or rewriting the code so it doesn't need a list at all. Particularly tricky is `map()` invoked for the side effects of the function; the correct transformation is to use a regular `for` loop (since creating a list would just be wasteful).
- `range()` now behaves like `xrange()` used to behave, except it works with values of arbitrary size. The latter no longer exists.
- `zip()` now returns an iterator.

Ordering Comparisons

Python 3.0 has simplified the rules for ordering comparisons:

- The ordering comparison operators (`<`, `<=`, `>=`, `>`) raise a `TypeError` exception when the operands don't have a meaningful natural ordering. Thus, expressions like `1 < ''`, `0 > None` or `len <= len` are no longer valid, and e.g. `None < None` raises `TypeError` instead of returning `False`. A corollary is that sorting a heterogeneous list no longer makes sense – all the elements must be comparable to each other. Note that this does not apply to the `==` and `!=` operators: objects of different incomparable types always compare unequal to each other.
- `builtin.sorted()` and `list.sort()` no longer accept the `cmp` argument providing a comparison function. Use the `key` argument instead. N.B. the `key` and `reverse` arguments are now “keyword-only”.
- The `cmp()` function should be treated as gone, and the `__cmp__()` special method is no longer supported. Use `__lt__()` for sorting, `__eq__()` with `__hash__()`, and other rich comparisons as needed. (If you really need the `cmp()` functionality, you could use the expression `(a > b) - (a < b)` as the equivalent for `cmp(a, b)`.)

Integers

- **PEP 0237**: Essentially, `long` renamed to `int`. That is, there is only one built-in integral type, named `int`; but it behaves mostly like the old `long` type.
- **PEP 0238**: An expression like `1/2` returns a float. Use `1//2` to get the truncating behavior. (The latter syntax has existed for years, at least since Python 2.2.)
- The `sys.maxint` constant was removed, since there is no longer a limit to the value of integers. However, `sys.maxsize` can be

used as an integer larger than any practical list or string index. It conforms to the implementation's "natural" integer size and is typically the same as `sys.maxint` in previous releases on the same platform (assuming the same build options).

- The `repr()` of a long integer doesn't include the trailing `L` anymore, so code that unconditionally strips that character will chop off the last digit instead. (Use `str()` instead.)
- Octal literals are no longer of the form `0720`; use `0o720` instead.

Text Vs. Data Instead Of Unicode Vs. 8-bit

Everything you thought you knew about binary data and Unicode has changed.

- Python 3.0 uses the concepts of *text* and (binary) *data* instead of Unicode strings and 8-bit strings. All text is Unicode; however *encoded* Unicode is represented as binary data. The type used to hold text is `str`, the type used to hold data is `bytes`. The biggest difference with the 2.x situation is that any attempt to mix text and data in Python 3.0 raises `TypeError`, whereas if you were to mix Unicode and 8-bit strings in Python 2.x, it would work if the 8-bit string happened to contain only 7-bit (ASCII) bytes, but you would get `UnicodeDecodeError` if it contained non-ASCII values. This value-specific behavior has caused numerous sad faces over the years.
- As a consequence of this change in philosophy, pretty much all code that uses Unicode, encodings or binary data most likely has to change. The change is for the better, as in the 2.x world there were numerous bugs having to do with mixing encoded and unencoded text. To be prepared in Python 2.x, start using `unicode` for all unencoded text, and `str` for binary or encoded data only. Then the `2to3` tool will do most of the work for you.
- You can no longer use `u"..."` literals for Unicode text. However,

you must use `b"..."` literals for binary data.

- As the `str` and `bytes` types cannot be mixed, you must always explicitly convert between them. Use `str.encode()` to go from `str` to `bytes`, and `bytes.decode()` to go from `bytes` to `str`. You can also use `bytes(s, encoding=...)` and `str(b, encoding=...)`, respectively.
- Like `str`, the `bytes` type is immutable. There is a separate *mutable* type to hold buffered binary data, `bytearray`. Nearly all APIs that accept `bytes` also accept `bytearray`. The mutable API is based on `collections.MutableSequence`.
- All backslashes in raw string literals are interpreted literally. This means that `'\u'` and `'\u'` escapes in raw strings are not treated specially. For example, `r'\u20ac'` is a string of 6 characters in Python 3.0, whereas in 2.6, `ur'\u20ac'` was the single “euro” character. (Of course, this change only affects raw string literals; the euro character is `'\u20ac'` in Python 3.0.)
- The built-in `basestring` abstract type was removed. Use `str` instead. The `str` and `bytes` types don't have functionality enough in common to warrant a shared base class. The `2to3` tool (see below) replaces every occurrence of `basestring` with `str`.
- Files opened as text files (still the default mode for `open()`) always use an encoding to map between strings (in memory) and bytes (on disk). Binary files (opened with a `b` in the mode argument) always use bytes in memory. This means that if a file is opened using an incorrect mode or encoding, I/O will likely fail loudly, instead of silently producing incorrect data. It also means that even Unix users will have to specify the correct mode (text or binary) when opening a file. There is a platform-dependent default encoding, which on Unixy platforms can be set with the `LANG` environment variable (and sometimes also with some other platform-specific locale-related environment variables). In many

cases, but not all, the system default is UTF-8; you should never count on this default. Any application reading or writing more than pure ASCII text should probably have a way to override the encoding. There is no longer any need for using the encoding-aware streams in the `codecs` module.

- Filenames are passed to and returned from APIs as (Unicode) strings. This can present platform-specific problems because on some platforms filenames are arbitrary byte strings. (On the other hand, on Windows filenames are natively stored as Unicode.) As a work-around, most APIs (e.g. `open()` and many functions in the `os` module) that take filenames accept `bytes` objects as well as strings, and a few APIs have a way to ask for a `bytes` return value. Thus, `os.listdir()` returns a list of `bytes` instances if the argument is a `bytes` instance, and `os.getcwd()` returns the current working directory as a `bytes` instance. Note that when `os.listdir()` returns a list of strings, filenames that cannot be decoded properly are omitted rather than raising `UnicodeError`.
- Some system APIs like `os.environ` and `sys.argv` can also present problems when the bytes made available by the system is not interpretable using the default encoding. Setting the `LANG` variable and rerunning the program is probably the best approach.
- **PEP 3138**: The `repr()` of a string no longer escapes non-ASCII characters. It still escapes control characters and code points with non-printable status in the Unicode standard, however.
- **PEP 3120**: The default source encoding is now UTF-8.
- **PEP 3131**: Non-ASCII letters are now allowed in identifiers. (However, the standard library remains ASCII-only with the exception of contributor names in comments.)
- The `StringIO` and `cStringIO` modules are gone. Instead, import the `io` module and use `io.StringIO` or `io.BytesIO` for text and data respectively.

- See also the *Unicode HOWTO*, which was updated for Python 3.0.

Overview Of Syntax Changes

This section gives a brief overview of every *syntactic* change in Python 3.0.

New Syntax

- **PEP 3107:** Function argument and return value annotations. This provides a standardized way of annotating a function's parameters and return value. There are no semantics attached to such annotations except that they can be introspected at runtime using the `__annotations__` attribute. The intent is to encourage experimentation through metaclasses, decorators or frameworks.
- **PEP 3102:** Keyword-only arguments. Named parameters occurring after `*args` in the parameter list *must* be specified using keyword syntax in the call. You can also use a bare `*` in the parameter list to indicate that you don't accept a variable-length argument list, but you do have keyword-only arguments.
- Keyword arguments are allowed after the list of base classes in a class definition. This is used by the new convention for specifying a metaclass (see next section), but can be used for other purposes as well, as long as the metaclass supports it.
- **PEP 3104:** `nonlocal` statement. Using `nonlocal x` you can now assign directly to a variable in an outer (but non-global) scope. `nonlocal` is a new reserved word.
- **PEP 3132:** Extended Iterable Unpacking. You can now write things like `a, b, *rest = some_sequence`. And even `*rest, a = stuff`. The `rest` object is always a (possibly empty) list; the

right-hand side may be any iterable. Example:

```
(a, *rest, b) = range(5)
```

This sets *a* to 0, *b* to 4, and *rest* to [1, 2, 3].

- Dictionary comprehensions: `{k: v for k, v in stuff}` means the same thing as `dict(stuff)` but is more flexible. (This is **PEP 0274** vindicated. :-)
- Set literals, e.g. `{1, 2}`. Note that `{}` is an empty dictionary; use `set()` for an empty set. Set comprehensions are also supported; e.g., `{x for x in stuff}` means the same thing as `set(stuff)` but is more flexible.
- New octal literals, e.g. `0o720` (already in 2.6). The old octal literals (`0720`) are gone.
- New binary literals, e.g. `0b1010` (already in 2.6), and there is a new corresponding built-in function, `bin()`.
- Bytes literals are introduced with a leading `b` or `B`, and there is a new corresponding built-in function, `bytes()`.

Changed Syntax

- **PEP 3109** and **PEP 3134**: new `raise` statement syntax: `raise [expr [from expr]]`. See below.
- `as` and `with` are now reserved words. (Since 2.6, actually.)
- `True`, `False`, and `None` are reserved words. (2.6 partially enforced the restrictions on `None` already.)

- Change from `except exc, var` to `except exc as var`. See [PEP 3110](#).
- [PEP 3115](#): New Metaclass Syntax. Instead of:

```
class C:  
    __metaclass__ = M  
    ...
```

you must now use:

```
class C(metaclass=M):  
    ...
```

The module-global `__metaclass__` variable is no longer supported. (It was a crutch to make it easier to default to new-style classes without deriving every class from `object`.)

- List comprehensions no longer support the syntactic form `[... for var in item1, item2, ...]`. Use `[... for var in (item1, item2, ...)]` instead. Also note that list comprehensions have different semantics: they are closer to syntactic sugar for a generator expression inside a `list()` constructor, and in particular the loop control variables are no longer leaked into the surrounding scope.
- The *ellipsis* (`...`) can be used as an atomic expression anywhere. (Previously it was only allowed in slices.) Also, it *must* now be spelled as `...`. (Previously it could also be spelled as `. . .`, by a mere accident of the grammar.)

Removed Syntax

- [PEP 3113](#): Tuple parameter unpacking removed. You can no longer write `def foo(a, (b, c)): ...`. Use `def foo(a, b_c): b,`

`c = b_c` instead.

- Removed backticks (use `repr()` instead).
- Removed `<>` (use `!=` instead).
- Removed keyword: `exec()` is no longer a keyword; it remains as a function. (Fortunately the function syntax was also accepted in 2.x.) Also note that `exec()` no longer takes a stream argument; instead of `exec(f)` you can use `exec(f.read())`.
- Integer literals no longer support a trailing `L` or `l`.
- String literals no longer support a leading `u` or `U`.
- The `from module import *` syntax is only allowed at the module level, no longer inside functions.
- The only acceptable syntax for relative imports is `from . [module] import name`. All `import` forms not starting with `.` are interpreted as absolute imports. (**PEP 0328**)
- Classic classes are gone.

Changes Already Present In Python 2.6

Since many users presumably make the jump straight from Python 2.5 to Python 3.0, this section reminds the reader of new features that were originally designed for Python 3.0 but that were back-ported to Python 2.6. The corresponding sections in *What's New in Python 2.6* should be consulted for longer descriptions.

- *PEP 343: The 'with' statement.* The `with` statement is now a standard feature and no longer needs to be imported from the `__future__`. Also check out *Writing Context Managers* and *The contextlib module*.
- *PEP 366: Explicit Relative Imports From a Main Module.* This enhances the usefulness of the `-m` option when the referenced module lives in a package.
- *PEP 370: Per-user site-packages Directory.*
- *PEP 371: The multiprocessing Package.*
- *PEP 3101: Advanced String Formatting.* Note: the 2.6 description mentions the `format()` method for both 8-bit and Unicode strings. In 3.0, only the `str` type (text strings with Unicode support) supports this method; the `bytes` type does not. The plan is to eventually make this the only API for string formatting, and to start deprecating the `%` operator in Python 3.1.
- *PEP 3105: print As a Function.* This is now a standard feature and no longer needs to be imported from `__future__`. More details were given above.
- *PEP 3110: Exception-Handling Changes.* The `except exc as var` syntax is now standard and `except exc, var` is no longer supported. (Of course, the `as var` part is still optional.)
- *PEP 3112: Byte Literals.* The `b"..."` string literal notation (and its variants like `b'...'`, `b"..."`, and `br"..."`) now produces a literal of type `bytes`.

- *PEP 3116: New I/O Library*. The `io` module is now the standard way of doing file I/O, and the initial values of `sys.stdin`, `sys.stdout` and `sys.stderr` are now instances of `io.TextIOBase`. The built-in `open()` function is now an alias for `io.open()` and has additional keyword arguments *encoding*, *errors*, *newline* and *closefd*. Also note that an invalid *mode* argument now raises `ValueError`, not `IOError`. The binary file object underlying a text file object can be accessed as `f.buffer` (but beware that the text object maintains a buffer of itself in order to speed up the encoding and decoding operations).
- *PEP 3118: Revised Buffer Protocol*. The old builtin `buffer()` is now really gone; the new builtin `memoryview()` provides (mostly) similar functionality.
- *PEP 3119: Abstract Base Classes*. The `abc` module and the ABCs defined in the `collections` module plays a somewhat more prominent role in the language now, and built-in collection types like `dict` and `list` conform to the `collections.MutableMapping` and `collections.MutableSequence` ABCs, respectively.
- *PEP 3127: Integer Literal Support and Syntax*. As mentioned above, the new octal literal notation is the only one supported, and binary literals have been added.
- *PEP 3129: Class Decorators*.
- *PEP 3141: A Type Hierarchy for Numbers*. The `numbers` module is another new use of ABCs, defining Python's "numeric tower". Also note the new `fractions` module which implements `numbers.Rational`.

Library Changes

Due to time constraints, this document does not exhaustively cover the very extensive changes to the standard library. **PEP 3108** is the reference for the major changes to the library. Here's a capsule review:

- Many old modules were removed. Some, like `gopherlib` (no longer used) and `md5` (replaced by `hashlib`), were already deprecated by **PEP 0004**. Others were removed as a result of the removal of support for various platforms such as Irix, BeOS and Mac OS 9 (see **PEP 0011**). Some modules were also selected for removal in Python 3.0 due to lack of use or because a better replacement exists. See **PEP 3108** for an exhaustive list.
- The `bsddb3` package was removed because its presence in the core standard library has proved over time to be a particular burden for the core developers due to testing instability and Berkeley DB's release schedule. However, the package is alive and well, externally maintained at <http://www.jcea.es/programacion/pybsddb.htm>.
- Some modules were renamed because their old name disobeyed **PEP 0008**, or for various other reasons. Here's the list:

Old Name	New Name
<code>_winreg</code>	<code>winreg</code>
<code>ConfigParser</code>	<code>configparser</code>
<code>copy_reg</code>	<code>copyreg</code>
<code>Queue</code>	<code>queue</code>

SocketServer	socketserver
markupbase	_markupbase
repr	reprlib
test.test_support	test.support

- A common pattern in Python 2.x is to have one version of a module implemented in pure Python, with an optional accelerated version implemented as a C extension; for example, `pickle` and `cPickle`. This places the burden of importing the accelerated version and falling back on the pure Python version on each user of these modules. In Python 3.0, the accelerated versions are considered implementation details of the pure Python versions. Users should always import the standard version, which attempts to import the accelerated version and falls back to the pure Python version. The `pickle` / `cPickle` pair received this treatment. The `profile` module is on the list for 3.1. The `stringIO` module has been turned into a class in the `io` module.
- Some related modules have been grouped into packages, and usually the submodule names have been simplified. The resulting new packages are:
 - `dbm` (`anydbm`, `dbhash`, `dbm`, `dumbdbm`, `gdbm`, `whichdb`).
 - `html` (`HTMLParser`, `htmlentitydefs`).
 - `http` (`httplib`, `BaseHTTPServer`, `CGIHTTPServer`, `SimpleHTTPServer`, `Cookie`, `cookielib`).
 - `tkinter` (all `Tkinter`-related modules except `turtle`). The target audience of `turtle` doesn't really care about `tkinter`. Also note that as of Python 2.6, the functionality of `turtle` has been greatly enhanced.
 - `urllib` (`urllib`, `urllib2`, `urlparse`, `robotparse`).
 - `xmlrpc` (`xmlrpclib`, `DocXMLRPCServer`, `SimpleXMLRPCServer`).

Some other changes to standard library modules, not covered by **PEP 3108**:

- Killed `sets`. Use the built-in `set()` class.
- Cleanup of the `sys` module: removed `sys.exitfunc()`, `sys.exc_clear()`, `sys.exc_type`, `sys.exc_value`, `sys.exc_traceback`. (Note that `sys.last_type` etc. remain.)
- Cleanup of the `array.array` type: the `read()` and `write()` methods are gone; use `fromfile()` and `tofile()` instead. Also, the `'c'` typecode for array is gone – use either `'b'` for bytes or `'u'` for Unicode characters.
- Cleanup of the `operator` module: removed `sequenceIncludes()` and `isCallable()`.
- Cleanup of the `thread` module: `acquire_lock()` and `release_lock()` are gone; use `acquire()` and `release()` instead.
- Cleanup of the `random` module: removed the `jumpahead()` API.
- The `new` module is gone.
- The functions `os.tmpnam()`, `os.temppam()` and `os.tmpfile()` have been removed in favor of the `tempfile` module.
- The `tokenize` module has been changed to work with bytes. The main entry point is now `tokenize.tokenize()`, instead of `generate_tokens`.
- `string.letters` and its friends (`string.lowercase` and `string.uppercase`) are gone. Use `string.ascii_letters` etc. instead. (The reason for the removal is that `string.letters` and friends had locale-specific behavior, which is a bad idea for such attractively-named global “constants”.)
- Renamed module `__builtin__` to `builtins` (removing the underscores, adding an ‘s’). The `__builtins__` variable found in most global namespaces is unchanged. To modify a builtin, you should use `builtins`, not `__builtins__`!

PEP 3101: A New Approach To String Formatting

- A new system for built-in string formatting operations replaces the `%` string formatting operator. (However, the `%` operator is still supported; it will be deprecated in Python 3.1 and removed from the language at some later time.) Read [PEP 3101](#) for the full scoop.

Changes To Exceptions

The APIs for raising and catching exception have been cleaned up and new powerful features added:

- **PEP 0352**: All exceptions must be derived (directly or indirectly) from `BaseException`. This is the root of the exception hierarchy. This is not new as a recommendation, but the *requirement* to inherit from `BaseException` is new. (Python 2.6 still allowed classic classes to be raised, and placed no restriction on what you can catch.) As a consequence, string exceptions are finally truly and utterly dead.
- Almost all exceptions should actually derive from `Exception`; `BaseException` should only be used as a base class for exceptions that should only be handled at the top level, such as `SystemExit` or `KeyboardInterrupt`. The recommended idiom for handling all exceptions except for this latter category is to use `except Exception`.
- `StandardError` was removed.
- Exceptions no longer behave as sequences. Use the `args` attribute instead.
- **PEP 3109**: Raising exceptions. You must now use `raise Exception(args)` instead of `raise Exception, args`. Additionally, you can no longer explicitly specify a traceback; instead, if you *have* to do this, you can assign directly to the `__traceback__` attribute (see below).
- **PEP 3110**: Catching exceptions. You must now use `except SomeException as variable` instead of `except SomeException,`

variable. Moreover, the *variable* is explicitly deleted when the `except` block is left.

- **PEP 3134**: Exception chaining. There are two cases: implicit chaining and explicit chaining. Implicit chaining happens when an exception is raised in an `except` or `finally` handler block. This usually happens due to a bug in the handler block; we call this a *secondary* exception. In this case, the original exception (that was being handled) is saved as the `__context__` attribute of the secondary exception. Explicit chaining is invoked with this syntax:

```
raise SecondaryException() from primary_exception
```

(where *primary_exception* is any expression that produces an exception object, probably an exception that was previously caught). In this case, the primary exception is stored on the `__cause__` attribute of the secondary exception. The traceback printed when an unhandled exception occurs walks the chain of `__cause__` and `__context__` attributes and prints a separate traceback for each component of the chain, with the primary exception at the top. (Java users may recognize this behavior.)

- **PEP 3134**: Exception objects now store their traceback as the `__traceback__` attribute. This means that an exception object now contains all the information pertaining to an exception, and there are fewer reasons to use `sys.exc_info()` (though the latter is not removed).
- A few exception messages are improved when Windows fails to load an extension module. For example, `error code 193` is now `%1 is not a valid win32 application`. Strings now deal with non-English locales.

Miscellaneous Other Changes

Operators And Special Methods

- `!=` now returns the opposite of `==`, unless `==` returns `NotImplemented`.
- The concept of “unbound methods” has been removed from the language. When referencing a method as a class attribute, you now get a plain function object.
- `__getslice__()`, `__setslice__()` and `__delslice__()` were killed. The syntax `a[i:j]` now translates to `a.__getitem__(slice(i, j))` (or `__setitem__()` or `__delitem__()`, when used as an assignment or deletion target, respectively).
- **PEP 3114**: the standard `next()` method has been renamed to `__next__()`.
- The `__oct__()` and `__hex__()` special methods are removed – `oct()` and `hex()` use `__index__()` now to convert the argument to an integer.
- Removed support for `__members__` and `__methods__`.
- The function attributes named `func_x` have been renamed to use the `__x__` form, freeing up these names in the function attribute namespace for user-defined attributes. To wit, `func_closure`, `func_code`, `func_defaults`, `func_dict`, `func_doc`, `func_globals`, `func_name` were renamed to `__closure__`, `__code__`, `__defaults__`, `__dict__`, `__doc__`, `__globals__`, `__name__`, respectively.
- `__nonzero__()` is now `__bool__()`.

Builtins

- **PEP 3135:** New `super()`. You can now invoke `super()` without arguments and (assuming this is in a regular instance method defined inside a `class` statement) the right class and instance will automatically be chosen. With arguments, the behavior of `super()` is unchanged.
- **PEP 3111:** `raw_input()` was renamed to `input()`. That is, the new `input()` function reads a line from `sys.stdin` and returns it with the trailing newline stripped. It raises `EOFError` if the input is terminated prematurely. To get the old behavior of `input()`, use `eval(input())`.
- A new built-in function `next()` was added to call the `__next__()` method on an object.
- The `round()` function rounding strategy and return type have changed. Exact halfway cases are now rounded to the nearest even result instead of away from zero. (For example, `round(2.5)` now returns `2` rather than `3`.) `round(x[, n])()` now delegates to `x.__round__([n])` instead of always returning a float. It generally returns an integer when called with a single argument and a value of the same type as `x` when called with two arguments.
- Moved `intern()` to `sys.intern()`.
- Removed: `apply()`. Instead of `apply(f, args)` use `f(*args)`.
- Removed `callable()`. Instead of `callable(f)` you can use `isinstance(f, collections.Callable)`. The `operator.isCallable()` function is also gone.
- Removed `coerce()`. This function no longer serves a purpose now that classic classes are gone.
- Removed `execfile()`. Instead of `execfile(fn)` use `exec(open(fn).read())`.
- Removed the `file` type. Use `open()`. There are now several different kinds of streams that `open` can return in the `io` module.
- Removed `reduce()`. Use `functools.reduce()` if you really need

it; however, 99 percent of the time an explicit `for` loop is more readable.

- Removed `reload()`. Use `imp.reload()`.
- Removed. `dict.has_key()` – use the `in` operator instead.

Build and C API Changes

Due to time constraints, here is a very incomplete list of changes to the C API.

- Support for several platforms was dropped, including but not limited to Mac OS 9, BeOS, RISCOS, Irix, and Tru64.
- **PEP 3118**: New Buffer API.
- **PEP 3121**: Extension Module Initialization & Finalization.
- **PEP 3123**: Making `PyObject_HEAD` conform to standard C.
- No more C API support for restricted execution.
- `PyNumber_Coerce()`, `PyNumber_CoerceEx()`, `PyMember_Get()`, and `PyMember_Set()` C APIs are removed.
- New C API `PyImport_ImportModuleNoBlock()`, works like `PyImport_ImportModule()` but won't block on the import lock (returning an error instead).
- Renamed the boolean conversion C-level slot and method: `nb_nonzero` is now `nb_bool`.
- Removed `METH_OLDARGS` and `WITH_CYCLE_GC` from the C API.

Performance

The net result of the 3.0 generalizations is that Python 3.0 runs the pystone benchmark around 10% slower than Python 2.5. Most likely the biggest cause is the removal of special-casing for small integers. There's room for improvement, but it will happen after 3.0 is released!

Porting To Python 3.0

For porting existing Python 2.5 or 2.6 source code to Python 3.0, the best strategy is the following:

0. (Prerequisite:) Start with excellent test coverage.
1. Port to Python 2.6. This should be no more work than the average port from Python 2.x to Python 2.(x+1). Make sure all your tests pass.
2. (Still using 2.6:) Turn on the `-3` command line switch. This enables warnings about features that will be removed (or change) in 3.0. Run your test suite again, and fix code that you get warnings about until there are no warnings left, and all your tests still pass.
3. Run the `2to3` source-to-source translator over your source code tree. (See [2to3 - Automated Python 2 to 3 code translation](#) for more on this tool.) Run the result of the translation under Python 3.0. Manually fix up any remaining issues, fixing problems until all tests pass again.

It is not recommended to try to write source code that runs unchanged under both Python 2.6 and 3.0; you'd have to use a very contorted coding style, e.g. avoiding `print` statements, metaclasses, and much more. If you are maintaining a library that needs to support both Python 2.6 and Python 3.0, the best approach is to modify step 3 above by editing the 2.6 version of the source code and running the `2to3` translator again, rather than editing the 3.0 version of the source code.

For porting C extensions to Python 3.0, please see [Porting Extension Modules to 3.0](#).

What's New in Python 2.7

Author: A.M. Kuchling (amk at amk.ca)

Release: 3.2

Date: February 20, 2011

This article explains the new features in Python 2.7. The final release of 2.7 is currently scheduled for July 2010; the detailed schedule is described in [PEP 373](#).

Numeric handling has been improved in many ways, for both floating-point numbers and for the `Decimal` class. There are some useful additions to the standard library, such as a greatly enhanced `unittest` module, the `argparse` module for parsing command-line options, convenient ordered-dictionary and `counter` classes in the `collections` module, and many other improvements.

Python 2.7 is planned to be the last of the 2.x releases, so we worked on making it a good release for the long term. To help with porting to Python 3, several new features from the Python 3.x series have been included in 2.7.

This article doesn't attempt to provide a complete specification of the new features, but instead provides a convenient overview. For full details, you should refer to the documentation for Python 2.7 at <http://docs.python.org>. If you want to understand the rationale for the design and implementation, refer to the PEP for a particular new feature or the issue on <http://bugs.python.org> in which a change was discussed. Whenever possible, "What's New in Python" links to the bug/patch item for each change.

The Future for Python 2.x

Python 2.7 is intended to be the last major release in the 2.x series. The Python maintainers are planning to focus their future efforts on the Python 3.x series.

This means that 2.7 will remain in place for a long time, running production systems that have not been ported to Python 3.x. Two consequences of the long-term significance of 2.7 are:

- It's very likely the 2.7 release will have a longer period of maintenance compared to earlier 2.x versions. Python 2.7 will continue to be maintained while the transition to 3.x continues, and the developers are planning to support Python 2.7 with bug-fix releases beyond the typical two years.
- A policy decision was made to silence warnings only of interest to developers. `DeprecationWarning` and its descendants are now ignored unless otherwise requested, preventing users from seeing warnings triggered by an application. This change was also made in the branch that will become Python 3.2. (Discussed on [stdlib-sig](#) and carried out in [issue 7319](#).)

In previous releases, `DeprecationWarning` messages were enabled by default, providing Python developers with a clear indication of where their code may break in a future major version of Python.

However, there are increasingly many users of Python-based applications who are not directly involved in the development of those applications. `DeprecationWarning` messages are irrelevant to such users, making them worry about an application that's actually working correctly and burdening application developers with responding to these concerns.

You can re-enable display of `DeprecationWarning` messages by running Python with the `-Wdefault` (short form: `-Wd`) switch, or by setting the `PYTHONWARNINGS` environment variable to `"default"` (or `"d"`) before running Python. Python code can also re-enable them by calling `warnings.simplefilter('default')`.

Python 3.1 Features

Much as Python 2.6 incorporated features from Python 3.0, version 2.7 incorporates some of the new features in Python 3.1. The 2.x series continues to provide tools for migrating to the 3.x series.

A partial list of 3.1 features that were backported to 2.7:

- The syntax for set literals (`{1, 2, 3}` is a mutable set).
- Dictionary and set comprehensions (`{ i: i*2 for i in range(3)}`).
- Multiple context managers in a single `with` statement.
- A new version of the `io` library, rewritten in C for performance.
- The ordered-dictionary type described in *PEP 372: Adding an Ordered Dictionary to collections*.
- The new `","` format specifier described in *PEP 378: Format Specifier for Thousands Separator*.
- The `memoryview` object.
- A small subset of the `importlib` module, described below.
- The `repr()` of a float `x` is shorter in many cases: it's now based on the shortest decimal string that's guaranteed to round back to `x`. As in previous versions of Python, it's guaranteed that `float(repr(x))` recovers `x`.
- Float-to-string and string-to-float conversions are correctly rounded. The `round()` function is also now correctly rounded.
- The `PyCapsule` type, used to provide a C API for extension modules.
- The `PyLong_AsLongAndOverflow()` C API function.

Other new Python3-mode warnings include:

- `operator.isCallable()` and `operator.sequenceIncludes()`,

which are not supported in 3.x, now trigger warnings.

- The `-3` switch now automatically enables the `-Qwarn` switch that causes warnings about using classic division with integers and long integers.

PEP 372: Adding an Ordered Dictionary to collections

Regular Python dictionaries iterate over key/value pairs in arbitrary order. Over the years, a number of authors have written alternative implementations that remember the order that the keys were originally inserted. Based on the experiences from those implementations, 2.7 introduces a new `OrderedDict` class in the `collections` module.

The `OrderedDict` API provides the same interface as regular dictionaries but iterates over keys and values in a guaranteed order depending on when a key was first inserted:

```
>>> from collections import OrderedDict
>>> d = OrderedDict([('first', 1),
...                 ('second', 2),
...                 ('third', 3)])
>>> d.items()
[('first', 1), ('second', 2), ('third', 3)]
```

If a new entry overwrites an existing entry, the original insertion position is left unchanged:

```
>>> d['second'] = 4
>>> d.items()
[('first', 1), ('second', 4), ('third', 3)]
```

Deleting an entry and reinserting it will move it to the end:

```
>>> del d['second']
>>> d['second'] = 5
>>> d.items()
[('first', 1), ('third', 3), ('second', 5)]
```

The `popitem()` method has an optional *last* argument that defaults to

True. If *last* is True, the most recently added key is returned and removed; if it's False, the oldest key is selected:

```
>>> od = OrderedDict([(x,0) for x in range(20)])
>>> od.popitem()
(19, 0)
>>> od.popitem()
(18, 0)
>>> od.popitem(last=False)
(0, 0)
>>> od.popitem(last=False)
(1, 0)
```

Comparing two ordered dictionaries checks both the keys and values, and requires that the insertion order was the same:

```
>>> od1 = OrderedDict([('first', 1),
...                   ('second', 2),
...                   ('third', 3)])
>>> od2 = OrderedDict([('third', 3),
...                   ('first', 1),
...                   ('second', 2)])
>>> od1 == od2
False
>>> # Move 'third' key to the end
>>> del od2['third']; od2['third'] = 3
>>> od1 == od2
True
```

Comparing an `OrderedDict` with a regular dictionary ignores the insertion order and just compares the keys and values.

How does the `OrderedDict` work? It maintains a doubly-linked list of keys, appending new keys to the list as they're inserted. A secondary dictionary maps keys to their corresponding list node, so deletion doesn't have to traverse the entire linked list and therefore remains $O(1)$.

The standard library now supports use of ordered dictionaries in several modules.

- The `configParser` module uses them by default, meaning that configuration files can now be read, modified, and then written back in their original order.
- The `_asdict()` method for `collections.namedtuple()` now returns an ordered dictionary with the values appearing in the same order as the underlying tuple indices.
- The `json` module's `JSONDecoder` class constructor was extended with an `object_pairs_hook` parameter to allow `OrderedDict` instances to be built by the decoder. Support was also added for third-party tools like `PyYAML`.

PEP 372 - Adding an ordered dictionary to collections

PEP written by Armin Ronacher and Raymond Hettinger; implemented by Raymond Hettinger.

PEP 378: Format Specifier for Thousands Separator

To make program output more readable, it can be useful to add separators to large numbers, rendering them as 18,446,744,073,709,551,616 instead of 18446744073709551616.

The fully general solution for doing this is the `locale` module, which can use different separators ("," in North America, "." in Europe) and different grouping sizes, but `locale` is complicated to use and unsuitable for multi-threaded applications where different threads are producing output for different locales.

Therefore, a simple comma-grouping mechanism has been added to the mini-language used by the `str.format()` method. When formatting a floating-point number, simply include a comma between the width and the precision:

```
>>> '{:20,.2f}'.format(18446744073709551616.0)
'18,446,744,073,709,551,616.00'
```

When formatting an integer, include the comma after the width:

```
>>> '{:20,d}'.format(18446744073709551616)
'18,446,744,073,709,551,616'
```

This mechanism is not adaptable at all; commas are always used as the separator and the grouping is always into three-digit groups. The comma-formatting mechanism isn't as general as the `locale` module, but it's easier to use.

See also:

[PEP 378 - Format Specifier for Thousands Separator](#)

PEP written by Raymond Hettinger; implemented by Eric Smith.

PEP 389: The `argparse` Module for Parsing Command Lines

The `argparse` module for parsing command-line arguments was added as a more powerful replacement for the `optparse` module.

This means Python now supports three different modules for parsing command-line arguments: `getopt`, `optparse`, and `argparse`. The `getopt` module closely resembles the C library's `getopt()` function, so it remains useful if you're writing a Python prototype that will eventually be rewritten in C. `optparse` becomes redundant, but there are no plans to remove it because there are many scripts still using it, and there's no automated way to update these scripts. (Making the `argparse` API consistent with `optparse`'s interface was discussed but rejected as too messy and difficult.)

In short, if you're writing a new script and don't need to worry about compatibility with earlier versions of Python, use `argparse` instead of `optparse`.

Here's an example:

```
import argparse

parser = argparse.ArgumentParser(description='Command-line exam

# Add optional switches
parser.add_argument('-v', action='store_true', dest='is_verbose',
                    help='produce verbose output')
parser.add_argument('-o', action='store', dest='output',
                    metavar='FILE',
                    help='direct output to FILE instead of stdo
parser.add_argument('-C', action='store', type=int, dest='conte
                    metavar='NUM', default=0,
                    help='display NUM lines of added context')
```

```
# Allow any number of additional arguments.
parser.add_argument(nargs='*', action='store', dest='inputs',
                    help='input filenames (default is stdin)')

args = parser.parse_args()
print args.__dict__
```

Unless you override it, `-h` and `--help` switches are automatically added, and produce neatly formatted output:

```
-> ./python.exe argparse-example.py --help
usage: argparse-example.py [-h] [-v] [-o FILE] [-C NUM] [inputs]

Command-line example.

positional arguments:
  inputs      input filenames (default is stdin)

optional arguments:
  -h, --help  show this help message and exit
  -v          produce verbose output
  -o FILE     direct output to FILE instead of stdout
  -C NUM     display NUM lines of added context
```

As with `optparse`, the command-line switches and arguments are returned as an object with attributes named by the `dest` parameters:

```
-> ./python.exe argparse-example.py -v
{'output': None,
 'is_verbose': True,
 'context': 0,
 'inputs': []}

-> ./python.exe argparse-example.py -v -o /tmp/output -C 4 file
{'output': '/tmp/output',
 'is_verbose': True,
 'context': 4,
 'inputs': ['file1', 'file2']}
```

`argparse` has much fancier validation than `optparse`; you can specify

an exact number of arguments as an integer, 0 or more arguments by passing `'*'`, 1 or more by passing `'+'`, or an optional argument with `'?'`. A top-level parser can contain sub-parsers to define subcommands that have different sets of switches, as in `svn commit`, `svn checkout`, etc. You can specify an argument's type as `FileType`, which will automatically open files for you and understands that `'-'` means standard input or output.

Upgrading optparse code to use argparse

Part of the Python documentation, describing how to convert code that uses `optparse`.

PEP 389 - argparse - New Command Line Parsing Module

PEP written and implemented by Steven Bethard.

PEP 391: Dictionary-Based Configuration For Logging

The `logging` module is very flexible; applications can define a tree of logging subsystems, and each logger in this tree can filter out certain messages, format them differently, and direct messages to a varying number of handlers.

All this flexibility can require a lot of configuration. You can write Python statements to create objects and set their properties, but a complex set-up requires verbose but boring code. `logging` also supports a `fileConfig()` function that parses a file, but the file format doesn't support configuring filters, and it's messier to generate programmatically.

Python 2.7 adds a `dictConfig()` function that uses a dictionary to configure logging. There are many ways to produce a dictionary from different sources: construct one with code; parse a file containing JSON; or use a YAML parsing library if one is installed.

The following example configures two loggers, the root logger and a logger named “network”. Messages sent to the root logger will be sent to the system log using the syslog protocol, and messages to the “network” logger will be written to a `network.log` file that will be rotated once the log reaches 1Mb.

```
import logging
import logging.config

configdict = {
    'version': 1,          # Configuration schema in use; must be 1 for
    'formatters': {
        'standard': {
            'format': ('%(asctime)s %(name)-15s '
                       '%(levelname)-8s %(message)s')},
    },
```

```

'handlers': {'netlog': {'backupCount': 10,
                        'class': 'logging.handlers.RotatingFileHan
                        'filename': '/logs/network.log',
                        'formatter': 'standard',
                        'level': 'INFO',
                        'maxBytes': 1024*1024},
             'syslog': {'class': 'logging.handlers.SysLogHandl
                        'formatter': 'standard',
                        'level': 'ERROR'}}},

# Specify all the subordinate loggers
'loggers': {
    'network': {
        'handlers': ['netlog']
    }
},
# Specify properties of the root logger
'root': {
    'handlers': ['syslog']
},
}

# Set up configuration
logging.config.dictConfig(configdict)

# As an example, log two error messages
logger = logging.getLogger('/')
logger.error('Database not found')

netlogger = logging.getLogger('network')
netlogger.error('Connection failed')

```

Three smaller enhancements to the `logging` module, all implemented by Vinay Sajip, are:

- The `SysLogHandler` class now supports syslogging over TCP. The constructor has a `socktype` parameter giving the type of socket to use, either `socket.SOCK_DGRAM` for UDP or `socket.SOCK_STREAM` for TCP. The default protocol remains UDP.
- `Logger` instances gained a `getChild()` method that retrieves a descendant logger using a relative path. For example, once you

retrieve a logger by doing `log = getLogger('app')`, calling `log.getChild('network.listen')` is equivalent to `getLogger('app.network.listen')`.

- The `LoggerAdapter` class gained a `isEnabledFor()` method that takes a *level* and returns whether the underlying logger would process a message of that level of importance.

See also:

PEP 391 - Dictionary-Based Configuration For Logging

PEP written and implemented by Vinay Sajip.

PEP 3106: Dictionary Views

The dictionary methods `keys()`, `values()`, and `items()` are different in Python 3.x. They return an object called a *view* instead of a fully materialized list.

It's not possible to change the return values of `keys()`, `values()`, and `items()` in Python 2.7 because too much code would break. Instead the 3.x versions were added under the new names `viewkeys()`, `viewvalues()`, and `viewitems()`.

```
>>> d = dict((i*10, chr(65+i)) for i in range(26))
>>> d
{0: 'A', 130: 'N', 10: 'B', 140: 'O', 20: ..., 250: 'Z'}
>>> d.viewkeys()
dict_keys([0, 130, 10, 140, 20, 150, 30, ..., 250])
```

Views can be iterated over, but the key and item views also behave like sets. The `&` operator performs intersection, and `|` performs a union:

```
>>> d1 = dict((i*10, chr(65+i)) for i in range(26))
>>> d2 = dict((i*.5, i) for i in range(1000))
>>> d1.viewkeys() & d2.viewkeys()
set([0.0, 10.0, 20.0, 30.0])
>>> d1.viewkeys() | range(0, 30)
set([0, 1, 130, 3, 4, 5, 6, ..., 120, 250])
```

The view keeps track of the dictionary and its contents change as the dictionary is modified:

```
>>> vk = d.viewkeys()
>>> vk
dict_keys([0, 130, 10, ..., 250])
>>> d[260] = '&'
>>> vk
dict_keys([0, 130, 260, 10, ..., 250])
```

However, note that you can't add or remove keys while you're iterating over the view:

```
>>> for k in vk:
...     d[k*2] = k
...
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
RuntimeError: dictionary changed size during iteration
```

You can use the view methods in Python 2.x code, and the 2to3 converter will change them to the standard `keys()`, `values()`, and `items()` methods.

See also:

PEP 3106 - Revamping dict.keys(), .values() and .items()

PEP written by Guido van Rossum. Backported to 2.7 by Alexandre Vassalotti; [issue 1967](#).

PEP 3137: The memoryview Object

The `memoryview` object provides a view of another object's memory content that matches the `bytes` type's interface.

```
>>> import string
>>> m = memoryview(string.letters)
>>> m
<memory at 0x37f850>
>>> len(m)           # Returns length of underlying object
52
>>> m[0], m[25], m[26] # Indexing returns one byte
('a', 'z', 'A')
>>> m2 = m[0:26]      # Slicing returns another memoryview
>>> m2
<memory at 0x37f080>
```

The content of the view can be converted to a string of bytes or a list of integers:

```
>>> m2.tobytes()
'abcdefghijklmnopqrstuvwxy'
>>> m2.tolist()
[97, 98, 99, 100, 101, 102, 103, ... 121, 122]
>>>
```

`memoryview` objects allow modifying the underlying object if it's a mutable object.

```
>>> m2[0] = 75
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
TypeError: cannot modify read-only memory
>>> b = bytearray(string.letters) # Creating a mutable object
>>> b
bytearray(b'abcdefghijklmnopqrstuvwxyABCDEFGHIJKLMNOPQRSTUVWXYZ')
>>> mb = memoryview(b)
>>> mb[0] = '*' # Assign to view, changing the bytearray
>>> b[0:5] # The bytearray has been changed.
bytearray(b'*bcde')
```

>>>

See also:

PEP 3137 - Immutable Bytes and Mutable Buffer

PEP written by Guido van Rossum. Implemented by Travis Oliphant, Antoine Pitrou and others. Backported to 2.7 by Antoine Pitrou; [issue 2396](#).

Other Language Changes

Some smaller changes made to the core Python language are:

- The syntax for set literals has been backported from Python 3.x. Curly brackets are used to surround the contents of the resulting mutable set; set literals are distinguished from dictionaries by not containing colons and values. `{}` continues to represent an empty dictionary; use `set()` for an empty set.

```
>>> {1,2,3,4,5}
set([1, 2, 3, 4, 5])
>>> set() # empty set
set([])
>>> {}    # empty dict
{}
```

Backported by Alexandre Vassalotti; [issue 2335](#).

- Dictionary and set comprehensions are another feature backported from 3.x, generalizing list/generator comprehensions to use the literal syntax for sets and dictionaries.

```
>>> {x: x*x for x in range(6)}
{0: 0, 1: 1, 2: 4, 3: 9, 4: 16, 5: 25}
>>> {'a'*x for x in range(6)}
set(['', 'a', 'aa', 'aaa', 'aaaa', 'aaaaa'])
```

Backported by Alexandre Vassalotti; [issue 2333](#).

- The `with` statement can now use multiple context managers in one statement. Context managers are processed from left to right and each one is treated as beginning a new `with` statement. This means that:

```
with A() as a, B() as b:
```

```
... suite of statements ...
```

is equivalent to:

```
with A() as a:  
    with B() as b:  
        ... suite of statements ...
```

The `contextlib.nested()` function provides a very similar function, so it's no longer necessary and has been deprecated.

(Proposed in <http://codereview.appspot.com/53094>; implemented by Georg Brandl.)

- Conversions between floating-point numbers and strings are now correctly rounded on most platforms. These conversions occur in many different places: `str()` on floats and complex numbers; the `float` and `complex` constructors; numeric formatting; serializing and deserializing floats and complex numbers using the `marshal`, `pickle` and `json` modules; parsing of float and imaginary literals in Python code; and `Decimal`-to-float conversion.

Related to this, the `repr()` of a floating-point number `x` now returns a result based on the shortest decimal string that's guaranteed to round back to `x` under correct rounding (with round-half-to-even rounding mode). Previously it gave a string based on rounding `x` to 17 decimal digits.

The rounding library responsible for this improvement works on Windows and on Unix platforms using the gcc, icc, or suncc compilers. There may be a small number of platforms where correct operation of this code cannot be guaranteed, so the code is not used on such systems. You can find out which code is being used by checking `sys.float_repr_style`, which will be

`short` if the new code is in use and `legacy` if it isn't.

Implemented by Eric Smith and Mark Dickinson, using David Gay's `dtoa.c` library; [issue 7117](#).

- Conversions from long integers and regular integers to floating point now round differently, returning the floating-point number closest to the number. This doesn't matter for small integers that can be converted exactly, but for large numbers that will unavoidably lose precision, Python 2.7 now approximates more closely. For example, Python 2.6 computed the following:

```
>>> n = 295147905179352891391
>>> float(n)
2.9514790517935283e+20
>>> n - long(float(n))
65535L
```

Python 2.7's floating-point result is larger, but much closer to the true value:

```
>>> n = 295147905179352891391
>>> float(n)
2.9514790517935289e+20
>>> n - long(float(n))
-1L
```

(Implemented by Mark Dickinson; [issue 3166](#).)

Integer division is also more accurate in its rounding behaviours. (Also implemented by Mark Dickinson; [issue 1811](#).)

- Implicit coercion for complex numbers has been removed; the interpreter will no longer ever attempt to call a `__coerce__()` method on complex objects. (Removed by Meador Inge and Mark Dickinson; [issue 5211](#).)
- The `str.format()` method now supports automatic numbering of

the replacement fields. This makes using `str.format()` more closely resemble using `%s` formatting:

```
>>> '{}: {}: {}'.format(2009, 04, 'Sunday')
'2009:4:Sunday'
>>> '{}: {}: {day}'.format(2009, 4, day='Sunday')
'2009:4:Sunday'
```

The auto-numbering takes the fields from left to right, so the first `{...}` specifier will use the first argument to `str.format()`, the next specifier will use the next argument, and so on. You can't mix auto-numbering and explicit numbering – either number all of your specifier fields or none of them – but you can mix auto-numbering and named fields, as in the second example above. (Contributed by Eric Smith; [issue 5237](#).)

Complex numbers now correctly support usage with `format()`, and default to being right-aligned. Specifying a precision or comma-separation applies to both the real and imaginary parts of the number, but a specified field width and alignment is applied to the whole of the resulting `1.5+3j` output. (Contributed by Eric Smith; [issue 1588](#) and [issue 7988](#).)

The 'F' format code now always formats its output using uppercase characters, so it will now produce 'INF' and 'NAN'. (Contributed by Eric Smith; [issue 3382](#).)

A low-level change: the `object.__format__()` method now triggers a `PendingDeprecationWarning` if it's passed a format string, because the `__format__()` method for `object` converts the object to a string representation and formats that. Previously the method silently applied the format string to the string representation, but that could hide mistakes in Python code. If you're supplying formatting information such as an alignment or precision, presumably you're expecting the formatting to be

applied in some object-specific way. (Fixed by Eric Smith; [issue 7994](#).)

- The `int()` and `long()` types gained a `bit_length` method that returns the number of bits necessary to represent its argument in binary:

```
>>> n = 37
>>> bin(n)
'0b100101'
>>> n.bit_length()
6
>>> n = 2**123-1
>>> n.bit_length()
123
>>> (n+1).bit_length()
124
```

(Contributed by Fredrik Johansson and Victor Stinner; [issue 3439](#).)

- The `import` statement will no longer try a relative import if an absolute import (e.g. `from .os import sep`) fails. This fixes a bug, but could possibly break certain `import` statements that were only working by accident. (Fixed by Meador Inge; [issue 7902](#).)
- It's now possible for a subclass of the built-in `unicode` type to override the `__unicode__()` method. (Implemented by Victor Stinner; [issue 1583863](#).)
- The `bytearray` type's `translate()` method now accepts `None` as its first argument. (Fixed by Georg Brandl; [issue 4759](#).)
- When using `@classmethod` and `@staticmethod` to wrap methods as class or static methods, the wrapper object now exposes the wrapped function as their `__func__` attribute. (Contributed by

Amaury Forgeot d’Arc, after a suggestion by George Sakkis; [issue 5982](#).)

- When a restricted set of attributes were set using `__slots__`, deleting an unset attribute would not raise `AttributeError` as you would expect. Fixed by Benjamin Peterson; [issue 7604](#).)
- Two new encodings are now supported: “cp720”, used primarily for Arabic text; and “cp858”, a variant of CP 850 that adds the euro symbol. (CP720 contributed by Alexander Belchenko and Amaury Forgeot d’Arc in [issue 1616979](#); CP858 contributed by Tim Hatch in [issue 8016](#).)
- The `file` object will now set the `filename` attribute on the `IOError` exception when trying to open a directory on POSIX platforms (noted by Jan Kaliszewski; [issue 4764](#)), and now explicitly checks for and forbids writing to read-only file objects instead of trusting the C library to catch and report the error (fixed by Stefan Kraah; [issue 5677](#)).
- The Python tokenizer now translates line endings itself, so the `compile()` built-in function now accepts code using any line-ending convention. Additionally, it no longer requires that the code end in a newline.
- Extra parentheses in function definitions are illegal in Python 3.x, meaning that you get a syntax error from `def f((x)): pass`. In Python3-warning mode, Python 2.7 will now warn about this odd usage. (Noted by James Lingard; [issue 7362](#).)
- It’s now possible to create weak references to old-style class objects. New-style classes were always weak-referenceable. (Fixed by Antoine Pitrou; [issue 8268](#).)
- When a module object is garbage-collected, the module’s

dictionary is now only cleared if no one else is holding a reference to the dictionary ([issue 7140](#)).

Interpreter Changes

A new environment variable, `PYTHONWARNINGS`, allows controlling warnings. It should be set to a string containing warning settings, equivalent to those used with the `-W` switch, separated by commas. (Contributed by Brian Curtin; [issue 7301](#).)

For example, the following setting will print warnings every time they occur, but turn warnings from the `cookie` module into an error. (The exact syntax for setting an environment variable varies across operating systems and shells.)

```
export PYTHONWARNINGS=all,error:::Cookie:0
```

Optimizations

Several performance enhancements have been added:

- A new opcode was added to perform the initial setup for `with` statements, looking up the `__enter__()` and `__exit__()` methods. (Contributed by Benjamin Peterson.)
- The garbage collector now performs better for one common usage pattern: when many objects are being allocated without deallocating any of them. This would previously take quadratic time for garbage collection, but now the number of full garbage collections is reduced as the number of objects on the heap grows. The new logic only performs a full garbage collection pass when the middle generation has been collected 10 times and when the number of survivor objects from the middle generation exceeds 10% of the number of objects in the oldest

generation. (Suggested by Martin von Löwis and implemented by Antoine Pitrou; [issue 4074](#).)

- The garbage collector tries to avoid tracking simple containers which can't be part of a cycle. In Python 2.7, this is now true for tuples and dicts containing atomic types (such as ints, strings, etc.). Transitively, a dict containing tuples of atomic types won't be tracked either. This helps reduce the cost of each garbage collection by decreasing the number of objects to be considered and traversed by the collector. (Contributed by Antoine Pitrou; [issue 4688](#).)
- Long integers are now stored internally either in base 2^{15} or in base 2^{30} , the base being determined at build time. Previously, they were always stored in base 2^{15} . Using base 2^{30} gives significant performance improvements on 64-bit machines, but benchmark results on 32-bit machines have been mixed. Therefore, the default is to use base 2^{30} on 64-bit machines and base 2^{15} on 32-bit machines; on Unix, there's a new configure option `--enable-big-digits` that can be used to override this default.

Apart from the performance improvements this change should be invisible to end users, with one exception: for testing and debugging purposes there's a new structseq `sys.long_info` that provides information about the internal format, giving the number of bits per digit and the size in bytes of the C type used to store each digit:

```
>>> import sys
>>> sys.long_info
sys.long_info(bits_per_digit=30, sizeof_digit=4)
```

(Contributed by Mark Dickinson; [issue 4258](#).)

Another set of changes made long objects a few bytes smaller:

2 bytes smaller on 32-bit systems and 6 bytes on 64-bit. (Contributed by Mark Dickinson; [issue 5260](#).)

- The division algorithm for long integers has been made faster by tightening the inner loop, doing shifts instead of multiplications, and fixing an unnecessary extra iteration. Various benchmarks show speedups of between 50% and 150% for long integer divisions and modulo operations. (Contributed by Mark Dickinson; [issue 5512](#).) Bitwise operations are also significantly faster (initial patch by Gregory Smith; [issue 1087418](#)).
- The implementation of `%` checks for the left-side operand being a Python string and special-cases it; this results in a 1-3% performance increase for applications that frequently use `%` with strings, such as templating libraries. (Implemented by Collin Winter; [issue 5176](#).)
- List comprehensions with an `if` condition are compiled into faster bytecode. (Patch by Antoine Pitrou, back-ported to 2.7 by Jeffrey Yasskin; [issue 4715](#).)
- Converting an integer or long integer to a decimal string was made faster by special-casing base 10 instead of using a generalized conversion function that supports arbitrary bases. (Patch by Gawain Bolton; [issue 6713](#).)
- The `split()`, `replace()`, `rindex()`, `rpartition()`, and `rsplit()` methods of string-like types (strings, Unicode strings, and `bytearray` objects) now use a fast reverse-search algorithm instead of a character-by-character scan. This is sometimes faster by a factor of 10. (Added by Florent Xicluna; [issue 7462](#) and [issue 7622](#).)
- The `pickle` and `cPickle` modules now automatically intern the strings used for attribute names, reducing memory usage of the

objects resulting from unpickling. (Contributed by Jake McGuire; [issue 5084](#).)

- The `cPickle` module now special-cases dictionaries, nearly halving the time required to pickle them. (Contributed by Collin Winter; [issue 5670](#).)

New and Improved Modules

As in every release, Python's standard library received a number of enhancements and bug fixes. Here's a partial list of the most notable changes, sorted alphabetically by module name. Consult the `Misc/NEWS` file in the source tree for a more complete list of changes, or look through the Subversion logs for all the details.

- The `bdb` module's base debugging class `Bdb` gained a feature for skipping modules. The constructor now takes an iterable containing glob-style patterns such as `django.*`; the debugger will not step into stack frames from a module that matches one of these patterns. (Contributed by Maru Newby after a suggestion by Senthil Kumaran; [issue 5142](#).)
- The `binascii` module now supports the buffer API, so it can be used with `memoryview` instances and other similar buffer objects. (Backported from 3.x by Florent Xicluna; [issue 7703](#).)
- Updated module: the `bsddb` module has been updated from 4.7.2devel9 to version 4.8.4 of [the pybsddb package](#). The new version features better Python 3.x compatibility, various bug fixes, and adds several new BerkeleyDB flags and methods. (Updated by Jesús Cea Avión; [issue 8156](#). The `pybsddb` changelog can be read at <http://hg.jcea.es/pybsddb/file/tip/ChangeLog>.)
- The `bz2` module's `BZ2File` now supports the context management protocol, so you can write with `bz2.BZ2File(...)` as `f:`. (Contributed by Hagen Fürstenau; [issue 3860](#).)
- New class: the `Counter` class in the `collections` module is useful for tallying data. `Counter` instances behave mostly like

dictionaries but return zero for missing keys instead of raising a `KeyError`:

```
>>> from collections import Counter
>>> c = Counter()
>>> for letter in 'here is a sample of english text':
...     c[letter] += 1
...
>>> c
Counter({' ': 6, 'e': 5, 's': 3, 'a': 2, 'i': 2, 'h': 2,
'l': 2, 't': 2, 'g': 1, 'f': 1, 'm': 1, 'o': 1, 'n': 1,
'p': 1, 'r': 1, 'x': 1})
>>> c['e']
5
>>> c['z']
0
```

There are three additional `Counter` methods. `most_common()` returns the N most common elements and their counts. `elements()` returns an iterator over the contained elements, repeating each element as many times as its count. `subtract()` takes an iterable and subtracts one for each element instead of adding; if the argument is a dictionary or another `Counter`, the counts are subtracted.

```
>>> c.most_common(5)
[(' ', 6), ('e', 5), ('s', 3), ('a', 2), ('i', 2)]
>>> c.elements() ->
'a', 'a', ' ', ' ', ' ', ' ', ' ', ' ', ' ', ' ',
'e', 'e', 'e', 'e', 'e', 'g', 'f', 'i', 'i',
'h', 'h', 'm', 'l', 'l', 'o', 'n', 'p', 's',
's', 's', 'r', 't', 't', 'x'
>>> c['e']
5
>>> c.subtract('very heavy on the letter e')
>>> c['e']      # Count is now lower
-1
```

Contributed by Raymond Hettinger; issue 1696199.

New class: `OrderedDict` is described in the earlier section [PEP 372: Adding an Ordered Dictionary to collections](#).

New method: The `deque` data type now has a `count()` method that returns the number of contained elements equal to the supplied argument `x`, and a `reverse()` method that reverses the elements of the deque in-place. `deque` also exposes its maximum length as the read-only `maxlen` attribute. (Both features added by Raymond Hettinger.)

The `namedtuple` class now has an optional `rename` parameter. If `rename` is true, field names that are invalid because they've been repeated or aren't legal Python identifiers will be renamed to legal names that are derived from the field's position within the list of fields:

```
>>> from collections import namedtuple
>>> T = namedtuple('T', ['field1', '$illegal', 'for', 'field2'])
>>> T._fields
('field1', '_1', '_2', 'field2')
```

(Added by Raymond Hettinger; [issue 1818](#).)

Finally, the `Mapping` abstract base class now returns `NotImplemented` if a mapping is compared to another type that isn't a `Mapping`. (Fixed by Daniel Stutzbach; [issue 8729](#).)

- Constructors for the parsing classes in the `ConfigParser` module now take a `allow_no_value` parameter, defaulting to false; if true, options without values will be allowed. For example:

```
>>> import ConfigParser, StringIO
>>> sample_config = """
... [mysqld]
... user = mysql
... pid-file = /var/run/mysqld/mysqld.pid
```

```
... skip-bdb
... """
>>> config = ConfigParser.RawConfigParser(allow_no_value=True)
>>> config.readfp(StringIO.StringIO(sample_config))
>>> config.get('mysqld', 'user')
'mysql'
>>> print config.get('mysqld', 'skip-bdb')
None
>>> print config.get('mysqld', 'unknown')
Traceback (most recent call last):
...
NoOptionError: No option 'unknown' in section: 'mysqld'
```

(Contributed by Mats Kindahl; [issue 7005](#).)

- Deprecated function: `contextlib.nested()`, which allows handling more than one context manager with a single `with` statement, has been deprecated, because the `with` statement now supports multiple context managers.
- The `cookielib` module now ignores cookies that have an invalid version field, one that doesn't contain an integer value. (Fixed by John J. Lee; [issue 3924](#).)
- The `copy` module's `deepcopy()` function will now correctly copy bound instance methods. (Implemented by Robert Collins; [issue 1515](#).)
- The `ctypes` module now always converts `None` to a C NULL pointer for arguments declared as pointers. (Changed by Thomas Heller; [issue 4606](#).) The underlying `libffi` library has been updated to version 3.0.9, containing various fixes for different platforms. (Updated by Matthias Klose; [issue 8142](#).)
- New method: the `datetime` module's `timedelta` class gained a `total_seconds()` method that returns the number of seconds in the duration. (Contributed by Brian Quinlan; [issue 5788](#).)

- New method: the `Decimal` class gained a `from_float()` class method that performs an exact conversion of a floating-point number to a `Decimal`. This exact conversion strives for the closest decimal approximation to the floating-point representation's value; the resulting decimal value will therefore still include the inaccuracy, if any. For example, `Decimal.from_float(0.1)` returns `Decimal('0.10000000000000000005551115123125782702118158340454101')` (Implemented by Raymond Hettinger; [issue 4796](#).)

Comparing instances of `Decimal` with floating-point numbers now produces sensible results based on the numeric values of the operands. Previously such comparisons would fall back to Python's default rules for comparing objects, which produced arbitrary results based on their type. Note that you still cannot combine `Decimal` and floating-point in other operations such as addition, since you should be explicitly choosing how to convert between float and `Decimal`. (Fixed by Mark Dickinson; [issue 2531](#).)

The constructor for `Decimal` now accepts floating-point numbers (added by Raymond Hettinger; [issue 8257](#)) and non-European Unicode characters such as Arabic-Indic digits (contributed by Mark Dickinson; [issue 6595](#)).

Most of the methods of the `Context` class now accept integers as well as `Decimal` instances; the only exceptions are the `canonical()` and `is_canonical()` methods. (Patch by Juan José Conti; [issue 7633](#).)

When using `Decimal` instances with a string's `format()` method, the default alignment was previously left-alignment. This has been changed to right-alignment, which is more sensible for numeric types. (Changed by Mark Dickinson; [issue 6857](#).)

Comparisons involving a signaling NaN value (or `sNaN`) now signal `InvalidOperation` instead of silently returning a true or false value depending on the comparison operator. Quiet NaN values (or `NaN`) are now hashable. (Fixed by Mark Dickinson; [issue 7279](#).)

- The `difflib` module now produces output that is more compatible with modern `diff/patch` tools through one small change, using a tab character instead of spaces as a separator in the header giving the filename. (Fixed by Anatoly Techtonik; [issue 7585](#).)
- The Distutils `sdist` command now always regenerates the `MANIFEST` file, since even if the `MANIFEST.in` or `setup.py` files haven't been modified, the user might have created some new files that should be included. (Fixed by Tarek Ziadé; [issue 8688](#).)
- The `doctest` module's `IGNORE_EXCEPTION_DETAIL` flag will now ignore the name of the module containing the exception being tested. (Patch by Lennart Regebro; [issue 7490](#).)
- The `email` module's `Message` class will now accept a Unicode-valued payload, automatically converting the payload to the encoding specified by `output_charset`. (Added by R. David Murray; [issue 1368247](#).)
- The `Fraction` class now accepts a single float or `Decimal` instance, or two rational numbers, as arguments to its constructor. (Implemented by Mark Dickinson; rationals added in [issue 5812](#), and float/decimal in [issue 8294](#).)

Ordering comparisons (`<`, `<=`, `>`, `>=`) between fractions and complex numbers now raise a `TypeError`. This fixes an oversight, making the `Fraction` match the other numeric types.

- New class: `FTP_TLS` in the `ftplib` module provides secure FTP connections using TLS encapsulation of authentication as well as subsequent control and data transfers. (Contributed by Giampaolo Rodola; [issue 2054](#).)

The `storbinary()` method for binary uploads can now restart uploads thanks to an added `rest` parameter (patch by Pablo Mouzo; [issue 6845](#).)

- New class decorator: `total_ordering()` in the `functools` module takes a class that defines an `__eq__()` method and one of `__lt__()`, `__le__()`, `__gt__()`, or `__ge__()`, and generates the missing comparison methods. Since the `__cmp__()` method is being deprecated in Python 3.x, this decorator makes it easier to define ordered classes. (Added by Raymond Hettinger; [issue 5479](#).)

New function: `cmp_to_key()` will take an old-style comparison function that expects two arguments and return a new callable that can be used as the `key` parameter to functions such as `sorted()`, `min()` and `max()`, etc. The primary intended use is to help with making code compatible with Python 3.x. (Added by Raymond Hettinger.)

- New function: the `gc` module's `is_tracked()` returns true if a given instance is tracked by the garbage collector, false otherwise. (Contributed by Antoine Pitrou; [issue 4688](#).)
- The `gzip` module's `GzipFile` now supports the context management protocol, so you can write `with gzip.GzipFile(...) as f:` (contributed by Hagen Fürstenau; [issue 3860](#)), and it now implements the `io.BufferedIOBase` ABC, so you can wrap it with `io.BufferedReader` for faster processing (contributed by Nir Aides; [issue 7471](#)). It's also now possible to

override the modification time recorded in a gzipped file by providing an optional timestamp to the constructor. (Contributed by Jacques Frechet; [issue 4272](#).)

Files in gzip format can be padded with trailing zero bytes; the `gzip` module will now consume these trailing bytes. (Fixed by Tadek Pietraszek and Brian Curtin; [issue 2846](#).)

- New attribute: the `hashlib` module now has an `algorithms` attribute containing a tuple naming the supported algorithms. In Python 2.7, `hashlib.algorithms` contains `('md5', 'sha1', 'sha224', 'sha256', 'sha384', 'sha512')`. (Contributed by Carl Chenet; [issue 7418](#).)
- The default `HTTPResponse` class used by the `httplib` module now supports buffering, resulting in much faster reading of HTTP responses. (Contributed by Kristján Valur Jónsson; [issue 4879](#).)

The `HTTPConnection` and `HTTPSConnection` classes now support a `source_address` parameter, a `(host, port)` 2-tuple giving the source address that will be used for the connection. (Contributed by Eldon Ziegler; [issue 3972](#).)

- The `ihooks` module now supports relative imports. Note that `ihooks` is an older module for customizing imports, superseded by the `importlib` module added in Python 2.0. (Relative import support added by Neil Schemenauer.)
- The `imaplib` module now supports IPv6 addresses. (Contributed by Derek Morr; [issue 1655](#).)
- New function: the `inspect` module's `getcallargs()` takes a callable and its positional and keyword arguments, and figures

out which of the callable's parameters will receive each argument, returning a dictionary mapping argument names to their values. For example:

```
>>> from inspect import getcallargs
>>> def f(a, b=1, *pos, **named):
...     pass
>>> getcallargs(f, 1, 2, 3)
{'a': 1, 'b': 2, 'pos': (3,), 'named': {}}
>>> getcallargs(f, a=2, x=4)
{'a': 2, 'b': 1, 'pos': (), 'named': {'x': 4}}
>>> getcallargs(f)
Traceback (most recent call last):
...
TypeError: f() takes at least 1 argument (0 given)
```

Contributed by George Sakkis; [issue 3135](#).

- Updated module: The `io` library has been upgraded to the version shipped with Python 3.1. For 3.1, the I/O library was entirely rewritten in C and is 2 to 20 times faster depending on the task being performed. The original Python version was renamed to the `_pyio` module.

One minor resulting change: the `io.TextIOBase` class now has an `errors` attribute giving the error setting used for encoding and decoding errors (one of `'strict'`, `'replace'`, `'ignore'`).

The `io.FileIO` class now raises an `OSError` when passed an invalid file descriptor. (Implemented by Benjamin Peterson; [issue 4991](#).) The `truncate()` method now preserves the file position; previously it would change the file position to the end of the new file. (Fixed by Pascal Chambon; [issue 6939](#).)

- New function: `itertools.compress(data, selectors)` takes two iterators. Elements of `data` are returned if the corresponding value in `selectors` is true:

```
itertools.compress('ABCDEF', [1,0,1,0,1,1]) =>
A, C, E, F
```

New function: `itertools.combinations_with_replacement(iter, r)` returns all the possible r -length combinations of elements from the iterable *iter*. Unlike `combinations()`, individual elements can be repeated in the generated combinations:

```
itertools.combinations_with_replacement('abc', 2) =>
('a', 'a'), ('a', 'b'), ('a', 'c'),
('b', 'b'), ('b', 'c'), ('c', 'c')
```

Note that elements are treated as unique depending on their position in the input, not their actual values.

The `itertools.count()` function now has a *step* argument that allows incrementing by values other than 1. `count()` also now allows keyword arguments, and using non-integer values such as floats or `Decimal` instances. (Implemented by Raymond Hettinger; [issue 5032](#).)

`itertools.combinations()` and `itertools.product()` previously raised `ValueError` for values of r larger than the input iterable. This was deemed a specification error, so they now return an empty iterator. (Fixed by Raymond Hettinger; [issue 4816](#).)

- Updated module: The `json` module was upgraded to version 2.0.9 of the `simplejson` package, which includes a C extension that makes encoding and decoding faster. (Contributed by Bob Ippolito; [issue 4136](#).)

To support the new `collections.OrderedDict` type, `json.load()` now has an optional `object_pairs_hook` parameter that will be called with any object literal that decodes to a list of pairs. (Contributed by Raymond Hettinger; [issue 5381](#).)

- The `mailbox` module's `Maildir` class now records the timestamp on the directories it reads, and only re-reads them if the modification time has subsequently changed. This improves performance by avoiding unneeded directory scans. (Fixed by A.M. Kuchling and Antoine Pitrou; [issue 1607951](#), [issue 6896](#).)
- New functions: the `math` module gained `erf()` and `erfc()` for the error function and the complementary error function, `expm1()` which computes $e^{*x} - 1$ with more precision than using `exp()` and subtracting 1, `gamma()` for the Gamma function, and `lgamma()` for the natural log of the Gamma function. (Contributed by Mark Dickinson and nirinA raseliarison; [issue 3366](#).)
- The `multiprocessing` module's `Manager*` classes can now be passed a callable that will be called whenever a subprocess is started, along with a set of arguments that will be passed to the callable. (Contributed by lekma; [issue 5585](#).)

The `Pool` class, which controls a pool of worker processes, now has an optional `maxtasksperchild` parameter. Worker processes will perform the specified number of tasks and then exit, causing the `Pool` to start a new worker. This is useful if tasks may leak memory or other resources, or if some tasks will cause the worker to become very large. (Contributed by Charles Cazabon; [issue 6963](#).)

- The `nntplib` module now supports IPv6 addresses. (Contributed by Derek Morr; [issue 1664](#).)
- New functions: the `os` module wraps the following POSIX system calls: `getresgid()` and `getresuid()`, which return the real, effective, and saved GIDs and UIDs; `setresgid()` and `setresuid()`, which set real, effective, and saved GIDs and UIDs to new values; `initgroups()`, which initialize the group access

list for the current process. (GID/UID functions contributed by Travis H.; [issue 6508](#). Support for `initgroups` added by Jean-Paul Calderone; [issue 7333](#).)

The `os.fork()` function now re-initializes the import lock in the child process; this fixes problems on Solaris when `fork()` is called from a thread. (Fixed by Zsolt Cserna; [issue 7242](#).)

- In the `os.path` module, the `normpath()` and `abspath()` functions now preserve Unicode; if their input path is a Unicode string, the return value is also a Unicode string. (`normpath()` fixed by Matt Giuca in [issue 5827](#); `abspath()` fixed by Ezio Melotti in [issue 3426](#).)
- The `pydoc` module now has help for the various symbols that Python uses. You can now do `help('<<')` or `help('@')`, for example. (Contributed by David Laban; [issue 4739](#).)
- The `re` module's `split()`, `sub()`, and `subn()` now accept an optional *flags* argument, for consistency with the other functions in the module. (Added by Gregory P. Smith.)
- New function: `run_path()` in the `runpy` module will execute the code at a provided *path* argument. *path* can be the path of a Python source file (`example.py`), a compiled bytecode file (`example.pyc`), a directory (`./package/`), or a zip archive (`example.zip`). If a directory or zip path is provided, it will be added to the front of `sys.path` and the module `__main__` will be imported. It's expected that the directory or zip contains a `__main__.py`; if it doesn't, some other `__main__.py` might be imported from a location later in `sys.path`. This makes more of the machinery of `runpy` available to scripts that want to mimic the way Python's command line processes an explicit path

name. (Added by Nick Coghlan; [issue 6816](#).)

- New function: in the `shutil` module, `make_archive()` takes a filename, archive type (zip or tar-format), and a directory path, and creates an archive containing the directory's contents. (Added by Tarek Ziadé.)

`shutil`'s `copyfile()` and `copytree()` functions now raise a `SpecialFileError` exception when asked to copy a named pipe. Previously the code would treat named pipes like a regular file by opening them for reading, and this would block indefinitely. (Fixed by Antoine Pitrou; [issue 3002](#).)

- The `signal` module no longer re-installs the signal handler unless this is truly necessary, which fixes a bug that could make it impossible to catch the `EINTR` signal robustly. (Fixed by Charles-Francois Natali; [issue 8354](#).)
- New functions: in the `site` module, three new functions return various site- and user-specific paths. `getsitepackages()` returns a list containing all global site-packages directories, `getusersitepackages()` returns the path of the user's site-packages directory, and `getuserbase()` returns the value of the `USER_BASE` environment variable, giving the path to a directory that can be used to store data. (Contributed by Tarek Ziadé; [issue 6693](#).)

The `site` module now reports exceptions occurring when the `sitecustomize` module is imported, and will no longer catch and swallow the `KeyboardInterrupt` exception. (Fixed by Victor Stinner; [issue 3137](#).)

- The `create_connection()` function gained a `source_address` parameter, a `(host, port)` 2-tuple giving the source address

that will be used for the connection. (Contributed by Eldon Ziegler; [issue 3972](#).)

The `recv_into()` and `recvfrom_into()` methods will now write into objects that support the buffer API, most usefully the `bytearray` and `memoryview` objects. (Implemented by Antoine Pitrou; [issue 8104](#).)

- The `socketServer` module's `TCPServer` class now supports socket timeouts and disabling the Nagle algorithm. The `disable_nagle_algorithm` class attribute defaults to `False`; if overridden to be `True`, new request connections will have the `TCP_NODELAY` option set to prevent buffering many small sends into a single TCP packet. The `timeout` class attribute can hold a timeout in seconds that will be applied to the request socket; if no request is received within that time, `handle_timeout()` will be called and `handle_request()` will return. (Contributed by Kristján Valur Jónsson; [issue 6192](#) and [issue 6267](#).)
- Updated module: the `sqlite3` module has been updated to version 2.6.0 of the `pysqlite package`. Version 2.6.0 includes a number of bugfixes, and adds the ability to load SQLite extensions from shared libraries. Call the `enable_load_extension(True)` method to enable extensions, and then call `load_extension()` to load a particular shared library. (Updated by Gerhard Häring.)
- The `ssl` module's `ssl.SSLSocket` objects now support the buffer API, which fixed a test suite failure (fix by Antoine Pitrou; [issue 7133](#)) and automatically set OpenSSL's `SSL_MODE_AUTO_RETRY`, which will prevent an error code being returned from `recv()` operations that trigger an SSL renegotiation (fix by Antoine Pitrou; [issue 8222](#)).

The `ssl.wrap_socket()` constructor function now takes a *ciphers* argument that's a string listing the encryption algorithms to be allowed; the format of the string is described in the [OpenSSL documentation](#). (Added by Antoine Pitrou; [issue 8322](#).)

Another change makes the extension load all of OpenSSL's ciphers and digest algorithms so that they're all available. Some SSL certificates couldn't be verified, reporting an "unknown algorithm" error. (Reported by Beda Kosata, and fixed by Antoine Pitrou; [issue 8484](#).)

The version of OpenSSL being used is now available as the module attributes `ssl.OPENSLL_VERSION` (a string), `ssl.OPENSLL_VERSION_INFO` (a 5-tuple), and `ssl.OPENSLL_VERSION_NUMBER` (an integer). (Added by Antoine Pitrou; [issue 8321](#).)

- The `struct` module will no longer silently ignore overflow errors when a value is too large for a particular integer format code (one of `bBhHiIiLlqQ`); it now always raises a `struct.error` exception. (Changed by Mark Dickinson; [issue 1523](#).) The `pack()` function will also attempt to use `__index__()` to convert and pack non-integers before trying the `__int__()` method or reporting an error. (Changed by Mark Dickinson; [issue 8300](#).)
- New function: the `subprocess` module's `check_output()` runs a command with a specified set of arguments and returns the command's output as a string when the command runs without error, or raises a `CalledProcessError` exception otherwise.

```
>>> subprocess.check_output(['df', '-h', '.'])
'Filesystem      Size  Used Avail Capacity  Mounted on\n
/dev/disk0s2    52G   49G   3.0G    94%   /\n'

>>> subprocess.check_output(['df', '-h', '/bogus'])
...
```

```
subprocess.CalledProcessError: Command '['df', '-h', '/bogu
```

(Contributed by Gregory P. Smith.)

The `subprocess` module will now retry its internal system calls on receiving an `EINTR` signal. (Reported by several people; final patch by Gregory P. Smith in [issue 1068268](#).)

- New function: `is_declared_global()` in the `symtable` module returns true for variables that are explicitly declared to be global, false for ones that are implicitly global. (Contributed by Jeremy Hylton.)
- The `syslog` module will now use the value of `sys.argv[0]` as the identifier instead of the previous default value of `'python'`. (Changed by Sean Reifschneider; [issue 8451](#).)
- The `sys.version_info` value is now a named tuple, with attributes named `major`, `minor`, `micro`, `releaselevel`, and `serial`. (Contributed by Ross Light; [issue 4285](#).)

`sys.getwindowsversion()` also returns a named tuple, with attributes named `major`, `minor`, `build`, `platform`, `service_pack`, `service_pack_major`, `service_pack_minor`, `suite_mask`, and `product_type`. (Contributed by Brian Curtin; [issue 7766](#).)

- The `tarfile` module's default error handling has changed, to no longer suppress fatal errors. The default error level was previously 0, which meant that errors would only result in a message being written to the debug log, but because the debug log is not activated by default, these errors go unnoticed. The default error level is now 1, which raises an exception if there's an error. (Changed by Lars Gustäbel; [issue 7357](#).)

`tarfile` now supports filtering the `TarInfo` objects being added to a tar file. When you call `add()`, you may supply an optional *filter* argument that's a callable. The *filter* callable will be passed the `TarInfo` for every file being added, and can modify and return it. If the callable returns `None`, the file will be excluded from the resulting archive. This is more powerful than the existing *exclude* argument, which has therefore been deprecated. (Added by Lars Gustäbel; [issue 6856](#).) The `TarFile` class also now supports the context manager protocol. (Added by Lars Gustäbel; [issue 7232](#).)

- The `wait()` method of the `threading.Event` class now returns the internal flag on exit. This means the method will usually return true because `wait()` is supposed to block until the internal flag becomes true. The return value will only be false if a timeout was provided and the operation timed out. (Contributed by Tim Leshner; [issue 1674032](#).)
- The Unicode database provided by the `unicodedata` module is now used internally to determine which characters are numeric, whitespace, or represent line breaks. The database also includes information from the `Unihan.txt` data file (patch by Anders Chrigström and Amaury Forgeot d'Arc; [issue 1571184](#)) and has been updated to version 5.2.0 (updated by Florent Xicluna; [issue 8024](#)).
- The `urlparse` module's `urlsplit()` now handles unknown URL schemes in a fashion compliant with [RFC 3986](#): if the URL is of the form "`<something>://...`", the text before the `://` is treated as the scheme, even if it's a made-up scheme that the module doesn't know about. This change may break code that worked around the old behaviour. For example, Python 2.6.4 or 2.5 will return the following:

```
>>> import urlparse
>>> urlparse.urlsplit('invented://host/filename?query')
('invented', '', '//host/filename?query', '', '')
```

Python 2.7 (and Python 2.6.5) will return:

```
>>> import urlparse
>>> urlparse.urlsplit('invented://host/filename?query')
('invented', 'host', '/filename?query', '', '')
```

(Python 2.7 actually produces slightly different output, since it returns a named tuple instead of a standard tuple.)

The `urlparse` module also supports IPv6 literal addresses as defined by [RFC 2732](#) (contributed by Senthil Kumaran; [issue 2987](#)).

```
>>> urlparse.urlparse('http://[1080::8:800:200C:417A]/foo')
ParseResult(scheme='http', netloc='[1080::8:800:200C:417A]',
            path='/foo', params='', query='', fragment='')
```

- New class: the `WeakSet` class in the `weakref` module is a set that only holds weak references to its elements; elements will be removed once there are no references pointing to them. (Originally implemented in Python 3.x by Raymond Hettinger, and backported to 2.7 by Michael Foord.)
- The `ElementTree` library, `xml.etree`, no longer escapes ampersands and angle brackets when outputting an XML processing instruction (which looks like `<?xml-stYLESHEET href="#style1"?)` or comment (which looks like `<!-- comment ->`). (Patch by Neil Muller; [issue 2746](#).)
- The XML-RPC client and server, provided by the `xmlrpclib` and `SimpleXMLRPCServer` modules, have improved performance by supporting HTTP/1.1 keep-alive and by optionally using gzip

encoding to compress the XML being exchanged. The gzip compression is controlled by the `encode_threshold` attribute of `SimpleXMLRPCRequestHandler`, which contains a size in bytes; responses larger than this will be compressed. (Contributed by Kristján Valur Jónsson; [issue 6267](#).)

- The `zipfile` module's `ZipFile` now supports the context management protocol, so you can write `with zipfile.ZipFile(...) as f:`. (Contributed by Brian Curtin; [issue 5511](#).)

`zipfile` now also supports archiving empty directories and extracts them correctly. (Fixed by Kuba Wiczorek; [issue 4710](#).) Reading files out of an archive is faster, and interleaving `read()` and `readline()` now works correctly. (Contributed by Nir Aides; [issue 7610](#).)

The `is_zipfile()` function now accepts a file object, in addition to the path names accepted in earlier versions. (Contributed by Gabriel Genellina; [issue 4756](#).)

The `writestr()` method now has an optional `compress_type` parameter that lets you override the default compression method specified in the `ZipFile` constructor. (Contributed by Ronald Oussoren; [issue 6003](#).)

New module: `importlib`

Python 3.1 includes the `importlib` package, a re-implementation of the logic underlying Python's `import` statement. `importlib` is useful for implementors of Python interpreters and to users who wish to write new importers that can participate in the import process. Python 2.7 doesn't contain the complete `importlib` package, but

instead has a tiny subset that contains a single function, `import_module()`.

`import_module(name, package=None)` imports a module. *name* is a string containing the module or package's name. It's possible to do relative imports by providing a string that begins with a `.` character, such as `..utils.errors`. For relative imports, the *package* argument must be provided and is the name of the package that will be used as the anchor for the relative import. `import_module()` both inserts the imported module into `sys.modules` and returns the module object.

Here are some examples:

```
>>> from importlib import import_module
>>> anydbm = import_module('anydbm') # Standard absolute import
>>> anydbm
<module 'anydbm' from '/p/python/Lib/anydbm.py'>
>>> # Relative import
>>> file_util = import_module('..file_util', 'distutils.command
>>> file_util
<module 'distutils.file_util' from '/python/Lib/distutils/file_
```

`importlib` was implemented by Brett Cannon and introduced in Python 3.1.

New module: sysconfig

The `sysconfig` module has been pulled out of the Distutils package, becoming a new top-level module in its own right. `sysconfig` provides functions for getting information about Python's build process: compiler switches, installation paths, the platform name, and whether Python is running from its source directory.

Some of the functions in the module are:

- `get_config_var()` returns variables from Python's Makefile and the `pyconfig.h` file.
- `get_config_vars()` returns a dictionary containing all of the configuration variables.
- `getpath()` returns the configured path for a particular type of module: the standard library, site-specific modules, platform-specific modules, etc.
- `is_python_build()` returns true if you're running a binary from a Python source tree, and false otherwise.

Consult the `sysconfig` documentation for more details and for a complete list of functions.

The Distutils package and `sysconfig` are now maintained by Tarek Ziadé, who has also started a Distutils2 package (source repository at <http://hg.python.org/distutils2/>) for developing a next-generation version of Distutils.

ttk: Themed Widgets for Tk

Tcl/Tk 8.5 includes a set of themed widgets that re-implement basic Tk widgets but have a more customizable appearance and can therefore more closely resemble the native platform's widgets. This widget set was originally called Tile, but was renamed to Ttk (for "themed Tk") on being added to Tcl/Tk release 8.5.

To learn more, read the `ttk` module documentation. You may also wish to read the Tcl/Tk manual page describing the Ttk theme engine, available at http://www.tcl.tk/man/tcl8.5/TkCmd/ttk_intro.htm. Some screenshots of the Python/Ttk code in use are at <http://code.google.com/p/python-ttk/wiki/Screenshots>.

The `ttk` module was written by Guilherme Polo and added in [issue 2983](#). An alternate version called `Tile.py`, written by Martin Franklin

and maintained by Kevin Walzer, was proposed for inclusion in [issue 2618](#), but the authors argued that Guilherme Polo's work was more comprehensive.

Updated module: unittest

The `unittest` module was greatly enhanced; many new features were added. Most of these features were implemented by Michael Foord, unless otherwise noted. The enhanced version of the module is downloadable separately for use with Python versions 2.4 to 2.6, packaged as the `unittest2` package, from <http://pypi.python.org/pypi/unittest2>.

When used from the command line, the module can automatically discover tests. It's not as fancy as `py.test` or `nose`, but provides a simple way to run tests kept within a set of package directories. For example, the following command will search the `test/` subdirectory for any importable test files named `test*.py`:

```
python -m unittest discover -s test
```

Consult the `unittest` module documentation for more details. (Developed in [issue 6001](#).)

The `main()` function supports some other new options:

- `-b` or `--buffer` will buffer the standard output and standard error streams during each test. If the test passes, any resulting output will be discarded; on failure, the buffered output will be displayed.
- `-c` or `--catch` will cause the control-C interrupt to be handled more gracefully. Instead of interrupting the test process immediately, the currently running test will be completed and then the partial results up to the interruption will be reported. If

you're impatient, a second press of control-C will cause an immediate interruption.

This control-C handler tries to avoid causing problems when the code being tested or the tests being run have defined a signal handler of their own, by noticing that a signal handler was already set and calling it. If this doesn't work for you, there's a `removeHandler()` decorator that can be used to mark tests that should have the control-C handling disabled.

- `-f` or `--failfast` makes test execution stop immediately when a test fails instead of continuing to execute further tests. (Suggested by Cliff Dyer and implemented by Michael Foord; [issue 8074](#).)

The progress messages now show 'x' for expected failures and 'u' for unexpected successes when run in verbose mode. (Contributed by Benjamin Peterson.)

Test cases can raise the `skipTest` exception to skip a test ([issue 1034053](#)).

The error messages for `assertEqual()`, `assertTrue()`, and `assertFalse()` failures now provide more information. If you set the `longMessage` attribute of your `TestCase` classes to True, both the standard error message and any additional message you provide will be printed for failures. (Added by Michael Foord; [issue 5663](#).)

The `assertRaises()` method now returns a context handler when called without providing a callable object to run. For example, you can write this:

```
with self.assertRaises(KeyError):  
    {}['foo']
```

(Implemented by Antoine Pitrou; [issue 4444](#).)

Module- and class-level setup and teardown fixtures are now supported. Modules can contain `setUpModule()` and `tearDownModule()` functions. Classes can have `setUpClass()` and `tearDownClass()` methods that must be defined as class methods (using `@classmethod` or equivalent). These functions and methods are invoked when the test runner switches to a test case in a different module or class.

The methods `addCleanup()` and `doCleanups()` were added. `addCleanup()` lets you add cleanup functions that will be called unconditionally (after `setUp()` if `setUp()` fails, otherwise after `tearDown()`). This allows for much simpler resource allocation and deallocation during tests ([issue 5679](#)).

A number of new methods were added that provide more specialized tests. Many of these methods were written by Google engineers for use in their test suites; Gregory P. Smith, Michael Foord, and GvR worked on merging them into Python's version of `unittest`.

- `assertIsNone()` and `assertIsNotNone()` take one expression and verify that the result is or is not `None`.
- `assertIs()` and `assertIsNot()` take two values and check whether the two values evaluate to the same object or not. (Added by Michael Foord; [issue 2578](#).)
- `assertIsInstance()` and `assertNotIsInstance()` check whether the resulting object is an instance of a particular class, or of one of a tuple of classes. (Added by Georg Brandl; [issue 7031](#).)
- `assertGreater()`, `assertGreaterEqual()`, `assertLess()`, and `assertLessEqual()` compare two quantities.
- `assertMultiLineEqual()` compares two strings, and if they're not equal, displays a helpful comparison that highlights the differences in the two strings. This comparison is now used by default when Unicode strings are compared with `assertEqual()`.

- `assertRegexMatches()` and `assertNotRegexMatches()` checks whether the first argument is a string matching or not matching the regular expression provided as the second argument ([issue 8038](#)).
- `assertRaisesRegex()` checks whether a particular exception is raised, and then also checks that the string representation of the exception matches the provided regular expression.
- `assertIn()` and `assertNotIn()` tests whether *first* is or is not in *second*.
- `assertItemsEqual()` tests whether two provided sequences contain the same elements.
- `assertSetEqual()` compares whether two sets are equal, and only reports the differences between the sets in case of error.
- Similarly, `assertListEqual()` and `assertTupleEqual()` compare the specified types and explain any differences without necessarily printing their full values; these methods are now used by default when comparing lists and tuples using `assertEqual()`. More generally, `assertSequenceEqual()` compares two sequences and can optionally check whether both sequences are of a particular type.
- `assertDictEqual()` compares two dictionaries and reports the differences; it's now used by default when you compare two dictionaries using `assertEqual()`. `assertDictContainsSubset()` checks whether all of the key/value pairs in *first* are found in *second*.
- `assertAlmostEqual()` and `assertNotAlmostEqual()` test whether *first* and *second* are approximately equal. This method can either round their difference to an optionally-specified number of *places* (the default is 7) and compare it to zero, or require the difference to be smaller than a supplied *delta* value.
- `loadTestsFromName()` properly honors the `suiteClass` attribute of the `TestLoader`. (Fixed by Mark Roddy; [issue 6866](#).)
- A new hook lets you extend the `assertEqual()` method to handle

new data types. The `addTypeEqualityFunc()` method takes a type object and a function. The function will be used when both of the objects being compared are of the specified type. This function should compare the two objects and raise an exception if they don't match; it's a good idea for the function to provide additional information about why the two objects aren't matching, much as the new sequence comparison methods do.

`unittest.main()` now takes an optional `exit` argument. If `False`, `main()` doesn't call `sys.exit()`, allowing `main()` to be used from the interactive interpreter. (Contributed by J. Pablo Fernández; [issue 3379](#).)

`TestResult` has new `startTestRun()` and `stopTestRun()` methods that are called immediately before and after a test run. (Contributed by Robert Collins; [issue 5728](#).)

With all these changes, the `unittest.py` was becoming awkwardly large, so the module was turned into a package and the code split into several files (by Benjamin Peterson). This doesn't affect how the module is imported or used.

<http://www.voidspace.org.uk/python/articles/unittest2.shtml>

Describes the new features, how to use them, and the rationale for various design decisions. (By Michael Foord.)

Updated module: ElementTree 1.3

The version of the ElementTree library included with Python was updated to version 1.3. Some of the new features are:

- The various parsing functions now take a *parser* keyword

argument giving an `XMLParser` instance that will be used. This makes it possible to override the file's internal encoding:

```
p = ET.XMLParser(encoding='utf-8')
t = ET.XML("""<root/>""", parser=p)
```

Errors in parsing XML now raise a `ParseError` exception, whose instances have a `position` attribute containing a *(line, column)* tuple giving the location of the problem.

- `ElementTree`'s code for converting trees to a string has been significantly reworked, making it roughly twice as fast in many cases. The `ElementTree write()` and `Element write()` methods now have a *method* parameter that can be "xml" (the default), "html", or "text". HTML mode will output empty elements as `<empty></empty>` instead of `<empty/>`, and text mode will skip over elements and only output the text chunks. If you set the `tag` attribute of an element to `None` but leave its children in place, the element will be omitted when the tree is written out, so you don't need to do more extensive rearrangement to remove a single element.

Namespace handling has also been improved. All `xmlns:` `<whatever>` declarations are now output on the root element, not scattered throughout the resulting XML. You can set the default namespace for a tree by setting the `default_namespace` attribute and can register new prefixes with `register_namespace()`. In XML mode, you can use the `true/false xml_declaration` parameter to suppress the XML declaration.

- New `Element` method: `extend()` appends the items from a sequence to the element's children. Elements themselves behave like sequences, so it's easy to move children from one element to another:

```

from xml.etree import ElementTree as ET

t = ET.XML("""<list>
  <item>1</item> <item>2</item> <item>3</item>
</list>""")
new = ET.XML('<root/>')
new.extend(t)

# Outputs <root><item>1</item>...</root>
print ET.tostring(new)

```

- New **Element** method: `iter()` yields the children of the element as a generator. It's also possible to write `for child in elem:` to loop over an element's children. The existing method `getiterator()` is now deprecated, as is `getchildren()` which constructs and returns a list of children.
- New **Element** method: `itertext()` yields all chunks of text that are descendants of the element. For example:

```

t = ET.XML("""<list>
  <item>1</item> <item>2</item> <item>3</item>
</list>""")

# Outputs ['\n ', '1', ' ', '2', ' ', '3', '\n']
print list(t.itertext())

```

- **Deprecated:** using an element as a Boolean (i.e., `if elem:`) would return true if the element had any children, or false if there were no children. This behaviour is confusing – `None` is false, but so is a childless element? – so it will now trigger a **FutureWarning**. In your code, you should be explicit: write `len(elem) != 0` if you're interested in the number of children, or `elem is not None`.

Fredrik Lundh develops ElementTree and produced the 1.3 version; you can read his article describing 1.3 at <http://effbot.org/zone/elementtree-13-intro.htm>. Florent Xicluna

updated the version included with Python, after discussions on python-dev and in [issue 6472](#).)

Build and C API Changes

Changes to Python's build process and to the C API include:

- The latest release of the GNU Debugger, GDB 7, can be [scripted using Python](#). When you begin debugging an executable program P, GDB will look for a file named `P-gdb.py` and automatically read it. Dave Malcolm contributed a `python-gdb.py` that adds a number of commands useful when debugging Python itself. For example, `py-up` and `py-down` go up or down one Python stack frame, which usually corresponds to several C stack frames. `py-print` prints the value of a Python variable, and `py-bt` prints the Python stack trace. (Added as a result of [issue 8032](#).)
- If you use the `.gdbinit` file provided with Python, the “pyo” macro in the 2.7 version now works correctly when the thread being debugged doesn't hold the GIL; the macro now acquires it before printing. (Contributed by Victor Stinner; [issue 3632](#).)
- `Py_AddPendingCall()` is now thread-safe, letting any worker thread submit notifications to the main Python thread. This is particularly useful for asynchronous IO operations. (Contributed by Kristján Valur Jónsson; [issue 4293](#).)
- New function: `PyCode_NewEmpty()` creates an empty code object; only the filename, function name, and first line number are required. This is useful for extension modules that are attempting to construct a more useful traceback stack. Previously such extensions needed to call `PyCode_New()`, which had many more arguments. (Added by Jeffrey Yasskin.)
- New function: `PyErr_NewExceptionWithDoc()` creates a new

exception class, just as the existing `PyErr_NewException()` does, but takes an extra `char *` argument containing the docstring for the new exception class. (Added by 'lekma' on the Python bug tracker; [issue 7033](#).)

- New function: `PyFrame_GetLineNumber()` takes a frame object and returns the line number that the frame is currently executing. Previously code would need to get the index of the bytecode instruction currently executing, and then look up the line number corresponding to that address. (Added by Jeffrey Yasskin.)
- New functions: `PyLong_AsLongAndOverflow()` and `PyLong_AsLongLongAndOverflow()` approximates a Python long integer as a C `long` or `long long`. If the number is too large to fit into the output type, an *overflow* flag is set and returned to the caller. (Contributed by Case Van Hosen; [issue 7528](#) and [issue 7767](#).)
- New function: stemming from the rewrite of string-to-float conversion, a new `PyOS_string_to_double()` function was added. The old `PyOS_ascii_strtod()` and `PyOS_ascii_atof()` functions are now deprecated.
- New function: `PySys_SetArgvEx()` sets the value of `sys.argv` and can optionally update `sys.path` to include the directory containing the script named by `sys.argv[0]` depending on the value of an *updatepath* parameter.

This function was added to close a security hole for applications that embed Python. The old function, `PySys_SetArgv()`, would always update `sys.path`, and sometimes it would add the current directory. This meant that, if you ran an application embedding Python in a directory controlled by someone else,

attackers could put a Trojan-horse module in the directory (say, a file named `os.py`) that your application would then import and run.

If you maintain a C/C++ application that embeds Python, check whether you're calling `PySys_SetArgv()` and carefully consider whether the application should be using `PySys_SetArgvEx()` with `updatepath` set to `false`.

Security issue reported as [CVE-2008-5983](#); discussed in [issue 5753](#), and fixed by Antoine Pitrou.

- New macros: the Python header files now define the following macros: `Py_ISALNUM`, `Py_ISALPHA`, `Py_ISDIGIT`, `Py_ISLOWER`, `Py_ISSPACE`, `Py_ISUPPER`, `Py_ISXDIGIT`, and `Py_TOLOWER`, `Py_TOUPPER`. All of these functions are analogous to the C standard macros for classifying characters, but ignore the current locale setting, because in several places Python needs to analyze characters in a locale-independent way. (Added by Eric Smith; [issue 5793](#).)
- Removed function: `PyEval_CallObject` is now only available as a macro. A function version was being kept around to preserve ABI linking compatibility, but that was in 1997; it can certainly be deleted by now. (Removed by Antoine Pitrou; [issue 8276](#).)
- New format codes: the `PyFormat_FromString()`, `PyFormat_FromStringV()`, and `PyErr_Format()` functions now accept `%lld` and `%llu` format codes for displaying C's `long long` types. (Contributed by Mark Dickinson; [issue 7228](#).)
- The complicated interaction between threads and process forking has been changed. Previously, the child process created by `os.fork()` might fail because the child is created with only a

single thread running, the thread performing the `os.fork()`. If other threads were holding a lock, such as Python's import lock, when the fork was performed, the lock would still be marked as "held" in the new process. But in the child process nothing would ever release the lock, since the other threads weren't replicated, and the child process would no longer be able to perform imports.

Python 2.7 acquires the import lock before performing an `os.fork()`, and will also clean up any locks created using the `threading` module. C extension modules that have internal locks, or that call `fork()` themselves, will not benefit from this clean-up.

(Fixed by Thomas Wouters; [issue 1590864](#).)

- The `Py_Finalize()` function now calls the internal `threading._shutdown()` function; this prevents some exceptions from being raised when an interpreter shuts down. (Patch by Adam Olsen; [issue 1722344](#).)
- When using the `PyMemberDef` structure to define attributes of a type, Python will no longer let you try to delete or set a `T_STRING_INPLACE` attribute.
- Global symbols defined by the `ctypes` module are now prefixed with `Py`, or with `_ctypes`. (Implemented by Thomas Heller; [issue 3102](#).)
- New configure option: the `--with-system-expat` switch allows building the `pyexpat` module to use the system Expat library. (Contributed by Arfrever Frehtes Taifersar Arahesis; [issue 7609](#).)

- New configure option: the `--with-valgrind` option will now disable the pymalloc allocator, which is difficult for the Valgrind memory-error detector to analyze correctly. Valgrind will therefore be better at detecting memory leaks and overruns. (Contributed by James Henstridge; [issue 2422](#).)
- New configure option: you can now supply an empty string to `--with-dbmliborder=` in order to disable all of the various DBM modules. (Added by Arfrever Frehtes Taifersar Arahesis; [issue 6491](#).)
- The **configure** script now checks for floating-point rounding bugs on certain 32-bit Intel chips and defines a `X87_DOUBLE_ROUNDING` preprocessor definition. No code currently uses this definition, but it's available if anyone wishes to use it. (Added by Mark Dickinson; [issue 2937](#).)

configure also now sets a `LDCXXSHARED` Makefile variable for supporting C++ linking. (Contributed by Arfrever Frehtes Taifersar Arahesis; [issue 1222585](#).)

- The build process now creates the necessary files for pkg-config support. (Contributed by Clinton Roy; [issue 3585](#).)
- The build process now supports Subversion 1.7. (Contributed by Arfrever Frehtes Taifersar Arahesis; [issue 6094](#).)

Capsules

Python 3.1 adds a new C datatype, **PyCapsule**, for providing a C API to an extension module. A capsule is essentially the holder of a `void *` pointer, and is made available as a module attribute; for example, the `socket` module's API is exposed as `socket.CAPI`, and `unicodedata` exposes `ucnhash_CAPI`. Other extensions can import the module, access its dictionary to get the capsule object, and then get

the `void *` pointer, which will usually point to an array of pointers to the module's various API functions.

There is an existing data type already used for this, `PyObject`, but it doesn't provide type safety. Evil code written in pure Python could cause a segmentation fault by taking a `PyObject` from module A and somehow substituting it for the `PyObject` in module B. Capsules know their own name, and getting the pointer requires providing the name:

```
void *vtable;

if (!PyCapsule_IsValid(capsule, "mymodule.CAPI") {
    PyErr_SetString(PyExc_ValueError, "argument type invalid");
    return NULL;
}

vtable = PyCapsule_GetPointer(capsule, "mymodule.CAPI");
```

You are assured that `vtable` points to whatever you're expecting. If a different capsule was passed in, `PyCapsule_IsValid()` would detect the mismatched name and return false. Refer to *Providing a C API for an Extension Module* for more information on using these objects.

Python 2.7 now uses capsules internally to provide various extension-module APIs, but the `PyObject_AsVoidPtr()` was modified to handle capsules, preserving compile-time compatibility with the `cobject` interface. Use of `PyObject_AsVoidPtr()` will signal a `PendingDeprecationWarning`, which is silent by default.

Implemented in Python 3.1 and backported to 2.7 by Larry Hastings; discussed in [issue 5630](#).

Port-Specific Changes: Windows

- The `msvcrt` module now contains some constants from the `crtassem.h` header file: `CRT_ASSEMBLY_VERSION`, `VC_ASSEMBLY_PUBLICKEYTOKEN`, and `LIBRARIES_ASSEMBLY_NAME_PREFIX`. (Contributed by David Cournapeau; [issue 4365](#).)
- The `_winreg` module for accessing the registry now implements the `CreateKeyEx()` and `DeleteKeyEx()` functions, extended versions of previously-supported functions that take several extra arguments. The `DisableReflectionKey()`, `EnableReflectionKey()`, and `QueryReflectionKey()` were also tested and documented. (Implemented by Brian Curtin: [issue 7347](#).)
- The new `_beginthreadex()` API is used to start threads, and the native thread-local storage functions are now used. (Contributed by Kristján Valur Jónsson; [issue 3582](#).)
- The `os.kill()` function now works on Windows. The signal value can be the constants `CTRL_C_EVENT`, `CTRL_BREAK_EVENT`, or any integer. The first two constants will send Control-C and Control-Break keystroke events to subprocesses; any other value will use the `TerminateProcess()` API. (Contributed by Miki Tebeka; [issue 1220212](#).)
- The `os.listdir()` function now correctly fails for an empty path. (Fixed by Hirokazu Yamamoto; [issue 5913](#).)
- The `mimelib` module will now read the MIME database from the Windows registry when initializing. (Patch by Gabriel Genellina; [issue 4969](#).)

Port-Specific Changes: Mac OS X

- The path `/Library/Python/2.7/site-packages` is now appended to `sys.path`, in order to share added packages between the system installation and a user-installed copy of the same

version. (Changed by Ronald Oussoren; [issue 4865](#).)

Port-Specific Changes: FreeBSD

- FreeBSD 7.1's `SO_SETFIB` constant, used with `getsockopt()/setsockopt()` to select an alternate routing table, is now available in the `socket` module. (Added by Kyle VanderBeek; [issue 8235](#).)

Other Changes and Fixes

- Two benchmark scripts, `iobench` and `ccbench`, were added to the `Tools` directory. `iobench` measures the speed of the built-in file I/O objects returned by `open()` while performing various operations, and `ccbench` is a concurrency benchmark that tries to measure computing throughput, thread switching latency, and IO processing bandwidth when performing several tasks using a varying number of threads.
- The `Tools/i18n/msgfmt.py` script now understands plural forms in `.po` files. (Fixed by Martin von Löwis; [issue 5464](#).)
- When importing a module from a `.pyc` or `.pyo` file with an existing `.py` counterpart, the `co_filename` attributes of the resulting code objects are overwritten when the original filename is obsolete. This can happen if the file has been renamed, moved, or is accessed through different paths. (Patch by Ziga Seilnacht and Jean-Paul Calderone; [issue 1180193](#).)
- The `regtest.py` script now takes a `--randseed=` switch that takes an integer that will be used as the random seed for the `-r` option that executes tests in random order. The `-r` option also reports the seed that was used (Added by Collin Winter.)
- Another `regtest.py` switch is `-j`, which takes an integer specifying how many tests run in parallel. This allows reducing the total runtime on multi-core machines. This option is compatible with several other options, including the `-R` switch which is known to produce long runtimes. (Added by Antoine Pitrou, [issue 6152](#).) This can also be used with a new `-F` switch that runs selected tests in a loop until they fail. (Added by Antoine Pitrou; [issue 7312](#).)
- When executed as a script, the `py_compile.py` module now accepts `'-'` as an argument, which will read standard input for

the list of filenames to be compiled. (Contributed by Piotr Ożarowski; [issue 8233](#).)

Porting to Python 2.7

This section lists previously described changes and other bugfixes that may require changes to your code:

- The `range()` function processes its arguments more consistently; it will now call `__int__()` on non-float, non-integer arguments that are supplied to it. (Fixed by Alexander Belopolsky; [issue 1533](#).)
- The string `format()` method changed the default precision used for floating-point and complex numbers from 6 decimal places to 12, which matches the precision used by `str()`. (Changed by Eric Smith; [issue 5920](#).)
- Because of an optimization for the `with` statement, the special methods `__enter__()` and `__exit__()` must belong to the object's type, and cannot be directly attached to the object's instance. This affects new-style classes (derived from `object`) and C extension types. ([issue 6101](#).)
- Due to a bug in Python 2.6, the `exc_value` parameter to `__exit__()` methods was often the string representation of the exception, not an instance. This was fixed in 2.7, so `exc_value` will be an instance as expected. (Fixed by Florent Xicluna; [issue 7853](#).)
- When a restricted set of attributes were set using `__slots__`, deleting an unset attribute would not raise `AttributeError` as you would expect. Fixed by Benjamin Peterson; [issue 7604](#).)

In the standard library:

- Operations with `datetime` instances that resulted in a year falling outside the supported range didn't always raise `OverflowError`. Such errors are now checked more carefully and will now raise

the exception. (Reported by Mark Leander, patch by Anand B. Pillai and Alexander Belopolsky; [issue 7150](#).)

- When using `Decimal` instances with a string's `format()` method, the default alignment was previously left-alignment. This has been changed to right-alignment, which might change the output of your programs. (Changed by Mark Dickinson; [issue 6857](#).)

Comparisons involving a signaling NaN value (or `sNaN`) now signal `InvalidOperation` instead of silently returning a true or false value depending on the comparison operator. Quiet NaN values (or `NaN`) are now hashable. (Fixed by Mark Dickinson; [issue 7279](#).)

- The `ElementTree` library, `xml.etree`, no longer escapes ampersands and angle brackets when outputting an XML processing instruction (which looks like `<?xml-stylesheet href="#style1"?>`) or comment (which looks like `<!-- comment -->`). (Patch by Neil Muller; [issue 2746](#).)
- The `readline()` method of `StringIO` objects now does nothing when a negative length is requested, as other file-like objects do. ([issue 7348](#)).
- The `syslog` module will now use the value of `sys.argv[0]` as the identifier instead of the previous default value of `'python'`. (Changed by Sean Reifschneider; [issue 8451](#).)
- The `tarfile` module's default error handling has changed, to no longer suppress fatal errors. The default error level was previously 0, which meant that errors would only result in a message being written to the debug log, but because the debug log is not activated by default, these errors go unnoticed. The default error level is now 1, which raises an exception if there's

an error. (Changed by Lars Gustäbel; [issue 7357](#).)

- The `urlparse` module's `urlsplit()` now handles unknown URL schemes in a fashion compliant with [RFC 3986](#): if the URL is of the form "`<something>://...`", the text before the `://` is treated as the scheme, even if it's a made-up scheme that the module doesn't know about. This change may break code that worked around the old behaviour. For example, Python 2.6.4 or 2.5 will return the following:

```
>>> import urlparse
>>> urlparse.urlsplit('invented://host/filename?query')
('invented', '', '//host/filename?query', '', '')
```

Python 2.7 (and Python 2.6.5) will return:

```
>>> import urlparse
>>> urlparse.urlsplit('invented://host/filename?query')
('invented', 'host', '/filename?query', '', '')
```

(Python 2.7 actually produces slightly different output, since it returns a named tuple instead of a standard tuple.)

For C extensions:

- C extensions that use integer format codes with the `PyArg_Parse*` family of functions will now raise a `TypeError` exception instead of triggering a `DeprecationWarning` ([issue 5080](#)).
- Use the new `PyOS_string_to_double()` function instead of the old `PyOS_ascii_strtod()` and `PyOS_ascii_atof()` functions, which are now deprecated.

For applications that embed Python:

- The `PySys_SetArgvEx()` function was added, letting applications

close a security hole when the existing `PySys_SetArgv()` function was used. Check whether you're calling `PySys_SetArgv()` and carefully consider whether the application should be using `PySys_SetArgvEx()` with *updatepath* set to false.

What's New in Python 2.6

Author: A.M. Kuchling (amk at amk.ca)

Release: 3.2

Date: February 20, 2011

This article explains the new features in Python 2.6, released on October 1 2008. The release schedule is described in [PEP 361](#).

The major theme of Python 2.6 is preparing the migration path to Python 3.0, a major redesign of the language. Whenever possible, Python 2.6 incorporates new features and syntax from 3.0 while remaining compatible with existing code by not removing older features or syntax. When it's not possible to do that, Python 2.6 tries to do what it can, adding compatibility functions in a `future_builtins` module and a `-3` switch to warn about usages that will become unsupported in 3.0.

Some significant new packages have been added to the standard library, such as the `multiprocessing` and `json` modules, but there aren't many new features that aren't related to Python 3.0 in some way.

Python 2.6 also sees a number of improvements and bugfixes throughout the source. A search through the change logs finds there were 259 patches applied and 612 bugs fixed between Python 2.5 and 2.6. Both figures are likely to be underestimates.

This article doesn't attempt to provide a complete specification of the new features, but instead provides a convenient overview. For full details, you should refer to the documentation for Python 2.6. If you want to understand the rationale for the design and implementation, refer to the PEP for a particular new feature. Whenever possible, "What's New in Python" links to the bug/patch item for each change.

Python 3.0

The development cycle for Python versions 2.6 and 3.0 was synchronized, with the alpha and beta releases for both versions being made on the same days. The development of 3.0 has influenced many features in 2.6.

Python 3.0 is a far-ranging redesign of Python that breaks compatibility with the 2.x series. This means that existing Python code will need some conversion in order to run on Python 3.0. However, not all the changes in 3.0 necessarily break compatibility. In cases where new features won't cause existing code to break, they've been backported to 2.6 and are described in this document in the appropriate place. Some of the 3.0-derived features are:

- A `__complex__()` method for converting objects to a complex number.
- Alternate syntax for catching exceptions: `except TypeError as exc`.
- The addition of `functools.reduce()` as a synonym for the built-in `reduce()` function.

Python 3.0 adds several new built-in functions and changes the semantics of some existing builtins. Functions that are new in 3.0 such as `bin()` have simply been added to Python 2.6, but existing builtins haven't been changed; instead, the `future_builtins` module has versions with the new 3.0 semantics. Code written to be compatible with 3.0 can do `from future_builtins import hex, map` as necessary.

A new command-line switch, `-3`, enables warnings about features that will be removed in Python 3.0. You can run code with this switch to see how much work will be necessary to port code to 3.0. The

value of this switch is available to Python code as the boolean variable `sys.py3kwarning`, and to C extension code as `Py_Py3kWarningFlag`.

Changes to the Development Process

While 2.6 was being developed, the Python development process underwent two significant changes: we switched from SourceForge's issue tracker to a customized Roundup installation, and the documentation was converted from LaTeX to reStructuredText.

New Issue Tracker: Roundup

For a long time, the Python developers had been growing increasingly annoyed by SourceForge's bug tracker. SourceForge's hosted solution doesn't permit much customization; for example, it wasn't possible to customize the life cycle of issues.

The infrastructure committee of the Python Software Foundation therefore posted a call for issue trackers, asking volunteers to set up different products and import some of the bugs and patches from SourceForge. Four different trackers were examined: [Jira](#), [Launchpad](#), [Roundup](#), and [Trac](#). The committee eventually settled on Jira and Roundup as the two candidates. Jira is a commercial product that offers no-cost hosted instances to free-software projects; Roundup is an open-source project that requires volunteers to administer it and a server to host it.

After posting a call for volunteers, a new Roundup installation was set up at <http://bugs.python.org>. One installation of Roundup can host multiple trackers, and this server now also hosts issue trackers for Jython and for the Python web site. It will surely find other uses in the future. Where possible, this edition of "What's New in Python" links to the bug/patch item for each change.

Hosting of the Python bug tracker is kindly provided by [Upfront Systems](#) of Stellenbosch, South Africa. Martin von Loewis put a lot of

effort into importing existing bugs and patches from SourceForge; his scripts for this import operation are at <http://svn.python.org/view/tracker/importer/> and may be useful to other projects wishing to move from SourceForge to Roundup.

New Documentation Format: reStructuredText Using Sphinx

The Python documentation was written using LaTeX since the project started around 1989. In the 1980s and early 1990s, most documentation was printed out for later study, not viewed online. LaTeX was widely used because it provided attractive printed output while remaining straightforward to write once the basic rules of the markup were learned.

Today LaTeX is still used for writing publications destined for printing, but the landscape for programming tools has shifted. We no longer print out reams of documentation; instead, we browse through it online and HTML has become the most important format to support. Unfortunately, converting LaTeX to HTML is fairly complicated and Fred L. Drake Jr., the long-time Python documentation editor, spent

a lot of time maintaining the conversion process. Occasionally people would suggest converting the documentation into SGML and later XML, but performing a good conversion is a major task and no one ever committed the time required to finish the job.

During the 2.6 development cycle, Georg Brandl put a lot of effort into building a new toolchain for processing the documentation. The resulting package is called Sphinx, and is available from <http://sphinx.pocoo.org/>.

Sphinx concentrates on HTML output, producing attractively styled and modern HTML; printed output is still supported through conversion to LaTeX. The input format is reStructuredText, a markup syntax supporting custom extensions and directives that is commonly used in the Python community.

Sphinx is a standalone package that can be used for writing, and almost two dozen other projects ([listed on the Sphinx web site](#)) have adopted Sphinx as their documentation tool.

PEP 343: The 'with' statement

The previous version, Python 2.5, added the `'with'` statement as an optional feature, to be enabled by a `from __future__ import with_statement` directive. In 2.6 the statement no longer needs to be specially enabled; this means that `with` is now always a keyword. The rest of this section is a copy of the corresponding section from the “What’s New in Python 2.5” document; if you’re familiar with the `'with'` statement from Python 2.5, you can skip this section.

The `'with'` statement clarifies code that previously would use `try...finally` blocks to ensure that clean-up code is executed. In this section, I’ll discuss the statement as it will commonly be used. In the next section, I’ll examine the implementation details and show how to write objects for use with this statement.

The `'with'` statement is a control-flow structure whose basic structure is:

```
with expression [as variable]:  
    with-block
```

The expression is evaluated, and it should result in an object that supports the context management protocol (that is, has `__enter__()` and `__exit__()` methods).

The object’s `__enter__()` is called before *with-block* is executed and therefore can run set-up code. It also may return a value that is bound to the name *variable*, if given. (Note carefully that *variable* is *not* assigned the result of *expression*.)

After execution of the *with-block* is finished, the object’s `__exit__()` method is called, even if the block raised an exception, and can

therefore run clean-up code.

Some standard Python objects now support the context management protocol and can be used with the `'with'` statement. File objects are one example:

```
with open('/etc/passwd', 'r') as f:
    for line in f:
        print line
    ... more processing code ...
```

After this statement has executed, the file object in `f` will have been automatically closed, even if the `for` loop raised an exception part-way through the block.

Note: In this case, `f` is the same object created by `open()`, because `file.__enter__()` returns `self`.

The `threading` module's locks and condition variables also support the `'with'` statement:

```
lock = threading.Lock()
with lock:
    # Critical section of code
    ...
```

The lock is acquired before the block is executed and always released once the block is complete.

The `localcontext()` function in the `decimal` module makes it easy to save and restore the current decimal context, which encapsulates the desired precision and rounding characteristics for computations:

```
from decimal import Decimal, Context, localcontext

# Displays with default precision of 28 digits
v = Decimal('578')
```

```
print v.sqrt()

with localcontext(Context(prec=16)):
    # All code in this block uses a precision of 16 digits.
    # The original context is restored on exiting the block.
    print v.sqrt()
```

Writing Context Managers

Under the hood, the `with` statement is fairly complicated. Most people will only use `with` in company with existing objects and don't need to know these details, so you can skip the rest of this section if you like. Authors of new objects will need to understand the details of the underlying implementation and should keep reading.

A high-level explanation of the context management protocol is:

- The expression is evaluated and should result in an object called a “context manager”. The context manager must have `__enter__()` and `__exit__()` methods.
- The context manager's `__enter__()` method is called. The value returned is assigned to `VAR`. If no `as VAR` clause is present, the value is simply discarded.
- The code in `BLOCK` is executed.
- If `BLOCK` raises an exception, the context manager's `__exit__()` method is called with three arguments, the exception details (`type`, `value`, `traceback`, the same values returned by `sys.exc_info()`, which can also be `None` if no exception occurred). The method's return value controls whether an exception is re-raised: any false value re-raises the exception, and `True` will result in suppressing it. You'll only rarely want to suppress the exception, because if you do the author of the code containing the `with` statement will never realize anything went wrong.
- If `BLOCK` didn't raise an exception, the `__exit__()` method is

still called, but *type*, *value*, and *traceback* are all **None**.

Let's think through an example. I won't present detailed code but will only sketch the methods necessary for a database that supports transactions.

(For people unfamiliar with database terminology: a set of changes to the database are grouped into a transaction. Transactions can be either committed, meaning that all the changes are written into the database, or rolled back, meaning that the changes are all discarded and the database is unchanged. See any database textbook for more information.)

Let's assume there's an object representing a database connection. Our goal will be to let the user write code like this:

```
db_connection = DatabaseConnection()
with db_connection as cursor:
    cursor.execute('insert into ...')
    cursor.execute('delete from ...')
    # ... more operations ...
```

The transaction should be committed if the code in the block runs flawlessly or rolled back if there's an exception. Here's the basic interface for **DatabaseConnection** that I'll assume:

```
class DatabaseConnection:
    # Database interface
    def cursor(self):
        "Returns a cursor object and starts a new transaction"
    def commit(self):
        "Commits current transaction"
    def rollback(self):
        "Rolls back current transaction"
```

The `__enter__()` method is pretty easy, having only to start a new transaction. For this application the resulting cursor object would be a useful result, so the method will return it. The user can then add `as`

cursor to their `'with'` statement to bind the cursor to a variable name.

```
class DatabaseConnection:
    ...
    def __enter__(self):
        # Code to start a new transaction
        cursor = self.cursor()
        return cursor
```

The `__exit__()` method is the most complicated because it's where most of the work has to be done. The method has to check if an exception occurred. If there was no exception, the transaction is committed. The transaction is rolled back if there was an exception.

In the code below, execution will just fall off the end of the function, returning the default value of `None`. `None` is false, so the exception will be re-raised automatically. If you wished, you could be more explicit and add a `return` statement at the marked location.

```
class DatabaseConnection:
    ...
    def __exit__(self, type, value, tb):
        if tb is None:
            # No exception, so commit
            self.commit()
        else:
            # Exception occurred, so rollback.
            self.rollback()
            # return False
```

The contextlib module

The `contextlib` module provides some functions and a decorator that are useful when writing objects for use with the `'with'` statement.

The decorator is called `contextmanager()`, and lets you write a single generator function instead of defining a new class. The generator should yield exactly one value. The code up to the `yield` will be

executed as the `__enter__()` method, and the value yielded will be the method's return value that will get bound to the variable in the 'with' statement's `as` clause, if any. The code after the `yield` will be executed in the `__exit__()` method. Any exception raised in the block will be raised by the `yield` statement.

Using this decorator, our database example from the previous section could be written as:

```
from contextlib import contextmanager

@contextmanager
def db_transaction(connection):
    cursor = connection.cursor()
    try:
        yield cursor
    except:
        connection.rollback()
        raise
    else:
        connection.commit()

db = DatabaseConnection()
with db_transaction(db) as cursor:
    ...
```

The `contextlib` module also has a `nested(mgr1, mgr2, ...)` function that combines a number of context managers so you don't need to write nested 'with' statements. In this example, the single 'with' statement both starts a database transaction and acquires a thread lock:

```
lock = threading.Lock()
with nested (db_transaction(db), lock) as (cursor, locked):
    ...
```

Finally, the `closing()` function returns its argument so that it can be bound to a variable, and calls the argument's `.close()` method at the end of the block.

```
import urllib, sys
from contextlib import closing

with closing(urllib.urlopen('http://www.yahoo.com')) as f:
    for line in f:
        sys.stdout.write(line)
```

PEP 343 - The “with” statement

PEP written by Guido van Rossum and Nick Coghlan; implemented by Mike Bland, Guido van Rossum, and Neal Norwitz. The PEP shows the code generated for a ‘with’ statement, which can be helpful in learning how the statement works.

The documentation for the `contextlib` module.

PEP 366: Explicit Relative Imports From a Main Module

Python's `-m` switch allows running a module as a script. When you ran a module that was located inside a package, relative imports didn't work correctly.

The fix for Python 2.6 adds a `__package__` attribute to modules. When this attribute is present, relative imports will be relative to the value of this attribute instead of the `__name__` attribute.

PEP 302-style importers can then set `__package__` as necessary. The `runpy` module that implements the `-m` switch now does this, so relative imports will now work correctly in scripts running from inside a package.

PEP 370: Per-user `site-packages` Directory

When you run Python, the module search path `sys.path` usually includes a directory whose path ends in "`site-packages`". This directory is intended to hold locally-installed packages available to all users using a machine or a particular site installation.

Python 2.6 introduces a convention for user-specific site directories. The directory varies depending on the platform:

- Unix and Mac OS X: `~/.local/`
- Windows: `%APPDATA%/Python`

Within this directory, there will be version-specific subdirectories, such as `lib/python2.6/site-packages` on Unix/Mac OS and `Python26/site-packages` on Windows.

If you don't like the default directory, it can be overridden by an environment variable. `PYTHONUSERBASE` sets the root directory used for all Python versions supporting this feature. On Windows, the directory for application-specific data can be changed by setting the `APPDATA` environment variable. You can also modify the `site.py` file for your Python installation.

The feature can be disabled entirely by running Python with the `-s` option or setting the `PYTHONNOUSERSITE` environment variable.

See also:

PEP 370 - Per-user `site-packages` Directory

PEP written and implemented by Christian Heimes.

PEP 371: The multiprocessing Package

The new `multiprocessing` package lets Python programs create new processes that will perform a computation and return a result to the parent. The parent and child processes can communicate using queues and pipes, synchronize their operations using locks and semaphores, and can share simple arrays of data.

The `multiprocessing` module started out as an exact emulation of the `threading` module using processes instead of threads. That goal was discarded along the path to Python 2.6, but the general approach of the module is still similar. The fundamental class is the `Process`, which is passed a callable object and a collection of arguments. The `start()` method sets the callable running in a subprocess, after which you can call the `is_alive()` method to check whether the subprocess is still running and the `join()` method to wait for the process to exit.

Here's a simple example where the subprocess will calculate a factorial. The function doing the calculation is written strangely so that it takes significantly longer when the input argument is a multiple of 4.

```
import time
from multiprocessing import Process, Queue

def factorial(queue, N):
    "Compute a factorial."
    # If N is a multiple of 4, this function will take much lon
    if (N % 4) == 0:
        time.sleep(.05 * N/4)

    # Calculate the result
    fact = 1L
    for i in range(1, N+1):
```

```

        fact = fact * i

    # Put the result on the queue
    queue.put(fact)

if __name__ == '__main__':
    queue = Queue()

    N = 5

    p = Process(target=factorial, args=(queue, N))
    p.start()
    p.join()

    result = queue.get()
    print 'Factorial', N, '=', result

```

A **Queue** is used to communicate the input parameter N and the result. The **Queue** object is stored in a global variable. The child process will use the value of the variable when the child was created; because it's a **Queue**, parent and child can use the object to communicate. (If the parent were to change the value of the global variable, the child's value would be unaffected, and vice versa.)

Two other classes, **Pool** and **Manager**, provide higher-level interfaces. **Pool** will create a fixed number of worker processes, and requests can then be distributed to the workers by calling **apply()** or **apply_async()** to add a single request, and **map()** or **map_async()** to add a number of requests. The following code uses a **Pool** to spread requests across 5 worker processes and retrieve a list of results:

```

from multiprocessing import Pool

def factorial(N, dictionary):
    "Compute a factorial."
    ...
p = Pool(5)
result = p.map(factorial, range(1, 1000, 10))
for v in result:
    print v

```

This produces the following output:

```
1
39916800
51090942171709440000
8222838654177922817725562880000000
33452526613163807108170062053440751665152000000000
...
```

The other high-level interface, the `Manager` class, creates a separate server process that can hold master copies of Python data structures. Other processes can then access and modify these data structures using proxy objects. The following example creates a shared dictionary by calling the `dict()` method; the worker processes then insert values into the dictionary. (Locking is not done for you automatically, which doesn't matter in this example. `Manager`'s methods also include `Lock()`, `RLock()`, and `Semaphore()` to create shared locks.)

```
import time
from multiprocessing import Pool, Manager

def factorial(N, dictionary):
    "Compute a factorial."
    # Calculate the result
    fact = 1L
    for i in range(1, N+1):
        fact = fact * i

    # Store result in dictionary
    dictionary[N] = fact

if __name__ == '__main__':
    p = Pool(5)
    mgr = Manager()
    d = mgr.dict()          # Create shared dictionary

    # Run tasks using the pool
    for N in range(1, 1000, 10):
        p.apply_async(factorial, (N, d))
```

```
# Mark pool as closed -- no more tasks can be added.
p.close()

# Wait for tasks to exit
p.join()

# Output results
for k, v in sorted(d.items()):
    print k, v
```

This will produce the output:

```
1 1
11 39916800
21 51090942171709440000
31 8222838654177922817725562880000000
41 33452526613163807108170062053440751665152000000000
51 15511187532873822802242430164693032110632597200169861120000.
```

PEP 371 - Addition of the multiprocessing package

PEP written by Jesse Noller and Richard Oudkerk;
implemented by Richard Oudkerk and Jesse Noller.

PEP 3101: Advanced String Formatting

In Python 3.0, the `%` operator is supplemented by a more powerful string formatting method, `format()`. Support for the `str.format()` method has been backported to Python 2.6.

In 2.6, both 8-bit and Unicode strings have a `.format()` method that treats the string as a template and takes the arguments to be formatted. The formatting template uses curly brackets (`{`, `}`) as special characters:

```
>>> # Substitute positional argument 0 into the string.
>>> "User ID: {0}".format("root")
'User ID: root'
>>> # Use the named keyword arguments
>>> "User ID: {uid}    Last seen: {last_login}".format(
...     uid="root",
...     last_login = "5 Mar 2008 07:20")
'User ID: root    Last seen: 5 Mar 2008 07:20'
```

Curly brackets can be escaped by doubling them:

```
>>> "Empty dict: {}".format()
"Empty dict: {}"
```

Field names can be integers indicating positional arguments, such as `{0}`, `{1}`, etc. or names of keyword arguments. You can also supply compound field names that read attributes or access dictionary keys:

```
>>> import sys
>>> print 'Platform: {0.platform}\nPython version: {0.version}'
Platform: darwin
Python version: 2.6a1+ (trunk:61261M, Mar  5 2008, 20:29:41)
[GCC 4.0.1 (Apple Computer, Inc. build 5367)]'

>>> import mimetypes
>>> 'Content-type: {0[.mp4]}'.format(mimetypes.types_map)
```

```
'Content-type: video/mp4'
```

Note that when using dictionary-style notation such as `[.mp4]`, you don't need to put any quotation marks around the string; it will look up the value using `.mp4` as the key. Strings beginning with a number will be converted to an integer. You can't write more complicated expressions inside a format string.

So far we've shown how to specify which field to substitute into the resulting string. The precise formatting used is also controllable by adding a colon followed by a format specifier. For example:

```
>>> # Field 0: left justify, pad to 15 characters
>>> # Field 1: right justify, pad to 6 characters
>>> fmt = '{0:15} ${1:>6}'
>>> fmt.format('Registration', 35)
'Registration      $    35'
>>> fmt.format('Tutorial', 50)
'Tutorial          $    50'
>>> fmt.format('Banquet', 125)
'Banquet           $   125'
```

Format specifiers can reference other fields through nesting:

```
>>> fmt = '{0:{1}}'
>>> width = 15
>>> fmt.format('Invoice #1234', width)
'Invoice #1234   '
>>> width = 35
>>> fmt.format('Invoice #1234', width)
'Invoice #1234                                     '
>>>
```

The alignment of a field within the desired width can be specified:

Character	Effect
< (default)	Left-align
>	Right-align
^	Center

=

(For numeric types only) Pad after the sign.

Format specifiers can also include a presentation type, which controls how the value is formatted. For example, floating-point numbers can be formatted as a general number or in exponential notation:

```
>>> '{0:g}'.format(3.75)
'3.75'
>>> '{0:e}'.format(3.75)
'3.750000e+00'
```

A variety of presentation types are available. Consult the 2.6 documentation for a [complete list](#); here's a sample:

b	Binary. Outputs the number in base 2.
c	Character. Converts the integer to the corresponding Unicode character before printing.
d	Decimal Integer. Outputs the number in base 10.
o	Octal format. Outputs the number in base 8.
x	Hex format. Outputs the number in base 16, using lower-case letters for the digits above 9.
e	Exponent notation. Prints the number in scientific notation using the letter 'e' to indicate the exponent.
g	General format. This prints the number as a fixed-point number, unless the number is too large, in which case it switches to 'e' exponent notation.
n	Number. This is the same as 'g' (for floats) or 'd' (for integers), except that it uses the current locale setting to insert the appropriate number separator characters.
%	Percentage. Multiplies the number by 100 and displays in fixed ('f') format, followed by a percent sign.

Classes and types can define a `__format__()` method to control how they're formatted. It receives a single argument, the format specifier:

```
def __format__(self, format_spec):
    if isinstance(format_spec, unicode):
        return unicode(str(self))
    else:
        return str(self)
```

There's also a `format()` builtin that will format a single value. It calls the type's `__format__()` method with the provided specifier:

```
>>> format(75.6564, '.2f')
'75.66'
```

Format String Syntax

The reference documentation for format fields.

PEP 3101 - Advanced String Formatting

PEP written by Talin. Implemented by Eric Smith.

PEP 3105: `print` As a Function

The `print` statement becomes the `print()` function in Python 3.0. Making `print()` a function makes it possible to replace the function by doing `def print(...)` or importing a new function from somewhere else.

Python 2.6 has a `__future__` import that removes `print` as language syntax, letting you use the functional form instead. For example:

```
>>> from __future__ import print_function
>>> print('# of entries', len(dictionary), file=sys.stderr)
```

The signature of the new function is:

```
def print(*args, sep=' ', end='\n', file=None)
```

The parameters are:

- *args*: positional arguments whose values will be printed out.
- *sep*: the separator, which will be printed between arguments.
- *end*: the ending text, which will be printed after all of the arguments have been output.
- *file*: the file object to which the output will be sent.

[PEP 3105 - Make print a function](#)

PEP written by Georg Brandl.

PEP 3110: Exception-Handling Changes

One error that Python programmers occasionally make is writing the following code:

```
try:
    ...
except TypeError, ValueError: # Wrong!
    ...
```

The author is probably trying to catch both `TypeError` and `ValueError` exceptions, but this code actually does something different: it will catch `TypeError` and bind the resulting exception object to the local name `"ValueError"`. The `ValueError` exception will not be caught at all. The correct code specifies a tuple of exceptions:

```
try:
    ...
except (TypeError, ValueError):
    ...
```

This error happens because the use of the comma here is ambiguous: does it indicate two different nodes in the parse tree, or a single node that's a tuple?

Python 3.0 makes this unambiguous by replacing the comma with the word "as". To catch an exception and store the exception object in the variable `exc`, you must write:

```
try:
    ...
except TypeError as exc:
    ...
```

Python 3.0 will only support the use of "as", and therefore interprets the first example as catching two different exceptions. Python 2.6

supports both the comma and “as”, so existing code will continue to work. We therefore suggest using “as” when writing new Python code that will only be executed with 2.6.

See also:

[PEP 3110](#) - Catching Exceptions in Python 3000

PEP written and implemented by Collin Winter.

PEP 3112: Byte Literals

Python 3.0 adopts Unicode as the language's fundamental string type and denotes 8-bit literals differently, either as `b'string'` or using a `bytes` constructor. For future compatibility, Python 2.6 adds `bytes` as a synonym for the `str` type, and it also supports the `b''` notation.

The 2.6 `str` differs from 3.0's `bytes` type in various ways; most notably, the constructor is completely different. In 3.0, `bytes([65, 66, 67])` is 3 elements long, containing the bytes representing `ABC`; in 2.6, `bytes([65, 66, 67])` returns the 12-byte string representing the `str()` of the list.

The primary use of `bytes` in 2.6 will be to write tests of object type such as `isinstance(x, bytes)`. This will help the 2to3 converter, which can't tell whether 2.x code intends strings to contain either characters or 8-bit bytes; you can now use either `bytes` or `str` to represent your intention exactly, and the resulting code will also be correct in Python 3.0.

There's also a `__future__` import that causes all string literals to become Unicode strings. This means that `\u` escape sequences can be used to include Unicode characters:

```
from __future__ import unicode_literals

s = ('\u751f\u3080\u304e\u3000\u751f\u3054'
     '\u3081\u3000\u751f\u305f\u307e\u3054')

print len(s)           # 12 Unicode characters
```

At the C level, Python 3.0 will rename the existing 8-bit string type, called `PyStringObject` in Python 2.x, to `PyBytesObject`. Python 2.6

uses `#define` to support using the names `PyBytesObject()`, `PyBytes_Check()`, `PyBytes_FromStringAndSize()`, and all the other functions and macros used with strings.

Instances of the `bytes` type are immutable just as strings are. A new `bytearray` type stores a mutable sequence of bytes:

```
>>> bytearray([65, 66, 67])
bytearray(b'ABC')
>>> b = bytearray(u'\u21ef\u3244', 'utf-8')
>>> b
bytearray(b'\xe2\x87\xaf\xe3\x89\x84')
>>> b[0] = '\xe3'
>>> b
bytearray(b'\xe3\x87\xaf\xe3\x89\x84')
>>> unicode(str(b), 'utf-8')
u'\u31ef \u3244'
```

Byte arrays support most of the methods of string types, such as `startswith()/endswith()`, `find()/rfind()`, and some of the methods of lists, such as `append()`, `pop()`, and `reverse()`.

```
>>> b = bytearray('ABC')
>>> b.append('d')
>>> b.append(ord('e'))
>>> b
bytearray(b'ABCde')
```

There's also a corresponding C API, with `PyByteArray_FromObject()`, `PyByteArray_FromStringAndSize()`, and various other functions.

PEP 3112 - Bytes literals in Python 3000

PEP written by Jason Orendorff; backported to 2.6 by Christian Heimes.

PEP 3116: New I/O Library

Python's built-in file objects support a number of methods, but file-like objects don't necessarily support all of them. Objects that imitate files usually support `read()` and `write()`, but they may not support `readline()`, for example. Python 3.0 introduces a layered I/O library in the `io` module that separates buffering and text-handling features from the fundamental read and write operations.

There are three levels of abstract base classes provided by the `io` module:

- **RawIOBase** defines raw I/O operations: `read()`, `readinto()`, `write()`, `seek()`, `tell()`, `truncate()`, and `close()`. Most of the methods of this class will often map to a single system call. There are also `readable()`, `writable()`, and `seekable()` methods for determining what operations a given object will allow.

Python 3.0 has concrete implementations of this class for files and sockets, but Python 2.6 hasn't restructured its file and socket objects in this way.

- **BufferedIOBase** is an abstract base class that buffers data in memory to reduce the number of system calls used, making I/O processing more efficient. It supports all of the methods of **RawIOBase**, and adds a `raw` attribute holding the underlying raw object.

There are five concrete classes implementing this ABC. **BufferedWriter** and **BufferedReader** are for objects that support write-only or read-only usage that have a `seek()` method for random access. **BufferedRandom** objects support read and write

access upon the same underlying stream, and `BufferedRWPair` is for objects such as TTYs that have both read and write operations acting upon unconnected streams of data. The `BytesIO` class supports reading, writing, and seeking over an in-memory buffer.

- `TextIOBase`: Provides functions for reading and writing strings (remember, strings will be Unicode in Python 3.0), and supporting universal newlines. `TextIOBase` defines the `readline()` method and supports iteration upon objects.

There are two concrete implementations. `TextIOWrapper` wraps a buffered I/O object, supporting all of the methods for text I/O and adding a `buffer` attribute for access to the underlying object. `StringIO` simply buffers everything in memory without ever writing anything to disk.

(In Python 2.6, `io.StringIO` is implemented in pure Python, so it's pretty slow. You should therefore stick with the existing `StringIO` module or `cStringIO` for now. At some point Python 3.0's `io` module will be rewritten into C for speed, and perhaps the C implementation will be backported to the 2.x releases.)

In Python 2.6, the underlying implementations haven't been restructured to build on top of the `io` module's classes. The module is being provided to make it easier to write code that's forward-compatible with 3.0, and to save developers the effort of writing their own implementations of buffering and text I/O.

Doerwald, Jeremy Hylton, Martin von Loewis, Tony Lownds,
and others.

PEP 3118: Revised Buffer Protocol

The buffer protocol is a C-level API that lets Python types exchange pointers into their internal representations. A memory-mapped file can be viewed as a buffer of characters, for example, and this lets another module such as `re` treat memory-mapped files as a string of characters to be searched.

The primary users of the buffer protocol are numeric-processing packages such as NumPy, which expose the internal representation of arrays so that callers can write data directly into an array instead of going through a slower API. This PEP updates the buffer protocol in light of experience from NumPy development, adding a number of new features such as indicating the shape of an array or locking a memory region.

The most important new C API function is `PyObject_GetBuffer(PyObject *obj, Py_buffer *view, int flags)`, which takes an object and a set of flags, and fills in the `Py_buffer` structure with information about the object's memory representation. Objects can use this operation to lock memory in place while an external caller could be modifying the contents, so there's a corresponding `PyBuffer_Release(Py_buffer *view)` to indicate that the external caller is done.

The *flags* argument to `PyObject_GetBuffer()` specifies constraints upon the memory returned. Some examples are:

- `PyBUF_WRITABLE` indicates that the memory must be writable.
- `PyBUF_LOCK` requests a read-only or exclusive lock on the memory.
- `PyBUF_C_CONTIGUOUS` and `PyBUF_F_CONTIGUOUS` requests a C-contiguous (last dimension varies the fastest) or Fortran-

contiguous (first dimension varies the fastest) array layout.

Two new argument codes for `PyArg_ParseTuple()`, `s*` and `z*`, return locked buffer objects for a parameter.

PEP 3118 - Revising the buffer protocol

PEP written by Travis Oliphant and Carl Banks; implemented by Travis Oliphant.

PEP 3119: Abstract Base Classes

Some object-oriented languages such as Java support interfaces, declaring that a class has a given set of methods or supports a given access protocol. Abstract Base Classes (or ABCs) are an equivalent feature for Python. The ABC support consists of an `abc` module containing a metaclass called `ABCMeta`, special handling of this metaclass by the `isinstance()` and `issubclass()` builtins, and a collection of basic ABCs that the Python developers think will be widely useful. Future versions of Python will probably add more ABCs.

Let's say you have a particular class and wish to know whether it supports dictionary-style access. The phrase "dictionary-style" is vague, however. It probably means that accessing items with `obj[1]` works. Does it imply that setting items with `obj[2] = value` works? Or that the object will have `keys()`, `values()`, and `items()` methods? What about the iterative variants such as `iterkeys()`? `copy()` and `update()`? Iterating over the object with `iter()`?

The Python 2.6 `collections` module includes a number of different ABCs that represent these distinctions. `Iterable` indicates that a class defines `__iter__()`, and `Container` means the class defines a `__contains__()` method and therefore supports `x in y` expressions. The basic dictionary interface of getting items, setting items, and `keys()`, `values()`, and `items()`, is defined by the `MutableMapping` ABC.

You can derive your own classes from a particular ABC to indicate they support that ABC's interface:

```
import collections
```

```
class Storage(collections.MutableMapping):
    ...
```

Alternatively, you could write the class without deriving from the desired ABC and instead register the class by calling the ABC's `register()` method:

```
import collections

class Storage:
    ...

collections.MutableMapping.register(Storage)
```

For classes that you write, deriving from the ABC is probably clearer. The `register()` method is useful when you've written a new ABC that can describe an existing type or class, or if you want to declare that some third-party class implements an ABC. For example, if you defined a `PrintableType` ABC, it's legal to do:

```
# Register Python's types
PrintableType.register(int)
PrintableType.register(float)
PrintableType.register(str)
```

Classes should obey the semantics specified by an ABC, but Python can't check this; it's up to the class author to understand the ABC's requirements and to implement the code accordingly.

To check whether an object supports a particular interface, you can now write:

```
def func(d):
    if not isinstance(d, collections.MutableMapping):
        raise ValueError("Mapping object expected, not %r" % d)
```

Don't feel that you must now begin writing lots of checks as in the

above example. Python has a strong tradition of duck-typing, where explicit type-checking is never done and code simply calls methods on an object, trusting that those methods will be there and raising an exception if they aren't. Be judicious in checking for ABCs and only do it where it's absolutely necessary.

You can write your own ABCs by using `abc.ABCMeta` as the metaclass in a class definition:

```
from abc import ABCMeta, abstractmethod

class Drawable():
    __metaclass__ = ABCMeta

    @abstractmethod
    def draw(self, x, y, scale=1.0):
        pass

    def draw_doubled(self, x, y):
        self.draw(x, y, scale=2.0)

class Square(Drawable):
    def draw(self, x, y, scale):
        ...
```

In the `Drawable` ABC above, the `draw_doubled()` method renders the object at twice its size and can be implemented in terms of other methods described in `Drawable`. Classes implementing this ABC therefore don't need to provide their own implementation of `draw_doubled()`, though they can do so. An implementation of `draw()` is necessary, though; the ABC can't provide a useful generic implementation.

You can apply the `@abstractmethod` decorator to methods such as `draw()` that must be implemented; Python will then raise an exception for classes that don't define the method. Note that the exception is only raised when you actually try to create an instance

of a subclass lacking the method:

```
>>> class Circle(Drawable):
...     pass
...
>>> c = Circle()
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
TypeError: Can't instantiate abstract class Circle with abstrac
>>>
```

Abstract data attributes can be declared using the `@abstractmethod` decorator:

```
from abc import abstractproperty
...

@abstractproperty
def readonly(self):
    return self._x
```

Subclasses must then define a `readonly()` property.

See also:

PEP 3119 - Introducing Abstract Base Classes

PEP written by Guido van Rossum and Talin. Implemented by Guido van Rossum. Backported to 2.6 by Benjamin Aranguren, with Alex Martelli.

PEP 3127: Integer Literal Support and Syntax

Python 3.0 changes the syntax for octal (base-8) integer literals, prefixing them with “0o” or “OO” instead of a leading zero, and adds support for binary (base-2) integer literals, signalled by a “0b” or “0B” prefix.

Python 2.6 doesn't drop support for a leading 0 signalling an octal number, but it does add support for “0o” and “0b”:

```
>>> 0o21, 2*8 + 1
(17, 17)
>>> 0b101111
47
```

The `oct()` builtin still returns numbers prefixed with a leading zero, and a new `bin()` builtin returns the binary representation for a number:

```
>>> oct(42)
'052'
>>> future_builtins.oct(42)
'0o52'
>>> bin(173)
'0b10101101'
```

The `int()` and `long()` builtins will now accept the “0o” and “0b” prefixes when base-8 or base-2 are requested, or when the *base* argument is zero (signalling that the base used should be determined from the string):

```
>>> int('0o52', 0)
42
>>> int('1101', 2)
13
```

```
>>> int('0b1101', 2)
13
>>> int('0b1101', 0)
13
```

See also:

[PEP 3127 - Integer Literal Support and Syntax](#)

PEP written by Patrick Maupin; backported to 2.6 by Eric Smith.

PEP 3129: Class Decorators

Decorators have been extended from functions to classes. It's now legal to write:

```
@foo
@bar
class A:
    pass
```

This is equivalent to:

```
class A:
    pass

A = foo(bar(A))
```

See also:

PEP 3129 - Class Decorators

PEP written by Collin Winter.

PEP 3141: A Type Hierarchy for Numbers

Python 3.0 adds several abstract base classes for numeric types inspired by Scheme's numeric tower. These classes were backported to 2.6 as the `numbers` module.

The most general ABC is `Number`. It defines no operations at all, and only exists to allow checking if an object is a number by doing `isinstance(obj, Number)`.

`Complex` is a subclass of `Number`. Complex numbers can undergo the basic operations of addition, subtraction, multiplication, division, and exponentiation, and you can retrieve the real and imaginary parts and obtain a number's conjugate. Python's built-in complex type is an implementation of `Complex`.

`Real` further derives from `Complex`, and adds operations that only work on real numbers: `floor()`, `trunc()`, rounding, taking the remainder mod N, floor division, and comparisons.

`Rational` numbers derive from `Real`, have `numerator` and `denominator` properties, and can be converted to floats. Python 2.6 adds a simple rational-number class, `Fraction`, in the `fractions` module. (It's called `Fraction` instead of `Rational` to avoid a name clash with `numbers.Rational`.)

`Integral` numbers derive from `Rational`, and can be shifted left and right with `<<` and `>>`, combined using bitwise operations such as `&` and `|`, and can be used as array indexes and slice boundaries.

In Python 3.0, the PEP slightly redefines the existing builtins `round()`, `math.floor()`, `math.ceil()`, and adds a new one,

`math.trunc()`, that's been backported to Python 2.6. `math.trunc()` rounds toward zero, returning the closest `Integral` that's between the function's argument and zero.

See also:

PEP 3141 - A Type Hierarchy for Numbers

PEP written by Jeffrey Yasskin.

Scheme's numerical tower, from the Guile manual.

Scheme's number datatypes from the R5RS Scheme specification.

The `fractions` Module

To fill out the hierarchy of numeric types, the `fractions` module provides a rational-number class. Rational numbers store their values as a numerator and denominator forming a fraction, and can exactly represent numbers such as $2/3$ that floating-point numbers can only approximate.

The `Fraction` constructor takes two `Integral` values that will be the numerator and denominator of the resulting fraction.

```
>>> from fractions import Fraction
>>> a = Fraction(2, 3)
>>> b = Fraction(2, 5)
>>> float(a), float(b)
(0.66666666666666663, 0.40000000000000002)
>>> a+b
Fraction(16, 15)
>>> a/b
Fraction(5, 3)
```

For converting floating-point numbers to rationals, the `float` type now has an `as_integer_ratio()` method that returns the numerator and

denominator for a fraction that evaluates to the same floating-point value:

```
>>> (2.5) .as_integer_ratio()
(5, 2)
>>> (3.1415) .as_integer_ratio()
(7074029114692207L, 2251799813685248L)
>>> (1./3) .as_integer_ratio()
(6004799503160661L, 18014398509481984L)
```

Note that values that can only be approximated by floating-point numbers, such as $1/3$, are not simplified to the number being approximated; the fraction attempts to match the floating-point value **exactly**.

The `fractions` module is based upon an implementation by Sjoerd Mullender that was in Python's `Demo/classes/` directory for a long time. This implementation was significantly updated by Jeffrey Yasskin.

Other Language Changes

Some smaller changes made to the core Python language are:

- Directories and zip archives containing a `__main__.py` file can now be executed directly by passing their name to the interpreter. The directory or zip archive is automatically inserted as the first entry in `sys.path`. (Suggestion and initial patch by Andy Chu, subsequently revised by Phillip J. Eby and Nick Coghlan; [issue 1739468](#).)
- The `hasattr()` function was catching and ignoring all errors, under the assumption that they meant a `__getattr__()` method was failing somehow and the return value of `hasattr()` would therefore be `False`. This logic shouldn't be applied to `KeyboardInterrupt` and `SystemExit`, however; Python 2.6 will no longer discard such exceptions when `hasattr()` encounters them. (Fixed by Benjamin Peterson; [issue 2196](#).)
- When calling a function using the `**` syntax to provide keyword arguments, you are no longer required to use a Python dictionary; any mapping will now work:

```
>>> def f(**kw):
...     print sorted(kw)
...
>>> ud=UserDict.UserDict()
>>> ud['a'] = 1
>>> ud['b'] = 'string'
>>> f(**ud)
['a', 'b']
```

(Contributed by Alexander Belopolsky; [issue 1686487](#).)

It's also become legal to provide keyword arguments after a

`*args` argument to a function call.

```
>>> def f(*args, **kw):
...     print args, kw
...
>>> f(1,2,3, *(4,5,6), keyword=13)
(1, 2, 3, 4, 5, 6) {'keyword': 13}
```

Previously this would have been a syntax error. (Contributed by Amaury Forgeot d’Arc; [issue 3473](#).)

- A new builtin, `next(iterator, [default])` returns the next item from the specified iterator. If the *default* argument is supplied, it will be returned if *iterator* has been exhausted; otherwise, the `StopIteration` exception will be raised. (Backported in [issue 2719](#).)
- Tuples now have `index()` and `count()` methods matching the list type’s `index()` and `count()` methods:

```
>>> t = (0,1,2,3,4,0,1,2)
>>> t.index(3)
3
>>> t.count(0)
2
```

(Contributed by Raymond Hettinger)

- The built-in types now have improved support for extended slicing syntax, accepting various combinations of `(start, stop, step)`. Previously, the support was partial and certain corner cases wouldn’t work. (Implemented by Thomas Wouters.)
- Properties now have three attributes, `getter`, `setter` and `deleter`, that are decorators providing useful shortcuts for adding a getter, setter or deleter function to an existing property. You would use them like this:

```

class C(object):
    @property
    def x(self):
        return self._x

    @x.setter
    def x(self, value):
        self._x = value

    @x.deleter
    def x(self):
        del self._x

class D(C):
    @C.x.getter
    def x(self):
        return self._x * 2

    @x.setter
    def x(self, value):
        self._x = value / 2

```

- Several methods of the built-in set types now accept multiple iterables: `intersection()`, `intersection_update()`, `union()`, `update()`, `difference()` and `difference_update()`.

```

>>> s=set('1234567890')
>>> s.intersection('abc123', 'cdf246') # Intersection betw
set(['2'])
>>> s.difference('246', '789')
set(['1', '0', '3', '5'])

```

(Contributed by Raymond Hettinger.)

- Many floating-point features were added. The `float()` function will now turn the string `nan` into an IEEE 754 Not A Number value, and `+inf` and `-inf` into positive or negative infinity. This works on any platform with IEEE 754 semantics. (Contributed by Christian Heimes; [issue 1635](#).)

Other functions in the `math` module, `isinf()` and `isnan()`, return true if their floating-point argument is infinite or Not A Number. (issue 1640)

Conversion functions were added to convert floating-point numbers into hexadecimal strings (issue 3008). These functions convert floats to and from a string representation without introducing rounding errors from the conversion between decimal and binary. Floats have a `hex()` method that returns a string representation, and the `float.fromhex()` method converts a string back into a number:

```
>>> a = 3.75
>>> a.hex()
'0x1.e0000000000000p+1'
>>> float.fromhex('0x1.e0000000000000p+1')
3.75
>>> b=1./3
>>> b.hex()
'0x1.55555555555555p-2'
```

- A numerical nicety: when creating a complex number from two floats on systems that support signed zeros (-0 and +0), the `complex()` constructor will now preserve the sign of the zero. (Fixed by Mark T. Dickinson; issue 1507.)
- Classes that inherit a `__hash__()` method from a parent class can set `__hash__ = None` to indicate that the class isn't hashable. This will make `hash(obj)` raise a `TypeError` and the class will not be indicated as implementing the `Hashable` ABC.

You should do this when you've defined a `__cmp__()` or `__eq__()` method that compares objects by their value rather than by identity. All objects have a default hash method that uses `id(obj)` as the hash value. There's no tidy way to remove the `__hash__()` method inherited from a parent class, so assigning

`None` was implemented as an override. At the C level, extensions can set `tp_hash` to `PyObject_HashNotImplemented()`. (Fixed by Nick Coghlan and Amaury Forgeot d'Arc; [issue 2235](#).)

- The `GeneratorExit` exception now subclasses `BaseException` instead of `Exception`. This means that an exception handler that does `except Exception:` will not inadvertently catch `GeneratorExit`. (Contributed by Chad Austin; [issue 1537](#).)
- Generator objects now have a `gi_code` attribute that refers to the original code object backing the generator. (Contributed by Collin Winter; [issue 1473257](#).)
- The `compile()` built-in function now accepts keyword arguments as well as positional parameters. (Contributed by Thomas Wouters; [issue 1444529](#).)
- The `complex()` constructor now accepts strings containing parenthesized complex numbers, meaning that `complex(repr(cplx))` will now round-trip values. For example, `complex('(3+4j)')` now returns the value `(3+4j)`. ([issue 1491866](#))
- The string `translate()` method now accepts `None` as the translation table parameter, which is treated as the identity transformation. This makes it easier to carry out operations that only delete characters. (Contributed by Bengt Richter and implemented by Raymond Hettinger; [issue 1193128](#).)
- The built-in `dir()` function now checks for a `__dir__()` method on the objects it receives. This method must return a list of strings containing the names of valid attributes for the object, and lets the object control the value that `dir()` produces. Objects that have `__getattr__()` or `__getattribute__()`

methods can use this to advertise pseudo-attributes they will honor. ([issue 1591665](#))

- Instance method objects have new attributes for the object and function comprising the method; the new synonym for `im_self` is `__self__`, and `im_func` is also available as `__func__`. The old names are still supported in Python 2.6, but are gone in 3.0.
- An obscure change: when you use the `locals()` function inside a `class` statement, the resulting dictionary no longer returns free variables. (Free variables, in this case, are variables referenced in the `class` statement that aren't attributes of the class.)

Optimizations

- The `warnings` module has been rewritten in C. This makes it possible to invoke warnings from the parser, and may also make the interpreter's startup faster. (Contributed by Neal Norwitz and Brett Cannon; [issue 1631171](#).)
- Type objects now have a cache of methods that can reduce the work required to find the correct method implementation for a particular class; once cached, the interpreter doesn't need to traverse base classes to figure out the right method to call. The cache is cleared if a base class or the class itself is modified, so the cache should remain correct even in the face of Python's dynamic nature. (Original optimization implemented by Armin Rigo, updated for Python 2.6 by Kevin Jacobs; [issue 1700288](#).)

By default, this change is only applied to types that are included with the Python core. Extension modules may not necessarily be compatible with this cache, so they must explicitly add `Py_TPFLAGS_HAVE_VERSION_TAG` to the module's `tp_flags` field to enable the method cache. (To be compatible with the method

cache, the extension module's code must not directly access and modify the `tp_dict` member of any of the types it implements. Most modules don't do this, but it's impossible for the Python interpreter to determine that. See [issue 1878](#) for some discussion.)

- Function calls that use keyword arguments are significantly faster by doing a quick pointer comparison, usually saving the time of a full string comparison. (Contributed by Raymond Hettinger, after an initial implementation by Antoine Pitrou; [issue 1819](#).)
- All of the functions in the `struct` module have been rewritten in C, thanks to work at the Need For Speed sprint. (Contributed by Raymond Hettinger.)
- Some of the standard built-in types now set a bit in their type objects. This speeds up checking whether an object is a subclass of one of these types. (Contributed by Neal Norwitz.)
- Unicode strings now use faster code for detecting whitespace and line breaks; this speeds up the `split()` method by about 25% and `splitlines()` by 35%. (Contributed by Antoine Pitrou.) Memory usage is reduced by using `pymalloc` for the Unicode string's data.
- The `with` statement now stores the `__exit__()` method on the stack, producing a small speedup. (Implemented by Jeffrey Yasskin.)
- To reduce memory usage, the garbage collector will now clear internal free lists when garbage-collecting the highest generation of objects. This may return memory to the operating system sooner.

Interpreter Changes

Two command-line options have been reserved for use by other Python implementations. The `-J` switch has been reserved for use by Jython for Jython-specific options, such as switches that are passed to the underlying JVM. `-X` has been reserved for options specific to a particular implementation of Python such as CPython, Jython, or IronPython. If either option is used with Python 2.6, the interpreter will report that the option isn't currently used.

Python can now be prevented from writing `.pyc` or `.pyo` files by supplying the `-B` switch to the Python interpreter, or by setting the `PYTHONDONTWRITEBYTECODE` environment variable before running the interpreter. This setting is available to Python programs as the `sys.dont_write_bytecode` variable, and Python code can change the value to modify the interpreter's behaviour. (Contributed by Neal Norwitz and Georg Brandl.)

The encoding used for standard input, output, and standard error can be specified by setting the `PYTHONIOENCODING` environment variable before running the interpreter. The value should be a string in the form `<encoding>` or `<encoding>:<errorhandler>`. The *encoding* part specifies the encoding's name, e.g. `utf-8` or `latin-1`; the optional *errorhandler* part specifies what to do with characters that can't be handled by the encoding, and should be one of "error", "ignore", or "replace". (Contributed by Martin von Loewis.)

New and Improved Modules

As in every release, Python's standard library received a number of enhancements and bug fixes. Here's a partial list of the most notable changes, sorted alphabetically by module name. Consult the `Misc/NEWS` file in the source tree for a more complete list of changes, or look through the Subversion logs for all the details.

- The `asyncore` and `asynchat` modules are being actively maintained again, and a number of patches and bugfixes were applied. (Maintained by Josiah Carlson; see [issue 1736190](#) for one patch.)
- The `bsddb` module also has a new maintainer, Jesús Cea Avion, and the package is now available as a standalone package. The web page for the package is www.jcea.es/programacion/pybsddb.htm. The plan is to remove the package from the standard library in Python 3.0, because its pace of releases is much more frequent than Python's.

The `bsddb.dbshe1ve` module now uses the highest pickling protocol available, instead of restricting itself to protocol 1. (Contributed by W. Barnes.)

- The `cgi` module will now read variables from the query string of an HTTP POST request. This makes it possible to use form actions with URLs that include query strings such as `"/cgi-bin/add.py?category=1"`. (Contributed by Alexandre Fiori and Nubis; [issue 1817](#).)

The `parse_qs()` and `parse_qs1()` functions have been relocated from the `cgi` module to the `urllib` module. The versions still available in the `cgi` module will trigger

[PendingDeprecationWarning](#) messages in 2.6 ([issue 600362](#)).

- The `cmath` module underwent extensive revision, contributed by Mark Dickinson and Christian Heimes. Five new functions were added:
 - `polar()` converts a complex number to polar form, returning the modulus and argument of the complex number.
 - `rect()` does the opposite, turning a modulus, argument pair back into the corresponding complex number.
 - `phase()` returns the argument (also called the angle) of a complex number.
 - `isnan()` returns True if either the real or imaginary part of its argument is a NaN.
 - `isinf()` returns True if either the real or imaginary part of its argument is infinite.

The revisions also improved the numerical soundness of the `cmath` module. For all functions, the real and imaginary parts of the results are accurate to within a few units of least precision (ulps) whenever possible. See [issue 1381](#) for the details. The branch cuts for `asinh()`, `atanh()`: and `atan()` have also been corrected.

The tests for the module have been greatly expanded; nearly 2000 new test cases exercise the algebraic functions.

On IEEE 754 platforms, the `cmath` module now handles IEEE 754 special values and floating-point exceptions in a manner consistent with Annex 'G' of the C99 standard.

- A new data type in the `collections` module: `namedtuple(typename, fieldnames)` is a factory function that creates subclasses of the standard tuple whose fields are

accessible by name as well as index. For example:

```
>>> var_type = collections.namedtuple('variable',
...                                   'id name type size')
>>> # Names are separated by spaces or commas.
>>> # 'id, name, type, size' would also work.
>>> var_type._fields
('id', 'name', 'type', 'size')

>>> var = var_type(1, 'frequency', 'int', 4)
>>> print var[0], var.id      # Equivalent
1 1
>>> print var[2], var.type   # Equivalent
int int
>>> var._asdict()
{'size': 4, 'type': 'int', 'id': 1, 'name': 'frequency'}
>>> v2 = var._replace(name='amplitude')
>>> v2
variable(id=1, name='amplitude', type='int', size=4)
```

Several places in the standard library that returned tuples have been modified to return `namedtuple` instances. For example, the `Decimal.as_tuple()` method now returns a named tuple with `sign`, `digits`, and `exponent` fields.

(Contributed by Raymond Hettinger.)

- Another change to the `collections` module is that the `deque` type now supports an optional `maxlen` parameter; if supplied, the deque's size will be restricted to no more than `maxlen` items. Adding more items to a full deque causes old items to be discarded.

```
>>> from collections import deque
>>> dq=deque(maxlen=3)
>>> dq
deque([], maxlen=3)
>>> dq.append(1) ; dq.append(2) ; dq.append(3)
>>> dq
deque([1, 2, 3], maxlen=3)
>>> dq.append(4)
```

```
>>> dq
deque([2, 3, 4], maxlen=3)
```

(Contributed by Raymond Hettinger.)

- The `cookie` module's `Morse1` objects now support an `httponly` attribute. In some browsers, cookies with this attribute set cannot be accessed or manipulated by JavaScript code. (Contributed by Arvin Schnell; [issue 1638033](#).)
- A new window method in the `curses` module, `chgat()`, changes the display attributes for a certain number of characters on a single line. (Contributed by Fabian Kreutz.)

```
# Boldface text starting at y=0,x=21
# and affecting the rest of the line.
stdscr.chgat(0, 21, curses.A_BOLD)
```

The `Textbox` class in the `curses.textpad` module now supports editing in insert mode as well as overwrite mode. Insert mode is enabled by supplying a true value for the `insert_mode` parameter when creating the `Textbox` instance.

- The `datetime` module's `strftime()` methods now support a `%f` format code that expands to the number of microseconds in the object, zero-padded on the left to six places. (Contributed by Skip Montanaro; [issue 1158](#).)
- The `decimal` module was updated to version 1.66 of the [General Decimal Specification](#). New features include some methods for some basic mathematical functions such as `exp()` and `log10()`:

```
>>> Decimal(1).exp()
Decimal("2.718281828459045235360287471")
>>> Decimal("2.7182818").ln()
Decimal("0.9999999895305022877376682436")
>>> Decimal(1000).log10()
```

```
Decimal("3")
```

The `as_tuple()` method of `Decimal` objects now returns a named tuple with `sign`, `digits`, and `exponent` fields.

(Implemented by Facundo Batista and Mark Dickinson. Named tuple support added by Raymond Hettinger.)

- The `difflib` module's `SequenceMatcher` class now returns named tuples representing matches, with `a`, `b`, and `size` attributes. (Contributed by Raymond Hettinger.)
- An optional `timeout` parameter, specifying a timeout measured in seconds, was added to the `ftplib.FTP` class constructor as well as the `connect()` method. (Added by Facundo Batista.) Also, the `FTP` class's `storbinary()` and `storlines()` now take an optional `callback` parameter that will be called with each block of data after the data has been sent. (Contributed by Phil Schwartz; [issue 1221598](#).)
- The `reduce()` built-in function is also available in the `functools` module. In Python 3.0, the builtin has been dropped and `reduce()` is only available from `functools`; currently there are no plans to drop the builtin in the 2.x series. (Patched by Christian Heimes; [issue 1739906](#).)
- When possible, the `getpass` module will now use `/dev/tty` to print a prompt message and read the password, falling back to standard error and standard input. If the password may be echoed to the terminal, a warning is printed before the prompt is displayed. (Contributed by Gregory P. Smith.)
- The `glob.glob()` function can now return Unicode filenames if a Unicode path was used and Unicode filenames are matched

within the directory. ([issue 1001604](#))

- A new function in the `heapq` module, `merge(iter1, iter2, ...)`, takes any number of iterables returning data in sorted order, and returns a new generator that returns the contents of all the iterators, also in sorted order. For example:

```
>>> list(heapq.merge([1, 3, 5, 9], [2, 8, 16]))  
[1, 2, 3, 5, 8, 9, 16]
```

Another new function, `heappushpop(heap, item)`, pushes *item* onto *heap*, then pops off and returns the smallest item. This is more efficient than making a call to `heappush()` and then `heappop()`.

`heapq` is now implemented to only use less-than comparison, instead of the less-than-or-equal comparison it previously used. This makes `heapq`'s usage of a type match the `list.sort()` method. (Contributed by Raymond Hettinger.)

- An optional `timeout` parameter, specifying a timeout measured in seconds, was added to the `httplib.HTTPConnection` and `HTTPSConnection` class constructors. (Added by Facundo Batista.)
- Most of the `inspect` module's functions, such as `getmoduleinfo()` and `getargs()`, now return named tuples. In addition to behaving like tuples, the elements of the return value can also be accessed as attributes. (Contributed by Raymond Hettinger.)

Some new functions in the module include `isgenerator()`, `isgeneratorfunction()`, and `isabstract()`.

- The `itertools` module gained several new functions.

`izip_longest(iter1, iter2, ..., [, fillvalue])` makes tuples from each of the elements; if some of the iterables are shorter than others, the missing values are set to *fillvalue*. For example:

```
>>> tuple(itertools.izip_longest([1,2,3], [1,2,3,4,5]))
((1, 1), (2, 2), (3, 3), (None, 4), (None, 5))
```

`product(iter1, iter2, ..., [repeat=N])` returns the Cartesian product of the supplied iterables, a set of tuples containing every possible combination of the elements returned from each iterable.

```
>>> list(itertools.product([1,2,3], [4,5,6]))
[(1, 4), (1, 5), (1, 6),
 (2, 4), (2, 5), (2, 6),
 (3, 4), (3, 5), (3, 6)]
```

The optional *repeat* keyword argument is used for taking the product of an iterable or a set of iterables with themselves, repeated *N* times. With a single iterable argument, *N*-tuples are returned:

```
>>> list(itertools.product([1,2], repeat=3))
[(1, 1, 1), (1, 1, 2), (1, 2, 1), (1, 2, 2),
 (2, 1, 1), (2, 1, 2), (2, 2, 1), (2, 2, 2)]
```

With two iterables, $2N$ -tuples are returned.

```
>>> list(itertools.product([1,2], [3,4], repeat=2))
[(1, 3, 1, 3), (1, 3, 1, 4), (1, 3, 2, 3), (1, 3, 2, 4),
 (1, 4, 1, 3), (1, 4, 1, 4), (1, 4, 2, 3), (1, 4, 2, 4),
 (2, 3, 1, 3), (2, 3, 1, 4), (2, 3, 2, 3), (2, 3, 2, 4),
 (2, 4, 1, 3), (2, 4, 1, 4), (2, 4, 2, 3), (2, 4, 2, 4)]
```

`combinations(iterable, r)` returns sub-sequences of length *r* from the elements of *iterable*.

```
>>> list(itertools.combinations('123', 2))
[('1', '2'), ('1', '3'), ('2', '3')]
>>> list(itertools.combinations('123', 3))
[('1', '2', '3')]
>>> list(itertools.combinations('1234', 3))
[('1', '2', '3'), ('1', '2', '4'),
 ('1', '3', '4'), ('2', '3', '4')]
```

`permutations(iter[, r])` returns all the permutations of length *r* of the iterable's elements. If *r* is not specified, it will default to the number of elements produced by the iterable.

```
>>> list(itertools.permutations([1,2,3,4], 2))
[(1, 2), (1, 3), (1, 4),
 (2, 1), (2, 3), (2, 4),
 (3, 1), (3, 2), (3, 4),
 (4, 1), (4, 2), (4, 3)]
```

`itertools.chain(*iterables)` is an existing function in `itertools` that gained a new constructor in Python 2.6. `itertools.chain.from_iterable(iterable)` takes a single iterable that should return other iterables. `chain()` will then return all the elements of the first iterable, then all the elements of the second, and so on.

```
>>> list(itertools.chain.from_iterable([[1,2,3], [4,5,6]]))
[1, 2, 3, 4, 5, 6]
```

(All contributed by Raymond Hettinger.)

- The `logging` module's `FileHandler` class and its subclasses `WatchedFileHandler`, `RotatingFileHandler`, and `TimedRotatingFileHandler` now have an optional `delay` parameter to their constructors. If `delay` is true, opening of the log file is deferred until the first `emit()` call is made. (Contributed by Vinay Sajip.)

`TimedRotatingFileHandler` also has a `utc` constructor parameter. If the argument is true, UTC time will be used in determining when midnight occurs and in generating filenames; otherwise local time will be used.

- Several new functions were added to the `math` module:
 - `isinf()` and `isnan()` determine whether a given float is a (positive or negative) infinity or a NaN (Not a Number), respectively.
 - `copysign()` copies the sign bit of an IEEE 754 number, returning the absolute value of `x` combined with the sign bit of `y`. For example, `math.copysign(1, -0.0)` returns `-1.0`. (Contributed by Christian Heimes.)
 - `factorial()` computes the factorial of a number. (Contributed by Raymond Hettinger; [issue 2138](#).)
 - `fsum()` adds up the stream of numbers from an iterable, and is careful to avoid loss of precision through using partial sums. (Contributed by Jean Brouwers, Raymond Hettinger, and Mark Dickinson; [issue 2819](#).)
 - `acosh()`, `asinh()` and `atanh()` compute the inverse hyperbolic functions.
 - `log1p()` returns the natural logarithm of $1+x$ (base e).
 - `trunc()` rounds a number toward zero, returning the closest `Integral` that's between the function's argument and zero. Added as part of the backport of [PEP 3141's type hierarchy for numbers](#).
- The `math` module has been improved to give more consistent behaviour across platforms, especially with respect to handling of floating-point exceptions and IEEE 754 special values.

Whenever possible, the module follows the recommendations of the C99 standard about 754's special values. For example,

`sqrt(-1.)` should now give a `ValueError` across almost all platforms, while `sqrt(float('NaN'))` should return a NaN on all IEEE 754 platforms. Where Annex 'F' of the C99 standard recommends signaling 'divide-by-zero' or 'invalid', Python will raise `ValueError`. Where Annex 'F' of the C99 standard recommends signaling 'overflow', Python will raise `OverflowError`. (See [issue 711019](#) and [issue 1640](#).)

(Contributed by Christian Heimes and Mark Dickinson.)

- `mmap` objects now have a `rfind()` method that searches for a substring beginning at the end of the string and searching backwards. The `find()` method also gained an `end` parameter giving an index at which to stop searching. (Contributed by John Lenton.)
- The `operator` module gained a `methodcaller()` function that takes a name and an optional set of arguments, returning a callable that will call the named function on any arguments passed to it. For example:

```
>>> # Equivalent to lambda s: s.replace('old', 'new')
>>> replacer = operator.methodcaller('replace', 'old', 'new')
>>> replacer('old wine in old bottles')
'new wine in new bottles'
```

(Contributed by Georg Brandl, after a suggestion by Gregory Petrosyan.)

The `attrgetter()` function now accepts dotted names and performs the corresponding attribute lookups:

```
>>> inst_name = operator.attrgetter(
...     '__class__.__name__')
>>> inst_name('')
'str'
```

```
>>> inst_name(help)
'_Helper'
```

(Contributed by Georg Brandl, after a suggestion by Barry Warsaw.)

- The `os` module now wraps several new system calls. `fchmod(fd, mode)` and `fchown(fd, uid, gid)` change the mode and ownership of an opened file, and `lchmod(path, mode)` changes the mode of a symlink. (Contributed by Georg Brandl and Christian Heimes.)

`chflags()` and `lchflags()` are wrappers for the corresponding system calls (where they're available), changing the flags set on a file. Constants for the flag values are defined in the `stat` module; some possible values include `UF_IMMUTABLE` to signal the file may not be changed and `UF_APPEND` to indicate that data can only be appended to the file. (Contributed by M. Levinson.)

`os.closerange(low, high)` efficiently closes all file descriptors from *low* to *high*, ignoring any errors and not including *high* itself. This function is now used by the `subprocess` module to make starting processes faster. (Contributed by Georg Brandl; [issue 1663329](#).)

- The `os.environ` object's `clear()` method will now unset the environment variables using `os.unsetenv()` in addition to clearing the object's keys. (Contributed by Martin Horcicka; [issue 1181](#).)
- The `os.walk()` function now has a `followlinks` parameter. If set to True, it will follow symlinks pointing to directories and visit the directory's contents. For backward compatibility, the parameter's default value is false. Note that the function can fall into an

infinite recursion if there's a symlink that points to a parent directory. ([issue 1273829](#))

- In the `os.path` module, the `splitext()` function has been changed to not split on leading period characters. This produces better results when operating on Unix's dot-files. For example, `os.path.splitext('.ipython')` now returns `('.ipython', '')` instead of `('', '.ipython')`. ([issue 1115886](#))

A new function, `os.path.relpath(path, start='.')`, returns a relative path from the `start` path, if it's supplied, or from the current working directory to the destination `path`. (Contributed by Richard Barran; [issue 1339796](#).)

On Windows, `os.path.expandvars()` will now expand environment variables given in the form “%var%”, and “~user” will be expanded into the user's home directory path. (Contributed by Josiah Carlson; [issue 957650](#).)

- The Python debugger provided by the `pdb` module gained a new command: “run” restarts the Python program being debugged and can optionally take new command-line arguments for the program. (Contributed by Rocky Bernstein; [issue 1393667](#).)
- The `pdb.post_mortem()` function, used to begin debugging a traceback, will now use the traceback returned by `sys.exc_info()` if no traceback is supplied. (Contributed by Facundo Batista; [issue 1106316](#).)
- The `pickletools` module now has an `optimize()` function that takes a string containing a pickle and removes some unused opcodes, returning a shorter pickle that contains the same data structure. (Contributed by Raymond Hettinger.)

- A `get_data()` function was added to the `pkgutil` module that returns the contents of resource files included with an installed Python package. For example:

```
>>> import pkgutil
>>> print pkgutil.get_data('test', 'exception_hierarchy.txt')
BaseException
+-- SystemExit
+-- KeyboardInterrupt
+-- GeneratorExit
+-- Exception
    +-- StopIteration
    +-- StandardError
    ...
```

(Contributed by Paul Moore; [issue 2439](#).)

- The `pyexpat` module's `Parser` objects now allow setting their `buffer_size` attribute to change the size of the buffer used to hold character data. (Contributed by Achim Gaedke; [issue 1137](#).)
- The `queue` module now provides queue variants that retrieve entries in different orders. The `PriorityQueue` class stores queued items in a heap and retrieves them in priority order, and `LifoQueue` retrieves the most recently added entries first, meaning that it behaves like a stack. (Contributed by Raymond Hettinger.)
- The `random` module's `Random` objects can now be pickled on a 32-bit system and unpickled on a 64-bit system, and vice versa. Unfortunately, this change also means that Python 2.6's `Random` objects can't be unpickled correctly on earlier versions of Python. (Contributed by Shawn Ligocki; [issue 1727780](#).)

The new `triangular(low, high, mode)` function returns random

numbers following a triangular distribution. The returned values are between *low* and *high*, not including *high* itself, and with *mode* as the most frequently occurring value in the distribution. (Contributed by Wladimir van der Laan and Raymond Hettinger; [issue 1681432](#).)

- Long regular expression searches carried out by the `re` module will check for signals being delivered, so time-consuming searches can now be interrupted. (Contributed by Josh Hoyt and Ralf Schmitt; [issue 846388](#).)

The regular expression module is implemented by compiling bytecodes for a tiny regex-specific virtual machine. Untrusted code could create malicious strings of bytecode directly and cause crashes, so Python 2.6 includes a verifier for the regex bytecode. (Contributed by Guido van Rossum from work for Google App Engine; [issue 3487](#).)

- The `rlcompleter` module's `Completer.complete()` method will now ignore exceptions triggered while evaluating a name. (Fixed by Lorenz Quack; [issue 2250](#).)
- The `sched` module's `Scheduler` instances now have a read-only `queue` attribute that returns the contents of the scheduler's queue, represented as a list of named tuples with the fields `(time, priority, action, argument)`. (Contributed by Raymond Hettinger; [issue 1861](#).)
- The `select` module now has wrapper functions for the Linux `epoll()` and BSD `kqueue()` system calls. `modify()` method was added to the existing `poll` objects; `pollobj.modify(fd, eventmask)` takes a file descriptor or file object and an event mask, modifying the recorded event mask for that file. (Contributed by Christian Heimes; [issue 1657](#).)

- The `shutil.copytree()` function now has an optional *ignore* argument that takes a callable object. This callable will receive each directory path and a list of the directory's contents, and returns a list of names that will be ignored, not copied.

The `shutil` module also provides an `ignore_patterns()` function for use with this new parameter. `ignore_patterns()` takes an arbitrary number of glob-style patterns and returns a callable that will ignore any files and directories that match any of these patterns. The following example copies a directory tree, but skips both `.svn` directories and Emacs backup files, which have names ending with `~`:

```
shutil.copytree('Doc/library', '/tmp/library',
               ignore=shutil.ignore_patterns('*~', '.svn'))
```

(Contributed by Tarek Ziadé; [issue 2663](#).)

- Integrating signal handling with GUI handling event loops like those used by Tkinter or GTK+ has long been a problem; most software ends up polling, waking up every fraction of a second to check if any GUI events have occurred. The `signal` module can now make this more efficient. Calling `signal.set_wakeup_fd(fd)` sets a file descriptor to be used; when a signal is received, a byte is written to that file descriptor. There's also a C-level function, `PySignal_SetWakeupFd()`, for setting the descriptor.

Event loops will use this by opening a pipe to create two descriptors, one for reading and one for writing. The writable descriptor will be passed to `set_wakeup_fd()`, and the readable descriptor will be added to the list of descriptors monitored by the event loop via `select()` or `poll()`. On receiving a signal, a byte will be written and the main event loop will be woken up,

avoiding the need to poll.

(Contributed by Adam Olsen; [issue 1583](#).)

The `siginterrupt()` function is now available from Python code, and allows changing whether signals can interrupt system calls or not. (Contributed by Ralf Schmitt.)

The `setitimer()` and `getitimer()` functions have also been added (where they're available). `setitimer()` allows setting interval timers that will cause a signal to be delivered to the process after a specified time, measured in wall-clock time, consumed process time, or combined process+system time. (Contributed by Guilherme Polo; [issue 2240](#).)

- The `smtplib` module now supports SMTP over SSL thanks to the addition of the `SMTP_SSL` class. This class supports an interface identical to the existing `SMTP` class. (Contributed by Monty Taylor.) Both class constructors also have an optional `timeout` parameter that specifies a timeout for the initial connection attempt, measured in seconds. (Contributed by Facundo Batista.)

An implementation of the LMTP protocol ([RFC 2033](#)) was also added to the module. LMTP is used in place of SMTP when transferring e-mail between agents that don't manage a mail queue. (LMTP implemented by Leif Hedstrom; [issue 957003](#).)

`SMTP.starttls()` now complies with [RFC 3207](#) and forgets any knowledge obtained from the server not obtained from the TLS negotiation itself. (Patch contributed by Bill Fenner; [issue 829951](#).)

- The `socket` module now supports TIPC (<http://tipc.sf.net>), a high-performance non-IP-based protocol designed for use in

clustered environments. TIPC addresses are 4- or 5-tuples. (Contributed by Alberto Bertogli; [issue 1646](#).)

A new function, `create_connection()`, takes an address and connects to it using an optional timeout value, returning the connected socket object. This function also looks up the address's type and connects to it using IPv4 or IPv6 as appropriate. Changing your code to use `create_connection()` instead of `socket(socket.AF_INET, ...)` may be all that's required to make your code work with IPv6.

- The base classes in the `socketServer` module now support calling a `handle_timeout()` method after a span of inactivity specified by the server's `timeout` attribute. (Contributed by Michael Pomraning.) The `serve_forever()` method now takes an optional poll interval measured in seconds, controlling how often the server will check for a shutdown request. (Contributed by Pedro Werneck and Jeffrey Yasskin; [issue 742598](#), [issue 1193577](#).)
- The `sqlite3` module, maintained by Gerhard Haering, has been updated from version 2.3.2 in Python 2.5 to version 2.4.1.
- The `struct` module now supports the C99 `_Bool` type, using the format character `'?'`. (Contributed by David Remahl.)
- The `Popen` objects provided by the `subprocess` module now have `terminate()`, `kill()`, and `send_signal()` methods. On Windows, `send_signal()` only supports the `SIGTERM` signal, and all these methods are aliases for the Win32 API function `TerminateProcess()`. (Contributed by Christian Heimes.)
- A new variable in the `sys` module, `float_info`, is an object containing information derived from the `float.h` file about the

platform's floating-point support. Attributes of this object include `mant_dig` (number of digits in the mantissa), `epsilon` (smallest difference between 1.0 and the next largest value representable), and several others. (Contributed by Christian Heimes; [issue 1534](#).)

Another new variable, `dont_write_bytecode`, controls whether Python writes any `.pyc` or `.pyo` files on importing a module. If this variable is true, the compiled files are not written. The variable is initially set on start-up by supplying the `-B` switch to the Python interpreter, or by setting the `PYTHONDONTWRITEBYTECODE` environment variable before running the interpreter. Python code can subsequently change the value of this variable to control whether bytecode files are written or not. (Contributed by Neal Norwitz and Georg Brandl.)

Information about the command-line arguments supplied to the Python interpreter is available by reading attributes of a named tuple available as `sys.flags`. For example, the `verbose` attribute is true if Python was executed in verbose mode, `debug` is true in debugging mode, etc. These attributes are all read-only. (Contributed by Christian Heimes.)

A new function, `getsizeof()`, takes a Python object and returns the amount of memory used by the object, measured in bytes. Built-in objects return correct results; third-party extensions may not, but can define a `__sizeof__()` method to return the object's size. (Contributed by Robert Schuppenies; [issue 2898](#).)

It's now possible to determine the current profiler and tracer functions by calling `sys.getprofile()` and `sys.gettrace()`. (Contributed by Georg Brandl; [issue 1648](#).)

- The `tarfile` module now supports POSIX.1-2001 (pax) tarfiles

in addition to the POSIX.1-1988 (ustar) and GNU tar formats that were already supported. The default format is GNU tar; specify the `format` parameter to open a file using a different format:

```
tar = tarfile.open("output.tar", "w",  
                  format=tarfile.PAX_FORMAT)
```

The new `encoding` and `errors` parameters specify an encoding and an error handling scheme for character conversions. `'strict'`, `'ignore'`, and `'replace'` are the three standard ways Python can handle errors; `'utf-8'` is a special value that replaces bad characters with their UTF-8 representation. (Character conversions occur because the PAX format supports Unicode filenames, defaulting to UTF-8 encoding.)

The `TarFile.add()` method now accepts an `exclude` argument that's a function that can be used to exclude certain filenames from an archive. The function must take a filename and return true if the file should be excluded or false if it should be archived. The function is applied to both the name initially passed to `add()` and to the names of files in recursively-added directories.

(All changes contributed by Lars Gustäbel).

- An optional `timeout` parameter was added to the `telnetlib.Telnet` class constructor, specifying a timeout measured in seconds. (Added by Facundo Batista.)
- The `tempfile.NamedTemporaryFile` class usually deletes the temporary file it created when the file is closed. This behaviour can now be changed by passing `delete=False` to the constructor. (Contributed by Damien Miller; [issue 1537850](#).)

A new class, `SpooledTemporaryFile`, behaves like a temporary file but stores its data in memory until a maximum size is exceeded. On reaching that limit, the contents will be written to an on-disk temporary file. (Contributed by Dustin J. Mitchell.)

The `NamedTemporaryFile` and `SpooledTemporaryFile` classes both work as context managers, so you can write `with tempfile.NamedTemporaryFile()` as `tmp: ...`. (Contributed by Alexander Belopolsky; [issue 2021](#).)

- The `test.test_support` module gained a number of context managers useful for writing tests. `EnvironmentVarGuard()` is a context manager that temporarily changes environment variables and automatically restores them to their old values.

Another context manager, `TransientResource`, can surround calls to resources that may or may not be available; it will catch and ignore a specified list of exceptions. For example, a network test may ignore certain failures when connecting to an external web site:

```
with test_support.TransientResource(IOError,
                                   errno=errno.ETIMEDOUT):
    f = urllib.urlopen('https://sf.net')
    ...
```

Finally, `check_warnings()` resets the `warning` module's warning filters and returns an object that will record all warning messages triggered ([issue 3781](#)):

```
with test_support.check_warnings() as wrec:
    warnings.simplefilter("always")
    # ... code that triggers a warning ...
    assert str(wrec.message) == "function is outdated"
    assert len(wrec.warnings) == 1, "Multiple warnings rais
```

(Contributed by Brett Cannon.)

- The `textwrap` module can now preserve existing whitespace at the beginnings and ends of the newly-created lines by specifying `drop_whitespace=False` as an argument:

```
>>> S = """This sentence has a bunch of
... extra whitespace."""
>>> print textwrap.fill(S, width=15)
This sentence
has a bunch
of extra
whitespace.
>>> print textwrap.fill(S, drop_whitespace=False, width=15)
This sentence
  has a bunch
    of extra
      whitespace.
>>>
```

(Contributed by Dwayne Bailey; [issue 1581073](#).)

- The `threading` module API is being changed to use properties such as `daemon` instead of `setDaemon()` and `isDaemon()` methods, and some methods have been renamed to use underscores instead of camel-case; for example, the `activeCount()` method is renamed to `active_count()`. Both the 2.6 and 3.0 versions of the module support the same properties and renamed methods, but don't remove the old methods. No date has been set for the deprecation of the old APIs in Python 3.x; the old APIs won't be removed in any 2.x version. (Carried out by several people, most notably Benjamin Peterson.)

The `threading` module's `Thread` objects gained an `ident` property that returns the thread's identifier, a nonzero integer. (Contributed by Gregory P. Smith; [issue 2871](#).)

- The `timeit` module now accepts callables as well as strings for the statement being timed and for the setup code. Two convenience functions were added for creating `Timer` instances: `repeat(stmt, setup, time, repeat, number)` and `timeit(stmt, setup, time, number)` create an instance and call the corresponding method. (Contributed by Erik Demaine; [issue 1533909](#).)
- The `tkinter` module now accepts lists and tuples for options, separating the elements by spaces before passing the resulting value to Tcl/Tk. (Contributed by Guilherme Polo; [issue 2906](#).)
- The `turtle` module for turtle graphics was greatly enhanced by Gregor Lingl. New features in the module include:
 - Better animation of turtle movement and rotation.
 - Control over turtle movement using the new `delay()`, `tracer()`, and `speed()` methods.
 - The ability to set new shapes for the turtle, and to define a new coordinate system.
 - Turtles now have an `undo()` method that can roll back actions.
 - Simple support for reacting to input events such as mouse and keyboard activity, making it possible to write simple games.
 - A `turtle.cfg` file can be used to customize the starting appearance of the turtle's screen.
 - The module's docstrings can be replaced by new docstrings that have been translated into another language.

([issue 1513695](#))

- An optional `timeout` parameter was added to the `urllib.urlopen()` function and the `urllib.ftplibwrapper` class

constructor, as well as the `urllib2.urlopen()` function. The parameter specifies a timeout measured in seconds. For example:

```
>>> u = urllib2.urlopen("http://slow.example.com",
                        timeout=3)
Traceback (most recent call last):
  ...
urllib2.URLError: <urlopen error timed out>
>>>
```

(Added by Facundo Batista.)

- The Unicode database provided by the `unicodedata` module has been updated to version 5.1.0. (Updated by Martin von Loewis; [issue 3811](#).)
- The `warnings` module's `formatwarning()` and `showwarning()` gained an optional *line* argument that can be used to supply the line of source code. (Added as part of [issue 1631171](#), which re-implemented part of the `warnings` module in C code.)

A new function, `catch_warnings()`, is a context manager intended for testing purposes that lets you temporarily modify the warning filters and then restore their original values ([issue 3781](#)).

- The XML-RPC `SimpleXMLRPCServer` and `DocXMLRPCServer` classes can now be prevented from immediately opening and binding to their socket by passing `True` as the `bind_and_activate` constructor parameter. This can be used to modify the instance's `allow_reuse_address` attribute before calling the `server_bind()` and `server_activate()` methods to open the socket and begin listening for connections. (Contributed by Peter Parente; [issue 1599845](#).)

`SimpleXMLRPCServer` also has a `_send_traceback_header` attribute; if true, the exception and formatted traceback are returned as HTTP headers “X-Exception” and “X-Traceback”. This feature is for debugging purposes only and should not be used on production servers because the tracebacks might reveal passwords or other sensitive information. (Contributed by Alan McIntyre as part of his project for Google’s Summer of Code 2007.)

- The `xmlrpclib` module no longer automatically converts `datetime.date` and `datetime.time` to the `xmlrpclib.DateTime` type; the conversion semantics were not necessarily correct for all applications. Code using `xmlrpclib` should convert `date` and `time` instances. (issue 1330538) The code can also handle dates before 1900 (contributed by Ralf Schmitt; issue 2014) and 64-bit integers represented by using `<i8>` in XML-RPC responses (contributed by Riku Lindblad; issue 2985).
- The `zipfile` module’s `zipFile` class now has `extract()` and `extractall()` methods that will unpack a single file or all the files in the archive to the current directory, or to a specified directory:

```
z = zipfile.ZipFile('python-251.zip')

# Unpack a single file, writing it relative
# to the /tmp directory.
z.extract('Python/sysmodule.c', '/tmp')

# Unpack all the files in the archive.
z.extractall()
```

(Contributed by Alan McIntyre; issue 467924.)

The `open()`, `read()` and `extract()` methods can now take either a filename or a `zipInfo` object. This is useful when an archive

accidentally contains a duplicated filename. (Contributed by Graham Horler; [issue 1775025](#).)

Finally, `zipfile` now supports using Unicode filenames for archived files. (Contributed by Alexey Borzenkov; [issue 1734346](#).)

The `ast` module

The `ast` module provides an Abstract Syntax Tree representation of Python code, and Armin Ronacher contributed a set of helper functions that perform a variety of common tasks. These will be useful for HTML templating packages, code analyzers, and similar tools that process Python code.

The `parse()` function takes an expression and returns an AST. The `dump()` function outputs a representation of a tree, suitable for debugging:

```
import ast

t = ast.parse("""
d = {}
for i in 'abcdefghijklm':
    d[i + i] = ord(i) - ord('a') + 1
print d
""")
print ast.dump(t)
```

This outputs a deeply nested tree:

```
Module(body=[
  Assign(targets=[
    Name(id='d', ctx=Store())
  ], value=Dict(keys=[], values=[]))
  For(target=Name(id='i', ctx=Store()),
    iter=Str(s='abcdefghijklm'), body=[
  Assign(targets=[
    Subscript(value=
```

```

        Name(id='d', ctx=Load()),
        slice=
        Index(value=
            BinOp(left=Name(id='i', ctx=Load()), op=Add(),
                right=Name(id='i', ctx=Load()))), ctx=Store())
    ], value=
    BinOp(left=
    BinOp(left=
    Call(func=
        Name(id='ord', ctx=Load()), args=[
            Name(id='i', ctx=Load())
        ], keywords=[], starargs=None, kwargs=None),
    op=Sub(), right=Call(func=
        Name(id='ord', ctx=Load()), args=[
            Str(s='a')
        ], keywords=[], starargs=None, kwargs=None)),
    op=Add(), right=Num(n=1))
    ], or_else=[])
    Print(dest=None, values=[
        Name(id='d', ctx=Load())
    ], nl=True)
])

```

The `literal_eval()` method takes a string or an AST representing a literal expression, parses and evaluates it, and returns the resulting value. A literal expression is a Python expression containing only strings, numbers, dictionaries, etc. but no statements or function calls. If you need to evaluate an expression but cannot accept the security risk of using an `eval()` call, `literal_eval()` will handle it safely:

```

>>> literal = '("a", "b", {2:4, 3:8, 1:2})'
>>> print ast.literal_eval(literal)
('a', 'b', {1: 2, 2: 4, 3: 8})
>>> print ast.literal_eval('"a" + "b"')
Traceback (most recent call last):
...
ValueError: malformed string

```

The module also includes `NodeVisitor` and `NodeTransformer` classes for traversing and modifying an AST, and functions for common transformations such as changing line numbers.

The `future_builtins` module

Python 3.0 makes many changes to the repertoire of built-in functions, and most of the changes can't be introduced in the Python 2.x series because they would break compatibility. The `future_builtins` module provides versions of these built-in functions that can be imported when writing 3.0-compatible code.

The functions in this module currently include:

- `ascii(obj)`: equivalent to `repr()`. In Python 3.0, `repr()` will return a Unicode string, while `ascii()` will return a pure ASCII bytestring.
- `filter(predicate, iterable)`, `map(func, iterable1, ...)`: the 3.0 versions return iterators, unlike the 2.x builtins which return lists.
- `hex(value)`, `oct(value)`: instead of calling the `__hex__()` or `__oct__()` methods, these versions will call the `__index__()` method and convert the result to hexadecimal or octal. `oct()` will use the new `0o` notation for its result.

The `json` module: JavaScript Object Notation

The new `json` module supports the encoding and decoding of Python types in JSON (Javascript Object Notation). JSON is a lightweight interchange format often used in web applications. For more information about JSON, see <http://www.json.org>.

`json` comes with support for decoding and encoding most built-in Python types. The following example encodes and decodes a dictionary:

```
>>> import json
>>> data = {"spam" : "foo", "parrot" : 42}
```

```
>>> in_json = json.dumps(data) # Encode the data
>>> in_json
'{"parrot": 42, "spam": "foo"}'
>>> json.loads(in_json) # Decode into a Python object
{"spam" : "foo", "parrot" : 42}
```

It's also possible to write your own decoders and encoders to support more types. Pretty-printing of the JSON strings is also supported.

`json` (originally called `simplejson`) was written by Bob Ippolito.

The `plistlib` module: A Property-List Parser

The `.plist` format is commonly used on Mac OS X to store basic data types (numbers, strings, lists, and dictionaries) by serializing them into an XML-based format. It resembles the XML-RPC serialization of data types.

Despite being primarily used on Mac OS X, the format has nothing Mac-specific about it and the Python implementation works on any platform that Python supports, so the `plistlib` module has been promoted to the standard library.

Using the module is simple:

```
import sys
import plistlib
import datetime

# Create data structure
data_struct = dict(lastAccessed=datetime.datetime.now(),
                  version=1,
                  categories=('Personal', 'Shared', 'Private'))

# Create string containing XML.
plist_str = plistlib.writePlistToString(data_struct)
new_struct = plistlib.readPlistFromString(plist_str)
print data_struct
```

```
print new_struct

# Write data structure to a file and read it back.
plistlib.writePlist(data_struct, '/tmp/customizations.plist')
new_struct = plistlib.readPlist('/tmp/customizations.plist')

# read/writePlist accepts file-like objects as well as paths.
plistlib.writePlist(data_struct, sys.stdout)
```

ctypes Enhancements

Thomas Heller continued to maintain and enhance the `ctypes` module.

`ctypes` now supports a `c_bool` datatype that represents the C99 `bool` type. (Contributed by David Remahl; [issue 1649190](#).)

The `ctypes` string, buffer and array types have improved support for extended slicing syntax, where various combinations of `(start, stop, step)` are supplied. (Implemented by Thomas Wouters.)

All `ctypes` data types now support `from_buffer()` and `from_buffer_copy()` methods that create a `ctypes` instance based on a provided buffer object. `from_buffer_copy()` copies the contents of the object, while `from_buffer()` will share the same memory area.

A new calling convention tells `ctypes` to clear the `errno` or Win32 `LastError` variables at the outset of each wrapped call. (Implemented by Thomas Heller; [issue 1798](#).)

You can now retrieve the Unix `errno` variable after a function call. When creating a wrapped function, you can supply `use_errno=True` as a keyword parameter to the `DLL()` function and then call the module-level methods `set_errno()` and `get_errno()` to set and retrieve the error value.

The Win32 `LastError` variable is similarly supported by the `DLL()`, `oleDLL()`, and `winDLL()` functions. You supply `use_last_error=True` as a keyword parameter and then call the module-level methods `set_last_error()` and `get_last_error()`.

The `byref()` function, used to retrieve a pointer to a `ctypes` instance, now has an optional `offset` parameter that is a byte count that will be added to the returned pointer.

Improved SSL Support

Bill Janssen made extensive improvements to Python 2.6's support for the Secure Sockets Layer by adding a new module, `ssl`, that's built atop the [OpenSSL](#) library. This new module provides more control over the protocol negotiated, the X.509 certificates used, and has better support for writing SSL servers (as opposed to clients) in Python. The existing SSL support in the `socket` module hasn't been removed and continues to work, though it will be removed in Python 3.0.

To use the new module, you must first create a TCP connection in the usual way and then pass it to the `ssl.wrap_socket()` function. It's possible to specify whether a certificate is required, and to obtain certificate info by calling the `getpeercert()` method.

See also: The documentation for the `ssl` module.

Deprecations and Removals

- String exceptions have been removed. Attempting to use them raises a `TypeError`.
- Changes to the `Exception` interface as dictated by [PEP 352](#) continue to be made. For 2.6, the `message` attribute is being deprecated in favor of the `args` attribute.
- (3.0-warning mode) Python 3.0 will feature a reorganized standard library that will drop many outdated modules and rename others. Python 2.6 running in 3.0-warning mode will warn about these modules when they are imported.

The list of deprecated modules is: `audiodev`, `bgenlocations`, `buildtools`, `bundlebuilder`, `Canvas`, `compiler`, `dircache`, `dl`, `fpformat`, `gensuitemodule`, `ihooks`, `imageop`, `imgfile`, `linuxaudiodev`, `mhlib`, `mimertools`, `multifile`, `new`, `pure`, `statvfs`, `sunaudiodev`, `test.testall`, and `toaiff`.

- The `gopherlib` module has been removed.
- The `MimeWriter` module and `mimify` module have been deprecated; use the `email` package instead.
- The `md5` module has been deprecated; use the `hashlib` module instead.
- The `posixfile` module has been deprecated; `fcntl.lockf()` provides better locking.
- The `popen2` module has been deprecated; use the `subprocess` module.

- The `rgbimg` module has been removed.
- The `sets` module has been deprecated; it's better to use the built-in `set` and `frozenset` types.
- The `sha` module has been deprecated; use the `hashlib` module instead.

Build and C API Changes

Changes to Python's build process and to the C API include:

- Python now must be compiled with C89 compilers (after 19 years!). This means that the Python source tree has dropped its own implementations of `memcpy()` and `strerror()`, which are in the C89 standard library.
- Python 2.6 can be built with Microsoft Visual Studio 2008 (version 9.0), and this is the new default compiler. See the `PCbuild` directory for the build files. (Implemented by Christian Heimes.)
- On Mac OS X, Python 2.6 can be compiled as a 4-way universal build. The **configure** script can take a `--with-universal-archs=[32-bit|64-bit|all]` switch, controlling whether the binaries are built for 32-bit architectures (x86, PowerPC), 64-bit (x86-64 and PPC-64), or both. (Contributed by Ronald Oussoren.)
- The BerkeleyDB module now has a C API object, available as `bsddb.db.api`. This object can be used by other C extensions that wish to use the `bsddb` module for their own purposes. (Contributed by Duncan Grisby.)
- The new buffer interface, previously described in the [PEP 3118 section](#), adds `PyObject_GetBuffer()` and `PyBuffer_Release()`, as well as a few other functions.
- Python's use of the C `stdio` library is now thread-safe, or at least as thread-safe as the underlying library is. A long-standing potential bug occurred if one thread closed a file object while another thread was reading from or writing to the object. In 2.6 file objects have a reference count, manipulated by the

`PyFile_IncUseCount()` and `PyFile_DecUseCount()` functions. File objects can't be closed unless the reference count is zero. `PyFile_IncUseCount()` should be called while the GIL is still held, before carrying out an I/O operation using the `FILE *` pointer, and `PyFile_DecUseCount()` should be called immediately after the GIL is re-acquired. (Contributed by Antoine Pitrou and Gregory P. Smith.)

- Importing modules simultaneously in two different threads no longer deadlocks; it will now raise an `ImportError`. A new API function, `PyImport_ImportModuleNoBlock()`, will look for a module in `sys.modules` first, then try to import it after acquiring an import lock. If the import lock is held by another thread, an `ImportError` is raised. (Contributed by Christian Heimes.)
- Several functions return information about the platform's floating-point support. `PyFloat_GetMax()` returns the maximum representable floating point value, and `PyFloat_GetMin()` returns the minimum positive value. `PyFloat_GetInfo()` returns an object containing more information from the `float.h` file, such as `"mant_dig"` (number of digits in the mantissa), `"epsilon"` (smallest difference between 1.0 and the next largest value representable), and several others. (Contributed by Christian Heimes; [issue 1534](#).)
- C functions and methods that use `PyComplex_AsCComplex()` will now accept arguments that have a `__complex__()` method. In particular, the functions in the `cmath` module will now accept objects with this method. This is a backport of a Python 3.0 change. (Contributed by Mark Dickinson; [issue 1675423](#).)
- Python's C API now includes two functions for case-insensitive string comparisons, `PyOS_stricmp(char*, char*)` and

`PyOS_strnicmp(char*, char*, Py_ssize_t)`. (Contributed by Christian Heimes; [issue 1635](#).)

- Many C extensions define their own little macro for adding integers and strings to the module's dictionary in the `init*` function. Python 2.6 finally defines standard macros for adding values to a module, `PyModule_AddStringMacro` and `PyModule_AddIntMacro()`. (Contributed by Christian Heimes.)
- Some macros were renamed in both 3.0 and 2.6 to make it clearer that they are macros, not functions. `Py_Size()` became `Py_SIZE()`, `Py_Type()` became `Py_TYPE()`, and `Py_Refcnt()` became `Py_REFCNT()`. The mixed-case macros are still available in Python 2.6 for backward compatibility. ([issue 1629](#))
- Distutils now places C extensions it builds in a different directory when running on a debug version of Python. (Contributed by Collin Winter; [issue 1530959](#).)
- Several basic data types, such as integers and strings, maintain internal free lists of objects that can be re-used. The data structures for these free lists now follow a naming convention: the variable is always named `free_list`, the counter is always named `numfree`, and a macro `Py<typename>_MAXFREELIST` is always defined.
- A new Makefile target, “make patchcheck”, prepares the Python source tree for making a patch: it fixes trailing whitespace in all modified `.py` files, checks whether the documentation has been changed, and reports whether the `Misc/ACKS` and `Misc/NEWS` files have been updated. (Contributed by Brett Cannon.)

Another new target, “make profile-opt”, compiles a Python binary using GCC's profile-guided optimization. It compiles

Python with profiling enabled, runs the test suite to obtain a set of profiling results, and then compiles using these results for optimization. (Contributed by Gregory P. Smith.)

Port-Specific Changes: Windows

- The support for Windows 95, 98, ME and NT4 has been dropped. Python 2.6 requires at least Windows 2000 SP4.
- The new default compiler on Windows is Visual Studio 2008 (version 9.0). The build directories for Visual Studio 2003 (version 7.1) and 2005 (version 8.0) were moved into the PC/ directory. The new `PCbuild` directory supports cross compilation for X64, debug builds and Profile Guided Optimization (PGO). PGO builds are roughly 10% faster than normal builds. (Contributed by Christian Heimes with help from Amaury Forgeot d'Arc and Martin von Loewis.)
- The `msvcrt` module now supports both the normal and wide char variants of the console I/O API. The `getwch()` function reads a keypress and returns a Unicode value, as does the `getwche()` function. The `putwch()` function takes a Unicode character and writes it to the console. (Contributed by Christian Heimes.)
- `os.path.expandvars()` will now expand environment variables in the form “%var%”, and “~user” will be expanded into the user’s home directory path. (Contributed by Josiah Carlson; [issue 957650](#).)
- The `socket` module’s socket objects now have an `ioctl()` method that provides a limited interface to the `WSAIoct1()` system interface.
- The `_winreg` module now has a function,

`ExpandEnvironmentStrings()`, that expands environment variable references such as `%NAME%` in an input string. The handle objects provided by this module now support the context protocol, so they can be used in `with` statements. (Contributed by Christian Heimes.)

`_winreg` also has better support for x64 systems, exposing the `DisableReflectionKey()`, `EnableReflectionKey()`, and `QueryReflectionKey()` functions, which enable and disable registry reflection for 32-bit processes running on 64-bit systems. ([issue 1753245](#))

- The `msilib` module's `Record` object gained `GetInteger()` and `GetString()` methods that return field values as an integer or a string. (Contributed by Floris Bruynooghe; [issue 2125](#).)

Port-Specific Changes: Mac OS X

- When compiling a framework build of Python, you can now specify the framework name to be used by providing the `--with-framework-name=` option to the `configure` script.
- The `macfs` module has been removed. This in turn required the `macostools.touched()` function to be removed because it depended on the `macfs` module. ([issue 1490190](#))
- Many other Mac OS modules have been deprecated and will be removed in Python 3.0: `_builtinSuites`, `aepack`, `aetools`, `aetypes`, `applesingle`, `appletrawmain`, `appletrunner`, `argvemulator`, `Audio_mac`, `autoGIL`, `Carbon`, `cfmfile`, `CodeWarrior`, `ColorPicker`, `EasyDialogs`, `Explorer`, `Finder`, `FrameWork`, `findertools`, `ic`, `icglue`, `icopen`, `macerrors`, `MacOS`, `macfs`, `macostools`, `macresource`, `MiniAERFrame`, `Nav`, `Netscape`, `OSATerminology`, `pimp`, `PixmapWrapper`, `StdSuites`, `SystemEvents`,

`Terminal`, and `terminalcommand`.

Port-Specific Changes: IRIX

A number of old IRIX-specific modules were deprecated and will be removed in Python 3.0: `a1` and `AL`, `cd`, `cddb`, `cdplayer`, `CL` and `c1`, `DEVICE`, `ERRNO`, `FILE`, `FL` and `f1`, `f1p`, `fm`, `GET`, `GLWS`, `GL` and `g1`, `IN`, `IOCTL`, `jpeg`, `panelparser`, `readcd`, `SV` and `sv`, `torgb`, `videoreader`, and `WAIT`.

Porting to Python 2.6

This section lists previously described changes and other bugfixes that may require changes to your code:

- Classes that aren't supposed to be hashable should set `__hash__ = None` in their definitions to indicate the fact.
- String exceptions have been removed. Attempting to use them raises a `TypeError`.
- The `__init__()` method of `collections.deque` now clears any existing contents of the deque before adding elements from the iterable. This change makes the behavior match `list.__init__()`.
- `object.__init__()` previously accepted arbitrary arguments and keyword arguments, ignoring them. In Python 2.6, this is no longer allowed and will result in a `TypeError`. This will affect `__init__()` methods that end up calling the corresponding method on `object` (perhaps through using `super()`). See [issue 1683368](#) for discussion.
- The `Decimal` constructor now accepts leading and trailing whitespace when passed a string. Previously it would raise an `InvalidOperation` exception. On the other hand, the `create_decimal()` method of `context` objects now explicitly disallows extra whitespace, raising a `ConversionSyntax` exception.
- Due to an implementation accident, if you passed a file path to the built-in `__import__()` function, it would actually import the specified file. This was never intended to work, however, and

the implementation now explicitly checks for this case and raises an `ImportError`.

- C API: the `PyImport_Import()` and `PyImport_ImportModule()` functions now default to absolute imports, not relative imports. This will affect C extensions that import other modules.
- C API: extension data types that shouldn't be hashable should define their `tp_hash` slot to `PyObject_HashNotImplemented()`.
- The `socket` module exception `socket.error` now inherits from `IOError`. Previously it wasn't a subclass of `StandardError` but now it is, through `IOError`. (Implemented by Gregory P. Smith; [issue 1706815](#).)
- The `xmlrpclib` module no longer automatically converts `datetime.date` and `datetime.time` to the `xmlrpclib.DateTime` type; the conversion semantics were not necessarily correct for all applications. Code using `xmlrpclib` should convert `date` and `time` instances. ([issue 1330538](#))
- (3.0-warning mode) The `Exception` class now warns when accessed using slicing or index access; having `Exception` behave like a tuple is being phased out.
- (3.0-warning mode) inequality comparisons between two dictionaries or two objects that don't implement comparison methods are reported as warnings. `dict1 == dict2` still works, but `dict1 < dict2` is being phased out.

Comparisons between cells, which are an implementation detail of Python's scoping rules, also cause warnings because such comparisons are forbidden entirely in 3.0.

What's New in Python 2.5

Author: A.M. Kuchling

This article explains the new features in Python 2.5. The final release of Python 2.5 is scheduled for August 2006; [PEP 356](#) describes the planned release schedule.

The changes in Python 2.5 are an interesting mix of language and library improvements. The library enhancements will be more important to Python's user community, I think, because several widely-useful packages were added. New modules include ElementTree for XML processing (`xml.etree`), the SQLite database module (`sqlite`), and the `ctypes` module for calling C functions.

The language changes are of middling significance. Some pleasant new features were added, but most of them aren't features that you'll use every day. Conditional expressions were finally added to the language using a novel syntax; see section [PEP 308: Conditional Expressions](#). The new `'with'` statement will make writing cleanup code easier (section [PEP 343: The 'with' statement](#)). Values can now be passed into generators (section [PEP 342: New Generator Features](#)). Imports are now visible as either absolute or relative (section [PEP 328: Absolute and Relative Imports](#)). Some corner cases of exception handling are handled better (section [PEP 341: Unified try/except/finally](#)). All these improvements are worthwhile, but they're improvements to one specific language feature or another; none of them are broad modifications to Python's semantics.

As well as the language and library additions, other improvements and bugfixes were made throughout the source tree. A search through the SVN change logs finds there were 353 patches applied and 458 bugs fixed between Python 2.4 and 2.5. (Both figures are likely to be underestimates.)

This article doesn't try to be a complete specification of the new features; instead changes are briefly introduced using helpful examples. For full details, you should always refer to the documentation for Python 2.5 at <http://docs.python.org>. If you want to understand the complete implementation and design rationale, refer to the PEP for a particular new feature.

Comments, suggestions, and error reports for this document are welcome; please e-mail them to the author or open a bug in the Python bug tracker.

PEP 308: Conditional Expressions

For a long time, people have been requesting a way to write conditional expressions, which are expressions that return value A or value B depending on whether a Boolean value is true or false. A conditional expression lets you write a single assignment statement that has the same effect as the following:

```
if condition:
    x = true_value
else:
    x = false_value
```

There have been endless tedious discussions of syntax on both python-dev and comp.lang.python. A vote was even held that found the majority of voters wanted conditional expressions in some form, but there was no syntax that was preferred by a clear majority. Candidates included C's `cond ? true_v : false_v`, `if cond then true_v else false_v`, and 16 other variations.

Guido van Rossum eventually chose a surprising syntax:

```
x = true_value if condition else false_value
```

Evaluation is still lazy as in existing Boolean expressions, so the order of evaluation jumps around a bit. The *condition* expression in the middle is evaluated first, and the *true_value* expression is evaluated only if the condition was true. Similarly, the *false_value* expression is only evaluated when the condition is false.

This syntax may seem strange and backwards; why does the condition go in the *middle* of the expression, and not in the front as in C's `c ? x : y`? The decision was checked by applying the new syntax to the modules in the standard library and seeing how the

resulting code read. In many cases where a conditional expression is used, one value seems to be the ‘common case’ and one value is an ‘exceptional case’, used only on rarer occasions when the condition isn’t met. The conditional syntax makes this pattern a bit more obvious:

```
contents = ((doc + '\n') if doc else '')
```

I read the above statement as meaning “here *contents* is usually assigned a value of `doc+'\n'`; sometimes *doc* is empty, in which special case an empty string is returned.” I doubt I will use conditional expressions very often where there isn’t a clear common and uncommon case.

There was some discussion of whether the language should require surrounding conditional expressions with parentheses. The decision was made to *not* require parentheses in the Python language’s grammar, but as a matter of style I think you should always use them. Consider these two statements:

```
# First version -- no parens
level = 1 if logging else 0

# Second version -- with parens
level = (1 if logging else 0)
```

In the first version, I think a reader’s eye might group the statement into ‘level = 1’, ‘if logging’, ‘else 0’, and think that the condition decides whether the assignment to *level* is performed. The second version reads better, in my opinion, because it makes it clear that the assignment is always performed and the choice is being made between two values.

Another reason for including the brackets: a few odd combinations of list comprehensions and lambdas could look like incorrect conditional expressions. See [PEP 308](#) for some examples. If you put

parentheses around your conditional expressions, you won't run into this case.

PEP 308 - Conditional Expressions

PEP written by Guido van Rossum and Raymond D. Hettinger; implemented by Thomas Wouters.

PEP 309: Partial Function Application

The `functools` module is intended to contain tools for functional-style programming.

One useful tool in this module is the `partial()` function. For programs written in a functional style, you'll sometimes want to construct variants of existing functions that have some of the parameters filled in. Consider a Python function `f(a, b, c)`; you could create a new function `g(b, c)` that was equivalent to `f(1, b, c)`. This is called "partial function application".

`partial()` takes the arguments `(function, arg1, arg2, ... kwarg1=value1, kwarg2=value2)`. The resulting object is callable, so you can just call it to invoke *function* with the filled-in arguments.

Here's a small but realistic example:

```
import functools

def log (message, subsystem):
    "Write the contents of 'message' to the specified subsystem
    print '%s: %s' % (subsystem, message)
    ...

server_log = functools.partial(log, subsystem='server')
server_log('Unable to open socket')
```

Here's another example, from a program that uses PyGTK. Here a context-sensitive pop-up menu is being constructed dynamically. The callback provided for the menu option is a partially applied version of the `open_item()` method, where the first argument has been provided.

```
...
```

```

class Application:
    def open_item(self, path):
        ...
    def init (self):
        open_func = functools.partial(self.open_item, item_path)
        popup_menu.append( ("Open", open_func, 1) )

```

Another function in the `functools` module is the `update_wrapper(wrapper, wrapped)()` function that helps you write well-behaved decorators. `update_wrapper()` copies the name, module, and docstring attribute to a wrapper function so that tracebacks inside the wrapped function are easier to understand. For example, you might write:

```

def my_decorator(f):
    def wrapper(*args, **kwargs):
        print 'Calling decorated function'
        return f(*args, **kwargs)
    functools.update_wrapper(wrapper, f)
    return wrapper

```

`wraps()` is a decorator that can be used inside your own decorators to copy the wrapped function's information. An alternate version of the previous example would be:

```

def my_decorator(f):
    @functools.wraps(f)
    def wrapper(*args, **kwargs):
        print 'Calling decorated function'
        return f(*args, **kwargs)
    return wrapper

```

PEP 309 - Partial Function Application

PEP proposed and written by Peter Harris; implemented by Hye-Shik Chang and Nick Coghlan, with adaptations by Raymond Hettinger.

PEP 314: Metadata for Python Software Packages v1.1

Some simple dependency support was added to Distutils. The `setup()` function now has `requires`, `provides`, and `obsoletes` keyword parameters. When you build a source distribution using the `sdist` command, the dependency information will be recorded in the `PKG-INFO` file.

Another new keyword parameter is `download_url`, which should be set to a URL for the package's source code. This means it's now possible to look up an entry in the package index, determine the dependencies for a package, and download the required packages.

```
VERSION = '1.0'
setup(name='PyPackage',
      version=VERSION,
      requires=['numpy', 'zlib (>=1.1.4)'],
      obsoletes=['OldPackage']
      download_url=('http://www.example.com/pypackage/dist/pkg-'
                   % VERSION),
      )
```

Another new enhancement to the Python package index at <http://cheeseshop.python.org> is storing source and binary archives for a package. The new **upload** Distutils command will upload a package to the repository.

Before a package can be uploaded, you must be able to build a distribution using the `sdist` Distutils command. Once that works, you can run `python setup.py upload` to add your package to the PyPI archive. Optionally you can GPG-sign the package by supplying the `-sign` and `--identity` options.

Package uploading was implemented by Martin von Löwis and Richard Jones.

PEP 314 - Metadata for Python Software Packages v1.1

PEP proposed and written by A.M. Kuchling, Richard Jones, and Fred Drake; implemented by Richard Jones and Fred Drake.

PEP 328: Absolute and Relative Imports

The simpler part of PEP 328 was implemented in Python 2.4: parentheses could now be used to enclose the names imported from a module using the `from ... import ...` statement, making it easier to import many different names.

The more complicated part has been implemented in Python 2.5: importing a module can be specified to use absolute or package-relative imports. The plan is to move toward making absolute imports the default in future versions of Python.

Let's say you have a package directory like this:

```
pkg/  
pkg/__init__.py  
pkg/main.py  
pkg/string.py
```

This defines a package named `pkg` containing the `pkg.main` and `pkg.string` submodules.

Consider the code in the `main.py` module. What happens if it executes the statement `import string`? In Python 2.4 and earlier, it will first look in the package's directory to perform a relative import, finds `pkg/string.py`, imports the contents of that file as the `pkg.string` module, and that module is bound to the name `string` in the `pkg.main` module's namespace.

That's fine if `pkg.string` was what you wanted. But what if you wanted Python's standard `string` module? There's no clean way to ignore `pkg.string` and look for the standard module; generally you had to look at the contents of `sys.modules`, which is slightly unclean.

Holger Krekel's `py.std` package provides a tidier way to perform imports from the standard library, `import py ; py.std.string.join()`, but that package isn't available on all Python installations.

Reading code which relies on relative imports is also less clear, because a reader may be confused about which module, `string` or `pkg.string`, is intended to be used. Python users soon learned not to duplicate the names of standard library modules in the names of their packages' submodules, but you can't protect against having your submodule's name being used for a new module added in a future version of Python.

In Python 2.5, you can switch `import`'s behaviour to absolute imports using a `from __future__ import absolute_import` directive. This absolute-import behaviour will become the default in a future version (probably Python 2.7). Once absolute imports are the default, `import string` will always find the standard library's version. It's suggested that users should begin using absolute imports as much as possible, so it's preferable to begin writing `from pkg import string` in your code.

Relative imports are still possible by adding a leading period to the module name when using the `from ... import` form:

```
# Import names from pkg.string  
from .string import name1, name2  
# Import pkg.string  
from . import string
```

This imports the `string` module relative to the current package, so in `pkg.main` this will import `name1` and `name2` from `pkg.string`. Additional leading periods perform the relative import starting from the parent of the current package. For example, code in the `A.B.C`

module can do:

```
from . import D           # Imports A.B.D
from .. import E         # Imports A.E
from ..F import G       # Imports A.F.G
```

Leading periods cannot be used with the `import modname` form of the import statement, only the `from ... import` form.

PEP 328 - Imports: Multi-Line and Absolute/Relative

PEP written by Aahz; implemented by Thomas Wouters.

<http://codespeak.net/py/current/doc/index.html>

The py library by Holger Krekel, which contains the `py.std` package.

PEP 338: Executing Modules as Scripts

The `-m` switch added in Python 2.4 to execute a module as a script gained a few more abilities. Instead of being implemented in C code inside the Python interpreter, the switch now uses an implementation in a new module, `runpy`.

The `runpy` module implements a more sophisticated import mechanism so that it's now possible to run modules in a package such as `pychecker.checker`. The module also supports alternative import mechanisms such as the `zipimport` module. This means you can add a .zip archive's path to `sys.path` and then use the `-m` switch to execute code from the archive.

See also:

PEP 338 - Executing modules as scripts

PEP written and implemented by Nick Coghlan.

PEP 341: Unified try/except/finally

Until Python 2.5, the `try` statement came in two flavours. You could use a `finally` block to ensure that code is always executed, or one or more `except` blocks to catch specific exceptions. You couldn't combine both `except` blocks and a `finally` block, because generating the right bytecode for the combined version was complicated and it wasn't clear what the semantics of the combined statement should be.

Guido van Rossum spent some time working with Java, which does support the equivalent of combining `except` blocks and a `finally` block, and this clarified what the statement should mean. In Python 2.5, you can now write:

```
try:
    block-1 ...
except Exception1:
    handler-1 ...
except Exception2:
    handler-2 ...
else:
    else-block
finally:
    final-block
```

The code in *block-1* is executed. If the code raises an exception, the various `except` blocks are tested: if the exception is of class `Exception1`, *handler-1* is executed; otherwise if it's of class `Exception2`, *handler-2* is executed, and so forth. If no exception is raised, the *else-block* is executed.

No matter what happened previously, the *final-block* is executed once the code block is complete and any raised exceptions handled. Even if there's an error in an exception handler or the *else-block* and

a new exception is raised, the code in the *final-block* is still run.

[PEP 341](#) - Unifying try-except and try-finally

PEP written by Georg Brandl; implementation by Thomas Lee.

PEP 342: New Generator Features

Python 2.5 adds a simple way to pass values *into* a generator. As introduced in Python 2.3, generators only produce output; once a generator's code was invoked to create an iterator, there was no way to pass any new information into the function when its execution is resumed. Sometimes the ability to pass in some information would be useful. Hackish solutions to this include making the generator's code look at a global variable and then changing the global variable's value, or passing in some mutable object that callers then modify.

To refresh your memory of basic generators, here's a simple example:

```
def counter (maximum):  
    i = 0  
    while i < maximum:  
        yield i  
        i += 1
```

When you call `counter(10)`, the result is an iterator that returns the values from 0 up to 9. On encountering the `yield` statement, the iterator returns the provided value and suspends the function's execution, preserving the local variables. Execution resumes on the following call to the iterator's `next()` method, picking up after the `yield` statement.

In Python 2.3, `yield` was a statement; it didn't return any value. In 2.5, `yield` is now an expression, returning a value that can be assigned to a variable or otherwise operated on:

```
val = (yield i)
```

I recommend that you always put parentheses around a `yield` expression when you're doing something with the returned value, as in the above example. The parentheses aren't always necessary, but it's easier to always add them instead of having to remember when they're needed.

([PEP 342](#) explains the exact rules, which are that a `yield`-expression must always be parenthesized except when it occurs at the top-level expression on the right-hand side of an assignment. This means you can write `val = yield i` but have to use parentheses when there's an operation, as in `val = (yield i) + 12.`)

Values are sent into a generator by calling its `send(value)()` method. The generator's code is then resumed and the `yield` expression returns the specified *value*. If the regular `next()` method is called, the `yield` returns `None`.

Here's the previous example, modified to allow changing the value of the internal counter.

```
def counter (maximum):
    i = 0
    while i < maximum:
        val = (yield i)
        # If value provided, change counter
        if val is not None:
            i = val
        else:
            i += 1
```

And here's an example of changing the counter:

```
>>> it = counter(10)
>>> print it.next()
0
>>> print it.next()
1
>>> print it.send(8)
```

```
8
>>> print it.next()
9
>>> print it.next()
Traceback (most recent call last):
  File "t.py", line 15, in ?
    print it.next()
StopIteration
```

`yield` will usually return `None`, so you should always check for this case. Don't just use its value in expressions unless you're sure that the `send()` method will be the only method used to resume your generator function.

In addition to `send()`, there are two other new methods on generators:

- `throw(type, value=None, traceback=None)()` is used to raise an exception inside the generator; the exception is raised by the `yield` expression where the generator's execution is paused.
- `close()` raises a new `GeneratorExit` exception inside the generator to terminate the iteration. On receiving this exception, the generator's code must either raise `GeneratorExit` or `StopIteration`. Catching the `GeneratorExit` exception and returning a value is illegal and will trigger a `RuntimeError`; if the function raises some other exception, that exception is propagated to the caller. `close()` will also be called by Python's garbage collector when the generator is garbage-collected.

If you need to run cleanup code when a `GeneratorExit` occurs, I suggest using a `try: ... finally:` suite instead of catching `GeneratorExit`.

The cumulative effect of these changes is to turn generators from one-way producers of information into both producers and

consumers.

Generators also become *coroutines*, a more generalized form of subroutines. Subroutines are entered at one point and exited at another point (the top of the function, and a `return` statement), but coroutines can be entered, exited, and resumed at many different points (the `yield` statements). We'll have to figure out patterns for using coroutines effectively in Python.

The addition of the `close()` method has one side effect that isn't obvious. `close()` is called when a generator is garbage-collected, so this means the generator's code gets one last chance to run before the generator is destroyed. This last chance means that `try...finally` statements in generators can now be guaranteed to work; the `finally` clause will now always get a chance to run. The syntactic restriction that you couldn't mix `yield` statements with a `try...finally` suite has therefore been removed. This seems like a minor bit of language trivia, but using generators and `try...finally` is actually necessary in order to implement the `with` statement described by PEP 343. I'll look at this new statement in the following section.

Another even more esoteric effect of this change: previously, the `gi_frame` attribute of a generator was always a frame object. It's now possible for `gi_frame` to be `None` once the generator has been exhausted.

PEP 342 - Coroutines via Enhanced Generators

PEP written by Guido van Rossum and Phillip J. Eby; implemented by Phillip J. Eby. Includes examples of some fancier uses of generators as coroutines.

Earlier versions of these features were proposed in **PEP 288** by Raymond Hettinger and **PEP 325** by Samuele Pedroni.

<http://en.wikipedia.org/wiki/Coroutine>

The Wikipedia entry for coroutines.

<http://www.sidhe.org/~dan/blog/archives/000178.html>

An explanation of coroutines from a Perl point of view, written by Dan Sugalski.

PEP 343: The 'with' statement

The 'with' statement clarifies code that previously would use `try...finally` blocks to ensure that clean-up code is executed. In this section, I'll discuss the statement as it will commonly be used. In the next section, I'll examine the implementation details and show how to write objects for use with this statement.

The 'with' statement is a new control-flow structure whose basic structure is:

```
with expression [as variable]:  
    with-block
```

The expression is evaluated, and it should result in an object that supports the context management protocol (that is, has `__enter__()` and `__exit__()` methods).

The object's `__enter__()` is called before *with-block* is executed and therefore can run set-up code. It also may return a value that is bound to the name *variable*, if given. (Note carefully that *variable* is *not* assigned the result of *expression*.)

After execution of the *with-block* is finished, the object's `__exit__()` method is called, even if the block raised an exception, and can therefore run clean-up code.

To enable the statement in Python 2.5, you need to add the following directive to your module:

```
from __future__ import with_statement
```

The statement will always be enabled in Python 2.6.

Some standard Python objects now support the context management protocol and can be used with the `'with'` statement. File objects are one example:

```
with open('/etc/passwd', 'r') as f:
    for line in f:
        print line
    ... more processing code ...
```

After this statement has executed, the file object in `f` will have been automatically closed, even if the `for` loop raised an exception part-way through the block.

Note: In this case, `f` is the same object created by `open()`, because `file.__enter__()` returns `self`.

The `threading` module's locks and condition variables also support the `'with'` statement:

```
lock = threading.Lock()
with lock:
    # Critical section of code
    ...
```

The lock is acquired before the block is executed and always released once the block is complete.

The new `localcontext()` function in the `decimal` module makes it easy to save and restore the current decimal context, which encapsulates the desired precision and rounding characteristics for computations:

```
from decimal import Decimal, Context, localcontext

# Displays with default precision of 28 digits
v = Decimal('578')
print v.sqrt()
```

```
with localcontext(Context(prec=16)):
    # All code in this block uses a precision of 16 digits.
    # The original context is restored on exiting the block.
    print v.sqrt()
```

Writing Context Managers

Under the hood, the `with` statement is fairly complicated. Most people will only use `with` in company with existing objects and don't need to know these details, so you can skip the rest of this section if you like. Authors of new objects will need to understand the details of the underlying implementation and should keep reading.

A high-level explanation of the context management protocol is:

- The expression is evaluated and should result in an object called a “context manager”. The context manager must have `__enter__()` and `__exit__()` methods.
- The context manager's `__enter__()` method is called. The value returned is assigned to `VAR`. If no `'as VAR'` clause is present, the value is simply discarded.
- The code in `BLOCK` is executed.
- If `BLOCK` raises an exception, the `__exit__(type, value, traceback)()` is called with the exception details, the same values returned by `sys.exc_info()`. The method's return value controls whether the exception is re-raised: any false value re-raises the exception, and `True` will result in suppressing it. You'll only rarely want to suppress the exception, because if you do the author of the code containing the `with` statement will never realize anything went wrong.
- If `BLOCK` didn't raise an exception, the `__exit__()` method is still called, but `type`, `value`, and `traceback` are all `None`.

Let's think through an example. I won't present detailed code but will only sketch the methods necessary for a database that supports transactions.

(For people unfamiliar with database terminology: a set of changes to the database are grouped into a transaction. Transactions can be either committed, meaning that all the changes are written into the database, or rolled back, meaning that the changes are all discarded and the database is unchanged. See any database textbook for more information.)

Let's assume there's an object representing a database connection. Our goal will be to let the user write code like this:

```
db_connection = DatabaseConnection()
with db_connection as cursor:
    cursor.execute('insert into ...')
    cursor.execute('delete from ...')
    # ... more operations ...
```

The transaction should be committed if the code in the block runs flawlessly or rolled back if there's an exception. Here's the basic interface for `DatabaseConnection` that I'll assume:

```
class DatabaseConnection:
    # Database interface
    def cursor (self):
        "Returns a cursor object and starts a new transaction"
    def commit (self):
        "Commits current transaction"
    def rollback (self):
        "Rolls back current transaction"
```

The `__enter__()` method is pretty easy, having only to start a new transaction. For this application the resulting cursor object would be a useful result, so the method will return it. The user can then add `as cursor` to their `'with'` statement to bind the cursor to a variable name.

```
class DatabaseConnection:
    ...
    def __enter__ (self):
        # Code to start a new transaction
        cursor = self.cursor()
        return cursor
```

The `__exit__()` method is the most complicated because it's where most of the work has to be done. The method has to check if an exception occurred. If there was no exception, the transaction is committed. The transaction is rolled back if there was an exception.

In the code below, execution will just fall off the end of the function, returning the default value of `None`. `None` is false, so the exception will be re-raised automatically. If you wished, you could be more explicit and add a `return` statement at the marked location.

```
class DatabaseConnection:
    ...
    def __exit__ (self, type, value, tb):
        if tb is None:
            # No exception, so commit
            self.commit()
        else:
            # Exception occurred, so rollback.
            self.rollback()
            # return False
```

The contextlib module

The new `contextlib` module provides some functions and a decorator that are useful for writing objects for use with the `'with'` statement.

The decorator is called `contextmanager()`, and lets you write a single generator function instead of defining a new class. The generator should yield exactly one value. The code up to the `yield` will be

executed as the `__enter__()` method, and the value yielded will be the method's return value that will get bound to the variable in the 'with' statement's `as` clause, if any. The code after the `yield` will be executed in the `__exit__()` method. Any exception raised in the block will be raised by the `yield` statement.

Our database example from the previous section could be written using this decorator as:

```
from contextlib import contextmanager

@contextmanager
def db_transaction (connection):
    cursor = connection.cursor()
    try:
        yield cursor
    except:
        connection.rollback()
        raise
    else:
        connection.commit()

db = DatabaseConnection()
with db_transaction(db) as cursor:
    ...
```

The `contextlib` module also has a `nested(mgr1, mgr2, ...)`() function that combines a number of context managers so you don't need to write nested 'with' statements. In this example, the single 'with' statement both starts a database transaction and acquires a thread lock:

```
lock = threading.Lock()
with nested (db_transaction(db), lock) as (cursor, locked):
    ...
```

Finally, the `closing(object)()` function returns *object* so that it can be bound to a variable, and calls `object.close` at the end of the

block.

```
import urllib, sys
from contextlib import closing

with closing(urllib.urlopen('http://www.yahoo.com')) as f:
    for line in f:
        sys.stdout.write(line)
```

PEP 343 - The “with” statement

PEP written by Guido van Rossum and Nick Coghlan; implemented by Mike Bland, Guido van Rossum, and Neal Norwitz. The PEP shows the code generated for a ‘with’ statement, which can be helpful in learning how the statement works.

The documentation for the `contextlib` module.

PEP 352: Exceptions as New-Style Classes

Exception classes can now be new-style classes, not just classic classes, and the built-in `Exception` class and all the standard built-in exceptions (`NameError`, `ValueError`, etc.) are now new-style classes.

The inheritance hierarchy for exceptions has been rearranged a bit. In 2.5, the inheritance relationships are:

```
BaseException          # New in Python 2.5
|- KeyboardInterrupt
|- SystemExit
|- Exception
  |- (all other current built-in exceptions)
```

This rearrangement was done because people often want to catch all exceptions that indicate program errors. `KeyboardInterrupt` and `SystemExit` aren't errors, though, and usually represent an explicit action such as the user hitting Control-C or code calling `sys.exit()`. A bare `except:` will catch all exceptions, so you commonly need to list `KeyboardInterrupt` and `SystemExit` in order to re-raise them. The usual pattern is:

```
try:
    ...
except (KeyboardInterrupt, SystemExit):
    raise
except:
    # Log error...
    # Continue running program...
```

In Python 2.5, you can now write `except Exception` to achieve the same result, catching all the exceptions that usually indicate errors but leaving `KeyboardInterrupt` and `SystemExit` alone. As in previous versions, a bare `except:` still catches all exceptions.

The goal for Python 3.0 is to require any class raised as an exception to derive from `BaseException` or some descendant of `BaseException`, and future releases in the Python 2.x series may begin to enforce this constraint. Therefore, I suggest you begin making all your exception classes derive from `Exception` now. It's been suggested that the bare `except:` form should be removed in Python 3.0, but Guido van Rossum hasn't decided whether to do this or not.

Raising of strings as exceptions, as in the statement `raise "Error occurred"`, is deprecated in Python 2.5 and will trigger a warning. The aim is to be able to remove the string-exception feature in a few releases.

PEP 352 - Required Superclass for Exceptions

PEP written by Brett Cannon and Guido van Rossum; implemented by Brett Cannon.

PEP 353: Using `ssize_t` as the index type

A wide-ranging change to Python's C API, using a new `Py_ssize_t` type definition instead of `int`, will permit the interpreter to handle more data on 64-bit platforms. This change doesn't affect Python's capacity on 32-bit platforms.

Various pieces of the Python interpreter used C's `int` type to store sizes or counts; for example, the number of items in a list or tuple were stored in an `int`. The C compilers for most 64-bit platforms still define `int` as a 32-bit type, so that meant that lists could only hold up to $2^{31} - 1 = 2147483647$ items. (There are actually a few different programming models that 64-bit C compilers can use – see http://www.unix.org/version2/whatsnew/lp64_wp.html for a discussion – but the most commonly available model leaves `int` as 32 bits.)

A limit of 2147483647 items doesn't really matter on a 32-bit platform because you'll run out of memory before hitting the length limit. Each list item requires space for a pointer, which is 4 bytes, plus space for a `PyObject` representing the item. $2147483647 * 4$ is already more bytes than a 32-bit address space can contain.

It's possible to address that much memory on a 64-bit platform, however. The pointers for a list that size would only require 16 GiB of space, so it's not unreasonable that Python programmers might construct lists that large. Therefore, the Python interpreter had to be changed to use some type other than `int`, and this will be a 64-bit type on 64-bit platforms. The change will cause incompatibilities on 64-bit machines, so it was deemed worth making the transition now, while the number of 64-bit users is still relatively small. (In 5 or 10 years, we may *all* be on 64-bit machines, and the transition would be

more painful then.)

This change most strongly affects authors of C extension modules. Python strings and container types such as lists and tuples now use `Py_ssize_t` to store their size. Functions such as `PyList_Size()` now return `Py_ssize_t`. Code in extension modules may therefore need to have some variables changed to `Py_ssize_t`.

The `PyArg_ParseTuple()` and `Py_BuildValue()` functions have a new conversion code, `n`, for `Py_ssize_t`. `PyArg_ParseTuple()`'s `s#` and `t#` still output `int` by default, but you can define the macro `PY_SSIZE_T_CLEAN` before including `Python.h` to make them return `Py_ssize_t`.

PEP 353 has a section on conversion guidelines that extension authors should read to learn about supporting 64-bit platforms.

See also:

PEP 353 - Using `ssize_t` as the index type

PEP written and implemented by Martin von Löwis.

PEP 357: The ‘`__index__`’ method

The NumPy developers had a problem that could only be solved by adding a new special method, `__index__()`. When using slice notation, as in `[start:stop:step]`, the values of the *start*, *stop*, and *step* indexes must all be either integers or long integers. NumPy defines a variety of specialized integer types corresponding to unsigned and signed integers of 8, 16, 32, and 64 bits, but there was no way to signal that these types could be used as slice indexes.

Slicing can't just use the existing `__int__()` method because that method is also used to implement coercion to integers. If slicing used `__int__()`, floating-point numbers would also become legal slice indexes and that's clearly an undesirable behaviour.

Instead, a new special method called `__index__()` was added. It takes no arguments and returns an integer giving the slice index to use. For example:

```
class C:
    def __index__(self):
        return self.value
```

The return value must be either a Python integer or long integer. The interpreter will check that the type returned is correct, and raises a `TypeError` if this requirement isn't met.

A corresponding `nb_index` slot was added to the C-level `PyNumberMethods` structure to let C extensions implement this protocol. `PyNumber_Index(obj)()` can be used in extension code to call the `__index__()` function and retrieve its result.

PEP 357 - Allowing Any Object to be Used for Slicing

PEP written and implemented by Travis Oliphant.

Other Language Changes

Here are all of the changes that Python 2.5 makes to the core Python language.

- The `dict` type has a new hook for letting subclasses provide a default value when a key isn't contained in the dictionary. When a key isn't found, the dictionary's `__missing__(key)()` method will be called. This hook is used to implement the new `defaultdict` class in the `collections` module. The following example defines a dictionary that returns zero for any missing key:

```
class zerodict (dict):
    def __missing__ (self, key):
        return 0

d = zerodict({1:1, 2:2})
print d[1], d[2]    # Prints 1, 2
print d[3], d[4]    # Prints 0, 0
```

- Both 8-bit and Unicode strings have new `partition(sep)()` and `rpartition(sep)()` methods that simplify a common use case.

The `find(s)()` method is often used to get an index which is then used to slice the string and obtain the pieces that are before and after the separator. `partition(sep)()` condenses this pattern into a single method call that returns a 3-tuple containing the substring before the separator, the separator itself, and the substring after the separator. If the separator isn't found, the first element of the tuple is the entire string and the other two elements are empty. `rpartition(sep)()` also returns a 3-tuple but starts searching from the end of the string; the `r` stands for 'reverse'.

Some examples:

```
>>> ('http://www.python.org').partition('/://')
('http', '://', 'www.python.org')
>>> ('file:/usr/share/doc/index.html').partition('/://')
('file:/usr/share/doc/index.html', '', '')
>>> (u'Subject: a quick question').partition(':')
(u'Subject', u':', u' a quick question')
>>> 'www.python.org'.rpartition('.')
('www.python', '.', 'org')
>>> 'www.python.org'.rpartition(':')
('', '', 'www.python.org')
```

(Implemented by Fredrik Lundh following a suggestion by Raymond Hettinger.)

- The `startswith()` and `endswith()` methods of string types now accept tuples of strings to check for.

```
def is_image_file (filename):
    return filename.endswith(('.gif', '.jpg', '.tiff'))
```

(Implemented by Georg Brandl following a suggestion by Tom Lynn.)

- The `min()` and `max()` built-in functions gained a `key` keyword parameter analogous to the `key` argument for `sort()`. This parameter supplies a function that takes a single argument and is called for every value in the list; `min()/max()` will return the element with the smallest/largest return value from this function. For example, to find the longest string in a list, you can do:

```
L = ['medium', 'longest', 'short']
# Prints 'longest'
print max(L, key=len)
# Prints 'short', because lexicographically 'short' has the
print max(L)
```

(Contributed by Steven Bethard and Raymond Hettinger.)

- Two new built-in functions, `any()` and `all()`, evaluate whether an iterator contains any true or false values. `any()` returns `True` if any value returned by the iterator is true; otherwise it will return `False`. `all()` returns `True` only if all of the values returned by the iterator evaluate as true. (Suggested by Guido van Rossum, and implemented by Raymond Hettinger.)
- The result of a class's `__hash__()` method can now be either a long integer or a regular integer. If a long integer is returned, the hash of that value is taken. In earlier versions the hash value was required to be a regular integer, but in 2.5 the `id()` built-in was changed to always return non-negative numbers, and users often seem to use `id(self)` in `__hash__()` methods (though this is discouraged).
- ASCII is now the default encoding for modules. It's now a syntax error if a module contains string literals with 8-bit characters but doesn't have an encoding declaration. In Python 2.4 this triggered a warning, not a syntax error. See [PEP 263](#) for how to declare a module's encoding; for example, you might add a line like this near the top of the source file:

```
# -*- coding: latin1 -*-
```

- A new warning, `UnicodeWarning`, is triggered when you attempt to compare a Unicode string and an 8-bit string that can't be converted to Unicode using the default ASCII encoding. The result of the comparison is false:

```
>>> chr(128) == unichr(128)    # Can't convert chr(128) to U
__main__:1: UnicodeWarning: Unicode equal comparison failed
to convert both arguments to Unicode - interpreting them
as being unequal
False
```

```
>>> chr(127) == unichr(127)    # chr(127) can be converted
True
```

Previously this would raise a **UnicodeDecodeError** exception, but in 2.5 this could result in puzzling problems when accessing a dictionary. If you looked up `unichr(128)` and `chr(128)` was being used as a key, you'd get a **UnicodeDecodeError** exception. Other changes in 2.5 resulted in this exception being raised instead of suppressed by the code in `dictobject.c` that implements dictionaries.

Raising an exception for such a comparison is strictly correct, but the change might have broken code, so instead **UnicodeWarning** was introduced.

(Implemented by Marc-André Lemburg.)

- One error that Python programmers sometimes make is forgetting to include an `__init__.py` module in a package directory. Debugging this mistake can be confusing, and usually requires running Python with the `-v` switch to log all the paths searched. In Python 2.5, a new **ImportWarning** warning is triggered when an import would have picked up a directory as a package but no `__init__.py` was found. This warning is silently ignored by default; provide the `-Wd` option when running the Python executable to display the warning message. (Implemented by Thomas Wouters.)

- The list of base classes in a class definition can now be empty. As an example, this is now legal:

```
class C():
    pass
```

(Implemented by Brett Cannon.)

Interactive Interpreter Changes

In the interactive interpreter, `quit` and `exit` have long been strings so that new users get a somewhat helpful message when they try to quit:

```
>>> quit
'Use Ctrl-D (i.e. EOF) to exit.'
```

In Python 2.5, `quit` and `exit` are now objects that still produce string representations of themselves, but are also callable. Newbies who try `quit()` or `exit()` will now exit the interpreter as they expect. (Implemented by Georg Brandl.)

The Python executable now accepts the standard long options `--help` and `--version`; on Windows, it also accepts the `/?` option for displaying a help message. (Implemented by Georg Brandl.)

Optimizations

Several of the optimizations were developed at the NeedForSpeed sprint, an event held in Reykjavik, Iceland, from May 21–28 2006. The sprint focused on speed enhancements to the CPython implementation and was funded by EWT LLC with local support from CCP Games. Those optimizations added at this sprint are specially marked in the following list.

- When they were introduced in Python 2.4, the built-in `set` and `frozenset` types were built on top of Python's dictionary type. In 2.5 the internal data structure has been customized for implementing sets, and as a result sets will use a third less memory and are somewhat faster. (Implemented by Raymond Hettinger.)
- The speed of some Unicode operations, such as finding

substrings, string splitting, and character map encoding and decoding, has been improved. (Substring search and splitting improvements were added by Fredrik Lundh and Andrew Dalke at the NeedForSpeed sprint. Character maps were improved by Walter Dörwald and Martin von Löwis.)

- The `long(str, base)()` function is now faster on long digit strings because fewer intermediate results are calculated. The peak is for strings of around 800–1000 digits where the function is 6 times faster. (Contributed by Alan McIntyre and committed at the NeedForSpeed sprint.)
- It's now illegal to mix iterating over a file with `for line in file` and calling the file object's `read()/readline()/readlines()` methods. Iteration uses an internal buffer and the `read*()` methods don't use that buffer. Instead they would return the data following the buffer, causing the data to appear out of order. Mixing iteration and these methods will now trigger a `ValueError` from the `read*()` method. (Implemented by Thomas Wouters.)
- The `struct` module now compiles structure format strings into an internal representation and caches this representation, yielding a 20% speedup. (Contributed by Bob Ippolito at the NeedForSpeed sprint.)
- The `re` module got a 1 or 2% speedup by switching to Python's allocator functions instead of the system's `malloc()` and `free()`. (Contributed by Jack Diederich at the NeedForSpeed sprint.)
- The code generator's peephole optimizer now performs simple constant folding in expressions. If you write something like `a = 2+3`, the code generator will do the arithmetic and produce code corresponding to `a = 5`. (Proposed and implemented by Raymond Hettinger.)
- Function calls are now faster because code objects now keep the most recently finished frame (a "zombie frame") in an internal field of the code object, reusing it the next time the code

object is invoked. (Original patch by Michael Hudson, modified by Armin Rigo and Richard Jones; committed at the NeedForSpeed sprint.) Frame objects are also slightly smaller, which may improve cache locality and reduce memory usage a bit. (Contributed by Neal Norwitz.)

- Python's built-in exceptions are now new-style classes, a change that speeds up instantiation considerably. Exception handling in Python 2.5 is therefore about 30% faster than in 2.4. (Contributed by Richard Jones, Georg Brandl and Sean Reifschneider at the NeedForSpeed sprint.)
- Importing now caches the paths tried, recording whether they exist or not so that the interpreter makes fewer `open()` and `stat()` calls on startup. (Contributed by Martin von Löwis and Georg Brandl.)

New, Improved, and Removed Modules

The standard library received many enhancements and bug fixes in Python 2.5. Here's a partial list of the most notable changes, sorted alphabetically by module name. Consult the `Misc/NEWS` file in the source tree for a more complete list of changes, or look through the SVN logs for all the details.

- The `audioop` module now supports the a-LAW encoding, and the code for u-LAW encoding has been improved. (Contributed by Lars Immisch.)
- The `codecs` module gained support for incremental codecs. The `codec.lookup()` function now returns a `CodecInfo` instance instead of a tuple. `CodecInfo` instances behave like a 4-tuple to preserve backward compatibility but also have the attributes `encode`, `decode`, `incrementalencoder`, `incrementaldecoder`, `streamwriter`, and `streamreader`. Incremental codecs can receive input and produce output in multiple chunks; the output is the same as if the entire input was fed to the non-incremental codec. See the `codecs` module documentation for details. (Designed and implemented by Walter Dörwald.)
- The `collections` module gained a new type, `defaultdict`, that subclasses the standard `dict` type. The new type mostly behaves like a dictionary but constructs a default value when a key isn't present, automatically adding it to the dictionary for the requested key value.

The first argument to `defaultdict`'s constructor is a factory function that gets called whenever a key is requested but not found. This factory function receives no arguments, so you can

use built-in type constructors such as `list()` or `int()`. For example, you can make an index of words based on their initial letter like this:

```
words = """Nel mezzo del cammin di nostra vita
mi ritrovai per una selva oscura
che la diritta via era smarrita""".lower().split()

index = defaultdict(list)

for w in words:
    init_letter = w[0]
    index[init_letter].append(w)
```

Printing `index` results in the following output:

```
defaultdict(<type 'list'>, {'c': ['cammin', 'che'], 'e': ['e'],
    'd': ['del', 'di', 'diritta'], 'm': ['mezzo', 'mi']
    'l': ['la'], 'o': ['oscura'], 'n': ['nel', 'nostra']
    'p': ['per'], 's': ['selva', 'smarrita'],
    'r': ['ritrovai'], 'u': ['una'], 'v': ['vita', 'via']})
```

(Contributed by Guido van Rossum.)

- The `deque` double-ended queue type supplied by the `collections` module now has a `remove(value)()` method that removes the first occurrence of `value` in the queue, raising `ValueError` if the value isn't found. (Contributed by Raymond Hettinger.)
- New module: The `contextlib` module contains helper functions for use with the new `'with'` statement. See section [The `contextlib` module](#) for more about this module.
- New module: The `cProfile` module is a C implementation of the existing `profile` module that has much lower overhead. The module's interface is the same as `profile`: you run

`cProfile.run('main()')` to profile a function, can save profile data to a file, etc. It's not yet known if the Hotshot profiler, which is also written in C but doesn't match the `profile` module's interface, will continue to be maintained in future versions of Python. (Contributed by Armin Rigo.)

Also, the `pstats` module for analyzing the data measured by the profiler now supports directing the output to any file object by supplying a *stream* argument to the `stats` constructor. (Contributed by Skip Montanaro.)

- The `csv` module, which parses files in comma-separated value format, received several enhancements and a number of bugfixes. You can now set the maximum size in bytes of a field by calling the `csv.field_size_limit(new_limit)()` function; omitting the *new_limit* argument will return the currently-set limit. The `reader` class now has a `line_num` attribute that counts the number of physical lines read from the source; records can span multiple physical lines, so `line_num` is not the same as the number of records read.

The CSV parser is now stricter about multi-line quoted fields. Previously, if a line ended within a quoted field without a terminating newline character, a newline would be inserted into the returned field. This behavior caused problems when reading files that contained carriage return characters within fields, so the code was changed to return the field without inserting newlines. As a consequence, if newlines embedded within fields are important, the input should be split into lines in a manner that preserves the newline characters.

(Contributed by Skip Montanaro and Andrew McNamara.)

- The `datetime` class in the `datetime` module now has a

`strptime(string, format)()` method for parsing date strings, contributed by Josh Spoerri. It uses the same format characters as `time.strptime()` and `time.strftime()`:

```
from datetime import datetime

ts = datetime.strptime('10:13:15 2006-03-07',
                      '%H:%M:%S %Y-%m-%d')
```

- The `SequenceMatcher.get_matching_blocks()` method in the `difflib` module now guarantees to return a minimal list of blocks describing matching subsequences. Previously, the algorithm would occasionally break a block of matching elements into two list entries. (Enhancement by Tim Peters.)
- The `doctest` module gained a `SKIP` option that keeps an example from being executed at all. This is intended for code snippets that are usage examples intended for the reader and aren't actually test cases.

An *encoding* parameter was added to the `testfile()` function and the `DocFileSuite` class to specify the file's encoding. This makes it easier to use non-ASCII characters in tests contained within a docstring. (Contributed by Bjorn Tillenius.)

- The `email` package has been updated to version 4.0. (Contributed by Barry Warsaw.)
- The `fileinput` module was made more flexible. Unicode filenames are now supported, and a *mode* parameter that defaults to `"r"` was added to the `input()` function to allow opening files in binary or universal-newline mode. Another new parameter, *openhook*, lets you use a function other than `open()` to open the input files. Once you're iterating over the set of files, the `FileInput` object's new `fileno()` returns the file descriptor

for the currently opened file. (Contributed by Georg Brandl.)

- In the `gc` module, the new `get_count()` function returns a 3-tuple containing the current collection counts for the three GC generations. This is accounting information for the garbage collector; when these counts reach a specified threshold, a garbage collection sweep will be made. The existing `gc.collect()` function now takes an optional *generation* argument of 0, 1, or 2 to specify which generation to collect. (Contributed by Barry Warsaw.)
- The `nsmallest()` and `nlargest()` functions in the `heapq` module now support a `key` keyword parameter similar to the one provided by the `min()/max()` functions and the `sort()` methods. For example:

```
>>> import heapq
>>> L = ["short", 'medium', 'longest', 'longer still']
>>> heapq.nsmallest(2, L) # Return two lowest elements, le
['longer still', 'longest']
>>> heapq.nsmallest(2, L, key=len) # Return two shortest
['short', 'medium']
```

(Contributed by Raymond Hettinger.)

- The `itertools.islice()` function now accepts `None` for the start and step arguments. This makes it more compatible with the attributes of slice objects, so that you can now write the following:

```
s = slice(5) # Create slice object
itertools.islice(iterable, s.start, s.stop, s.step)
```

(Contributed by Raymond Hettinger.)

- The `format()` function in the `locale` module has been modified

and two new functions were added, `format_string()` and `currency()`.

The `format()` function's `val` parameter could previously be a string as long as no more than one `%char` specifier appeared; now the parameter must be exactly one `%char` specifier with no surrounding text. An optional *monetary* parameter was also added which, if `True`, will use the locale's rules for formatting currency in placing a separator between groups of three digits.

To format strings with multiple `%char` specifiers, use the new `format_string()` function that works like `format()` but also supports mixing `%char` specifiers with arbitrary text.

A new `currency()` function was also added that formats a number according to the current locale's settings.

(Contributed by Georg Brandl.)

- The `mailbox` module underwent a massive rewrite to add the capability to modify mailboxes in addition to reading them. A new set of classes that include `mbox`, `MH`, and `Maildir` are used to read mailboxes, and have an `add(message)()` method to add messages, `remove(key)()` to remove messages, and `lock()/unlock()` to lock/unlock the mailbox. The following example converts a maildir-format mailbox into an mbox-format one:

```
import mailbox

# 'factory=None' uses email.Message.Message as the class re
# individual messages.
src = mailbox.Maildir('maildir', factory=None)
dest = mailbox.mbox('/tmp/mbox')

for msg in src:
```

```
dest.add(msg)
```

(Contributed by Gregory K. Johnson. Funding was provided by Google's 2005 Summer of Code.)

- New module: the `msilib` module allows creating Microsoft Installer `.msi` files and CAB files. Some support for reading the `.msi` database is also included. (Contributed by Martin von Löwis.)
- The `nis` module now supports accessing domains other than the system default domain by supplying a *domain* argument to the `nis.match()` and `nis.maps()` functions. (Contributed by Ben Bell.)
- The `operator` module's `itemgetter()` and `attrgetter()` functions now support multiple fields. A call such as `operator.attrgetter('a', 'b')` will return a function that retrieves the `a` and `b` attributes. Combining this new feature with the `sort()` method's `key` parameter lets you easily sort lists using multiple fields. (Contributed by Raymond Hettinger.)
- The `optparse` module was updated to version 1.5.1 of the Optik library. The `OptionParser` class gained an `epilog` attribute, a string that will be printed after the help message, and a `destroy()` method to break reference cycles created by the object. (Contributed by Greg Ward.)
- The `os` module underwent several changes. The `stat_float_times` variable now defaults to true, meaning that `os.stat()` will now return time values as floats. (This doesn't necessarily mean that `os.stat()` will return times that are precise to fractions of a second; not all systems support such

precision.)

Constants named `os.SEEK_SET`, `os.SEEK_CUR`, and `os.SEEK_END` have been added; these are the parameters to the `os.lseek()` function. Two new constants for locking are `os.O_SHLOCK` and `os.O_EXLOCK`.

Two new functions, `wait3()` and `wait4()`, were added. They're similar the `waitpid()` function which waits for a child process to exit and returns a tuple of the process ID and its exit status, but `wait3()` and `wait4()` return additional information. `wait3()` doesn't take a process ID as input, so it waits for any child process to exit and returns a 3-tuple of *process-id*, *exit-status*, *resource-usage* as returned from the `resource.getrusage()` function. `wait4(pid)()` does take a process ID. (Contributed by Chad J. Schroeder.)

On FreeBSD, the `os.stat()` function now returns times with nanosecond resolution, and the returned object now has `st_gen` and `st_birthtime`. The `st_flags` member is also available, if the platform supports it. (Contributed by Antti Louko and Diego Pettenò.)

- The Python debugger provided by the `pdb` module can now store lists of commands to execute when a breakpoint is reached and execution stops. Once breakpoint #1 has been created, enter `commands 1` and enter a series of commands to be executed, finishing the list with `end`. The command list can include commands that resume execution, such as `continue` or `next`. (Contributed by Grégoire Doooms.)
- The `pickle` and `cPickle` modules no longer accept a return value of `None` from the `__reduce__()` method; the method must

return a tuple of arguments instead. The ability to return `None` was deprecated in Python 2.4, so this completes the removal of the feature.

- The `pkgutil` module, containing various utility functions for finding packages, was enhanced to support PEP 302's import hooks and now also works for packages stored in ZIP-format archives. (Contributed by Phillip J. Eby.)
- The `pybench` benchmark suite by Marc-André Lemburg is now included in the `Tools/pybench` directory. The `pybench` suite is an improvement on the commonly used `pystone.py` program because `pybench` provides a more detailed measurement of the interpreter's speed. It times particular operations such as function calls, tuple slicing, method lookups, and numeric operations, instead of performing many different operations and reducing the result to a single number as `pystone.py` does.
- The `pyexpat` module now uses version 2.0 of the Expat parser. (Contributed by Trent Mick.)
- The `Queue` class provided by the `queue` module gained two new methods. `join()` blocks until all items in the queue have been retrieved and all processing work on the items have been completed. Worker threads call the other new method, `task_done()`, to signal that processing for an item has been completed. (Contributed by Raymond Hettinger.)
- The old `regex` and `regexsub` modules, which have been deprecated ever since Python 2.0, have finally been deleted. Other deleted modules: `statcache`, `tzparse`, `whrandom`.
- Also deleted: the `lib-old` directory, which includes ancient modules such as `dircmp` and `ni`, was removed. `lib-old` wasn't

on the default `sys.path`, so unless your programs explicitly added the directory to `sys.path`, this removal shouldn't affect your code.

- The `rlcompleter` module is no longer dependent on importing the `readline` module and therefore now works on non-Unix platforms. (Patch from Robert Kiendl.)
- The `SimpleXMLRPCServer` and `DocXMLRPCServer` classes now have a `rpc_paths` attribute that constrains XML-RPC operations to a limited set of URL paths; the default is to allow only `'/'` and `'/RPC2'`. Setting `rpc_paths` to `None` or an empty tuple disables this path checking.
- The `socket` module now supports `AF_NETLINK` sockets on Linux, thanks to a patch from Philippe Biondi. Netlink sockets are a Linux-specific mechanism for communications between a user-space process and kernel code; an introductory article about them is at <http://www.linuxjournal.com/article/7356>. In Python code, netlink addresses are represented as a tuple of 2 integers, `(pid, group_mask)`.

Two new methods on socket objects, `recv_into(buffer)()` and `recvfrom_into(buffer)()`, store the received data in an object that supports the buffer protocol instead of returning the data as a string. This means you can put the data directly into an array or a memory-mapped file.

Socket objects also gained `getfamily()`, `gettype()`, and `getproto()` accessor methods to retrieve the family, type, and protocol values for the socket.

- New module: the `spwd` module provides functions for accessing the shadow password database on systems that support

shadow passwords.

- The `struct` is now faster because it compiles format strings into `struct` objects with `pack()` and `unpack()` methods. This is similar to how the `re` module lets you create compiled regular expression objects. You can still use the module-level `pack()` and `unpack()` functions; they'll create `struct` objects and cache them. Or you can use `struct` instances directly:

```
s = struct.Struct('ih3s')  
  
data = s.pack(1972, 187, 'abc')  
year, number, name = s.unpack(data)
```

You can also pack and unpack data to and from buffer objects directly using the `pack_into(buffer, offset, v1, v2, ...)` and `unpack_from(buffer, offset)` methods. This lets you store data directly into an array or a memory-mapped file.

(`struct` objects were implemented by Bob Ippolito at the NeedForSpeed sprint. Support for buffer objects was added by Martin Blais, also at the NeedForSpeed sprint.)

- The Python developers switched from CVS to Subversion during the 2.5 development process. Information about the exact build version is available as the `sys.subversion` variable, a 3-tuple of (interpreter-name, branch-name, revision-range). For example, at the time of writing my copy of 2.5 was reporting (`'CPython', 'trunk', '45313:45315'`).

This information is also available to C extensions via the `Py_GetBuildInfo()` function that returns a string of build information like this: `"trunk:45355:45356M, Apr 13 2006, 07:42:19"`. (Contributed by Barry Warsaw.)

- Another new function, `sys._current_frames()`, returns the current stack frames for all running threads as a dictionary mapping thread identifiers to the topmost stack frame currently active in that thread at the time the function is called. (Contributed by Tim Peters.)
- The `TarFile` class in the `tarfile` module now has an `extractall()` method that extracts all members from the archive into the current working directory. It's also possible to set a different directory as the extraction target, and to unpack only a subset of the archive's members.

The compression used for a tarfile opened in stream mode can now be autodetected using the mode `'r|*'`. (Contributed by Lars Gustäbel.)

- The `threading` module now lets you set the stack size used when new threads are created. The `stack_size([*size*])()` function returns the currently configured stack size, and supplying the optional `size` parameter sets a new value. Not all platforms support changing the stack size, but Windows, POSIX threading, and OS/2 all do. (Contributed by Andrew MacIntyre.)
- The `unicodedata` module has been updated to use version 4.1.0 of the Unicode character database. Version 3.2.0 is required by some specifications, so it's still available as `unicodedata.ucd_3_2_0`.
- New module: the `uuid` module generates universally unique identifiers (UUIDs) according to [RFC 4122](#). The RFC defines several different UUID versions that are generated from a starting string, from system properties, or purely randomly. This module contains a `UUID` class and functions named `uuid1()`, `uuid3()`, `uuid4()`, and `uuid5()` to generate different versions of

UUID. (Version 2 UUIDs are not specified in [RFC 4122](#) and are not supported by this module.)

```
>>> import uuid
>>> # make a UUID based on the host ID and current time
>>> uuid.uuid1()
UUID('a8098c1a-f86e-11da-bd1a-00112444be1e')

>>> # make a UUID using an MD5 hash of a namespace UUID and
>>> uuid.uuid3(uuid.NAMESPACE_DNS, 'python.org')
UUID('6fa459ea-ee8a-3ca4-894e-db77e160355e')

>>> # make a random UUID
>>> uuid.uuid4()
UUID('16fd2706-8baf-433b-82eb-8c7fada847da')

>>> # make a UUID using a SHA-1 hash of a namespace UUID an
>>> uuid.uuid5(uuid.NAMESPACE_DNS, 'python.org')
UUID('886313e1-3b8a-5372-9b90-0c9aee199e5d')
```

(Contributed by Ka-Ping Yee.)

- The `weakref` module's `WeakKeyDictionary` and `WeakValueDictionary` types gained new methods for iterating over the weak references contained in the dictionary. `iterkeyrefs()` and `keyrefs()` methods were added to `WeakKeyDictionary`, and `itervaluerefs()` and `valuerefs()` were added to `WeakValueDictionary`. (Contributed by Fred L. Drake, Jr.)
- The `webbrowser` module received a number of enhancements. It's now usable as a script with `python -m webbrowser`, taking a URL as the argument; there are a number of switches to control the behaviour (`-n` for a new browser window, `-t` for a new tab). New module-level functions, `open_new()` and `open_new_tab()`, were added to support this. The module's `open()` function supports an additional feature, an `autoraise` parameter that

signals whether to raise the open window when possible. A number of additional browsers were added to the supported list such as Firefox, Opera, Konqueror, and elinks. (Contributed by Oleg Broytmann and Georg Brandl.)

- The `xmlrpclib` module now supports returning `datetime` objects for the XML-RPC date type. Supply `use_datetime=True` to the `loads()` function or the `Unmarshaller` class to enable this feature. (Contributed by Skip Montanaro.)
- The `zipfile` module now supports the ZIP64 version of the format, meaning that a .zip archive can now be larger than 4 GiB and can contain individual files larger than 4 GiB. (Contributed by Ronald Oussoren.)
- The `zlib` module's `Compress` and `Decompress` objects now support a `copy()` method that makes a copy of the object's internal state and returns a new `Compress` or `Decompress` object. (Contributed by Chris AtLee.)

The `ctypes` package

The `ctypes` package, written by Thomas Heller, has been added to the standard library. `ctypes` lets you call arbitrary functions in shared libraries or DLLs. Long-time users may remember the `dll` module, which provides functions for loading shared libraries and calling functions in them. The `ctypes` package is much fancier.

To load a shared library or DLL, you must create an instance of the `CDLL` class and provide the name or path of the shared library or DLL. Once that's done, you can call arbitrary functions by accessing them as attributes of the `CDLL` object.

```
import ctypes
```

```
libc = ctypes.CDLL('libc.so.6')
result = libc.printf("Line of output\n")
```

Type constructors for the various C types are provided: `c_int()`, `c_float()`, `c_double()`, `c_char_p()` (equivalent to `char *`), and so forth. Unlike Python's types, the C versions are all mutable; you can assign to their `value` attribute to change the wrapped value. Python integers and strings will be automatically converted to the corresponding C types, but for other types you must call the correct type constructor. (And I mean *must*; getting it wrong will often result in the interpreter crashing with a segmentation fault.)

You shouldn't use `c_char_p()` with a Python string when the C function will be modifying the memory area, because Python strings are supposed to be immutable; breaking this rule will cause puzzling bugs. When you need a modifiable memory area, use `create_string_buffer()`:

```
s = "this is a string"
buf = ctypes.create_string_buffer(s)
libc.strfry(buf)
```

C functions are assumed to return integers, but you can set the `restype` attribute of the function object to change this:

```
>>> libc.atof('2.71828')
-1783957616
>>> libc.atof.restype = ctypes.c_double
>>> libc.atof('2.71828')
2.71828
```

`ctypes` also provides a wrapper for Python's C API as the `ctypes.pythonapi` object. This object does *not* release the global interpreter lock before calling a function, because the lock must be held when calling into the interpreter's code. There's a `py_object()`

type constructor that will create a `PyObject *` pointer. A simple usage:

```
import ctypes

d = {}
ctypes.pythonapi.PyObject_SetItem(ctypes.py_object(d),
                                   ctypes.py_object("abc"), ctypes.py_object(1))
# d is now {'abc', 1}.
```

Don't forget to use `py_object()`; if it's omitted you end up with a segmentation fault.

`ctypes` has been around for a while, but people still write and distribute hand-coded extension modules because you can't rely on `ctypes` being present. Perhaps developers will begin to write Python wrappers atop a library accessed through `ctypes` instead of extension modules, now that `ctypes` is included with core Python.

The `ctypes` web page, with a tutorial, reference, and FAQ.

The documentation for the `ctypes` module.

The ElementTree package

A subset of Fredrik Lundh's ElementTree library for processing XML has been added to the standard library as `xml.etree`. The available modules are `ElementTree`, `ElementPath`, and `ElementInclude` from ElementTree 1.2.6. The `cElementTree` accelerator module is also included.

The rest of this section will provide a brief overview of using

ElementTree. Full documentation for ElementTree is available at <http://effbot.org/zone/element-index.htm>.

ElementTree represents an XML document as a tree of element nodes. The text content of the document is stored as the `text` and `tail` attributes of (This is one of the major differences between ElementTree and the Document Object Model; in the DOM there are many different types of node, including `TextNode`.)

The most commonly used parsing function is `parse()`, that takes either a string (assumed to contain a filename) or a file-like object and returns an `ElementTree` instance:

```
from xml.etree import ElementTree as ET

tree = ET.parse('ex-1.xml')

feed = urllib.urlopen(
    'http://planet.python.org/rss10.xml')
tree = ET.parse(feed)
```

Once you have an `ElementTree` instance, you can call its `getroot()` method to get the root `Element` node.

There's also an `XML()` function that takes a string literal and returns an `Element` node (not an `ElementTree`). This function provides a tidy way to incorporate XML fragments, approaching the convenience of an XML literal:

```
svg = ET.XML("""<svg width="10px" version="1.0">
              </svg>""")
svg.set('height', '320px')
svg.append(elem1)
```

Each XML element supports some dictionary-like and some list-like access methods. Dictionary-like operations are used to access attribute values, and list-like operations are used to access child

nodes.

Operation	Result
<code>elem[n]</code>	Returns n'th child element.
<code>elem[m:n]</code>	Returns list of m'th through n'th child elements.
<code>len(elem)</code>	Returns number of child elements.
<code>list(elem)</code>	Returns list of child elements.
<code>elem.append(elem2)</code>	Adds <i>elem2</i> as a child.
<code>elem.insert(index, elem2)</code>	Inserts <i>elem2</i> at the specified location.
<code>del elem[n]</code>	Deletes n'th child element.
<code>elem.keys()</code>	Returns list of attribute names.
<code>elem.get(name)</code>	Returns value of attribute <i>name</i> .
<code>elem.set(name, value)</code>	Sets new value for attribute <i>name</i> .
<code>elem.attrib</code>	Retrieves the dictionary containing attributes.
<code>del elem.attrib[name]</code>	Deletes attribute <i>name</i> .

Comments and processing instructions are also represented as **E**lement nodes. To check if a node is a comment or processing instructions:

```
if elem.tag is ET.Comment:
    ...
elif elem.tag is ET.ProcessingInstruction:
    ...
```

To generate XML output, you should call the `ElementTree.write()` method. Like `parse()`, it can take either a string or a file-like object:

```
# Encoding is US-ASCII
tree.write('output.xml')

# Encoding is UTF-8
f = open('output.xml', 'w')
tree.write(f, encoding='utf-8')
```

(Caution: the default encoding used for output is ASCII. For general XML work, where an element's name may contain arbitrary Unicode characters, ASCII isn't a very useful encoding because it will raise an exception if an element's name contains any characters with values greater than 127. Therefore, it's best to specify a different encoding such as UTF-8 that can handle any Unicode character.)

This section is only a partial description of the ElementTree interfaces. Please read the package's official documentation for more details.

<http://effbot.org/zone/element-index.htm>

Official documentation for ElementTree.

The hashlib package

A new `hashlib` module, written by Gregory P. Smith, has been added to replace the `md5` and `sha` modules. `hashlib` adds support for additional secure hashes (SHA-224, SHA-256, SHA-384, and SHA-512). When available, the module uses OpenSSL for fast platform optimized implementations of algorithms.

The old `md5` and `sha` modules still exist as wrappers around `hashlib` to preserve backwards compatibility. The new module's interface is very close to that of the old modules, but not identical. The most significant difference is that the constructor functions for creating new hashing objects are named differently.

```
# Old versions  
h = md5.md5()  
h = md5.new()
```

```
# New version
h = hashlib.md5()

# Old versions
h = sha.sha()
h = sha.new()

# New version
h = hashlib.sha1()

# Hash that weren't previously available
h = hashlib.sha224()
h = hashlib.sha256()
h = hashlib.sha384()
h = hashlib.sha512()

# Alternative form
h = hashlib.new('md5')           # Provide algorithm as a string
```

Once a hash object has been created, its methods are the same as before: `update(string)()` hashes the specified string into the current digest state, `digest()` and `hexdigest()` return the digest value as a binary string or a string of hex digits, and `copy()` returns a new hashing object with the same digest state.

See also: The documentation for the `hashlib` module.

The sqlite3 package

The `pysqlite` module (<http://www.pysqlite.org>), a wrapper for the SQLite embedded database, has been added to the standard library under the package name `sqlite3`.

SQLite is a C library that provides a lightweight disk-based database that doesn't require a separate server process and allows accessing the database using a nonstandard variant of the SQL query language. Some applications can use SQLite for internal data storage. It's also possible to prototype an application using SQLite

and then port the code to a larger database such as PostgreSQL or Oracle.

pysqlite was written by Gerhard Häring and provides a SQL interface compliant with the DB-API 2.0 specification described by [PEP 249](#).

If you're compiling the Python source yourself, note that the source tree doesn't include the SQLite code, only the wrapper module. You'll need to have the SQLite libraries and headers installed before compiling Python, and the build process will compile the module when the necessary headers are available.

To use the module, you must first create a **connection** object that represents the database. Here the data will be stored in the `/tmp/example` file:

```
conn = sqlite3.connect('/tmp/example')
```

You can also supply the special name `:memory:` to create a database in RAM.

Once you have a **connection**, you can create a **cursor** object and call its `execute()` method to perform SQL commands:

```
c = conn.cursor()

# Create table
c.execute('''create table stocks
(date text, trans text, symbol text,
qty real, price real)''')

# Insert a row of data
c.execute("""insert into stocks
          values ('2006-01-05', 'BUY', 'RHAT', 100, 35.14)""")
```

Usually your SQL operations will need to use values from Python variables. You shouldn't assemble your query using Python's string

operations because doing so is insecure; it makes your program vulnerable to an SQL injection attack.

Instead, use the DB-API's parameter substitution. Put `?` as a placeholder wherever you want to use a value, and then provide a tuple of values as the second argument to the cursor's `execute()` method. (Other database modules may use a different placeholder, such as `%s` or `:1`.) For example:

```
# Never do this -- insecure!
symbol = 'IBM'
c.execute("... where symbol = '%s'" % symbol)

# Do this instead
t = (symbol,)
c.execute('select * from stocks where symbol=?', t)

# Larger example
for t in (('2006-03-28', 'BUY', 'IBM', 1000, 45.00),
         ('2006-04-05', 'BUY', 'MSOFT', 1000, 72.00),
         ('2006-04-06', 'SELL', 'IBM', 500, 53.00),
        ):
    c.execute('insert into stocks values (?, ?, ?, ?, ?)', t)
```

To retrieve data after executing a SELECT statement, you can either treat the cursor as an iterator, call the cursor's `fetchone()` method to retrieve a single matching row, or call `fetchall()` to get a list of the matching rows.

This example uses the iterator form:

```
>>> c = conn.cursor()
>>> c.execute('select * from stocks order by price')
>>> for row in c:
...     print row
...
(u'2006-01-05', u'BUY', u'RHAT', 100, 35.1400000000000001)
(u'2006-03-28', u'BUY', u'IBM', 1000, 45.0)
(u'2006-04-06', u'SELL', u'IBM', 500, 53.0)
(u'2006-04-05', u'BUY', u'MSOFT', 1000, 72.0)
```

```
>>>
```

For more information about the SQL dialect supported by SQLite, see <http://www.sqlite.org>.

PEP 249 - Database API Specification 2.0

PEP written by Marc-André Lemburg.

The wsgiref package

The Web Server Gateway Interface (WSGI) v1.0 defines a standard interface between web servers and Python web applications and is described in **PEP 333**. The `wsgiref` package is a reference implementation of the WSGI specification.

The package includes a basic HTTP server that will run a WSGI application; this server is useful for debugging but isn't intended for production use. Setting up a server takes only a few lines of code:

```
from wsgiref import simple_server

wsgi_app = ...

host = ''
port = 8000
httpd = simple_server.make_server(host, port, wsgi_app)
```

```
httpd.serve_forever()
```

A central web site for WSGI-related resources.

PEP 333 - Python Web Server Gateway Interface v1.0

PEP written by Phillip J. Eby.

Build and C API Changes

Changes to Python's build process and to the C API include:

- The Python source tree was converted from CVS to Subversion, in a complex migration procedure that was supervised and flawlessly carried out by Martin von Löwis. The procedure was developed as [PEP 347](#).
- Coverity, a company that markets a source code analysis tool called Prevent, provided the results of their examination of the Python source code. The analysis found about 60 bugs that were quickly fixed. Many of the bugs were recounting problems, often occurring in error-handling code. See <http://scan.coverity.com> for the statistics.
- The largest change to the C API came from [PEP 353](#), which modifies the interpreter to use a `Py_ssize_t` type definition instead of `int`. See the earlier section [PEP 353: Using `ssize_t` as the index type](#) for a discussion of this change.
- The design of the bytecode compiler has changed a great deal, no longer generating bytecode by traversing the parse tree. Instead the parse tree is converted to an abstract syntax tree (or AST), and it is the abstract syntax tree that's traversed to produce the bytecode.

It's possible for Python code to obtain AST objects by using the `compile()` built-in and specifying `_ast.PyCF_ONLY_AST` as the value of the `flags` parameter:

```
from _ast import PyCF_ONLY_AST
ast = compile("""a=0
for i in range(10):
    a += i
```

```
""", "<string>", 'exec', PyCF_ONLY_AST)

assignment = ast.body[0]
for_loop = ast.body[1]
```

No official documentation has been written for the AST code yet, but **PEP 339** discusses the design. To start learning about the code, read the definition of the various AST nodes in `Parser/Python.asdl`. A Python script reads this file and generates a set of C structure definitions in `Include/Python-ast.h`. The `PyParser_ASTFromString()` and `PyParser_ASTFromFile()`, defined in `Include/pythonrun.h`, take Python source as input and return the root of an AST representing the contents. This AST can then be turned into a code object by `PyAST_compile()`. For more information, read the source code, and then ask questions on python-dev.

The AST code was developed under Jeremy Hylton's management, and implemented by (in alphabetical order) Brett Cannon, Nick Coghlan, Grant Edwards, John Ehresman, Kurt Kaiser, Neal Norwitz, Tim Peters, Armin Rigo, and Neil Schemenauer, plus the participants in a number of AST sprints at conferences such as PyCon.

- Evan Jones's patch to `obmalloc`, first described in a talk at PyCon DC 2005, was applied. Python 2.4 allocated small objects in 256K-sized arenas, but never freed arenas. With this patch, Python will free arenas when they're empty. The net effect is that on some platforms, when you allocate many objects, Python's memory usage may actually drop when you delete them and the memory may be returned to the operating system. (Implemented by Evan Jones, and reworked by Tim Peters.)

Note that this change means extension modules must be more

careful when allocating memory. Python's API has many different functions for allocating memory that are grouped into families. For example, `PyMem_Malloc()`, `PyMem_Realloc()`, and `PyMem_Free()` are one family that allocates raw memory, while `PyObject_Malloc()`, `PyObject_Realloc()`, and `PyObject_Free()` are another family that's supposed to be used for creating Python objects.

Previously these different families all reduced to the platform's `malloc()` and `free()` functions. This meant it didn't matter if you got things wrong and allocated memory with the `PyMem()` function but freed it with the `PyObject()` function. With 2.5's changes to `obmalloc`, these families now do different things and mismatches will probably result in a segfault. You should carefully test your C extension modules with Python 2.5.

- The built-in set types now have an official C API. Call `PySet_New()` and `PyFrozenSet_New()` to create a new set, `PySet_Add()` and `PySet_Discard()` to add and remove elements, and `PySet_Contains()` and `PySet_Size()` to examine the set's state. (Contributed by Raymond Hettinger.)
- C code can now obtain information about the exact revision of the Python interpreter by calling the `Py_GetBuildInfo()` function that returns a string of build information like this: `"trunk:45355:45356M, Apr 13 2006, 07:42:19"`. (Contributed by Barry Warsaw.)
- Two new macros can be used to indicate C functions that are local to the current file so that a faster calling convention can be used. `Py_LOCAL(type)()` declares the function as returning a value of the specified *type* and uses a fast-calling qualifier. `Py_LOCAL_INLINE(type)()` does the same thing and also

requests the function be inlined. If `PY_LOCAL_AGGRESSIVE()` is defined before `python.h` is included, a set of more aggressive optimizations are enabled for the module; you should benchmark the results to find out if these optimizations actually make the code faster. (Contributed by Fredrik Lundh at the NeedForSpeed sprint.)

- `PyErr_NewException(name, base, dict)()` can now accept a tuple of base classes as its *base* argument. (Contributed by Georg Brandl.)
- The `PyErr_Warn()` function for issuing warnings is now deprecated in favour of `PyErr_WarnEx(category, message, stacklevel)()` which lets you specify the number of stack frames separating this function and the caller. A *stacklevel* of 1 is the function calling `PyErr_WarnEx()`, 2 is the function above that, and so forth. (Added by Neal Norwitz.)
- The CPython interpreter is still written in C, but the code can now be compiled with a C++ compiler without errors. (Implemented by Anthony Baxter, Martin von Löwis, Skip Montanaro.)
- The `PyRange_New()` function was removed. It was never documented, never used in the core code, and had dangerously lax error checking. In the unlikely case that your extensions were using it, you can replace it by something like the following:

```
range = PyObject_CallFunction((PyObject*) &PyRange_Type, "l  
start, stop, step);
```

Port-Specific Changes

- MacOS X (10.3 and higher): dynamic loading of modules now

uses the `dlopen()` function instead of MacOS-specific functions.

- MacOS X: an `--enable-universalsdk` switch was added to the **configure** script that compiles the interpreter as a universal binary able to run on both PowerPC and Intel processors. (Contributed by Ronald Oussoren; [issue 2573](#).)
- Windows: `.dll` is no longer supported as a filename extension for extension modules. `.pyd` is now the only filename extension that will be searched for.

Porting to Python 2.5

This section lists previously described changes that may require changes to your code:

- ASCII is now the default encoding for modules. It's now a syntax error if a module contains string literals with 8-bit characters but doesn't have an encoding declaration. In Python 2.4 this triggered a warning, not a syntax error.
- Previously, the `gi_frame` attribute of a generator was always a frame object. Because of the [PEP 342](#) changes described in section *PEP 342: New Generator Features*, it's now possible for `gi_frame` to be `None`.
- A new warning, `UnicodeWarning`, is triggered when you attempt to compare a Unicode string and an 8-bit string that can't be converted to Unicode using the default ASCII encoding. Previously such comparisons would raise a `UnicodeDecodeError` exception.
- Library: the `csv` module is now stricter about multi-line quoted fields. If your files contain newlines embedded within fields, the input should be split into lines in a manner which preserves the newline characters.
- Library: the `locale` module's `format()` function's would previously accept any string as long as no more than one `%char` specifier appeared. In Python 2.5, the argument must be exactly one `%char` specifier with no surrounding text.
- Library: The `pickle` and `cPickle` modules no longer accept a return value of `None` from the `__reduce__()` method; the method must return a tuple of arguments instead. The modules also no longer accept the deprecated `bin` keyword parameter.
- Library: The `SimpleXMLRPCServer` and `DocXMLRPCServer` classes now have a `rpc_paths` attribute that constrains XML-RPC

operations to a limited set of URL paths; the default is to allow only `'/'` and `'/RPC2'`. Setting `rpc_paths` to `None` or an empty tuple disables this path checking.

- C API: Many functions now use `Py_ssize_t` instead of `int` to allow processing more data on 64-bit machines. Extension code may need to make the same change to avoid warnings and to support 64-bit machines. See the earlier section [PEP 353: Using `ssize_t` as the index type](#) for a discussion of this change.
- C API: The obmalloc changes mean that you must be careful to not mix usage of the `PyMem_*`() and `PyObject_*`() families of functions. Memory allocated with one family's `*_Malloc()` must be freed with the corresponding family's `*_Free()` function.

What's New in Python 2.4

Author: A.M. Kuchling

This article explains the new features in Python 2.4.1, released on March 30, 2005.

Python 2.4 is a medium-sized release. It doesn't introduce as many changes as the radical Python 2.2, but introduces more features than the conservative 2.3 release. The most significant new language features are function decorators and generator expressions; most other changes are to the standard library.

According to the CVS change logs, there were 481 patches applied and 502 bugs fixed between Python 2.3 and 2.4. Both figures are likely to be underestimates.

This article doesn't attempt to provide a complete specification of every single new feature, but instead provides a brief introduction to each feature. For full details, you should refer to the documentation for Python 2.4, such as the Python Library Reference and the Python Reference Manual. Often you will be referred to the PEP for a particular new feature for explanations of the implementation and design rationale.

PEP 218: Built-In Set Objects

Python 2.3 introduced the `sets` module. C implementations of set data types have now been added to the Python core as two new built-in types, `set(iterable)()` and `frozenset(iterable)()`. They provide high speed operations for membership testing, for eliminating duplicates from sequences, and for mathematical operations like unions, intersections, differences, and symmetric differences.

```
>>> a = set('abracadabra')           # form a set from a string
>>> 'z' in a                         # fast membership testing
False
>>> a                                 # unique letters in a
set(['a', 'r', 'b', 'c', 'd'])
>>> ''.join(a)                       # convert back into a string
'arbcd'

>>> b = set('alacazam')             # form a second set
>>> a - b                             # letters in a but not in b
set(['r', 'd', 'b'])
>>> a | b                             # letters in either a or b
set(['a', 'c', 'r', 'd', 'b', 'm', 'z', 'l'])
>>> a & b                             # letters in both a and b
set(['a', 'c'])
>>> a ^ b                             # letters in a or b but not in both
set(['r', 'd', 'b', 'm', 'z', 'l'])

>>> a.add('z')                       # add a new element
>>> a.update('wxy')                 # add multiple new elements
>>> a
set(['a', 'c', 'b', 'd', 'r', 'w', 'y', 'x', 'z'])
>>> a.remove('x')                   # take one element out
>>> a
set(['a', 'c', 'b', 'd', 'r', 'w', 'y', 'z'])
```

The `frozenset()` type is an immutable version of `set()`. Since it is immutable and hashable, it may be used as a dictionary key or as a member of another set.

The `sets` module remains in the standard library, and may be useful if you wish to subclass the `Set` or `ImmutableSet` classes. There are currently no plans to deprecate the module.

PEP 218 - Adding a Built-In Set Object Type

Originally proposed by Greg Wilson and ultimately implemented by Raymond Hettinger.

PEP 237: Unifying Long Integers and Integers

The lengthy transition process for this PEP, begun in Python 2.2, takes another step forward in Python 2.4. In 2.3, certain integer operations that would behave differently after int/long unification triggered **FutureWarning** warnings and returned values limited to 32 or 64 bits (depending on your platform). In 2.4, these expressions no longer produce a warning and instead produce a different result that's usually a long integer.

The problematic expressions are primarily left shifts and lengthy hexadecimal and octal constants. For example, `2 << 32` results in a warning in 2.3, evaluating to 0 on 32-bit platforms. In Python 2.4, this expression now returns the correct answer, 8589934592.

PEP 237 - Unifying Long Integers and Integers

Original PEP written by Moshe Zadka and GvR. The changes for 2.4 were implemented by Kalle Svensson.

PEP 289: Generator Expressions

The iterator feature introduced in Python 2.2 and the `itertools` module make it easier to write programs that loop through large data sets without having the entire data set in memory at one time. List comprehensions don't fit into this picture very well because they produce a Python list object containing all of the items. This unavoidably pulls all of the objects into memory, which can be a problem if your data set is very large. When trying to write a functionally-styled program, it would be natural to write something like:

```
links = [link for link in get_all_links() if not link.followed]
for link in links:
    ...
```

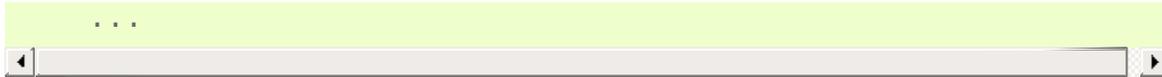

instead of

```
for link in get_all_links():
    if link.followed:
        continue
    ...
```

The first form is more concise and perhaps more readable, but if you're dealing with a large number of link objects you'd have to write the second form to avoid having all link objects in memory at the same time.

Generator expressions work similarly to list comprehensions but don't materialize the entire list; instead they create a generator that will return elements one by one. The above example could be written as:

```
links = (link for link in get_all_links() if not link.followed)
for link in links:
```

Generator expressions always have to be written inside parentheses, as in the above example. The parentheses signalling a function call also count, so if you want to create an iterator that will be immediately passed to a function you could write:

```
print sum(obj.count for obj in list_all_objects())
```

Generator expressions differ from list comprehensions in various small ways. Most notably, the loop variable (*obj* in the above example) is not accessible outside of the generator expression. List comprehensions leave the variable assigned to its last value; future versions of Python will change this, making list comprehensions match generator expressions in this respect.

PEP 289 - Generator Expressions

Proposed by Raymond Hettinger and implemented by Jiwon Seo with early efforts steered by Hye-Shik Chang.

PEP 292: Simpler String Substitutions

Some new classes in the standard library provide an alternative mechanism for substituting variables into strings; this style of substitution may be better for applications where untrained users need to edit templates.

The usual way of substituting variables by name is the `%` operator:

```
>>> '%(page)i: %(title)s' % {'page':2, 'title': 'The Best of Ti  
'2: The Best of Times'
```

When writing the template string, it can be easy to forget the `i` or `s` after the closing parenthesis. This isn't a big problem if the template is in a Python module, because you run the code, get an "Unsupported format character" `ValueError`, and fix the problem. However, consider an application such as Mailman where template strings or translations are being edited by users who aren't aware of the Python language. The format string's syntax is complicated to explain to such users, and if they make a mistake, it's difficult to provide helpful feedback to them.

PEP 292 adds a `Template` class to the `string` module that uses `$` to indicate a substitution:

```
>>> import string  
>>> t = string.Template('$page: $title')  
>>> t.substitute({'page':2, 'title': 'The Best of Times'})  
'2: The Best of Times'
```

If a key is missing from the dictionary, the `substitute()` method will raise a `KeyError`. There's also a `safe_substitute()` method that ignores missing keys:

```
>>> t = string.Template('$page: $title')
>>> t.safe_substitute({'page':3})
'3: $title'
```

See also:

PEP 292 - Simpler String Substitutions

Written and implemented by Barry Warsaw.

PEP 318: Decorators for Functions and Methods

Python 2.2 extended Python's object model by adding static methods and class methods, but it didn't extend Python's syntax to provide any new way of defining static or class methods. Instead, you had to write a `def` statement in the usual way, and pass the resulting method to a `staticmethod()` or `classmethod()` function that would wrap up the function as a method of the new type. Your code would look like this:

```
class C:
    def meth (cls):
        ...

    meth = classmethod(meth)  # Rebind name to wrapped-up class
```

If the method was very long, it would be easy to miss or forget the `classmethod()` invocation after the function body.

The intention was always to add some syntax to make such definitions more readable, but at the time of 2.2's release a good syntax was not obvious. Today a good syntax *still* isn't obvious but users are asking for easier access to the feature; a new syntactic feature has been added to meet this need.

The new feature is called "function decorators". The name comes from the idea that `classmethod()`, `staticmethod()`, and friends are storing additional information on a function object; they're *decorating* functions with more details.

The notation borrows from Java and uses the '@' character as an indicator. Using the new syntax, the example above would be

written:

```
class C:  
  
    @classmethod  
    def meth (cls):  
        ...
```

The `@classmethod` is shorthand for the `meth=classmethod(meth)` assignment. More generally, if you have the following:

```
@A  
@B  
@C  
def f ():  
    ...
```

It's equivalent to the following pre-decorator code:

```
def f(): ...  
f = A(B(C(f)))
```

Decorators must come on the line before a function definition, one decorator per line, and can't be on the same line as the `def` statement, meaning that `@A def f(): ...` is illegal. You can only decorate function definitions, either at the module level or inside a class; you can't decorate class definitions.

A decorator is just a function that takes the function to be decorated as an argument and returns either the same function or some new object. The return value of the decorator need not be callable (though it typically is), unless further decorators will be applied to the result. It's easy to write your own decorators. The following simple example just sets an attribute on the function object:

```
>>> def deco(func):  
...     func.attr = 'decorated'  
...     return func
```

```

...
>>> @deco
... def f(): pass
...
>>> f
<function f at 0x402ef0d4>
>>> f.attr
'decorated'
>>>

```

As a slightly more realistic example, the following decorator checks that the supplied argument is an integer:

```

def require_int (func):
    def wrapper (arg):
        assert isinstance(arg, int)
        return func(arg)

    return wrapper

@require_int
def p1 (arg):
    print arg

@require_int
def p2(arg):
    print arg*2

```

An example in [PEP 318](#) contains a fancier version of this idea that lets you both specify the required type and check the returned type.

Decorator functions can take arguments. If arguments are supplied, your decorator function is called with only those arguments and must return a new decorator function; this function must take a single function and return a function, as previously described. In other words, `@A @B @C(args)` becomes:

```

def f(): ...
_deco = C(args)
f = A(B(_deco(f)))

```

Getting this right can be slightly brain-bending, but it's not too difficult.

A small related change makes the `func_name` attribute of functions writable. This attribute is used to display function names in tracebacks, so decorators should change the name of any new function that's constructed and returned.

See also:

PEP 318 - Decorators for Functions, Methods and Classes

Written by Kevin D. Smith, Jim Jewett, and Skip Montanaro. Several people wrote patches implementing function decorators, but the one that was actually checked in was patch #979728, written by Mark Russell.

<http://www.python.org/moin/PythonDecoratorLibrary>

This Wiki page contains several examples of decorators.

PEP 322: Reverse Iteration

A new built-in function, `reversed(seq)()`, takes a sequence and returns an iterator that loops over the elements of the sequence in reverse order.

```
>>> for i in reversed(xrange(1,4)):
...     print i
...
3
2
1
```

Compared to extended slicing, such as `range(1,4)[::-1]`, `reversed()` is easier to read, runs faster, and uses substantially less memory.

Note that `reversed()` only accepts sequences, not arbitrary iterators. If you want to reverse an iterator, first convert it to a list with `list()`.

```
>>> input = open('/etc/passwd', 'r')
>>> for line in reversed(list(input)):
...     print line
...
root:*:0:0:System Administrator:/var/root:/bin/tcsh
...
```

See also:

PEP 322 - Reverse Iteration

Written and implemented by Raymond Hettinger.

PEP 324: New subprocess Module

The standard library provides a number of ways to execute a subprocess, offering different features and different levels of complexity. `os.system(command)()` is easy to use, but slow (it runs a shell process which executes the command) and dangerous (you have to be careful about escaping the shell's metacharacters). The `popen2` module offers classes that can capture standard output and standard error from the subprocess, but the naming is confusing. The `subprocess` module cleans this up, providing a unified interface that offers all the features you might need.

Instead of `popen2`'s collection of classes, `subprocess` contains a single class called `Popen` whose constructor supports a number of different keyword arguments.

```
class Popen(args, bufsize=0, executable=None,
            stdin=None, stdout=None, stderr=None,
            preexec_fn=None, close_fds=False, shell=False,
            cwd=None, env=None, universal_newlines=False,
            startupinfo=None, creationflags=0):
```

`args` is commonly a sequence of strings that will be the arguments to the program executed as the subprocess. (If the `shell` argument is true, `args` can be a string which will then be passed on to the shell for interpretation, just as `os.system()` does.)

`stdin`, `stdout`, and `stderr` specify what the subprocess's input, output, and error streams will be. You can provide a file object or a file descriptor, or you can use the constant `subprocess.PIPE` to create a pipe between the subprocess and the parent.

The constructor has a number of handy options:

- `close_fds` requests that all file descriptors be closed before running the subprocess.
- `cwd` specifies the working directory in which the subprocess will be executed (defaulting to whatever the parent's working directory is).
- `env` is a dictionary specifying environment variables.
- `preexec_fn` is a function that gets called before the child is started.
- `universal_newlines` opens the child's input and output using Python's universal newline feature.

Once you've created the `Popen` instance, you can call its `wait()` method to pause until the subprocess has exited, `poll()` to check if it's exited without pausing, or `communicate(data)()` to send the string `data` to the subprocess's standard input. `communicate(data)()` then reads any data that the subprocess has sent to its standard output or standard error, returning a tuple `(stdout_data, stderr_data)`.

`call()` is a shortcut that passes its arguments along to the `Popen` constructor, waits for the command to complete, and returns the status code of the subprocess. It can serve as a safer analog to `os.system()`:

```
sts = subprocess.call(['dpkg', '-i', '/tmp/new-package.deb'])
if sts == 0:
    # Success
    ...
else:
    # dpkg returned an error
    ...
```

The command is invoked without use of the shell. If you really do want to use the shell, you can add `shell=True` as a keyword argument and provide a string instead of a sequence:

```
sts = subprocess.call('dpkg -i /tmp/new-package.deb', shell=True)
```

The PEP takes various examples of shell and Python code and shows how they'd be translated into Python code that uses [subprocess](#). Reading this section of the PEP is highly recommended.

PEP 324 - subprocess - New process module

Written and implemented by Peter Åstrand, with assistance from Fredrik Lundh and others.

PEP 327: Decimal Data Type

Python has always supported floating-point (FP) numbers, based on the underlying C `double` type, as a data type. However, while most programming languages provide a floating-point type, many people (even programmers) are unaware that floating-point numbers don't represent certain decimal fractions accurately. The new `Decimal` type can represent these fractions accurately, up to a user-specified precision limit.

Why is Decimal needed?

The limitations arise from the representation used for floating-point numbers. FP numbers are made up of three components:

- The sign, which is positive or negative.
- The mantissa, which is a single-digit binary number followed by a fractional part. For example, `1.01` in base-2 notation is `1 + 0/2 + 1/4`, or 1.25 in decimal notation.
- The exponent, which tells where the decimal point is located in the number represented.

For example, the number 1.25 has positive sign, a mantissa value of 1.01 (in binary), and an exponent of 0 (the decimal point doesn't need to be shifted). The number 5 has the same sign and mantissa, but the exponent is 2 because the mantissa is multiplied by 4 (2 to the power of the exponent 2); $1.25 * 4$ equals 5.

Modern systems usually provide floating-point support that conforms to a standard called IEEE 754. C's `double` type is usually implemented as a 64-bit IEEE 754 number, which uses 52 bits of space for the mantissa. This means that numbers can only be specified to 52 bits of precision. If you're trying to represent numbers

whose expansion repeats endlessly, the expansion is cut off after 52 bits. Unfortunately, most software needs to produce output in base 10, and common fractions in base 10 are often repeating decimals in binary. For example, 1.1 decimal is binary `1.0001100110011 ...`; $.1 = 1/16 + 1/32 + 1/256$ plus an infinite number of additional terms. IEEE 754 has to chop off that infinitely repeated decimal after 52 digits, so the representation is slightly inaccurate.

Sometimes you can see this inaccuracy when the number is printed:

```
>>> 1.1
1.100000000000000001
```

The inaccuracy isn't always visible when you print the number because the FP-to-decimal-string conversion is provided by the C library, and most C libraries try to produce sensible output. Even if it's not displayed, however, the inaccuracy is still there and subsequent operations can magnify the error.

For many applications this doesn't matter. If I'm plotting points and displaying them on my monitor, the difference between 1.1 and 1.100000000000000001 is too small to be visible. Reports often limit output to a certain number of decimal places, and if you round the number to two or three or even eight decimal places, the error is never apparent. However, for applications where it does matter, it's a lot of work to implement your own custom arithmetic routines.

Hence, the `Decimal` type was created.

The `Decimal` type

A new module, `decimal`, was added to Python's standard library. It contains two classes, `Decimal` and `Context`. `Decimal` instances represent numbers, and `context` instances are used to wrap up various settings such as the precision and default rounding mode.

Decimal instances are immutable, like regular Python integers and FP numbers; once it's been created, you can't change the value an instance represents. **Decimal** instances can be created from integers or strings:

```
>>> import decimal
>>> decimal.Decimal(1972)
Decimal("1972")
>>> decimal.Decimal("1.1")
Decimal("1.1")
```

You can also provide tuples containing the sign, the mantissa represented as a tuple of decimal digits, and the exponent:

```
>>> decimal.Decimal((1, (1, 4, 7, 5), -2))
Decimal("-14.75")
```

Cautionary note: the sign bit is a Boolean value, so 0 is positive and 1 is negative.

Converting from floating-point numbers poses a bit of a problem: should the FP number representing 1.1 turn into the decimal number for exactly 1.1, or for 1.1 plus whatever inaccuracies are introduced? The decision was to dodge the issue and leave such a conversion out of the API. Instead, you should convert the floating-point number into a string using the desired precision and pass the string to the **Decimal** constructor:

```
>>> f = 1.1
>>> decimal.Decimal(str(f))
Decimal("1.1")
>>> decimal.Decimal('%0.12f' % f)
Decimal("1.100000000000")
```

Once you have **Decimal** instances, you can perform the usual mathematical operations on them. One limitation: exponentiation requires an integer exponent:

```

>>> a = decimal.Decimal('35.72')
>>> b = decimal.Decimal('1.73')
>>> a+b
Decimal("37.45")
>>> a-b
Decimal("33.99")
>>> a*b
Decimal("61.7956")
>>> a/b
Decimal("20.64739884393063583815028902")
>>> a ** 2
Decimal("1275.9184")
>>> a**b
Traceback (most recent call last):
...
decimal.InvalidOperation: x ** (non-integer)

```

You can combine `Decimal` instances with integers, but not with floating-point numbers:

```

>>> a + 4
Decimal("39.72")
>>> a + 4.5
Traceback (most recent call last):
...
TypeError: You can interact Decimal only with int, long or Deci
>>>

```

`Decimal` numbers can be used with the `math` and `cmath` modules, but note that they'll be immediately converted to floating-point numbers before the operation is performed, resulting in a possible loss of precision and accuracy. You'll also get back a regular floating-point number and not a `Decimal`.

```

>>> import math, cmath
>>> d = decimal.Decimal('123456789012.345')
>>> math.sqrt(d)
351364.18288201344
>>> cmath.sqrt(-d)
351364.18288201344j

```

`Decimal` instances have a `sqrt()` method that returns a `Decimal`, but if you need other things such as trigonometric functions you'll have to implement them.

```
>>> d.sqrt()  
Decimal("351364.1828820134592177245001")
```

The `context` type

Instances of the `context` class encapsulate several settings for decimal operations:

- `prec` is the precision, the number of decimal places.
- `rounding` specifies the rounding mode. The `decimal` module has constants for the various possibilities: `ROUND_DOWN`, `ROUND_CEILING`, `ROUND_HALF_EVEN`, and various others.
- `traps` is a dictionary specifying what happens on encountering certain error conditions: either an exception is raised or a value is returned. Some examples of error conditions are division by zero, loss of precision, and overflow.

There's a thread-local default context available by calling `getcontext()`; you can change the properties of this context to alter the default precision, rounding, or trap handling. The following example shows the effect of changing the precision of the default context:

```
>>> decimal.getcontext().prec  
28  
>>> decimal.Decimal(1) / decimal.Decimal(7)  
Decimal("0.1428571428571428571428571429")  
>>> decimal.getcontext().prec = 9  
>>> decimal.Decimal(1) / decimal.Decimal(7)  
Decimal("0.142857143")
```

The default action for error conditions is selectable; the module can

either return a special value such as infinity or not-a-number, or exceptions can be raised:

```
>>> decimal.Decimal(1) / decimal.Decimal(0)
Traceback (most recent call last):
...
decimal.DivisionByZero: x / 0
>>> decimal.getcontext().traps[decimal.DivisionByZero] = False
>>> decimal.Decimal(1) / decimal.Decimal(0)
Decimal("Infinity")
>>>
```

The `context` instance also has various methods for formatting numbers such as `to_eng_string()` and `to_sci_string()`.

For more information, see the documentation for the `decimal` module, which includes a quick-start tutorial and a reference.

PEP 327 - Decimal Data Type

Written by Facundo Batista and implemented by Facundo Batista, Eric Price, Raymond Hettinger, Aahz, and Tim Peters.

<http://www.lahey.com/float.htm>

The article uses Fortran code to illustrate many of the problems that floating-point inaccuracy can cause.

<http://www2.hursley.ibm.com/decimal/>

A description of a decimal-based representation. This representation is being proposed as a standard, and underlies the new Python decimal type. Much of this material was written by Mike Cowlishaw, designer of the Rexx language.

PEP 328: Multi-line Imports

One language change is a small syntactic tweak aimed at making it easier to import many names from a module. In a `from module import names` statement, *names* is a sequence of names separated by commas. If the sequence is very long, you can either write multiple imports from the same module, or you can use backslashes to escape the line endings like this:

```
from SimpleXMLRPCServer import SimpleXMLRPCServer, \
    SimpleXMLRPCRequestHandler, \
    CGIXMLRPCRequestHandler, \
    resolve_dotted_attribute
```

The syntactic change in Python 2.4 simply allows putting the names within parentheses. Python ignores newlines within a parenthesized expression, so the backslashes are no longer needed:

```
from SimpleXMLRPCServer import (SimpleXMLRPCServer,
                                SimpleXMLRPCRequestHandler,
                                CGIXMLRPCRequestHandler,
                                resolve_dotted_attribute)
```

The PEP also proposes that all `import` statements be absolute imports, with a leading `.` character to indicate a relative import. This part of the PEP was not implemented for Python 2.4, but was completed for Python 2.5.

See also:

PEP 328 - Imports: Multi-Line and Absolute/Relative

Written by Aahz. Multi-line imports were implemented by Dima Dorfman.

PEP 331: Locale-Independent Float/String Conversions

The `locale` module lets Python software select various conversions and display conventions that are localized to a particular country or language. However, the module was careful to not change the numeric locale because various functions in Python's implementation required that the numeric locale remain set to the `'c'` locale. Often this was because the code was using the C library's `atof()` function.

Not setting the numeric locale caused trouble for extensions that used third-party C libraries, however, because they wouldn't have the correct locale set. The motivating example was GTK+, whose user interface widgets weren't displaying numbers in the current locale.

The solution described in the PEP is to add three new functions to the Python API that perform ASCII-only conversions, ignoring the locale setting:

- `PyOS_ascii_strtod(str, ptr)()` and `PyOS_ascii_atof(str, ptr)()` both convert a string to a C `double`.
- `PyOS_ascii_formatd(buffer, buf_len, format, d)()` converts a `double` to an ASCII string.

The code for these functions came from the GLib library (<http://library.gnome.org/devel/glib/stable/>), whose developers kindly relicensed the relevant functions and donated them to the Python Software Foundation. The `locale` module can now change the numeric locale, letting extensions such as GTK+ produce the correct results.

See also:

PEP 331 - Locale-Independent Float/String Conversions

Written by Christian R. Reis, and implemented by Gustavo Carneiro.

Other Language Changes

Here are all of the changes that Python 2.4 makes to the core Python language.

- Decorators for functions and methods were added ([PEP 318](#)).
- Built-in `set()` and `frozenset()` types were added ([PEP 218](#)). Other new built-ins include the `reversed(seq)()` function ([PEP 322](#)).
- Generator expressions were added ([PEP 289](#)).
- Certain numeric expressions no longer return values restricted to 32 or 64 bits ([PEP 237](#)).
- You can now put parentheses around the list of names in a `from module import names` statement ([PEP 328](#)).
- The `dict.update()` method now accepts the same argument forms as the `dict` constructor. This includes any mapping, any iterable of key/value pairs, and keyword arguments. (Contributed by Raymond Hettinger.)
- The string methods `ljust()`, `rjust()`, and `center()` now take an optional argument for specifying a fill character other than a space. (Contributed by Raymond Hettinger.)
- Strings also gained an `rsplit()` method that works like the `split()` method but splits from the end of the string. (Contributed by Sean Reifschneider.)

```
>>> 'www.python.org'.split('.', 1)
['www', 'python.org']
```

```
'www.python.org'.rsplit('.', 1)
['www.python', 'org']
```

- Three keyword parameters, *cmp*, *key*, and *reverse*, were added to the `sort()` method of lists. These parameters make some common usages of `sort()` simpler. All of these parameters are optional.

For the *cmp* parameter, the value should be a comparison function that takes two parameters and returns -1, 0, or +1 depending on how the parameters compare. This function will then be used to sort the list. Previously this was the only parameter that could be provided to `sort()`.

key should be a single-parameter function that takes a list element and returns a comparison key for the element. The list is then sorted using the comparison keys. The following example sorts a list case-insensitively:

```
>>> L = ['A', 'b', 'c', 'D']
>>> L.sort() # Case-sensitive sort
>>> L
['A', 'D', 'b', 'c']
>>> # Using 'key' parameter to sort list
>>> L.sort(key=lambda x: x.lower())
>>> L
['A', 'b', 'c', 'D']
>>> # Old-fashioned way
>>> L.sort(cmp=lambda x,y: cmp(x.lower(), y.lower()))
>>> L
['A', 'b', 'c', 'D']
```

The last example, which uses the *cmp* parameter, is the old way to perform a case-insensitive sort. It works but is slower than using a *key* parameter. Using *key* calls `lower()` method once for each element in the list while using *cmp* will call it twice for each comparison, so using *key* saves on invocations of the `lower()` method.

For simple key functions and comparison functions, it is often possible to avoid a `lambda` expression by using an unbound method instead. For example, the above case-insensitive sort is best written as:

```
>>> L.sort(key=str.lower)
>>> L
['A', 'b', 'c', 'D']
```

Finally, the `reverse` parameter takes a Boolean value. If the value is true, the list will be sorted into reverse order. Instead of `L.sort()` ; `L.reverse()`, you can now write `L.sort(reverse=True)`.

The results of sorting are now guaranteed to be stable. This means that two entries with equal keys will be returned in the same order as they were input. For example, you can sort a list of people by name, and then sort the list by age, resulting in a list sorted by age where people with the same age are in name-sorted order.

(All changes to `sort()` contributed by Raymond Hettinger.)

- There is a new built-in function `sorted(iterable)()` that works like the in-place `list.sort()` method but can be used in expressions. The differences are:
 - the input may be any iterable;
 - a newly formed copy is sorted, leaving the original intact; and
 - the expression returns the new sorted copy

```
>>> L = [9,7,8,3,2,4,1,6,5]
>>> [10+i for i in sorted(L)]      # usable in a list comp
[11, 12, 13, 14, 15, 16, 17, 18, 19]
>>> L                             # original is left unch
```

```

[9,7,8,3,2,4,1,6,5]
>>> sorted('Monty Python')           # any iterable may be a
[' ', 'M', 'P', 'h', 'n', 'n', 'o', 'o', 't', 't', 'y', 'y']

>>> # List the contents of a dict sorted by key values
>>> colormap = dict(red=1, blue=2, green=3, black=4, yellow=5)
>>> for k, v in sorted(colormap.iteritems()):
...     print k, v
...
black 4
blue 2
green 3
red 1
yellow 5

```

(Contributed by Raymond Hettinger.)

- Integer operations will no longer trigger an `OverflowWarning`. The `overflowWarning` warning will disappear in Python 2.5.
- The interpreter gained a new switch, `-m`, that takes a name, searches for the corresponding module on `sys.path`, and runs the module as a script. For example, you can now run the Python profiler with `python -m profile`. (Contributed by Nick Coghlan.)
- The `eval(expr, globals, locals)()` and `execfile(filename, globals, locals)()` functions and the `exec` statement now accept any mapping type for the `locals` parameter. Previously this had to be a regular Python dictionary. (Contributed by Raymond Hettinger.)
- The `zip()` built-in function and `itertools.izip()` now return an empty list if called with no arguments. Previously they raised a `TypeError` exception. This makes them more suitable for use with variable length argument lists:

```

>>> def transpose(array):

```

```
...     return zip(*array)
...
>>> transpose([(1,2,3), (4,5,6)])
[(1, 4), (2, 5), (3, 6)]
>>> transpose([])
[]
```

(Contributed by Raymond Hettinger.)

- Encountering a failure while importing a module no longer leaves a partially- initialized module object in `sys.modules`. The incomplete module object left behind would fool further imports of the same module into succeeding, leading to confusing errors. (Fixed by Tim Peters.)
- `None` is now a constant; code that binds a new value to the name `None` is now a syntax error. (Contributed by Raymond Hettinger.)

Optimizations

- The inner loops for list and tuple slicing were optimized and now run about one-third faster. The inner loops for dictionaries were also optimized, resulting in performance boosts for `keys()`, `values()`, `items()`, `iterkeys()`, `itervalues()`, and `iteritems()`. (Contributed by Raymond Hettinger.)
- The machinery for growing and shrinking lists was optimized for speed and for space efficiency. Appending and popping from lists now runs faster due to more efficient code paths and less frequent use of the underlying system `realloc()`. List comprehensions also benefit. `list.extend()` was also optimized and no longer converts its argument into a temporary list before extending the base list. (Contributed by Raymond Hettinger.)
- `list()`, `tuple()`, `map()`, `filter()`, and `zip()` now run several times faster with non-sequence arguments that supply a

`__len__()` method. (Contributed by Raymond Hettinger.)

- The methods `list.__getitem__()`, `dict.__getitem__()`, and `dict.__contains__()` are now implemented as `method_descriptor` objects rather than `wrapper_descriptor` objects. This form of access doubles their performance and makes them more suitable for use as arguments to functionals: `map(mydict.__getitem__, keylist)`. (Contributed by Raymond Hettinger.)
- Added a new opcode, `LIST_APPEND`, that simplifies the generated bytecode for list comprehensions and speeds them up by about a third. (Contributed by Raymond Hettinger.)
- The peephole bytecode optimizer has been improved to produce shorter, faster bytecode; remarkably, the resulting bytecode is more readable. (Enhanced by Raymond Hettinger.)
- String concatenations in statements of the form `s = s + "abc"` and `s += "abc"` are now performed more efficiently in certain circumstances. This optimization won't be present in other Python implementations such as Jython, so you shouldn't rely on it; using the `join()` method of strings is still recommended when you want to efficiently glue a large number of strings together. (Contributed by Armin Rigo.)

The net result of the 2.4 optimizations is that Python 2.4 runs the pystone benchmark around 5% faster than Python 2.3 and 35% faster than Python 2.2. (pystone is not a particularly good benchmark, but it's the most commonly used measurement of Python's performance. Your own applications may show greater or smaller benefits from Python 2.4.)

New, Improved, and Deprecated Modules

As usual, Python's standard library received a number of enhancements and bug fixes. Here's a partial list of the most notable changes, sorted alphabetically by module name. Consult the `Misc/NEWS` file in the source tree for a more complete list of changes, or look through the CVS logs for all the details.

- The `asyncore` module's `loop()` function now has a *count* parameter that lets you perform a limited number of passes through the polling loop. The default is still to loop forever.
- The `base64` module now has more complete RFC 3548 support for Base64, Base32, and Base16 encoding and decoding, including optional case folding and optional alternative alphabets. (Contributed by Barry Warsaw.)
- The `bisect` module now has an underlying C implementation for improved performance. (Contributed by Dmitry Vasiliev.)
- The CJKCodecs collections of East Asian codecs, maintained by Hye-Shik Chang, was integrated into 2.4. The new encodings are:
 - Chinese (PRC): `gb2312`, `gbk`, `gb18030`, `big5hkscs`, `hz`
 - Chinese (ROC): `big5`, `cp950`
 - Japanese: `cp932`, `euc-jis-2004`, `euc-jp`, `euc-jisx0213`, `iso-2022-jp`,
`iso-2022-jp-1`, `iso-2022-jp-2`, `iso-2022-jp-3`, `iso-2022-jp-ext`,
`iso-2022-jp-2004`, `shift-jis`, `shift-jisx0213`, `shift-jis-2004`
 - Korean: `cp949`, `euc-kr`, `johab`, `iso-2022-kr`

- Some other new encodings were added: HP Roman8, ISO_8859-11, ISO_8859-16, PCTP-154, and TIS-620.
- The UTF-8 and UTF-16 codecs now cope better with receiving partial input. Previously the `StreamReader` class would try to read more data, making it impossible to resume decoding from the stream. The `read()` method will now return as much data as it can and future calls will resume decoding where previous ones left off. (Implemented by Walter Dörwald.)
- There is a new `collections` module for various specialized collection datatypes. Currently it contains just one type, `deque`, a double-ended queue that supports efficiently adding and removing elements from either end:

```
>>> from collections import deque
>>> d = deque('ghi')           # make a new deque with three i
>>> d.append('j')             # add a new entry to the right
>>> d.appendleft('f')         # add a new entry to the left s
>>> d                          # show the representation of th
deque(['f', 'g', 'h', 'i', 'j'])
>>> d.pop()                   # return and remove the rightmo
'j'
>>> d.popleft()               # return and remove the leftmos
'f'
>>> list(d)                   # list the contents of the deque
['g', 'h', 'i']
>>> 'h' in d                  # search the deque
True
```

Several modules, such as the `Queue` and `threading` modules, now take advantage of `collections.deque` for improved performance. (Contributed by Raymond Hettinger.)

- The `configParser` classes have been enhanced slightly. The `read()` method now returns a list of the files that were successfully parsed, and the `set()` method raises `TypeError` if

passed a *value* argument that isn't a string. (Contributed by John Belmonte and David Goodger.)

- The `curses` module now supports the `ncurses` extension `use_default_colors()`. On platforms where the terminal supports transparency, this makes it possible to use a transparent background. (Contributed by Jörg Lehmann.)
- The `difflib` module now includes an `HtmlDiff` class that creates an HTML table showing a side by side comparison of two versions of a text. (Contributed by Dan Gass.)
- The `email` package was updated to version 3.0, which dropped various deprecated APIs and removes support for Python versions earlier than 2.3. The 3.0 version of the package uses a new incremental parser for MIME messages, available in the `email.FeedParser` module. The new parser doesn't require reading the entire message into memory, and doesn't raise exceptions if a message is malformed; instead it records any problems in the `defect` attribute of the message. (Developed by Anthony Baxter, Barry Warsaw, Thomas Wouters, and others.)
- The `heapq` module has been converted to C. The resulting tenfold improvement in speed makes the module suitable for handling high volumes of data. In addition, the module has two new functions `nlargest()` and `nsmallest()` that use heaps to find the N largest or smallest values in a dataset without the expense of a full sort. (Contributed by Raymond Hettinger.)
- The `httplib` module now contains constants for HTTP status codes defined in various HTTP-related RFC documents. Constants have names such as `OK`, `CREATED`, `CONTINUE`, and `MOVED_PERMANENTLY`; use `pydoc` to get a full list. (Contributed by Andrew Eland.)

- The `imaplib` module now supports IMAP's THREAD command (contributed by Yves Dionne) and new `deleteacl()` and `myrights()` methods (contributed by Arnaud Mazin).
- The `itertools` module gained a `groupby(iterable[, *func*])()` function. *iterable* is something that can be iterated over to return a stream of elements, and the optional *func* parameter is a function that takes an element and returns a key value; if omitted, the key is simply the element itself. `groupby()` then groups the elements into subsequences which have matching values of the key, and returns a series of 2-tuples containing the key value and an iterator over the subsequence.

Here's an example to make this clearer. The *key* function simply returns whether a number is even or odd, so the result of `groupby()` is to return consecutive runs of odd or even numbers.

```
>>> import itertools
>>> L = [2, 4, 6, 7, 8, 9, 11, 12, 14]
>>> for key_val, it in itertools.groupby(L, lambda x: x % 2)
...     print key_val, list(it)
...
0 [2, 4, 6]
1 [7]
0 [8]
1 [9, 11]
0 [12, 14]
>>>
```

`groupby()` is typically used with sorted input. The logic for `groupby()` is similar to the Unix `uniq` filter which makes it handy for eliminating, counting, or identifying duplicate elements:

```
>>> word = 'abracadabra'
>>> letters = sorted(word) # Turn string into a sorted list
>>> letters
['a', 'a', 'a', 'a', 'a', 'b', 'b', 'c', 'd', 'r', 'r']
```

```
>>> for k, g in itertools.groupby(letters):
...     print k, list(g)
...
a ['a', 'a', 'a', 'a', 'a']
b ['b', 'b']
c ['c']
d ['d']
r ['r', 'r']
>>> # List unique letters
>>> [k for k, g in groupby(letters)]
['a', 'b', 'c', 'd', 'r']
>>> # Count letter occurrences
>>> [(k, len(list(g))) for k, g in groupby(letters)]
[('a', 5), ('b', 2), ('c', 1), ('d', 1), ('r', 2)]
```

(Contributed by Hye-Shik Chang.)

- `itertools` also gained a function named `tee(iterator, N)()` that returns N independent iterators that replicate *iterator*. If N is omitted, the default is 2.

```
>>> L = [1,2,3]
>>> i1, i2 = itertools.tee(L)
>>> i1, i2
(<itertools.tee object at 0x402c2080>, <itertools.tee objec
>>> list(i1) # Run the first iterator to exha
[1, 2, 3]
>>> list(i2) # Run the second iterator to exh
[1, 2, 3]
```

Note that `tee()` has to keep copies of the values returned by the iterator; in the worst case, it may need to keep all of them. This should therefore be used carefully if the leading iterator can run far ahead of the trailing iterator in a long stream of inputs. If the separation is large, then you might as well use `list()` instead. When the iterators track closely with one another, `tee()` is ideal. Possible applications include bookmarking, windowing, or lookahead iterators. (Contributed by Raymond Hettinger.)

- A number of functions were added to the `locale` module, such as `bind_textdomain_codeset()` to specify a particular encoding and a family of `l*gettext()` functions that return messages in the chosen encoding. (Contributed by Gustavo Niemeyer.)
- Some keyword arguments were added to the `logging` package's `basicConfig()` function to simplify log configuration. The default behavior is to log messages to standard error, but various keyword arguments can be specified to log to a particular file, change the logging format, or set the logging level. For example:

```
import logging
logging.basicConfig(filename='/var/log/application.log',
                    level=0, # Log all messages
                    format='%(levelname):%(process):%(thread):%(message)')
```

Other additions to the `logging` package include a `log(level, msg)()` convenience method, as well as a `TimedRotatingFileHandler` class that rotates its log files at a timed interval. The module already had `RotatingFileHandler`, which rotated logs once the file exceeded a certain size. Both classes derive from a new `BaseRotatingHandler` class that can be used to implement other rotating handlers.

(Changes implemented by Vinay Sajip.)

- The `marshal` module now shares interned strings on unpacking a data structure. This may shrink the size of certain pickle strings, but the primary effect is to make `.pyc` files significantly smaller. (Contributed by Martin von Löwis.)
- The `nntplib` module's `NNTP` class gained `description()` and `descriptions()` methods to retrieve newsgroup descriptions for a single group or for a range of groups. (Contributed by Jürgen A. Erhard.)

- Two new functions were added to the `operator` module, `attrgetter(attr)()` and `itemgetter(index)()`. Both functions return callables that take a single argument and return the corresponding attribute or item; these callables make excellent data extractors when used with `map()` or `sorted()`. For example:

```
>>> L = [('c', 2), ('d', 1), ('a', 4), ('b', 3)]
>>> map(operator.itemgetter(0), L)
['c', 'd', 'a', 'b']
>>> map(operator.itemgetter(1), L)
[2, 1, 4, 3]
>>> sorted(L, key=operator.itemgetter(1)) # Sort list by se
[('d', 1), ('c', 2), ('b', 3), ('a', 4)]
```

(Contributed by Raymond Hettinger.)

- The `optparse` module was updated in various ways. The module now passes its messages through `gettext.gettext()`, making it possible to internationalize Optik's help and error messages. Help messages for options can now include the string `'%default'`, which will be replaced by the option's default value. (Contributed by Greg Ward.)
- The long-term plan is to deprecate the `rfc822` module in some future Python release in favor of the `email` package. To this end, the `email.Utils.formatdate()` function has been changed to make it usable as a replacement for `rfc822.formatdate()`. You may want to write new e-mail processing code with this in mind. (Change implemented by Anthony Baxter.)
- A new `urandom(n)()` function was added to the `os` module, returning a string containing `n` bytes of random data. This function provides access to platform-specific sources of randomness such as `/dev/urandom` on Linux or the Windows

CryptoAPI. (Contributed by Trevor Perrin.)

- Another new function: `os.path.lexists(path)()` returns true if the file specified by *path* exists, whether or not it's a symbolic link. This differs from the existing `os.path.exists(path)()` function, which returns false if *path* is a symlink that points to a destination that doesn't exist. (Contributed by Beni Cherniavsky.)
- A new `getsid()` function was added to the `posix` module that underlies the `os` module. (Contributed by J. Raynor.)
- The `poplib` module now supports POP over SSL. (Contributed by Hector Urtubia.)
- The `profile` module can now profile C extension functions. (Contributed by Nick Bastin.)
- The `random` module has a new method called `getrandbits(N)()` that returns a long integer *N* bits in length. The existing `randrange()` method now uses `getrandbits()` where appropriate, making generation of arbitrarily large random numbers more efficient. (Contributed by Raymond Hettinger.)
- The regular expression language accepted by the `re` module was extended with simple conditional expressions, written as `(? (group)A|B)`. *group* is either a numeric group ID or a group name defined with `(?P<group>...)` earlier in the expression. If the specified group matched, the regular expression pattern *A* will be tested against the string; if the group didn't match, the pattern *B* will be used instead. (Contributed by Gustavo Niemeyer.)
- The `re` module is also no longer recursive, thanks to a massive

amount of work by Gustavo Niemeyer. In a recursive regular expression engine, certain patterns result in a large amount of C stack space being consumed, and it was possible to overflow the stack. For example, if you matched a 30000-byte string of `a` characters against the expression `(a|b)+`, one stack frame was consumed per character. Python 2.3 tried to check for stack overflow and raise a `RuntimeError` exception, but certain patterns could sidestep the checking and if you were unlucky Python could segfault. Python 2.4's regular expression engine can match this pattern without problems.

- The `signal` module now performs tighter error-checking on the parameters to the `signal.signal()` function. For example, you can't set a handler on the `SIGKILL` signal; previous versions of Python would quietly accept this, but 2.4 will raise a `RuntimeError` exception.
 - Two new functions were added to the `socket` module. `socketpair()` returns a pair of connected sockets and `getservbyport(port)()` looks up the service name for a given port number. (Contributed by Dave Cole and Barry Warsaw.)
 - The `sys.exitfunc()` function has been deprecated. Code should be using the existing `atexit` module, which correctly handles calling multiple exit functions. Eventually `sys.exitfunc()` will become a purely internal interface, accessed only by `atexit`.
 - The `tarfile` module now generates GNU-format tar files by default. (Contributed by Lars Gustaebel.)
 - The `threading` module now has an elegantly simple way to support thread-local data. The module contains a `local` class whose attribute values are local to different threads.
-

```
import threading

data = threading.local()
data.number = 42
data.url = ('www.python.org', 80)
```

Other threads can assign and retrieve their own values for the `number` and `url` attributes. You can subclass `local` to initialize attributes or to add methods. (Contributed by Jim Fulton.)

- The `timeit` module now automatically disables periodic garbage collection during the timing loop. This change makes consecutive timings more comparable. (Contributed by Raymond Hettinger.)
- The `weakref` module now supports a wider variety of objects including Python functions, class instances, sets, frozensets, deques, arrays, files, sockets, and regular expression pattern objects. (Contributed by Raymond Hettinger.)
- The `xmlrpclib` module now supports a multi-call extension for transmitting multiple XML-RPC calls in a single HTTP operation. (Contributed by Brian Quinlan.)
- The `mpz`, `rotor`, and `xreadlines` modules have been removed.

cookielib

The `cookielib` library supports client-side handling for HTTP cookies, mirroring the `cookie` module's server-side cookie support. Cookies are stored in cookie jars; the library transparently stores cookies offered by the web server in the cookie jar, and fetches the cookie from the jar when connecting to the server. As in web browsers, policy objects control whether cookies are accepted or not.

In order to store cookies across sessions, two implementations of cookie jars are provided: one that stores cookies in the Netscape format so applications can use the Mozilla or Lynx cookie files, and one that stores cookies in the same format as the Perl libwww library.

`urllib2` has been changed to interact with `cookielib`: `HTTPCookieProcessor` manages a cookie jar that is used when accessing URLs.

This module was contributed by John J. Lee.

doctest

The `doctest` module underwent considerable refactoring thanks to Edward Loper and Tim Peters. Testing can still be as simple as running `doctest.testmod()`, but the refactorings allow customizing the module's operation in various ways

The new `DocTestFinder` class extracts the tests from a given object's docstrings:

```
def f (x, y):
    """>>> f(2,2)
4
>>> f(3,2)
6
    """
    return x*y

finder = doctest.DocTestFinder()

# Get list of DocTest instances
tests = finder.find(f)
```

The new `DocTestRunner` class then runs individual tests and can produce a summary of the results:

```
runner = doctest.DocTestRunner()
for t in tests:
    tried, failed = runner.run(t)

runner.summarize(verbose=1)
```

The above example produces the following output:

```
1 items passed all tests:
  2 tests in f
2 tests in 1 items.
2 passed and 0 failed.
Test passed.
```

`DocTestRunner` uses an instance of the `OutputChecker` class to compare the expected output with the actual output. This class takes a number of different flags that customize its behaviour; ambitious users can also write a completely new subclass of `OutputChecker`.

The default output checker provides a number of handy features. For example, with the `doctest.ELLIPSIS` option flag, an ellipsis (...) in the expected output matches any substring, making it easier to accommodate outputs that vary in minor ways:

```
def o (n):
    """>>> o(1)
    <__main__.C instance at 0x...>
    >>>
    """
```

Another special string, `<BLANKLINE>`, matches a blank line:

```
def p (n):
    """>>> p(1)
    <BLANKLINE>
    >>>
    """
```

Another new capability is producing a diff-style display of the output

by specifying the `doctest.REPORT_UDIFF` (unified diffs), `doctest.REPORT_CDIF` (context diffs), or `doctest.REPORT_NDIFF` (delta-style) option flags. For example:

```
def g (n):
    """>>> g(4)
    here
    is
    a
    lengthy
    >>>"""
    L = 'here is a rather lengthy list of words'.split()
    for word in L[:n]:
        print word
```

Running the above function's tests with `doctest.REPORT_UDIFF` specified, you get the following output:

```
*****
File "t.py", line 15, in g
Failed example:
  g(4)
Differences (unified diff with -expected +actual):
  @@ -2,3 +2,3 @@
   is
   a
  -lengthy
  +rather
*****
```

Build and C API Changes

Some of the changes to Python's build process and to the C API are:

- Three new convenience macros were added for common return values from extension functions: `Py_RETURN_NONE`, `Py_RETURN_TRUE`, and `Py_RETURN_FALSE`. (Contributed by Brett Cannon.)
- Another new macro, `Py_CLEAR(obj)`, decreases the reference count of `obj` and sets `obj` to the null pointer. (Contributed by Jim Fulton.)
- A new function, `PyTuple_Pack(N, obj1, obj2, ..., objN())`, constructs tuples from a variable length argument list of Python objects. (Contributed by Raymond Hettinger.)
- A new function, `PyDict_Contains(d, k())`, implements fast dictionary lookups without masking exceptions raised during the look-up process. (Contributed by Raymond Hettinger.)
- The `Py_IS_NAN(x)` macro returns 1 if its float or double argument `X` is a NaN. (Contributed by Tim Peters.)
- C code can avoid unnecessary locking by using the new `PyEval_ThreadsInitialized()` function to tell if any thread operations have been performed. If this function returns false, no lock operations are needed. (Contributed by Nick Coghlan.)
- A new function, `PyArg_VaParseTupleAndKeywords()`, is the same as `PyArg_ParseTupleAndKeywords()` but takes a `va_list` instead of a number of arguments. (Contributed by Greg Chapman.)
- A new method flag, `METH_COEXISTS`, allows a function defined in slots to co-exist with a `PyCFunction` having the same name. This can halve the access time for a method such as `set.__contains__()`. (Contributed by Raymond Hettinger.)
- Python can now be built with additional profiling for the interpreter itself, intended as an aid to people developing the

Python core. Providing `---enable-profiling` to the **configure** script will let you profile the interpreter with **gprof**, and providing the `---with-tsc` switch enables profiling using the Pentium's Time-Stamp-Counter register. Note that the `---with-tsc` switch is slightly misnamed, because the profiling feature also works on the PowerPC platform, though that processor architecture doesn't call that register "the TSC register". (Contributed by Jeremy Hylton.)

- The `tracebackobject` type has been renamed to **PyTracebackObject**.

Port-Specific Changes

- The Windows port now builds under MSVC++ 7.1 as well as version 6. (Contributed by Martin von Löwis.)

Porting to Python 2.4

This section lists previously described changes that may require changes to your code:

- Left shifts and hexadecimal/octal constants that are too large no longer trigger a `FutureWarning` and return a value limited to 32 or 64 bits; instead they return a long integer.
- Integer operations will no longer trigger an `OverflowWarning`. The `OverflowWarning` warning will disappear in Python 2.5.
- The `zip()` built-in function and `itertools.izip()` now return an empty list instead of raising a `TypeError` exception if called with no arguments.
- You can no longer compare the `date` and `datetime` instances provided by the `datetime` module. Two instances of different classes will now always be unequal, and relative comparisons (`<`, `>`) will raise a `TypeError`.
- `dircache.listdir()` now passes exceptions to the caller instead of returning empty lists.
- `LexicalHandler.startDTD()` used to receive the public and system IDs in the wrong order. This has been corrected; applications relying on the wrong order need to be fixed.
- `fcntl.ioctl()` now warns if the *mutate* argument is omitted and relevant.
- The `tarfile` module now generates GNU-format tar files by default.
- Encountering a failure while importing a module no longer leaves a partially- initialized module object in `sys.modules`.
- `None` is now a constant; code that binds a new value to the name `None` is now a syntax error.
- The `signals.signal()` function now raises a `RuntimeError`

exception for certain illegal values; previously these errors would pass silently. For example, you can no longer set a handler on the `SIGKILL` signal.

The author would like to thank the following people for offering suggestions, corrections and assistance with various drafts of this article: Koray Can, Hye- Shik Chang, Michael Dyck, Raymond Hettinger, Brian Hurt, Hamish Lawson, Fredrik Lundh, Sean Reifschneider, Sadruddin Rejeb.

What's New in Python 2.3

Author: A.M. Kuchling

This article explains the new features in Python 2.3. Python 2.3 was released on July 29, 2003.

The main themes for Python 2.3 are polishing some of the features added in 2.2, adding various small but useful enhancements to the core language, and expanding the standard library. The new object model introduced in the previous version has benefited from 18 months of bugfixes and from optimization efforts that have improved the performance of new-style classes. A few new built-in functions have been added such as `sum()` and `enumerate()`. The `in` operator can now be used for substring searches (e.g. `"ab" in "abc"` returns `True`).

Some of the many new library features include Boolean, set, heap, and date/time data types, the ability to import modules from ZIP-format archives, metadata support for the long-awaited Python catalog, an updated version of IDLE, and modules for logging messages, wrapping text, parsing CSV files, processing command-line options, using BerkeleyDB databases... the list of new and enhanced modules is lengthy.

This article doesn't attempt to provide a complete specification of the new features, but instead provides a convenient overview. For full details, you should refer to the documentation for Python 2.3, such as the Python Library Reference and the Python Reference Manual. If you want to understand the complete implementation and design rationale, refer to the PEP for a particular new feature.

PEP 218: A Standard Set Datatype

The new `sets` module contains an implementation of a set datatype. The `set` class is for mutable sets, sets that can have members added and removed. The `ImmutableSet` class is for sets that can't be modified, and instances of `ImmutableSet` can therefore be used as dictionary keys. Sets are built on top of dictionaries, so the elements within a set must be hashable.

Here's a simple example:

```
>>> import sets
>>> S = sets.Set([1,2,3])
>>> S
Set([1, 2, 3])
>>> 1 in S
True
>>> 0 in S
False
>>> S.add(5)
>>> S.remove(3)
>>> S
Set([1, 2, 5])
>>>
```

The union and intersection of sets can be computed with the `union()` and `intersection()` methods; an alternative notation uses the bitwise operators `&` and `|`. Mutable sets also have in-place versions of these methods, `union_update()` and `intersection_update()`.

```
>>> S1 = sets.Set([1,2,3])
>>> S2 = sets.Set([4,5,6])
>>> S1.union(S2)
Set([1, 2, 3, 4, 5, 6])
>>> S1 | S2                                     # Alternative notation
Set([1, 2, 3, 4, 5, 6])
>>> S1.intersection(S2)
Set([])
```

```
>>> S1 & S2                                # Alternative notation
Set([])
>>> S1.union_update(S2)
>>> S1
Set([1, 2, 3, 4, 5, 6])
>>>
```

It's also possible to take the symmetric difference of two sets. This is the set of all elements in the union that aren't in the intersection. Another way of putting it is that the symmetric difference contains all elements that are in exactly one set. Again, there's an alternative notation (\wedge), and an in-place version with the ungainly name `symmetric_difference_update()`.

```
>>> S1 = sets.Set([1,2,3,4])
>>> S2 = sets.Set([3,4,5,6])
>>> S1.symmetric_difference(S2)
Set([1, 2, 5, 6])
>>> S1 ^ S2
Set([1, 2, 5, 6])
>>>
```

There are also `issubset()` and `issuperset()` methods for checking whether one set is a subset or superset of another:

```
>>> S1 = sets.Set([1,2,3])
>>> S2 = sets.Set([2,3])
>>> S2.issubset(S1)
True
>>> S1.issubset(S2)
False
>>> S1.issuperset(S2)
True
>>>
```

PEP 218 - Adding a Built-In Set Object Type

PEP written by Greg V. Wilson. Implemented by Greg V. Wilson, Alex Martelli, and GvR.

PEP 255: Simple Generators

In Python 2.2, generators were added as an optional feature, to be enabled by a `from __future__ import generators` directive. In 2.3 generators no longer need to be specially enabled, and are now always present; this means that `yield` is now always a keyword. The rest of this section is a copy of the description of generators from the “What’s New in Python 2.2” document; if you read it back when Python 2.2 came out, you can skip the rest of this section.

You’re doubtless familiar with how function calls work in Python or C. When you call a function, it gets a private namespace where its local variables are created. When the function reaches a `return` statement, the local variables are destroyed and the resulting value is returned to the caller. A later call to the same function will get a fresh new set of local variables. But, what if the local variables weren’t thrown away on exiting a function? What if you could later resume the function where it left off? This is what generators provide; they can be thought of as resumable functions.

Here’s the simplest example of a generator function:

```
def generate_ints(N):  
    for i in range(N):  
        yield i
```

A new keyword, `yield`, was introduced for generators. Any function containing a `yield` statement is a generator function; this is detected by Python’s bytecode compiler which compiles the function specially as a result.

When you call a generator function, it doesn’t return a single value; instead it returns a generator object that supports the iterator protocol. On executing the `yield` statement, the generator outputs

the value of `i`, similar to a `return` statement. The big difference between `yield` and a `return` statement is that on reaching a `yield` the generator's state of execution is suspended and local variables are preserved. On the next call to the generator's `.next()` method, the function will resume executing immediately after the `yield` statement. (For complicated reasons, the `yield` statement isn't allowed inside the `try` block of a `try...finally` statement; read [PEP 255](#) for a full explanation of the interaction between `yield` and exceptions.)

Here's a sample usage of the `generate_ints()` generator:

```
>>> gen = generate_ints(3)
>>> gen
<generator object at 0x8117f90>
>>> gen.next()
0
>>> gen.next()
1
>>> gen.next()
2
>>> gen.next()
Traceback (most recent call last):
  File "stdin", line 1, in ?
  File "stdin", line 2, in generate_ints
StopIteration
```

You could equally write `for i in generate_ints(5)`, or `a,b,c = generate_ints(3)`.

Inside a generator function, the `return` statement can only be used without a value, and signals the end of the procession of values; afterwards the generator cannot return any further values. `return` with a value, such as `return 5`, is a syntax error inside a generator function. The end of the generator's results can also be indicated by raising `StopIteration` manually, or by just letting the flow of execution fall off the bottom of the function.

You could achieve the effect of generators manually by writing your own class and storing all the local variables of the generator as instance variables. For example, returning a list of integers could be done by setting `self.count` to 0, and having the `next()` method increment `self.count` and return it. However, for a moderately complicated generator, writing a corresponding class would be much messier. `Lib/test/test_generators.py` contains a number of more interesting examples. The simplest one implements an in-order traversal of a tree using generators recursively.

```
# A recursive generator that generates Tree leaves in in-order.
def inorder(t):
    if t:
        for x in inorder(t.left):
            yield x
        yield t.label
        for x in inorder(t.right):
            yield x
```

Two other examples in `Lib/test/test_generators.py` produce solutions for the N-Queens problem (placing N queens on an $N \times N$ chess board so that no queen threatens another) and the Knight's Tour (a route that takes a knight to every square of an $N \times N$ chessboard without visiting any square twice).

The idea of generators comes from other programming languages, especially Icon (<http://www.cs.arizona.edu/icon/>), where the idea of generators is central. In Icon, every expression and function call behaves like a generator. One example from "An Overview of the Icon Programming Language" at <http://www.cs.arizona.edu/icon/docs/ipd266.htm> gives an idea of what this looks like:

```
sentence := "Store it in the neighboring harbor"
if (i := find("or", sentence)) > 5 then write(i)
```

In Icon the `find()` function returns the indexes at which the substring “or” is found: 3, 23, 33. In the `if` statement, `i` is first assigned a value of 3, but 3 is less than 5, so the comparison fails, and Icon retries it with the second value of 23. 23 is greater than 5, so the comparison now succeeds, and the code prints the value 23 to the screen.

Python doesn't go nearly as far as Icon in adopting generators as a central concept. Generators are considered part of the core Python language, but learning or using them isn't compulsory; if they don't solve any problems that you have, feel free to ignore them. One novel feature of Python's interface as compared to Icon's is that a generator's state is represented as a concrete object (the iterator) that can be passed around to other functions or stored in a data structure.

PEP 255 - Simple Generators

Written by Neil Schemenauer, Tim Peters, Magnus Lie Hetland. Implemented mostly by Neil Schemenauer and Tim Peters, with other fixes from the Python Labs crew.

PEP 263: Source Code Encodings

Python source files can now be declared as being in different character set encodings. Encodings are declared by including a specially formatted comment in the first or second line of the source file. For example, a UTF-8 file can be declared with:

```
#!/usr/bin/env python
# -*- coding: UTF-8 -*-
```

Without such an encoding declaration, the default encoding used is 7-bit ASCII. Executing or importing modules that contain string literals with 8-bit characters and have no encoding declaration will result in a **DeprecationWarning** being signalled by Python 2.3; in 2.4 this will be a syntax error.

The encoding declaration only affects Unicode string literals, which will be converted to Unicode using the specified encoding. Note that Python identifiers are still restricted to ASCII characters, so you can't have variable names that use characters outside of the usual alphanumerics.

See also:

PEP 263 - Defining Python Source Code Encodings

Written by Marc-André Lemburg and Martin von Löwis;
implemented by Suzuki Hisao and Martin von Löwis.

PEP 273: Importing Modules from ZIP Archives

The new `zipimport` module adds support for importing modules from a ZIP-format archive. You don't need to import the module explicitly; it will be automatically imported if a ZIP archive's filename is added to `sys.path`. For example:

```
amk@nyman:~/src/python$ unzip -l /tmp/example.zip
Archive:  /tmp/example.zip
 Length   Date    Time    Name
-----
  8467   11-26-02  22:30   jwzthreading.py
-----
  8467                               1 file
amk@nyman:~/src/python$ ./python
Python 2.3 (#1, Aug 1 2003, 19:54:32)
>>> import sys
>>> sys.path.insert(0, '/tmp/example.zip') # Add .zip file to
>>> import jwzthreading
>>> jwzthreading.__file__
'/tmp/example.zip/jwzthreading.py'
>>>
```

An entry in `sys.path` can now be the filename of a ZIP archive. The ZIP archive can contain any kind of files, but only files named `*.py`, `*.pyc`, or `*.pyo` can be imported. If an archive only contains `*.py` files, Python will not attempt to modify the archive by adding the corresponding `*.pyc` file, meaning that if a ZIP archive doesn't contain `*.pyc` files, importing may be rather slow.

A path within the archive can also be specified to only import from a subdirectory; for example, the path `/tmp/example.zip/lib/` would only import from the `lib/` subdirectory within the archive.

See also:

PEP 273 - Import Modules from Zip Archives

Written by James C. Ahlstrom, who also provided an implementation. Python 2.3 follows the specification in **PEP 273**, but uses an implementation written by Just van Rossum that uses the import hooks described in **PEP 302**. See section *PEP 302: New Import Hooks* for a description of the new import hooks.

PEP 277: Unicode file name support for Windows NT

On Windows NT, 2000, and XP, the system stores file names as Unicode strings. Traditionally, Python has represented file names as byte strings, which is inadequate because it renders some file names inaccessible.

Python now allows using arbitrary Unicode strings (within the limitations of the file system) for all functions that expect file names, most notably the `open()` built-in function. If a Unicode string is passed to `os.listdir()`, Python now returns a list of Unicode strings. A new function, `os.getcwdu()`, returns the current directory as a Unicode string.

Byte strings still work as file names, and on Windows Python will transparently convert them to Unicode using the `mbcs` encoding.

Other systems also allow Unicode strings as file names but convert them to byte strings before passing them to the system, which can cause a `UnicodeError` to be raised. Applications can test whether arbitrary Unicode strings are supported as file names by checking `os.path.supports_unicode_filenames`, a Boolean value.

Under MacOS, `os.listdir()` may now return Unicode filenames.

See also:

PEP 277 - Unicode file name support for Windows NT

Written by Neil Hodgson; implemented by Neil Hodgson, Martin von Löwis, and Mark Hammond.

PEP 278: Universal Newline Support

The three major operating systems used today are Microsoft Windows, Apple's Macintosh OS, and the various Unix derivatives. A minor irritation of cross-platform work is that these three platforms all use different characters to mark the ends of lines in text files. Unix uses the linefeed (ASCII character 10), MacOS uses the carriage return (ASCII character 13), and Windows uses a two-character sequence of a carriage return plus a newline.

Python's file objects can now support end of line conventions other than the one followed by the platform on which Python is running. Opening a file with the mode `'u'` or `'rU'` will open a file for reading in universal newline mode. All three line ending conventions will be translated to a `'\n'` in the strings returned by the various file methods such as `read()` and `readline()`.

Universal newline support is also used when importing modules and when executing a file with the `execfile()` function. This means that Python modules can be shared between all three operating systems without needing to convert the line-endings.

This feature can be disabled when compiling Python by specifying the `--without-universal-newlines` switch when running Python's **configure** script.

See also:

PEP 278 - Universal Newline Support

Written and implemented by Jack Jansen.

PEP 279: enumerate()

A new built-in function, `enumerate()`, will make certain loops a bit clearer. `enumerate(thing)`, where *thing* is either an iterator or a sequence, returns an iterator that will return `(0, thing[0])`, `(1, thing[1])`, `(2, thing[2])`, and so forth.

A common idiom to change every element of a list looks like this:

```
for i in range(len(L)):
    item = L[i]
    # ... compute some result based on item ...
    L[i] = result
```

This can be rewritten using `enumerate()` as:

```
for i, item in enumerate(L):
    # ... compute some result based on item ...
    L[i] = result
```

See also:

PEP 279 - The enumerate() built-in function

Written and implemented by Raymond D. Hettinger.

PEP 282: The logging Package

A standard package for writing logs, `logging`, has been added to Python 2.3. It provides a powerful and flexible mechanism for generating logging output which can then be filtered and processed in various ways. A configuration file written in a standard format can be used to control the logging behavior of a program. Python includes handlers that will write log records to standard error or to a file or socket, send them to the system log, or even e-mail them to a particular address; of course, it's also possible to write your own handler classes.

The `Logger` class is the primary class. Most application code will deal with one or more `Logger` objects, each one used by a particular subsystem of the application. Each `Logger` is identified by a name, and names are organized into a hierarchy using `.` as the component separator. For example, you might have `Logger` instances named `server`, `server.auth` and `server.network`. The latter two instances are below `server` in the hierarchy. This means that if you turn up the verbosity for `server` or direct `server` messages to a different handler, the changes will also apply to records logged to `server.auth` and `server.network`. There's also a root `Logger` that's the parent of all other loggers.

For simple uses, the `logging` package contains some convenience functions that always use the root log:

```
import logging

logging.debug('Debugging information')
logging.info('Informational message')
logging.warning('Warning:config file %s not found', 'server.con
logging.error('Error occurred')
logging.critical('Critical error -- shutting down')
```

This produces the following output:

```
WARNING:root:Warning:config file server.conf not found
ERROR:root:Error occurred
CRITICAL:root:Critical error -- shutting down
```

In the default configuration, informational and debugging messages are suppressed and the output is sent to standard error. You can enable the display of informational and debugging messages by calling the `setLevel()` method on the root logger.

Notice the `warning()` call's use of string formatting operators; all of the functions for logging messages take the arguments `(msg, arg1, arg2, ...)` and log the string resulting from `msg % (arg1, arg2, ...)`.

There's also an `exception()` function that records the most recent traceback. Any of the other functions will also record the traceback if you specify a true value for the keyword argument `exc_info`.

```
def f():
    try:    1/0
    except: logging.exception('Problem recorded')

f()
```

This produces the following output:

```
ERROR:root:Problem recorded
Traceback (most recent call last):
  File "t.py", line 6, in f
    1/0
ZeroDivisionError: integer division or modulo by zero
```

Slightly more advanced programs will use a logger other than the root logger. The `getLogger(name)()` function is used to get a

particular log, creating it if it doesn't exist yet. `getLogger(None)()` returns the root logger.

```
log = logging.getLogger('server')
...
log.info('Listening on port %i', port)
...
log.critical('Disk full')
...
```

Log records are usually propagated up the hierarchy, so a message logged to `server.auth` is also seen by `server` and `root`, but a `Logger` can prevent this by setting its `propagate` attribute to `False`.

There are more classes provided by the `logging` package that can be customized. When a `Logger` instance is told to log a message, it creates a `LogRecord` instance that is sent to any number of different `Handler` instances. Loggers and handlers can also have an attached list of filters, and each filter can cause the `LogRecord` to be ignored or can modify the record before passing it along. When they're finally output, `LogRecord` instances are converted to text by a `Formatter` class. All of these classes can be replaced by your own specially-written classes.

With all of these features the `logging` package should provide enough flexibility for even the most complicated applications. This is only an incomplete overview of its features, so please see the package's reference documentation for all of the details. Reading [PEP 282](#) will also be helpful.

See also:

[PEP 282 - A Logging System](#)

Written by Vinay Sajip and Trent Mick; implemented by Vinay Sajip.

PEP 285: A Boolean Type

A Boolean type was added to Python 2.3. Two new constants were added to the `__builtin__` module, `True` and `False`. (`True` and `False` constants were added to the built-ins in Python 2.2.1, but the 2.2.1 versions are simply set to integer values of 1 and 0 and aren't a different type.)

The type object for this new type is named `bool`; the constructor for it takes any Python value and converts it to `True` or `False`.

```
>>> bool(1)
True
>>> bool(0)
False
>>> bool([])
False
>>> bool( (1, ) )
True
```

Most of the standard library modules and built-in functions have been changed to return Booleans.

```
>>> obj = []
>>> hasattr(obj, 'append')
True
>>> isinstance(obj, list)
True
>>> isinstance(obj, tuple)
False
```

Python's Booleans were added with the primary goal of making code clearer. For example, if you're reading a function and encounter the statement `return 1`, you might wonder whether the `1` represents a Boolean truth value, an index, or a coefficient that multiplies some other quantity. If the statement is `return True`, however, the meaning of the return value is quite clear.

Python's Booleans were *not* added for the sake of strict type-checking. A very strict language such as Pascal would also prevent you performing arithmetic with Booleans, and would require that the expression in an `if` statement always evaluate to a Boolean result. Python is not this strict and never will be, as [PEP 285](#) explicitly says. This means you can still use any expression in an `if` statement, even ones that evaluate to a list or tuple or some random object. The Boolean type is a subclass of the `int` class so that arithmetic using a Boolean still works.

```
>>> True + 1
2
>>> False + 1
1
>>> False * 75
0
>>> True * 75
75
```

To sum up `True` and `False` in a sentence: they're alternative ways to spell the integer values 1 and 0, with the single difference that `str()` and `repr()` return the strings `'True'` and `'False'` instead of `'1'` and `'0'`.

[PEP 285 - Adding a bool type](#)

Written and implemented by GvR.

PEP 293: Codec Error Handling Callbacks

When encoding a Unicode string into a byte string, unencodable characters may be encountered. So far, Python has allowed specifying the error processing as either “strict” (raising `UnicodeError`), “ignore” (skipping the character), or “replace” (using a question mark in the output string), with “strict” being the default behavior. It may be desirable to specify alternative processing of such errors, such as inserting an XML character reference or HTML entity reference into the converted string.

Python now has a flexible framework to add different processing strategies. New error handlers can be added with `codecs.register_error()`, and codecs then can access the error handler with `codecs.lookup_error()`. An equivalent C API has been added for codecs written in C. The error handler gets the necessary state information such as the string being converted, the position in the string where the error was detected, and the target encoding. The handler can then either raise an exception or return a replacement string.

Two additional error handlers have been implemented using this framework: “backslashreplace” uses Python backslash quoting to represent unencodable characters and “xmlcharrefreplace” emits XML character references.

See also:

PEP 293 - Codec Error Handling Callbacks

Written and implemented by Walter Dörwald.

PEP 301: Package Index and Metadata for Distutils

Support for the long-requested Python catalog makes its first appearance in 2.3.

The heart of the catalog is the new Distutils **register** command. Running `python setup.py register` will collect the metadata describing a package, such as its name, version, maintainer, description, &c., and send it to a central catalog server. The resulting catalog is available from <http://www.python.org/pypi>.

To make the catalog a bit more useful, a new optional *classifiers* keyword argument has been added to the Distutils `setup()` function. A list of [Trove](#)-style strings can be supplied to help classify the software.

Here's an example `setup.py` with classifiers, written to be compatible with older versions of the Distutils:

```
from distutils import core
kw = {'name': "Quixote",
      'version': "0.5.1",
      'description': "A highly Pythonic Web application framewo
      # ...
      }

if (hasattr(core, 'setup_keywords') and
    'classifiers' in core.setup_keywords):
    kw['classifiers'] = \
        ['Topic :: Internet :: WWW/HTTP :: Dynamic Content',
         'Environment :: No Input/Output (Daemon)',
         'Intended Audience :: Developers'],

core.setup(**kw)
```

The full list of classifiers can be obtained by running `python setup.py register --list-classifiers`.

PEP 301 - Package Index and Metadata for Distutils

Written and implemented by Richard Jones.

PEP 302: New Import Hooks

While it's been possible to write custom import hooks ever since the `ihooks` module was introduced in Python 1.3, no one has ever been really happy with it because writing new import hooks is difficult and messy. There have been various proposed alternatives such as the `imputil` and `iu` modules, but none of them has ever gained much acceptance, and none of them were easily usable from C code.

PEP 302 borrows ideas from its predecessors, especially from Gordon McMillan's `iu` module. Three new items are added to the `sys` module:

- `sys.path_hooks` is a list of callable objects; most often they'll be classes. Each callable takes a string containing a path and either returns an importer object that will handle imports from this path or raises an `ImportError` exception if it can't handle this path.
- `sys.path_importer_cache` caches importer objects for each path, so `sys.path_hooks` will only need to be traversed once for each path.
- `sys.meta_path` is a list of importer objects that will be traversed before `sys.path` is checked. This list is initially empty, but user code can add objects to it. Additional built-in and frozen modules can be imported by an object added to this list.

Importer objects must have a single method, `find_module(fullname, path=None)()`. *fullname* will be a module or package name, e.g. `string` or `distutils.core`. `find_module()` must return a loader object that has a single method, `load_module(fullname)()`, that creates and returns the corresponding module object.

Pseudo-code for Python's new import logic, therefore, looks something like this (simplified a bit; see [PEP 302](#) for the full details):

```
for mp in sys.meta_path:
    loader = mp(fullname)
    if loader is not None:
        <module> = loader.load_module(fullname)

for path in sys.path:
    for hook in sys.path_hooks:
        try:
            importer = hook(path)
        except ImportError:
            # ImportError, so try the other path hooks
            pass
        else:
            loader = importer.find_module(fullname)
            <module> = loader.load_module(fullname)

# Not found!
raise ImportError
```

PEP 302 - New Import Hooks

Written by Just van Rossum and Paul Moore. Implemented by Just van Rossum.

PEP 305: Comma-separated Files

Comma-separated files are a format frequently used for exporting data from databases and spreadsheets. Python 2.3 adds a parser for comma-separated files.

Comma-separated format is deceptively simple at first glance:

```
Costs,150,200,3.95
```

Read a line and call `line.split(',')`: what could be simpler? But toss in string data that can contain commas, and things get more complicated:

```
"Costs",150,200,3.95,"Includes taxes, shipping, and sundry item
```

A big ugly regular expression can parse this, but using the new `csv` package is much simpler:

```
import csv

input = open('datafile', 'rb')
reader = csv.reader(input)
for line in reader:
    print line
```

The `reader()` function takes a number of different options. The field separator isn't limited to the comma and can be changed to any character, and so can the quoting and line-ending characters.

Different dialects of comma-separated files can be defined and registered; currently there are two dialects, both used by Microsoft Excel. A separate `csv.writer` class will generate comma-separated files from a succession of tuples or lists, quoting strings that contain

the delimiter.

PEP 305 - CSV File API

Written and implemented by Kevin Altis, Dave Cole, Andrew McNamara, Skip Montanaro, Cliff Wells.

PEP 307: Pickle Enhancements

The `pickle` and `cPickle` modules received some attention during the 2.3 development cycle. In 2.2, new-style classes could be pickled without difficulty, but they weren't pickled very compactly; **PEP 307** quotes a trivial example where a new-style class results in a pickled string three times longer than that for a classic class.

The solution was to invent a new pickle protocol. The `pickle.dumps()` function has supported a text-or-binary flag for a long time. In 2.3, this flag is redefined from a Boolean to an integer: 0 is the old text-mode pickle format, 1 is the old binary format, and now 2 is a new 2.3-specific format. A new constant, `pickle.HIGHEST_PROTOCOL`, can be used to select the fanciest protocol available.

Unpickling is no longer considered a safe operation. 2.2's `pickle` provided hooks for trying to prevent unsafe classes from being unpickled (specifically, a `__safe_for_unpickling__` attribute), but none of this code was ever audited and therefore it's all been ripped out in 2.3. You should not unpickle untrusted data in any version of Python.

To reduce the pickling overhead for new-style classes, a new interface for customizing pickling was added using three special methods: `__getstate__()`, `__setstate__()`, and `__getnewargs__()`. Consult **PEP 307** for the full semantics of these methods.

As a way to compress pickles yet further, it's now possible to use integer codes instead of long strings to identify pickled classes. The Python Software Foundation will maintain a list of standardized codes; there's also a range of codes for private use. Currently no codes have been specified.

PEP 307 - Extensions to the pickle protocol

Written and implemented by Guido van Rossum and Tim Peters.

Extended Slices

Ever since Python 1.4, the slicing syntax has supported an optional third “step” or “stride” argument. For example, these are all legal Python syntax: `L[1:10:2]`, `L[:-1:1]`, `L[::-1]`. This was added to Python at the request of the developers of Numerical Python, which uses the third argument extensively. However, Python’s built-in list, tuple, and string sequence types have never supported this feature, raising a `TypeError` if you tried it. Michael Hudson contributed a patch to fix this shortcoming.

For example, you can now easily extract the elements of a list that have even indexes:

```
>>> L = range(10)
>>> L[::2]
[0, 2, 4, 6, 8]
```

Negative values also work to make a copy of the same list in reverse order:

```
>>> L[::-1]
[9, 8, 7, 6, 5, 4, 3, 2, 1, 0]
```

This also works for tuples, arrays, and strings:

```
>>> s='abcd'
>>> s[::2]
'ac'
>>> s[::-1]
'dcba'
```

If you have a mutable sequence such as a list or an array you can assign to or delete an extended slice, but there are some differences between assignment to extended and regular slices. Assignment to a regular slice can be used to change the length of the sequence:

```
>>> a = range(3)
>>> a
[0, 1, 2]
>>> a[1:3] = [4, 5, 6]
>>> a
[0, 4, 5, 6]
```

Extended slices aren't this flexible. When assigning to an extended slice, the list on the right hand side of the statement must contain the same number of items as the slice it is replacing:

```
>>> a = range(4)
>>> a
[0, 1, 2, 3]
>>> a[::2]
[0, 2]
>>> a[::2] = [0, -1]
>>> a
[0, 1, -1, 3]
>>> a[::2] = [0,1,2]
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
ValueError: attempt to assign sequence of size 3 to extended slice
```

Deletion is more straightforward:

```
>>> a = range(4)
>>> a
[0, 1, 2, 3]
>>> a[::2]
[0, 2]
>>> del a[::2]
>>> a
[1, 3]
```

One can also now pass slice objects to the `__getitem__()` methods of the built-in sequences:

```
>>> range(10).__getitem__(slice(0, 5, 2))
[0, 2, 4]
```

Or use slice objects directly in subscripts:

```
>>> range(10)[slice(0, 5, 2)]  
[0, 2, 4]
```

To simplify implementing sequences that support extended slicing, slice objects now have a method `indices(length)()` which, given the length of a sequence, returns a `(start, stop, step)` tuple that can be passed directly to `range()`. `indices()` handles omitted and out-of-bounds indices in a manner consistent with regular slices (and this innocuous phrase hides a welter of confusing details!). The method is intended to be used like this:

```
class FakeSeq:  
    ...  
    def calc_item(self, i):  
        ...  
    def __getitem__(self, item):  
        if isinstance(item, slice):  
            indices = item.indices(len(self))  
            return FakeSeq([self.calc_item(i) for i in range(*i  
        else:  
            return self.calc_item(i)
```

From this example you can also see that the built-in `slice` object is now the type object for the slice type, and is no longer a function. This is consistent with Python 2.2, where `int`, `str`, etc., underwent the same change.

Other Language Changes

Here are all of the changes that Python 2.3 makes to the core Python language.

- The `yield` statement is now always a keyword, as described in section *PEP 255: Simple Generators* of this document.
- A new built-in function `enumerate()` was added, as described in section *PEP 279: enumerate()* of this document.
- Two new constants, `True` and `False` were added along with the built-in `bool` type, as described in section *PEP 285: A Boolean Type* of this document.
- The `int()` type constructor will now return a long integer instead of raising an `OverflowError` when a string or floating-point number is too large to fit into an integer. This can lead to the paradoxical result that `isinstance(int(expression), int)` is false, but that seems unlikely to cause problems in practice.
- Built-in types now support the extended slicing syntax, as described in section *Extended Slices* of this document.
- A new built-in function, `sum(iterable, start=0)()`, adds up the numeric items in the iterable object and returns their sum. `sum()` only accepts numbers, meaning that you can't use it to concatenate a bunch of strings. (Contributed by Alex Martelli.)
- `list.insert(pos, value)` used to insert `value` at the front of the list when `pos` was negative. The behaviour has now been changed to be consistent with slice indexing, so when `pos` is `-1` the value will be inserted before the last element, and so forth.

- `list.index(value)`, which searches for *value* within the list and returns its index, now takes optional *start* and *stop* arguments to limit the search to only part of the list.
- Dictionaries have a new method, `pop(key[, *default*])()`, that returns the value corresponding to *key* and removes that key/value pair from the dictionary. If the requested key isn't present in the dictionary, *default* is returned if it's specified and `KeyError` raised if it isn't.

```

>>> d = {1:2}
>>> d
{1: 2}
>>> d.pop(4)
Traceback (most recent call last):
  File "stdin", line 1, in ?
KeyError: 4
>>> d.pop(1)
2
>>> d.pop(1)
Traceback (most recent call last):
  File "stdin", line 1, in ?
KeyError: 'pop(): dictionary is empty'
>>> d
{}
>>>

```

There's also a new class method, `dict.fromkeys(iterable, value)()`, that creates a dictionary with keys taken from the supplied iterator *iterable* and all values set to *value*, defaulting to `None`.

(Patches contributed by Raymond Hettinger.)

Also, the `dict()` constructor now accepts keyword arguments to simplify creating small dictionaries:

```

>>> dict(red=1, blue=2, green=3, black=4)
{'blue': 2, 'black': 4, 'green': 3, 'red': 1}

```

(Contributed by Just van Rossum.)

- The `assert` statement no longer checks the `__debug__` flag, so you can no longer disable assertions by assigning to `__debug__`. Running Python with the `-O` switch will still generate code that doesn't execute any assertions.
- Most type objects are now callable, so you can use them to create new objects such as functions, classes, and modules. (This means that the `new` module can be deprecated in a future Python version, because you can now use the type objects available in the `types` module.) For example, you can create a new module object with the following code:

```
>>> import types
>>> m = types.ModuleType('abc', 'docstring')
>>> m
<module 'abc' (built-in)>
>>> m.__doc__
'docstring'
```

- A new warning, `PendingDeprecationWarning` was added to indicate features which are in the process of being deprecated. The warning will *not* be printed by default. To check for use of features that will be deprecated in the future, supply `-Wallways::PendingDeprecationWarning::` on the command line or use `warnings.filterwarnings()`.
- The process of deprecating string-based exceptions, as in `raise "Error occurred"`, has begun. Raising a string will now trigger `PendingDeprecationWarning`.
- Using `None` as a variable name will now result in a `SyntaxWarning` warning. In a future version of Python, `None` may finally become a keyword.

- The `xreadlines()` method of file objects, introduced in Python 2.1, is no longer necessary because files now behave as their own iterator. `xreadlines()` was originally introduced as a faster way to loop over all the lines in a file, but now you can simply write `for line in file_obj`. File objects also have a new read-only `encoding` attribute that gives the encoding used by the file; Unicode strings written to the file will be automatically converted to bytes using the given encoding.
- The method resolution order used by new-style classes has changed, though you'll only notice the difference if you have a really complicated inheritance hierarchy. Classic classes are unaffected by this change. Python 2.2 originally used a topological sort of a class's ancestors, but 2.3 now uses the C3 algorithm as described in the paper "[A Monotonic Superclass Linearization for Dylan](#)". To understand the motivation for this change, read Michele Simionato's article "[Python 2.3 Method Resolution Order](#)", or read the thread on python-dev starting with the message at <http://mail.python.org/pipermail/python-dev/2002-October/029035.html>. Samuele Pedroni first pointed out the problem and also implemented the fix by coding the C3 algorithm.
- Python runs multithreaded programs by switching between threads after executing N bytecodes. The default value for N has been increased from 10 to 100 bytecodes, speeding up single-threaded applications by reducing the switching overhead. Some multithreaded applications may suffer slower response time, but that's easily fixed by setting the limit back to a lower number using `sys.setcheckinterval(N)`. The limit can be retrieved with the new `sys.getcheckinterval()` function.
- One minor but far-reaching change is that the names of extension types defined by the modules included with Python

now contain the module and a `'.'` in front of the type name. For example, in Python 2.2, if you created a socket and printed its `__class__`, you'd get this output:

```
>>> s = socket.socket()
>>> s.__class__
<type 'socket'>
```

In 2.3, you get this:

```
>>> s.__class__
<type '_socket.socket'>
```

- One of the noted incompatibilities between old- and new-style classes has been removed: you can now assign to the `__name__` and `__bases__` attributes of new-style classes. There are some restrictions on what can be assigned to `__bases__` along the lines of those relating to assigning to an instance's `__class__` attribute.

String Changes

- The `in` operator now works differently for strings. Previously, when evaluating `x in Y` where `X` and `Y` are strings, `X` could only be a single character. That's now changed; `X` can be a string of any length, and `x in Y` will return `True` if `X` is a substring of `Y`. If `X` is the empty string, the result is always `True`.

```
>>> 'ab' in 'abcd'
True
>>> 'ad' in 'abcd'
False
>>> '' in 'abcd'
True
```

Note that this doesn't tell you where the substring starts; if you

need that information, use the `find()` string method.

- The `strip()`, `lstrip()`, and `rstrip()` string methods now have an optional argument for specifying the characters to strip. The default is still to remove all whitespace characters:

```
>>> '  abc '.strip()
'abc'
>>> '><<abc<><><>'.strip('<>')
'abc'
>>> '><<abc<><><>\n'.strip('<>')
'abc<><><>\n'
>>> u'\u4000\u4001abc\u4000'.strip(u'\u4000')
u'\u4001abc'
>>>
```

(Suggested by Simon Brunning and implemented by Walter Dörwald.)

- The `startswith()` and `endswith()` string methods now accept negative numbers for the *start* and *end* parameters.
- Another new string method is `zfill()`, originally a function in the `string` module. `zfill()` pads a numeric string with zeros on the left until it's the specified width. Note that the `%` operator is still more flexible and powerful than `zfill()`.

```
>>> '45'.zfill(4)
'0045'
>>> '12345'.zfill(4)
'12345'
>>> 'goofy'.zfill(6)
'0goofy'
```

(Contributed by Walter Dörwald.)

- A new type object, `basestring`, has been added. Both 8-bit strings and Unicode strings inherit from this type, so

`isinstance(obj, basestring)` will return **True** for either kind of string. It's a completely abstract type, so you can't create `basestring` instances.

- Interned strings are no longer immortal and will now be garbage-collected in the usual way when the only reference to them is from the internal dictionary of interned strings. (Implemented by Oren Tirosh.)

Optimizations

- The creation of new-style class instances has been made much faster; they're now faster than classic classes!
- The `sort()` method of list objects has been extensively rewritten by Tim Peters, and the implementation is significantly faster.
- Multiplication of large long integers is now much faster thanks to an implementation of Karatsuba multiplication, an algorithm that scales better than the $O(n*n)$ required for the grade-school multiplication algorithm. (Original patch by Christopher A. Craig, and significantly reworked by Tim Peters.)
- The `SET_LINENO` opcode is now gone. This may provide a small speed increase, depending on your compiler's idiosyncrasies. See section *Other Changes and Fixes* for a longer explanation. (Removed by Michael Hudson.)
- `xrange()` objects now have their own iterator, making `for i in xrange(n)` slightly faster than `for i in range(n)`. (Patch by Raymond Hettinger.)
- A number of small rearrangements have been made in various hotspots to improve performance, such as inlining a function or removing some code. (Implemented mostly by GvR, but lots of people have contributed single changes.)

The net result of the 2.3 optimizations is that Python 2.3 runs the pystone benchmark around 25% faster than Python 2.2.

New, Improved, and Deprecated Modules

As usual, Python's standard library received a number of enhancements and bug fixes. Here's a partial list of the most notable changes, sorted alphabetically by module name. Consult the `Misc/NEWS` file in the source tree for a more complete list of changes, or look through the CVS logs for all the details.

- The `array` module now supports arrays of Unicode characters using the `'u'` format character. Arrays also now support using the `+=` assignment operator to add another array's contents, and the `*=` assignment operator to repeat an array. (Contributed by Jason Orendorff.)
- The `bsddb` module has been replaced by version 4.1.6 of the `PyBSDDB` package, providing a more complete interface to the transactional features of the BerkeleyDB library.

The old version of the module has been renamed to `bsddb185` and is no longer built automatically; you'll have to edit `Modules/Setup` to enable it. Note that the new `bsddb` package is intended to be compatible with the old module, so be sure to file bugs if you discover any incompatibilities. When upgrading to Python 2.3, if the new interpreter is compiled with a new version of the underlying BerkeleyDB library, you will almost certainly have to convert your database files to the new version. You can do this fairly easily with the new scripts `db2pickle.py` and `pickle2db.py` which you will find in the distribution's `Tools/scripts` directory. If you've already been using the `PyBSDDB` package and importing it as `bsddb3`, you will have to change your `import` statements to import it as `bsddb`.

- The new `bz2` module is an interface to the bz2 data compression library. bz2-compressed data is usually smaller than corresponding `zlib`-compressed data. (Contributed by Gustavo Niemeyer.)
- A set of standard date/time types has been added in the new `datetime` module. See the following section for more details.
- The Distutils `Extension` class now supports an extra constructor argument named *depends* for listing additional source files that an extension depends on. This lets Distutils recompile the module if any of the dependency files are modified. For example, if `sampmodule.c` includes the header file `sample.h`, you would create the `Extension` object like this:

```
ext = Extension("samp",
                sources=["sampmodule.c"],
                depends=["sample.h"])
```

Modifying `sample.h` would then cause the module to be recompiled. (Contributed by Jeremy Hylton.)

- Other minor changes to Distutils: it now checks for the `CC`, `CFLAGS`, `CPP`, `LDFLAGS`, and `CPPFLAGS` environment variables, using them to override the settings in Python's configuration (contributed by Robert Weber).
- Previously the `doctest` module would only search the docstrings of public methods and functions for test cases, but it now also examines private ones as well. The `DocTestSuite()` function creates a `unittest.TestSuite` object from a set of `doctest` tests.
- The new `gc.get_referents(object)()` function returns a list of all the objects referenced by *object*.

- The `getopt` module gained a new function, `gnu_getopt()`, that supports the same arguments as the existing `getopt()` function but uses GNU-style scanning mode. The existing `getopt()` stops processing options as soon as a non-option argument is encountered, but in GNU-style mode processing continues, meaning that options and arguments can be mixed. For example:

```
>>> getopt.getopt(['-f', 'filename', 'output', '-v'], 'f:v'  
                (['-f', 'filename'], ['output', '-v']))  
>>> getopt.gnu_getopt(['-f', 'filename', 'output', '-v'], '  
                (['-f', 'filename'], ('-v', '')), ['output'])
```

(Contributed by Peter Åstrand.)

- The `grp`, `pwd`, and `resource` modules now return enhanced tuples:

```
>>> import grp  
>>> g = grp.getgrnam('amk')  
>>> g.gr_name, g.gr_gid  
( 'amk', 500)
```

- The `gzip` module can now handle files exceeding 2 GiB.
- The new `heapq` module contains an implementation of a heap queue algorithm. A heap is an array-like data structure that keeps items in a partially sorted order such that, for every index k , `heap[k] <= heap[2*k+1]` and `heap[k] <= heap[2*k+2]`. This makes it quick to remove the smallest item, and inserting a new item while maintaining the heap property is $O(\lg n)$. (See <http://www.nist.gov/dads/HTML/priorityqueue.html> for more information about the priority queue data structure.)

The `heapq` module provides `heappush()` and `heappop()` functions for adding and removing items while maintaining the heap

property on top of some other mutable Python sequence type. Here's an example that uses a Python list:

```
>>> import heapq
>>> heap = []
>>> for item in [3, 7, 5, 11, 1]:
...     heapq.heappush(heap, item)
...
>>> heap
[1, 3, 5, 11, 7]
>>> heapq.heappop(heap)
1
>>> heapq.heappop(heap)
3
>>> heap
[5, 7, 11]
```

(Contributed by Kevin O'Connor.)

- The IDLE integrated development environment has been updated using the code from the IDLEfork project (<http://idlefork.sf.net>). The most notable feature is that the code being developed is now executed in a subprocess, meaning that there's no longer any need for manual `reload()` operations. IDLE's core code has been incorporated into the standard library as the `idlelib` package.
- The `imaplib` module now supports IMAP over SSL. (Contributed by Piers Lauder and Tino Lange.)
- The `itertools` contains a number of useful functions for use with iterators, inspired by various functions provided by the ML and Haskell languages. For example, `itertools.ifilter(predicate, iterator)` returns all elements in the iterator for which the function `predicate()` returns `True`, and `itertools.repeat(obj, N)` returns `obj` *N* times. There are a number of other functions in the module; see the package's reference documentation for details. (Contributed by Raymond

Hettinger.)

- Two new functions in the `math` module, `degrees(rads)()` and `radians(degs)()`, convert between radians and degrees. Other functions in the `math` module such as `math.sin()` and `math.cos()` have always required input values measured in radians. Also, an optional *base* argument was added to `math.log()` to make it easier to compute logarithms for bases other than `e` and `10`. (Contributed by Raymond Hettinger.)
- Several new POSIX functions (`getpgid()`, `killpg()`, `lchown()`, `loadavg()`, `major()`, `makedev()`, `minor()`, and `mknod()`) were added to the `posix` module that underlies the `os` module. (Contributed by Gustavo Niemeyer, Geert Jansen, and Denis S. Otkidach.)
- In the `os` module, the `*stat()` family of functions can now report fractions of a second in a timestamp. Such time stamps are represented as floats, similar to the value returned by `time.time()`.

During testing, it was found that some applications will break if time stamps are floats. For compatibility, when using the tuple interface of the `stat_result` time stamps will be represented as integers. When using named fields (a feature first introduced in Python 2.2), time stamps are still represented as integers, unless `os.stat_float_times()` is invoked to enable float return values:

```
>>> os.stat("/tmp").st_mtime
1034791200
>>> os.stat_float_times(True)
>>> os.stat("/tmp").st_mtime
1034791200.6335014
```

In Python 2.4, the default will change to always returning floats.

Application developers should enable this feature only if all their libraries work properly when confronted with floating point time stamps, or if they use the tuple API. If used, the feature should be activated on an application level instead of trying to enable it on a per-use basis.

- The `optparse` module contains a new parser for command-line arguments that can convert option values to a particular Python type and will automatically generate a usage message. See the following section for more details.
- The old and never-documented `linuxaudiodev` module has been deprecated, and a new version named `ossaudiodev` has been added. The module was renamed because the OSS sound drivers can be used on platforms other than Linux, and the interface has also been tidied and brought up to date in various ways. (Contributed by Greg Ward and Nicholas FitzRoy-Dale.)
- The new `platform` module contains a number of functions that try to determine various properties of the platform you're running on. There are functions for getting the architecture, CPU type, the Windows OS version, and even the Linux distribution version. (Contributed by Marc-André Lemburg.)
- The parser objects provided by the `pyexpat` module can now optionally buffer character data, resulting in fewer calls to your character data handler and therefore faster performance. Setting the parser object's `buffer_text` attribute to `True` will enable buffering.
- The `sample(population, k)()` function was added to the `random` module. *population* is a sequence or `xrange` object containing

the elements of a population, and `sample()` chooses k elements from the population without replacing chosen elements. k can be any value up to `len(population)`. For example:

```
>>> days = ['Mo', 'Tu', 'We', 'Th', 'Fr', 'St', 'Sn']
>>> random.sample(days, 3)      # Choose 3 elements
['St', 'Sn', 'Th']
>>> random.sample(days, 7)      # Choose 7 elements
['Tu', 'Th', 'Mo', 'We', 'St', 'Fr', 'Sn']
>>> random.sample(days, 7)      # Choose 7 again
['We', 'Mo', 'Sn', 'Fr', 'Tu', 'St', 'Th']
>>> random.sample(days, 8)      # Can't choose eight
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
  File "random.py", line 414, in sample
    raise ValueError, "sample larger than population"
ValueError: sample larger than population
>>> random.sample(xrange(1,10000,2), 10)  # Choose ten odd
[3407, 3805, 1505, 7023, 2401, 2267, 9733, 3151, 8083, 9195]
```

The `random` module now uses a new algorithm, the Mersenne Twister, implemented in C. It's faster and more extensively studied than the previous algorithm.

(All changes contributed by Raymond Hettinger.)

- The `readline` module also gained a number of new functions: `get_history_item()`, `get_current_history_length()`, and `redisplay()`.
- The `rexec` and `Bastion` modules have been declared dead, and attempts to import them will fail with a `RuntimeError`. New-style classes provide new ways to break out of the restricted execution environment provided by `rexec`, and no one has interest in fixing them or time to do so. If you have applications using `rexec`, rewrite them to use something else.

(Sticking with Python 2.2 or 2.1 will not make your applications any safer because there are known bugs in the `rexec` module in those versions. To repeat: if you're using `rexec`, stop using it immediately.)

- The `rotor` module has been deprecated because the algorithm it uses for encryption is not believed to be secure. If you need encryption, use one of the several AES Python modules that are available separately.
- The `shutil` module gained a `move(src, dest)()` function that recursively moves a file or directory to a new location.
- Support for more advanced POSIX signal handling was added to the `signal` but then removed again as it proved impossible to make it work reliably across platforms.
- The `socket` module now supports timeouts. You can call the `settimeout(t)()` method on a socket object to set a timeout of *t* seconds. Subsequent socket operations that take longer than *t* seconds to complete will abort and raise a `socket.timeout` exception.

The original timeout implementation was by Tim O'Malley. Michael Gilfix integrated it into the Python `socket` module and shepherded it through a lengthy review. After the code was checked in, Guido van Rossum rewrote parts of it. (This is a good example of a collaborative development process in action.)

- On Windows, the `socket` module now ships with Secure Sockets Layer (SSL) support.
- The value of the C `PYTHON_API_VERSION` macro is now exposed at the Python level as `sys.api_version`. The current exception

can be cleared by calling the new `sys.exc_clear()` function.

- The new `tarfile` module allows reading from and writing to `tar`-format archive files. (Contributed by Lars Gustäbel.)
- The new `textwrap` module contains functions for wrapping strings containing paragraphs of text. The `wrap(text, width())` function takes a string and returns a list containing the text split into lines of no more than the chosen width. The `fill(text, width())` function returns a single string, reformatted to fit into lines no longer than the chosen width. (As you can guess, `fill()` is built on top of `wrap()`). For example:

```
>>> import textwrap
>>> paragraph = "Not a whit, we defy augury: ... more text
>>> textwrap.wrap(paragraph, 60)
["Not a whit, we defy augury: there's a special providence
  "the fall of a sparrow. If it be now, 'tis not to come; if
  ...]
>>> print textwrap.fill(paragraph, 35)
Not a whit, we defy augury: there's
a special providence in the fall of
a sparrow. If it be now, 'tis not
to come; if it be not to come, it
will be now; if it be not now, yet
it will come: the readiness is all.
>>>
```

The module also contains a `TextWrapper` class that actually implements the text wrapping strategy. Both the `TextWrapper` class and the `wrap()` and `fill()` functions support a number of additional keyword arguments for fine-tuning the formatting; consult the module's documentation for details. (Contributed by Greg Ward.)

- The `thread` and `threading` modules now have companion modules, `dummy_thread` and `dummy_threading`, that provide a do-

nothing implementation of the `thread` module's interface for platforms where threads are not supported. The intention is to simplify thread-aware modules (ones that *don't* rely on threads to run) by putting the following code at the top:

```
try:
    import threading as _threading
except ImportError:
    import dummy_threading as _threading
```

In this example, `_threading` is used as the module name to make it clear that the module being used is not necessarily the actual `threading` module. Code can call functions and use classes in `_threading` whether or not threads are supported, avoiding an `if` statement and making the code slightly clearer. This module will not magically make multithreaded code run without threads; code that waits for another thread to return or to do something will simply hang forever.

- The `time` module's `strptime()` function has long been an annoyance because it uses the platform C library's `strptime()` implementation, and different platforms sometimes have odd bugs. Brett Cannon contributed a portable implementation that's written in pure Python and should behave identically on all platforms.
- The new `timeit` module helps measure how long snippets of Python code take to execute. The `timeit.py` file can be run directly from the command line, or the module's `Timer` class can be imported and used directly. Here's a short example that figures out whether it's faster to convert an 8-bit string to Unicode by appending an empty Unicode string to it or by using the `unicode()` function:

```
import timeit
```

```
timer1 = timeit.Timer('unicode("abc")')
timer2 = timeit.Timer('"abc" + u"")

# Run three trials
print timer1.repeat(repeat=3, number=100000)
print timer2.repeat(repeat=3, number=100000)

# On my laptop this outputs:
# [0.36831796169281006, 0.37441694736480713, 0.353048920631
# [0.17574405670166016, 0.18193507194519043, 0.175657987594
```

- The `timeit` module has received various bug fixes and updates for the current version of the Tix package.
- The `tkinter` module now works with a thread-enabled version of Tcl. Tcl's threading model requires that widgets only be accessed from the thread in which they're created; accesses from another thread can cause Tcl to panic. For certain Tcl interfaces, `tkinter` will now automatically avoid this when a widget is accessed from a different thread by marshalling a command, passing it to the correct thread, and waiting for the results. Other interfaces can't be handled automatically but `tkinter` will now raise an exception on such an access so that you can at least find out about the problem. See <http://mail.python.org/pipermail/python-dev/2002-December/031107.html> for a more detailed explanation of this change. (Implemented by Martin von Löwis.)
- Calling Tcl methods through `_tkinter` no longer returns only strings. Instead, if Tcl returns other objects those objects are converted to their Python equivalent, if one exists, or wrapped with a `_tkinter.Tcl_Obj` object if no Python equivalent exists. This behavior can be controlled through the `wantobjects()` method of `tkapp` objects.

When using `_tkinter` through the `Tkinter` module (as most Tkinter applications will), this feature is always activated. It should not cause compatibility problems, since Tkinter would always convert string results to Python types where possible.

If any incompatibilities are found, the old behavior can be restored by setting the `wantobjects` variable in the `Tkinter` module to `false` before creating the first `tkapp` object.

```
import Tkinter
Tkinter.wantobjects = 0
```

Any breakage caused by this change should be reported as a bug.

- The `UserDict` module has a new `DictMixin` class which defines all dictionary methods for classes that already have a minimum mapping interface. This greatly simplifies writing classes that need to be substitutable for dictionaries, such as the classes in the `shelve` module.

Adding the mix-in as a superclass provides the full dictionary interface whenever the class defines `__getitem__()`, `__setitem__()`, `__delitem__()`, and `keys()`. For example:

```
>>> import UserDict
>>> class SeqDict(UserDict.DictMixin):
...     """Dictionary lookalike implemented with lists."""
...     def __init__(self):
...         self.keylist = []
...         self.valuelist = []
...     def __getitem__(self, key):
...         try:
...             i = self.keylist.index(key)
...         except ValueError:
...             raise KeyError
...         return self.valuelist[i]
...     def __setitem__(self, key, value):
```

```

...     try:
...         i = self.keylist.index(key)
...         self.valuelist[i] = value
...     except ValueError:
...         self.keylist.append(key)
...         self.valuelist.append(value)
...     def __delitem__(self, key):
...         try:
...             i = self.keylist.index(key)
...         except ValueError:
...             raise KeyError
...         self.keylist.pop(i)
...         self.valuelist.pop(i)
...     def keys(self):
...         return list(self.keylist)
...
>>> s = SeqDict()
>>> dir(s)      # See that other dictionary methods are imp
['_cmp__', '__contains__', '__delitem__', '__doc__', '__ge
['__init__', '__iter__', '__len__', '__module__', '__repr__
['__setitem__', 'clear', 'get', 'has_key', 'items', 'iterit
'iterkeys', 'itervalues', 'keylist', 'keys', 'pop', 'popit
'setdefault', 'update', 'valuelist', 'values']

```

(Contributed by Raymond Hettinger.)

- The DOM implementation in `xml.dom.minidom` can now generate XML output in a particular encoding by providing an optional encoding argument to the `toxml()` and `toprettyxml()` methods of DOM nodes.
- The `xmlrpc.lib` module now supports an XML-RPC extension for handling nil data values such as Python's `None`. Nil values are always supported on unmarshalling an XML-RPC response. To generate requests containing `None`, you must supply a true value for the `allow_none` parameter when creating a `Marshaller` instance.
- The new `DocXMLRPCServer` module allows writing self-documenting XML-RPC servers. Run it in demo mode (as a

program) to see it in action. Pointing the Web browser to the RPC server produces pydoc-style documentation; pointing xmlrpclib to the server allows invoking the actual methods. (Contributed by Brian Quinlan.)

- Support for internationalized domain names (RFCs 3454, 3490, 3491, and 3492) has been added. The “idna” encoding can be used to convert between a Unicode domain name and the ASCII-compatible encoding (ACE) of that name.

```
>{}>{}> u"www.Alliancefrançaise.nu".encode("idna")  
'www.xn--alliancefranaise-npb.nu'
```

The `socket` module has also been extended to transparently convert Unicode hostnames to the ACE version before passing them to the C library. Modules that deal with hostnames such as `httplib` and `ftplib`) also support Unicode host names; `httplib` also sends HTTP `Host` headers using the ACE version of the domain name. `urllib` supports Unicode URLs with non-ASCII host names as long as the `path` part of the URL is ASCII only.

To implement this change, the `stringprep` module, the `mkstringprep` tool and the `punycode` encoding have been added.

Date/Time Type

Date and time types suitable for expressing timestamps were added as the `datetime` module. The types don't support different calendars or many fancy features, and just stick to the basics of representing time.

The three primary types are: `date`, representing a day, month, and year; `time`, consisting of hour, minute, and second; and `datetime`, which contains all the attributes of both `date` and `time`. There's also

a `timedelta` class representing differences between two points in time, and time zone logic is implemented by classes inheriting from the abstract `tzinfo` class.

You can create instances of `date` and `time` by either supplying keyword arguments to the appropriate constructor, e.g. `datetime.date(year=1972, month=10, day=15)`, or by using one of a number of class methods. For example, the `date.today()` class method returns the current local date.

Once created, instances of the date/time classes are all immutable. There are a number of methods for producing formatted strings from objects:

```
>>> import datetime
>>> now = datetime.datetime.now()
>>> now.isoformat()
'2002-12-30T21:27:03.994956'
>>> now.ctime() # Only available on date, datetime
'Mon Dec 30 21:27:03 2002'
>>> now.strftime('%Y %d %b')
'2002 30 Dec'
```

The `replace()` method allows modifying one or more fields of a `date` or `datetime` instance, returning a new instance:

```
>>> d = datetime.datetime.now()
>>> d
datetime.datetime(2002, 12, 30, 22, 15, 38, 827738)
>>> d.replace(year=2001, hour = 12)
datetime.datetime(2001, 12, 30, 12, 15, 38, 827738)
>>>
```

Instances can be compared, hashed, and converted to strings (the result is the same as that of `isoformat()`). `date` and `datetime` instances can be subtracted from each other, and added to `timedelta` instances. The largest missing feature is that there's no

standard library support for parsing strings and getting back a `date` or `datetime`.

For more information, refer to the module's reference documentation. (Contributed by Tim Peters.)

The `optparse` Module

The `getopt` module provides simple parsing of command-line arguments. The new `optparse` module (originally named `Optik`) provides more elaborate command-line parsing that follows the Unix conventions, automatically creates the output for `--help`, and can perform different actions for different options.

You start by creating an instance of `OptionParser` and telling it what your program's options are.

```
import sys
from optparse import OptionParser

op = OptionParser()
op.add_option('-i', '--input',
              action='store', type='string', dest='input',
              help='set input filename')
op.add_option('-l', '--length',
              action='store', type='int', dest='length',
              help='set maximum length of output')
```

Parsing a command line is then done by calling the `parse_args()` method.

```
options, args = op.parse_args(sys.argv[1:])
print options
print args
```

This returns an object containing all of the option values, and a list of strings containing the remaining arguments.

Invoking the script with the various arguments now works as you'd expect it to. Note that the length argument is automatically converted to an integer.

```
$ ./python opt.py -i data arg1
<Values at 0x400cad4c: {'input': 'data', 'length': None}>
['arg1']
$ ./python opt.py --input=data --length=4
<Values at 0x400cad2c: {'input': 'data', 'length': 4}>
[]
$
```

The help message is automatically generated for you:

```
$ ./python opt.py --help
usage: opt.py [options]

options:
  -h, --help            show this help message and exit
  -iINPUT, --input=INPUT
                        set input filename
  -lLENGTH, --length=LENGTH
                        set maximum length of output
$
```

See the module's documentation for more details.

Optik was written by Greg Ward, with suggestions from the readers of the Getopt SIG.

Pymalloc: A Specialized Object Allocator

Pymalloc, a specialized object allocator written by Vladimir Marangozov, was a feature added to Python 2.1. Pymalloc is intended to be faster than the system `malloc()` and to have less memory overhead for allocation patterns typical of Python programs. The allocator uses C's `malloc()` function to get large pools of memory and then fulfills smaller memory requests from these pools.

In 2.1 and 2.2, pymalloc was an experimental feature and wasn't enabled by default; you had to explicitly enable it when compiling Python by providing the `--with-pymalloc` option to the **configure** script. In 2.3, pymalloc has had further enhancements and is now enabled by default; you'll have to supply `--without-pymalloc` to disable it.

This change is transparent to code written in Python; however, pymalloc may expose bugs in C extensions. Authors of C extension modules should test their code with pymalloc enabled, because some incorrect code may cause core dumps at runtime.

There's one particularly common error that causes problems. There are a number of memory allocation functions in Python's C API that have previously just been aliases for the C library's `malloc()` and `free()`, meaning that if you accidentally called mismatched functions the error wouldn't be noticeable. When the object allocator is enabled, these functions aren't aliases of `malloc()` and `free()` any more, and calling the wrong function to free memory may get you a core dump. For example, if memory was allocated using `PyObject_Malloc()`, it has to be freed using `PyObject_Free()`, not `free()`. A few modules included with Python fell afoul of this and had to be fixed; doubtless there are more third-party modules that will have the same problem.

As part of this change, the confusing multiple interfaces for allocating memory have been consolidated down into two API families. Memory allocated with one family must not be manipulated with functions from the other family. There is one family for allocating chunks of memory and another family of functions specifically for allocating Python objects.

- To allocate and free an undistinguished chunk of memory use the “raw memory” family: `PyMem_Malloc()`, `PyMem_Realloc()`, and `PyMem_Free()`.
- The “object memory” family is the interface to the pymalloc facility described above and is biased towards a large number of “small” allocations: `PyObject_Malloc()`, `PyObject_Realloc()`, and `PyObject_Free()`.
- To allocate and free Python objects, use the “object” family `PyObject_New()`, `PyObject_NewVar()`, and `PyObject_Del()`.

Thanks to lots of work by Tim Peters, pymalloc in 2.3 also provides debugging features to catch memory overwrites and doubled frees in both extension modules and in the interpreter itself. To enable this support, compile a debugging version of the Python interpreter by running **configure** with `--with-pydebug`.

To aid extension writers, a header file `Misc/pymemcompat.h` is distributed with the source to Python 2.3 that allows Python extensions to use the 2.3 interfaces to memory allocation while compiling against any version of Python since 1.5.2. You would copy the file from Python’s source distribution and bundle it with the source of your extension.

See also:

<http://svn.python.org/view/python/trunk/Objects/obmalloc.c>

For the full details of the pymalloc implementation, see the

comments at the top of the file `objects/obmalloc.c` in the Python source code. The above link points to the file within the python.org SVN browser.

Build and C API Changes

Changes to Python's build process and to the C API include:

- The cycle detection implementation used by the garbage collection has proven to be stable, so it's now been made mandatory. You can no longer compile Python without it, and the `--with-cycle-gc` switch to **configure** has been removed.
- Python can now optionally be built as a shared library (`libpython2.3.so`) by supplying `--enable-shared` when running Python's **configure** script. (Contributed by Ondrej Palkovsky.)
- The `DL_EXPORT` and `DL_IMPORT` macros are now deprecated. Initialization functions for Python extension modules should now be declared using the new macro `PyMODINIT_FUNC`, while the Python core will generally use the `PyAPI_FUNC` and `PyAPI_DATA` macros.
- The interpreter can be compiled without any docstrings for the built-in functions and modules by supplying `--without-doc-strings` to the **configure** script. This makes the Python executable about 10% smaller, but will also mean that you can't get help for Python's built-ins. (Contributed by Gustavo Niemeyer.)
- The `PyArg_NoArgs()` macro is now deprecated, and code that uses it should be changed. For Python 2.2 and later, the method definition table can specify the `METH_NOARGS` flag, signalling that there are no arguments, and the argument checking can then be removed. If compatibility with pre-2.2 versions of Python is important, the code could use `PyArg_ParseTuple(args, "")` instead, but this will be slower than using `METH_NOARGS`.
- `PyArg_ParseTuple()` accepts new format characters for various sizes of unsigned integers: `B` for unsigned char, `H` for unsigned short int, `I` for unsigned int, and `K` for unsigned long long.
- A new function, `PyObject_DelItemString(mapping, char *key)()`

was added as shorthand for `PyObject_DeItem(mapping, PyString_New(key))`.

- File objects now manage their internal string buffer differently, increasing it exponentially when needed. This results in the benchmark tests in `Lib/test/test_bufio.py` speeding up considerably (from 57 seconds to 1.7 seconds, according to one measurement).
- It's now possible to define class and static methods for a C extension type by setting either the `METH_CLASS` or `METH_STATIC` flags in a method's `PyMethodDef` structure.
- Python now includes a copy of the Expat XML parser's source code, removing any dependence on a system version or local installation of Expat.
- If you dynamically allocate type objects in your extension, you should be aware of a change in the rules relating to the `__module__` and `__name__` attributes. In summary, you will want to ensure the type's dictionary contains a `'__module__'` key; making the module name the part of the type name leading up to the final period will no longer have the desired effect. For more detail, read the API reference documentation or the source.

Port-Specific Changes

Support for a port to IBM's OS/2 using the EMX runtime environment was merged into the main Python source tree. EMX is a POSIX emulation layer over the OS/2 system APIs. The Python port for EMX tries to support all the POSIX-like capability exposed by the EMX runtime, and mostly succeeds; `fork()` and `fcntl()` are restricted by the limitations of the underlying emulation layer. The standard OS/2 port, which uses IBM's Visual Age compiler, also gained support for case-sensitive import semantics as part of the integration of the EMX port into CVS. (Contributed by Andrew

MacIntyre.)

On MacOS, most toolbox modules have been weaklinked to improve backward compatibility. This means that modules will no longer fail to load if a single routine is missing on the current OS version. Instead calling the missing routine will raise an exception. (Contributed by Jack Jansen.)

The RPM spec files, found in the `Misc/RPM/` directory in the Python source distribution, were updated for 2.3. (Contributed by Sean Reifschneider.)

Other new platforms now supported by Python include AtheOS (<http://www.atheos.cx/>), GNU/Hurd, and OpenVMS.

Other Changes and Fixes

As usual, there were a bunch of other improvements and bugfixes scattered throughout the source tree. A search through the CVS change logs finds there were 523 patches applied and 514 bugs fixed between Python 2.2 and 2.3. Both figures are likely to be underestimates.

Some of the more notable changes are:

- If the `PYTHONINSPECT` environment variable is set, the Python interpreter will enter the interactive prompt after running a Python program, as if Python had been invoked with the `-i` option. The environment variable can be set before running the Python interpreter, or it can be set by the Python program as part of its execution.
- The `regtest.py` script now provides a way to allow “all resources except *foo*.” A resource name passed to the `-u` option can now be prefixed with a hyphen (`'-'`) to mean “remove this resource.” For example, the option `'-ua11, -bsddb'` could be used to enable the use of all resources except `bsddb`.
- The tools used to build the documentation now work under Cygwin as well as Unix.
- The `SET_LINENO` opcode has been removed. Back in the mists of time, this opcode was needed to produce line numbers in tracebacks and support trace functions (for, e.g., `pdb`). Since Python 1.5, the line numbers in tracebacks have been computed using a different mechanism that works with “python -O”. For Python 2.3 Michael Hudson implemented a similar scheme to determine when to call the trace function, removing the need for

`SET_LINENO` entirely.

It would be difficult to detect any resulting difference from Python code, apart from a slight speed up when Python is run without `-O`.

C extensions that access the `f_lineno` field of frame objects should instead call `PyCode_Addr2Line(f->f_code, f->f_lasti)`. This will have the added effect of making the code work as desired under “python -O” in earlier versions of Python.

A nifty new feature is that trace functions can now assign to the `f_lineno` attribute of frame objects, changing the line that will be executed next. A `jump` command has been added to the `pdb` debugger taking advantage of this new feature. (Implemented by Richie Hindle.)

Porting to Python 2.3

This section lists previously described changes that may require changes to your code:

- `yield` is now always a keyword; if it's used as a variable name in your code, a different name must be chosen.
- For strings `X` and `Y`, `x in Y` now works if `X` is more than one character long.
- The `int()` type constructor will now return a long integer instead of raising an `OverflowError` when a string or floating-point number is too large to fit into an integer.
- If you have Unicode strings that contain 8-bit characters, you must declare the file's encoding (UTF-8, Latin-1, or whatever) by adding a comment to the top of the file. See section [PEP 263: Source Code Encodings](#) for more information.
- Calling Tcl methods through `_tkinter` no longer returns only strings. Instead, if Tcl returns other objects those objects are converted to their Python equivalent, if one exists, or wrapped with a `_tkinter.Tcl_obj` object if no Python equivalent exists.
- Large octal and hex literals such as `0xffffffff` now trigger a `FutureWarning`. Currently they're stored as 32-bit numbers and result in a negative value, but in Python 2.4 they'll become positive long integers.

There are a few ways to fix this warning. If you really need a positive number, just add an `L` to the end of the literal. If you're trying to get a 32-bit integer with low bits set and have

previously used an expression such as `~(1 << 31)`, it's probably clearest to start with all bits set and clear the desired upper bits. For example, to clear just the top bit (bit 31), you could write `0xffffffffL & ~(1L << 31)`.

- You can no longer disable assertions by assigning to `__debug__`.
- The Distutils `setup()` function has gained various new keyword arguments such as *depends*. Old versions of the Distutils will abort if passed unknown keywords. A solution is to check for the presence of the new `get_distutil_options()` function in your `setup.py` and only uses the new keywords with a version of the Distutils that supports them:

```
from distutils import core

kw = {'sources': 'foo.c', ...}
if hasattr(core, 'get_distutil_options'):
    kw['depends'] = ['foo.h']
ext = Extension(**kw)
```

- Using `None` as a variable name will now result in a `SyntaxWarning` warning.
- Names of extension types defined by the modules included with Python now contain the module and a `'.'` in front of the type name.

What's New in Python 2.2

Author: A.M. Kuchling

Introduction

This article explains the new features in Python 2.2.2, released on October 14, 2002. Python 2.2.2 is a bugfix release of Python 2.2, originally released on December 21, 2001.

Python 2.2 can be thought of as the “cleanup release”. There are some features such as generators and iterators that are completely new, but most of the changes, significant and far-reaching though they may be, are aimed at cleaning up irregularities and dark corners of the language design.

This article doesn't attempt to provide a complete specification of the new features, but instead provides a convenient overview. For full details, you should refer to the documentation for Python 2.2, such as the [Python Library Reference](#) and the [Python Reference Manual](#). If you want to understand the complete implementation and design rationale for a change, refer to the PEP for a particular new feature.

PEPs 252 and 253: Type and Class Changes

The largest and most far-reaching changes in Python 2.2 are to Python's model of objects and classes. The changes should be backward compatible, so it's likely that your code will continue to run unchanged, but the changes provide some amazing new capabilities. Before beginning this, the longest and most complicated section of this article, I'll provide an overview of the changes and offer some comments.

A long time ago I wrote a Web page listing flaws in Python's design. One of the most significant flaws was that it's impossible to subclass Python types implemented in C. In particular, it's not possible to subclass built-in types, so you can't just subclass, say, lists in order to add a single useful method to them. The `UserList` module provides a class that supports all of the methods of lists and that can be subclassed further, but there's lots of C code that expects a regular Python list and won't accept a `UserList` instance.

Python 2.2 fixes this, and in the process adds some exciting new capabilities. A brief summary:

- You can subclass built-in types such as lists and even integers, and your subclasses should work in every place that requires the original type.
- It's now possible to define static and class methods, in addition to the instance methods available in previous versions of Python.
- It's also possible to automatically call methods on accessing or setting an instance attribute by using a new mechanism called *properties*. Many uses of `__getattr__()` can be rewritten to use properties instead, making the resulting code simpler and faster.

As a small side benefit, attributes can now have docstrings, too.

- The list of legal attributes for an instance can be limited to a particular set using *slots*, making it possible to safeguard against typos and perhaps make more optimizations possible in future versions of Python.

Some users have voiced concern about all these changes. Sure, they say, the new features are neat and lend themselves to all sorts of tricks that weren't possible in previous versions of Python, but they also make the language more complicated. Some people have said that they've always recommended Python for its simplicity, and feel that its simplicity is being lost.

Personally, I think there's no need to worry. Many of the new features are quite esoteric, and you can write a lot of Python code without ever needed to be aware of them. Writing a simple class is no more difficult than it ever was, so you don't need to bother learning or teaching them unless they're actually needed. Some very complicated tasks that were previously only possible from C will now be possible in pure Python, and to my mind that's all for the better.

I'm not going to attempt to cover every single corner case and small change that were required to make the new features work. Instead this section will paint only the broad strokes. See section [Related Links](#), "Related Links", for further sources of information about Python 2.2's new object model.

Old and New Classes

First, you should know that Python 2.2 really has two kinds of classes: classic or old-style classes, and new-style classes. The old-style class model is exactly the same as the class model in earlier versions of Python. All the new features described in this section apply only to new-style classes. This divergence isn't intended to last forever; eventually old-style classes will be dropped, possibly in

Python 3.0.

So how do you define a new-style class? You do it by subclassing an existing new-style class. Most of Python's built-in types, such as integers, lists, dictionaries, and even files, are new-style classes now. A new-style class named `object`, the base class for all built-in types, has also been added so if no built-in type is suitable, you can just subclass `object`:

```
class C(object):
    def __init__(self):
        ...
    ...
```

This means that `class` statements that don't have any base classes are always classic classes in Python 2.2. (Actually you can also change this by setting a module-level variable named `__metaclass__` — see [PEP 253](#) for the details — but it's easier to just subclass `object`.)

The type objects for the built-in types are available as built-ins, named using a clever trick. Python has always had built-in functions named `int()`, `float()`, and `str()`. In 2.2, they aren't functions any more, but type objects that behave as factories when called.

```
>>> int
<type 'int'>
>>> int('123')
123
```

To make the set of types complete, new type objects such as `dict()` and `file()` have been added. Here's a more interesting example, adding a `lock()` method to file objects:

```
class LockableFile(file):
    def lock(self, operation, length=0, start=0, whence=0):
        import fcntl
```

```
return fcntl.lockf(self.fileno(), operation,
                  length, start, whence)
```

The now-obsolete `posixfile` module contained a class that emulated all of a file object's methods and also added a `lock()` method, but this class couldn't be passed to internal functions that expected a built-in file, something which is possible with our new `LockableFile`.

Descriptors

In previous versions of Python, there was no consistent way to discover what attributes and methods were supported by an object. There were some informal conventions, such as defining `__members__` and `__methods__` attributes that were lists of names, but often the author of an extension type or a class wouldn't bother to define them. You could fall back on inspecting the `__dict__` of an object, but when class inheritance or an arbitrary `__getattr__()` hook were in use this could still be inaccurate.

The one big idea underlying the new class model is that an API for describing the attributes of an object using *descriptors* has been formalized. Descriptors specify the value of an attribute, stating whether it's a method or a field. With the descriptor API, static methods and class methods become possible, as well as more exotic constructs.

Attribute descriptors are objects that live inside class objects, and have a few attributes of their own:

- `__name__` is the attribute's name.
- `__doc__` is the attribute's docstring.
- `__get__(object)()` is a method that retrieves the attribute value from *object*.

- `__set__(object, value)()` sets the attribute on *object* to *value*.
- `__delete__(object, value)()` deletes the *value* attribute of *object*.

For example, when you write `obj.x`, the steps that Python actually performs are:

```
descriptor = obj.__class__.x
descriptor.__get__(obj)
```

For methods, `descriptor.__get__()` returns a temporary object that's callable, and wraps up the instance and the method to be called on it. This is also why static methods and class methods are now possible; they have descriptors that wrap up just the method, or the method and the class. As a brief explanation of these new kinds of methods, static methods aren't passed the instance, and therefore resemble regular functions. Class methods are passed the class of the object, but not the object itself. Static and class methods are defined like this:

```
class C(object):
    def f(arg1, arg2):
        ...
    f = staticmethod(f)

    def g(cls, arg1, arg2):
        ...
    g = classmethod(g)
```

The `staticmethod()` function takes the function `f()`, and returns it wrapped up in a descriptor so it can be stored in the class object. You might expect there to be special syntax for creating such methods (`def static f`, `defstatic f()`, or something like that) but no such syntax has been defined yet; that's been left for future versions of Python.

More new features, such as slots and properties, are also

implemented as new kinds of descriptors, and it's not difficult to write a descriptor class that does something novel. For example, it would be possible to write a descriptor class that made it possible to write Eiffel-style preconditions and postconditions for a method. A class that used this feature might be defined like this:

```
from eiffel import eiffelmethod

class C(object):
    def f(self, arg1, arg2):
        # The actual function
        ...

    def pre_f(self):
        # Check preconditions
        ...

    def post_f(self):
        # Check postconditions
        ...

    f = eiffelmethod(f, pre_f, post_f)
```

Note that a person using the new `eiffelmethod()` doesn't have to understand anything about descriptors. This is why I think the new features don't increase the basic complexity of the language. There will be a few wizards who need to know about it in order to write `eiffelmethod()` or the ZODB or whatever, but most users will just write code on top of the resulting libraries and ignore the implementation details.

Multiple Inheritance: The Diamond Rule

Multiple inheritance has also been made more useful through changing the rules under which names are resolved. Consider this set of classes (diagram taken from [PEP 253](#) by Guido van Rossum):

```
class A:
    ^ ^
   / \
  /   \
 /     \
def save(self): ...
```

The lookup rule for classic classes is simple but not very smart; the base classes are searched depth-first, going from left to right. A reference to `D.save()` will search the classes `D`, `B`, and then `A`, where `save()` would be found and returned. `C.save()` would never be found at all. This is bad, because if `C`'s `save()` method is saving some internal state specific to `C`, not calling it will result in that state never getting saved.

New-style classes follow a different algorithm that's a bit more complicated to explain, but does the right thing in this situation. (Note that Python 2.3 changes this algorithm to one that produces the same results in most cases, but produces more useful results for really complicated inheritance graphs.)

1. List all the base classes, following the classic lookup rule and include a class multiple times if it's visited repeatedly. In the above example, the list of visited classes is `[D, B, A, C, A]`.
2. Scan the list for duplicated classes. If any are found, remove all but one occurrence, leaving the *last* one in the list. In the above example, the list becomes `[D, B, C, A]` after dropping duplicates.

Following this rule, referring to `D.save()` will return `C.save()`, which is the behaviour we're after. This lookup rule is the same as the one followed by Common Lisp. A new built-in function, `super()`, provides a way to get at a class's superclasses without having to reimplement Python's algorithm. The most commonly used form will be

`super(class, obj)()`, which returns a bound superclass object (not the actual class object). This form will be used in methods to call a method in the superclass; for example, `D`'s `save()` method would look like this:

```
class D (B,C):
    def save (self):
        # Call superclass .save()
        super(D, self).save()
        # Save D's private information here
        ...
```

`super()` can also return unbound superclass objects when called as `super(class)()` or `super(class1, class2)()`, but this probably won't often be useful.

Attribute Access

A fair number of sophisticated Python classes define hooks for attribute access using `__getattr__()`; most commonly this is done for convenience, to make code more readable by automatically mapping an attribute access such as `obj.parent` into a method call such as `obj.get_parent`. Python 2.2 adds some new ways of controlling attribute access.

First, `__getattr__(attr_name)()` is still supported by new-style classes, and nothing about it has changed. As before, it will be called when an attempt is made to access `obj.foo` and no attribute named `foo` is found in the instance's dictionary.

New-style classes also support a new method, `__getattribute__(attr_name)()`. The difference between the two methods is that `__getattribute__()` is *always* called whenever any attribute is accessed, while the old `__getattr__()` is only called if `foo` isn't found in the instance's dictionary.

However, Python 2.2's support for *properties* will often be a simpler way to trap attribute references. Writing a `__getattr__()` method is complicated because to avoid recursion you can't use regular attribute accesses inside them, and instead have to mess around with the contents of `__dict__`. `__getattr__()` methods also end up being called by Python when it checks for other methods such as `__repr__()` or `__coerce__()`, and so have to be written with this in mind. Finally, calling a function on every attribute access results in a sizable performance loss.

`property` is a new built-in type that packages up three functions that get, set, or delete an attribute, and a docstring. For example, if you want to define a `size` attribute that's computed, but also settable, you could write:

```
class C(object):
    def get_size (self):
        result = ... computation ...
        return result
    def set_size (self, size):
        ... compute something based on the size
        and set internal state appropriately ...

    # Define a property. The 'delete this attribute'
    # method is defined as None, so the attribute
    # can't be deleted.
    size = property(get_size, set_size,
                    None,
                    "Storage size of this instance")
```

That is certainly clearer and easier to write than a pair of `__getattr__()/__setattr__()` methods that check for the `size` attribute and handle it specially while retrieving all other attributes from the instance's `__dict__`. Accesses to `size` are also the only ones which have to perform the work of calling a function, so references to other attributes run at their usual speed.

Finally, it's possible to constrain the list of attributes that can be

referenced on an object using the new `__slots__` class attribute. Python objects are usually very dynamic; at any time it's possible to define a new attribute on an instance by just doing `obj.new_attr=1`. A new-style class can define a class attribute named `__slots__` to limit the legal attributes to a particular set of names. An example will make this clear:

```
>>> class C(object):
...     __slots__ = ('template', 'name')
...
>>> obj = C()
>>> print obj.template
None
>>> obj.template = 'Test'
>>> print obj.template
Test
>>> obj.newattr = None
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
AttributeError: 'C' object has no attribute 'newattr'
```

Note how you get an `AttributeError` on the attempt to assign to an attribute not listed in `__slots__`.

Related Links

This section has just been a quick overview of the new features, giving enough of an explanation to start you programming, but many details have been simplified or ignored. Where should you go to get a more complete picture?

<http://www.python.org/2.2/descrintro.html> is a lengthy tutorial introduction to the descriptor features, written by Guido van Rossum. If my description has whetted your appetite, go read this tutorial next, because it goes into much more detail about the new features while still remaining quite easy to read.

Next, there are two relevant PEPs, **PEP 252** and **PEP 253**. **PEP 252** is titled “Making Types Look More Like Classes”, and covers the descriptor API. **PEP 253** is titled “Subtyping Built-in Types”, and describes the changes to type objects that make it possible to subtype built-in objects. **PEP 253** is the more complicated PEP of the two, and at a few points the necessary explanations of types and meta-types may cause your head to explode. Both PEPs were written and implemented by Guido van Rossum, with substantial assistance from the rest of the Zope Corp. team.

Finally, there’s the ultimate authority: the source code. Most of the machinery for the type handling is in `objects/typeobject.c`, but you should only resort to it after all other avenues have been exhausted, including posting a question to python-list or python-dev.

PEP 234: Iterators

Another significant addition to 2.2 is an iteration interface at both the C and Python levels. Objects can define how they can be looped over by callers.

In Python versions up to 2.1, the usual way to make `for item in obj` work is to define a `__getitem__()` method that looks something like this:

```
def __getitem__(self, index):  
    return <next item>
```

`__getitem__()` is more properly used to define an indexing operation on an object so that you can write `obj[5]` to retrieve the sixth element. It's a bit misleading when you're using this only to support `for` loops. Consider some file-like object that wants to be looped over; the *index* parameter is essentially meaningless, as the class probably assumes that a series of `__getitem__()` calls will be made with *index* incrementing by one each time. In other words, the presence of the `__getitem__()` method doesn't mean that using `file[5]` to randomly access the sixth element will work, though it really should.

In Python 2.2, iteration can be implemented separately, and `__getitem__()` methods can be limited to classes that really do support random access. The basic idea of iterators is simple. A new built-in function, `iter(obj)()` or `iter(C, sentinel)`, is used to get an iterator. `iter(obj)()` returns an iterator for the object *obj*, while `iter(C, sentinel)` returns an iterator that will invoke the callable object *C* until it returns *sentinel* to signal that the iterator is done.

Python classes can define an `__iter__()` method, which should

create and return a new iterator for the object; if the object is its own iterator, this method can just return `self`. In particular, iterators will usually be their own iterators. Extension types implemented in C can implement a `tp_iter` function in order to return an iterator, and extension types that want to behave as iterators can define a `tp_iternext` function.

So, after all this, what do iterators actually do? They have one required method, `next()`, which takes no arguments and returns the next value. When there are no more values to be returned, calling `next()` should raise the `StopIteration` exception.

```
>>> L = [1,2,3]
>>> i = iter(L)
>>> print i
<iterator object at 0x8116870>
>>> i.next()
1
>>> i.next()
2
>>> i.next()
3
>>> i.next()
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
StopIteration
>>>
```

In 2.2, Python's `for` statement no longer expects a sequence; it expects something for which `iter()` will return an iterator. For backward compatibility and convenience, an iterator is automatically constructed for sequences that don't implement `__iter__()` or a `tp_iter` slot, so `for i in [1,2,3]` will still work. Wherever the Python interpreter loops over a sequence, it's been changed to use the iterator protocol. This means you can do things like this:

```
>>> L = [1,2,3]
>>> i = iter(L)
```

```
>>> a,b,c = i
>>> a,b,c
(1, 2, 3)
```

Iterator support has been added to some of Python's basic types. Calling `iter()` on a dictionary will return an iterator which loops over its keys:

```
>>> m = {'Jan': 1, 'Feb': 2, 'Mar': 3, 'Apr': 4, 'May': 5, 'Jun': 6,
...      'Jul': 7, 'Aug': 8, 'Sep': 9, 'Oct': 10, 'Nov': 11, 'Dec': 12}
>>> for key in m: print key, m[key]
...
Mar 3
Feb 2
Aug 8
Sep 9
May 5
Jun 6
Jul 7
Jan 1
Apr 4
Nov 11
Dec 12
Oct 10
```

That's just the default behaviour. If you want to iterate over keys, values, or key/value pairs, you can explicitly call the `iterkeys()`, `itervalues()`, or `iteritems()` methods to get an appropriate iterator. In a minor related change, the `in` operator now works on dictionaries, so `key in dict` is now equivalent to `dict.has_key(key)`.

Files also provide an iterator, which calls the `readline()` method until there are no more lines in the file. This means you can now read each line of a file using code like this:

```
for line in file:
    # do something for each line
    ...
```

Note that you can only go forward in an iterator; there's no way to get the previous element, reset the iterator, or make a copy of it. An iterator object could provide such additional capabilities, but the iterator protocol only requires a `next()` method.

See also:

PEP 234 - Iterators

Written by Ka-Ping Yee and GvR; implemented by the Python Labs crew, mostly by GvR and Tim Peters.

PEP 255: Simple Generators

Generators are another new feature, one that interacts with the introduction of iterators.

You're doubtless familiar with how function calls work in Python or C. When you call a function, it gets a private namespace where its local variables are created. When the function reaches a `return` statement, the local variables are destroyed and the resulting value is returned to the caller. A later call to the same function will get a fresh new set of local variables. But, what if the local variables weren't thrown away on exiting a function? What if you could later resume the function where it left off? This is what generators provide; they can be thought of as resumable functions.

Here's the simplest example of a generator function:

```
def generate_ints(N):  
    for i in range(N):  
        yield i
```

A new keyword, `yield`, was introduced for generators. Any function containing a `yield` statement is a generator function; this is detected by Python's bytecode compiler which compiles the function specially as a result. Because a new keyword was introduced, generators must be explicitly enabled in a module by including a `from __future__ import generators` statement near the top of the module's source code. In Python 2.3 this statement will become unnecessary.

When you call a generator function, it doesn't return a single value; instead it returns a generator object that supports the iterator protocol. On executing the `yield` statement, the generator outputs the value of `i`, similar to a `return` statement. The big difference

between `yield` and a `return` statement is that on reaching a `yield` the generator's state of execution is suspended and local variables are preserved. On the next call to the generator's `next()` method, the function will resume executing immediately after the `yield` statement. (For complicated reasons, the `yield` statement isn't allowed inside the `try` block of a `try...finally` statement; read [PEP 255](#) for a full explanation of the interaction between `yield` and exceptions.)

Here's a sample usage of the `generate_ints()` generator:

```
>>> gen = generate_ints(3)
>>> gen
<generator object at 0x8117f90>
>>> gen.next()
0
>>> gen.next()
1
>>> gen.next()
2
>>> gen.next()
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
  File "<stdin>", line 2, in generate_ints
StopIteration
```

You could equally write `for i in generate_ints(5)`, or `a,b,c = generate_ints(3)`.

Inside a generator function, the `return` statement can only be used without a value, and signals the end of the procession of values; afterwards the generator cannot return any further values. `return` with a value, such as `return 5`, is a syntax error inside a generator function. The end of the generator's results can also be indicated by raising `StopIteration` manually, or by just letting the flow of execution fall off the bottom of the function.

You could achieve the effect of generators manually by writing your own class and storing all the local variables of the generator as instance variables. For example, returning a list of integers could be done by setting `self.count` to 0, and having the `next()` method increment `self.count` and return it. However, for a moderately complicated generator, writing a corresponding class would be much messier. `Lib/test/test_generators.py` contains a number of more interesting examples. The simplest one implements an in-order traversal of a tree using generators recursively.

```
# A recursive generator that generates Tree leaves in in-order.
def inorder(t):
    if t:
        for x in inorder(t.left):
            yield x
        yield t.label
        for x in inorder(t.right):
            yield x
```

Two other examples in `Lib/test/test_generators.py` produce solutions for the N-Queens problem (placing N queens on an $N \times N$ chess board so that no queen threatens another) and the Knight's Tour (a route that takes a knight to every square of an $N \times N$ chessboard without visiting any square twice).

The idea of generators comes from other programming languages, especially Icon (<http://www.cs.arizona.edu/icon/>), where the idea of generators is central. In Icon, every expression and function call behaves like a generator. One example from "An Overview of the Icon Programming Language" at <http://www.cs.arizona.edu/icon/docs/ipd266.htm> gives an idea of what this looks like:

```
sentence := "Store it in the neighboring harbor"
if (i := find("or", sentence)) > 5 then write(i)
```

In Icon the `find()` function returns the indexes at which the substring “or” is found: 3, 23, 33. In the `if` statement, `i` is first assigned a value of 3, but 3 is less than 5, so the comparison fails, and Icon retries it with the second value of 23. 23 is greater than 5, so the comparison now succeeds, and the code prints the value 23 to the screen.

Python doesn’t go nearly as far as Icon in adopting generators as a central concept. Generators are considered a new part of the core Python language, but learning or using them isn’t compulsory; if they don’t solve any problems that you have, feel free to ignore them. One novel feature of Python’s interface as compared to Icon’s is that a generator’s state is represented as a concrete object (the iterator) that can be passed around to other functions or stored in a data structure.

PEP 255 - Simple Generators

Written by Neil Schemenauer, Tim Peters, Magnus Lie Hetland. Implemented mostly by Neil Schemenauer and Tim Peters, with other fixes from the Python Labs crew.

PEP 237: Unifying Long Integers and Integers

In recent versions, the distinction between regular integers, which are 32-bit values on most machines, and long integers, which can be of arbitrary size, was becoming an annoyance. For example, on platforms that support files larger than `2**32` bytes, the `tell()` method of file objects has to return a long integer. However, there were various bits of Python that expected plain integers and would raise an error if a long integer was provided instead. For example, in Python 1.5, only regular integers could be used as a slice index, and `'abc'[1L:]` would raise a `TypeError` exception with the message 'slice index must be int'.

Python 2.2 will shift values from short to long integers as required. The 'L' suffix is no longer needed to indicate a long integer literal, as now the compiler will choose the appropriate type. (Using the 'L' suffix will be discouraged in future 2.x versions of Python, triggering a warning in Python 2.4, and probably dropped in Python 3.0.) Many operations that used to raise an `OverflowError` will now return a long integer as their result. For example:

```
>>> 1234567890123
1234567890123L
>>> 2 ** 64
18446744073709551616L
```

In most cases, integers and long integers will now be treated identically. You can still distinguish them with the `type()` built-in function, but that's rarely needed.

See also:

PEP 237 - Unifying Long Integers and Integers

Written by Moshe Zadka and Guido van Rossum. Implemented mostly by Guido van Rossum.

PEP 238: Changing the Division Operator

The most controversial change in Python 2.2 heralds the start of an effort to fix an old design flaw that's been in Python from the beginning. Currently Python's division operator, `/`, behaves like C's division operator when presented with two integer arguments: it returns an integer result that's truncated down when there would be a fractional part. For example, `3/2` is 1, not 1.5, and `(-1)/2` is -1, not -0.5. This means that the results of division can vary unexpectedly depending on the type of the two operands and because Python is dynamically typed, it can be difficult to determine the possible types of the operands.

(The controversy is over whether this is *really* a design flaw, and whether it's worth breaking existing code to fix this. It's caused endless discussions on `python-dev`, and in July 2001 erupted into an storm of acidly sarcastic postings on `comp.lang.python`. I won't argue for either side here and will stick to describing what's implemented in 2.2. Read [PEP 238](#) for a summary of arguments and counter-arguments.)

Because this change might break code, it's being introduced very gradually. Python 2.2 begins the transition, but the switch won't be complete until Python 3.0.

First, I'll borrow some terminology from [PEP 238](#). "True division" is the division that most non-programmers are familiar with: `3/2` is 1.5, `1/4` is 0.25, and so forth. "Floor division" is what Python's `//` operator currently does when given integer operands; the result is the floor of the value returned by true division. "Classic division" is the current mixed behaviour of `/`; it returns the result of floor division when the operands are integers, and returns the result of true division when one of the operands is a floating-point number.

Here are the changes 2.2 introduces:

- A new operator, `//`, is the floor division operator. (Yes, we know it looks like C++'s comment symbol.) `//` *always* performs floor division no matter what the types of its operands are, so `1 // 2` is 0 and `1.0 // 2.0` is also 0.0.

`//` is always available in Python 2.2; you don't need to enable it using a `__future__` statement.

- By including a `from __future__ import division` in a module, the `/` operator will be changed to return the result of true division, so `1/2` is 0.5. Without the `__future__` statement, `/` still means classic division. The default meaning of `/` will not change until Python 3.0.
- Classes can define methods called `__truediv__()` and `__floordiv__()` to overload the two division operators. At the C level, there are also slots in the `PyNumberMethods` structure so extension types can define the two operators.
- Python 2.2 supports some command-line arguments for testing whether code will work with the changed division semantics. Running python with `-Q warn` will cause a warning to be issued whenever division is applied to two integers. You can use this to find code that's affected by the change and fix it. By default, Python 2.2 will simply perform classic division without a warning; the warning will be turned on by default in Python 2.3.

PEP 238 - Changing the Division Operator

Written by Moshe Zadka and Guido van Rossum. Implemented by Guido van Rossum..

Unicode Changes

Python's Unicode support has been enhanced a bit in 2.2. Unicode strings are usually stored as UCS-2, as 16-bit unsigned integers. Python 2.2 can also be compiled to use UCS-4, 32-bit unsigned integers, as its internal encoding by supplying `--enable-unicode=ucs4` to the configure script. (It's also possible to specify `--disable-unicode` to completely disable Unicode support.)

When built to use UCS-4 (a “wide Python”), the interpreter can natively handle Unicode characters from U+000000 to U+110000, so the range of legal values for the `unichr()` function is expanded accordingly. Using an interpreter compiled to use UCS-2 (a “narrow Python”), values greater than 65535 will still cause `unichr()` to raise a `ValueError` exception. This is all described in [PEP 261](#), “Support for ‘wide’ Unicode characters”; consult it for further details.

Another change is simpler to explain. Since their introduction, Unicode strings have supported an `encode()` method to convert the string to a selected encoding such as UTF-8 or Latin-1. A symmetric `decode([*encoding*])()` method has been added to 8-bit strings (though not to Unicode strings) in 2.2. `decode()` assumes that the string is in the specified encoding and decodes it, returning whatever is returned by the codec.

Using this new feature, codecs have been added for tasks not directly related to Unicode. For example, codecs have been added for uu-encoding, MIME's base64 encoding, and compression with the `zlib` module:

```
>>> s = """Here is a lengthy piece of redundant, overly verbose
... and repetitive text.
... """
>>> data = s.encode('zlib')
```

```
>>> data
'x\x9c\r\xc9\xc1\r\x80 \x10\x04\xc0?U1...'
>>> data.decode('zlib')
'Here is a lengthy piece of redundant, overly verbose,\nand rep
>>> print s.encode('uu')
begin 666 <data>
M2&5R92!I<R!A(&QE;F=T:'D@<&EE8V4@;V8@<F5D=6YD86YT+'!0=F5R;'D@
>=F5R8F]S92P*86YD(')E<&5T:71I=F4@=&5X="X*

end
>>> "sheesh".encode('rot-13')
'furrfu'
```

To convert a class instance to Unicode, a `__unicode__()` method can be defined by a class, analogous to `__str__()`.

`encode()`, `decode()`, and `__unicode__()` were implemented by Marc-André Lemburg. The changes to support using UCS-4 internally were implemented by Fredrik Lundh and Martin von Löwis.

Written by Paul Prescod.

PEP 227: Nested Scopes

In Python 2.1, statically nested scopes were added as an optional feature, to be enabled by a `from __future__ import nested_scopes` directive. In 2.2 nested scopes no longer need to be specially enabled, and are now always present. The rest of this section is a copy of the description of nested scopes from my “What’s New in Python 2.1” document; if you read it when 2.1 came out, you can skip the rest of this section.

The largest change introduced in Python 2.1, and made complete in 2.2, is to Python’s scoping rules. In Python 2.0, at any given time there are at most three namespaces used to look up variable names: local, module-level, and the built-in namespace. This often surprised people because it didn’t match their intuitive expectations. For example, a nested recursive function definition doesn’t work:

```
def f():
    ...
    def g(value):
        ...
        return g(value-1) + 1
    ...
```

The function `g()` will always raise a `NameError` exception, because the binding of the name `g` isn’t in either its local namespace or in the module-level namespace. This isn’t much of a problem in practice (how often do you recursively define interior functions like this?), but this also made using the `lambda` statement clumsier, and this was a problem in practice. In code which uses `lambda` you can often find local variables being copied by passing them as the default values of arguments.

```
def find(self, name):
    "Return list of any entries equal to 'name'"
```

```
L = filter(lambda x, name=name: x == name,
           self.list_attribute)
return L
```

The readability of Python code written in a strongly functional style suffers greatly as a result.

The most significant change to Python 2.2 is that static scoping has been added to the language to fix this problem. As a first effect, the `name=name` default argument is now unnecessary in the above example. Put simply, when a given variable name is not assigned a value within a function (by an assignment, or the `def`, `class`, or `import` statements), references to the variable will be looked up in the local namespace of the enclosing scope. A more detailed explanation of the rules, and a dissection of the implementation, can be found in the PEP.

This change may cause some compatibility problems for code where the same variable name is used both at the module level and as a local variable within a function that contains further function definitions. This seems rather unlikely though, since such code would have been pretty confusing to read in the first place.

One side effect of the change is that the `from module import *` and `exec` statements have been made illegal inside a function scope under certain conditions. The Python reference manual has said all along that `from module import *` is only legal at the top level of a module, but the CPython interpreter has never enforced this before. As part of the implementation of nested scopes, the compiler which turns Python source into bytecodes has to generate different code to access variables in a containing scope. `from module import *` and `exec` make it impossible for the compiler to figure this out, because they add names to the local namespace that are unknowable at compile time. Therefore, if a function contains function definitions or `lambda` expressions with free variables, the compiler will flag this by

raising a `SyntaxError` exception.

To make the preceding explanation a bit clearer, here's an example:

```
x = 1
def f():
    # The next line is a syntax error
    exec 'x=2'
    def g():
        return x
```

Line 4 containing the `exec` statement is a syntax error, since `exec` would define a new local variable named `x` whose value should be accessed by `g()`.

This shouldn't be much of a limitation, since `exec` is rarely used in most Python code (and when it is used, it's often a sign of a poor design anyway).

PEP 227 - Statically Nested Scopes

Written and implemented by Jeremy Hylton.

New and Improved Modules

- The `xmlrpclib` module was contributed to the standard library by Fredrik Lundh, providing support for writing XML-RPC clients. XML-RPC is a simple remote procedure call protocol built on top of HTTP and XML. For example, the following snippet retrieves a list of RSS channels from the O'Reilly Network, and then lists the recent headlines for one channel:

```
import xmlrpclib
s = xmlrpclib.Server(
    'http://www.oreillynet.com/meerkat/xml-rpc/server.php')
channels = s.meerkat.getChannels()
# channels is a list of dictionaries, like this:
# [{ 'id': 4, 'title': 'Freshmeat Daily News' }
#  { 'id': 190, 'title': '32Bits Online' },
#  { 'id': 4549, 'title': '3DGamers'}, ... ]

# Get the items for one channel
items = s.meerkat.getItems( {'channel': 4} )

# 'items' is another list of dictionaries, like this:
# [{ 'link': 'http://freshmeat.net/releases/52719/',
#    'description': 'A utility which converts HTML to XSL FO
#    'title': 'html2fo 0.3 (Default)' }, ... ]
```

The `SimpleXMLRPCServer` module makes it easy to create straightforward XML-RPC servers. See <http://www.xmlrpc.com/> for more information about XML-RPC.

- The new `hmac` module implements the HMAC algorithm described by **RFC 2104**. (Contributed by Gerhard Häring.)
- Several functions that originally returned lengthy tuples now return pseudo-sequences that still behave like tuples but also have mnemonic attributes such as `memberst_mtime` or `tm_year`.

The enhanced functions include `stat()`, `fstat()`, `statvfs()`, and `fstatvfs()` in the `os` module, and `localtime()`, `gmtime()`, and `strptime()` in the `time` module.

For example, to obtain a file's size using the old tuples, you'd end up writing something like `file_size = os.stat(filename)[stat.ST_SIZE]`, but now this can be written more clearly as `file_size = os.stat(filename).st_size`.

The original patch for this feature was contributed by Nick Mathewson.

- The Python profiler has been extensively reworked and various errors in its output have been corrected. (Contributed by Fred L. Drake, Jr. and Tim Peters.)
- The `socket` module can be compiled to support IPv6; specify the `--enable-ipv6` option to Python's configure script. (Contributed by Jun-ichiro "itojun" Hagino.)
- Two new format characters were added to the `struct` module for 64-bit integers on platforms that support the C `long long` type. `q` is for a signed 64-bit integer, and `Q` is for an unsigned one. The value is returned in Python's long integer type. (Contributed by Tim Peters.)
- In the interpreter's interactive mode, there's a new built-in function `help()` that uses the `pydoc` module introduced in Python 2.1 to provide interactive help. `help(object)` displays any available help text about `object`. `help()` with no argument puts you in an online help utility, where you can enter the names of functions, classes, or modules to read their help text. (Contributed by Guido van Rossum, using Ka-Ping Yee's `pydoc` module.)

- Various bugfixes and performance improvements have been made to the SRE engine underlying the `re` module. For example, the `re.sub()` and `re.split()` functions have been rewritten in C. Another contributed patch speeds up certain Unicode character ranges by a factor of two, and a new `finditer()` method that returns an iterator over all the non-overlapping matches in a given string. (SRE is maintained by Fredrik Lundh. The BIGCHARSET patch was contributed by Martin von Löwis.)
- The `smtplib` module now supports [RFC 2487](#), “Secure SMTP over TLS”, so it’s now possible to encrypt the SMTP traffic between a Python program and the mail transport agent being handed a message. `smtplib` also supports SMTP authentication. (Contributed by Gerhard Häring.)
- The `imaplib` module, maintained by Piers Lauder, has support for several new extensions: the NAMESPACE extension defined in [RFC 2342](#), SORT, GETACL and SETACL. (Contributed by Anthony Baxter and Michel Pelletier.)
- The `rfc822` module’s parsing of email addresses is now compliant with [RFC 2822](#), an update to [RFC 822](#). (The module’s name is *not* going to be changed to `rfc2822`.) A new package, `email`, has also been added for parsing and generating e-mail messages. (Contributed by Barry Warsaw, and arising out of his work on Mailman.)
- The `difflib` module now contains a new `Differ` class for producing human-readable lists of changes (a “delta”) between two sequences of lines of text. There are also two generator functions, `ndiff()` and `restore()`, which respectively return a delta from two sequences, or one of the original sequences from a delta. (Grunt work contributed by David Goodger, from `ndiff.py`)

code by Tim Peters who then did the generatorization.)

- New constants `ascii_letters`, `ascii_lowercase`, and `ascii_uppercase` were added to the `string` module. There were several modules in the standard library that used `string.letters` to mean the ranges A-Za-z, but that assumption is incorrect when locales are in use, because `string.letters` varies depending on the set of legal characters defined by the current locale. The buggy modules have all been fixed to use `ascii_letters` instead. (Reported by an unknown person; fixed by Fred L. Drake, Jr.)
- The `mimetypes` module now makes it easier to use alternative MIME-type databases by the addition of a `MimeTypes` class, which takes a list of filenames to be parsed. (Contributed by Fred L. Drake, Jr.)
- A `Timer` class was added to the `threading` module that allows scheduling an activity to happen at some future time. (Contributed by Itamar Shtull-Trauring.)

Interpreter Changes and Fixes

Some of the changes only affect people who deal with the Python interpreter at the C level because they're writing Python extension modules, embedding the interpreter, or just hacking on the interpreter itself. If you only write Python code, none of the changes described here will affect you very much.

- Profiling and tracing functions can now be implemented in C, which can operate at much higher speeds than Python-based functions and should reduce the overhead of profiling and tracing. This will be of interest to authors of development environments for Python. Two new C functions were added to Python's API, `PyEval_SetProfile()` and `PyEval_SetTrace()`. The existing `sys.setprofile()` and `sys.settrace()` functions still exist, and have simply been changed to use the new C-level interface. (Contributed by Fred L. Drake, Jr.)
- Another low-level API, primarily of interest to implementors of Python debuggers and development tools, was added. `PyInterpreterState_Head()` and `PyInterpreterState_Next()` let a caller walk through all the existing interpreter objects; `PyInterpreterState_ThreadHead()` and `PyThreadState_Next()` allow looping over all the thread states for a given interpreter. (Contributed by David Beazley.)
- The C-level interface to the garbage collector has been changed to make it easier to write extension types that support garbage collection and to debug misuses of the functions. Various functions have slightly different semantics, so a bunch of functions had to be renamed. Extensions that use the old API will still compile but will *not* participate in garbage collection, so updating them for 2.2 should be considered fairly high priority.

To upgrade an extension module to the new API, perform the following steps:

- Rename `Py_TPFLAGS_GC()` to `PyTPFLAGS_HAVE_GC()`.
- Use `PyObject_GC_New()` or `PyObject_GC_NewVar()` to allocate objects, and `PyObject_GC_De1()` to deallocate them.
- Rename `PyObject_GC_Init()` to `PyObject_GC_Track()` and `PyObject_GC_Fini()` to `PyObject_GC_UnTrack()`.
- Remove `PyGC_HEAD_SIZE()` from object size calculations.
- Remove calls to `PyObject_AS_GC()` and `PyObject_FROM_GC()`.
- A new `et` format sequence was added to `PyArg_ParseTuple()`; `et` takes both a parameter and an encoding name, and converts the parameter to the given encoding if the parameter turns out to be a Unicode string, or leaves it alone if it's an 8-bit string, assuming it to already be in the desired encoding. This differs from the `es` format character, which assumes that 8-bit strings are in Python's default ASCII encoding and converts them to the specified new encoding. (Contributed by M.-A. Lemburg, and used for the MBCS support on Windows described in the following section.)
- A different argument parsing function, `PyArg_UnpackTuple()`, has been added that's simpler and presumably faster. Instead of specifying a format string, the caller simply gives the minimum and maximum number of arguments expected, and a set of pointers to `PyObject*` variables that will be filled in with argument values.
- Two new flags `METH_NOARGS` and `METH_O` are available in method

definition tables to simplify implementation of methods with no arguments or a single untyped argument. Calling such methods is more efficient than calling a corresponding method that uses `METH_VARARGS`. Also, the old `METH_OLDARGS` style of writing C methods is now officially deprecated.

- Two new wrapper functions, `PyOS_snprintf()` and `PyOS_vsnprintf()` were added to provide cross-platform implementations for the relatively new `snprintf()` and `vsnprintf()` C lib APIs. In contrast to the standard `sprintf()` and `vsprintf()` functions, the Python versions check the bounds of the buffer used to protect against buffer overruns. (Contributed by M.-A. Lemburg.)
- The `_PyTuple_Resize()` function has lost an unused parameter, so now it takes 2 parameters instead of 3. The third argument was never used, and can simply be discarded when porting code from earlier versions to Python 2.2.

Other Changes and Fixes

As usual there were a bunch of other improvements and bugfixes scattered throughout the source tree. A search through the CVS change logs finds there were 527 patches applied and 683 bugs fixed between Python 2.1 and 2.2; 2.2.1 applied 139 patches and fixed 143 bugs; 2.2.2 applied 106 patches and fixed 82 bugs. These figures are likely to be underestimates.

Some of the more notable changes are:

- The code for the MacOS port for Python, maintained by Jack Jansen, is now kept in the main Python CVS tree, and many changes have been made to support MacOS X.

The most significant change is the ability to build Python as a framework, enabled by supplying the `--enable-framework` option to the configure script when compiling Python. According to Jack Jansen, “This installs a self-contained Python installation plus the OS X framework “glue” into `/Library/Frameworks/Python.framework` (or another location of choice). For now there is little immediate added benefit to this (actually, there is the disadvantage that you have to change your PATH to be able to find Python), but it is the basis for creating a full-blown Python application, porting the MacPython IDE, possibly using Python as a standard OSA scripting language and much more.”

Most of the MacPython toolbox modules, which interface to MacOS APIs such as windowing, QuickTime, scripting, etc. have been ported to OS X, but they’ve been left commented out in `setup.py`. People who want to experiment with these modules can uncomment them manually.

- Keyword arguments passed to built-in functions that don't take them now cause a `TypeError` exception to be raised, with the message “*function* takes no keyword arguments”.
- Weak references, added in Python 2.1 as an extension module, are now part of the core because they're used in the implementation of new-style classes. The `ReferenceError` exception has therefore moved from the `weakref` module to become a built-in exception.
- A new script, `Tools/scripts/cleanfuture.py` by Tim Peters, automatically removes obsolete `__future__` statements from Python source code.
- An additional *flags* argument has been added to the built-in function `compile()`, so the behaviour of `__future__` statements can now be correctly observed in simulated shells, such as those presented by IDLE and other development environments. This is described in [PEP 264](#). (Contributed by Michael Hudson.)
- The new license introduced with Python 1.6 wasn't GPL-compatible. This is fixed by some minor textual changes to the 2.2 license, so it's now legal to embed Python inside a GPLed program again. Note that Python itself is not GPLed, but instead is under a license that's essentially equivalent to the BSD license, same as it always was. The license changes were also applied to the Python 2.0.1 and 2.1.1 releases.
- When presented with a Unicode filename on Windows, Python will now convert it to an MBCS encoded string, as used by the Microsoft file APIs. As MBCS is explicitly used by the file APIs, Python's choice of ASCII as the default encoding turns out to be an annoyance. On Unix, the locale's character set is used if `locale.nl_langinfo(CODESET)()` is available. (Windows support

was contributed by Mark Hammond with assistance from Marc-André Lemburg. Unix support was added by Martin von Löwis.)

- Large file support is now enabled on Windows. (Contributed by Tim Peters.)
- The `Tools/scripts/ftpmirror.py` script now parses a `.netrc` file, if you have one. (Contributed by Mike Romberg.)
- Some features of the object returned by the `xrange()` function are now deprecated, and trigger warnings when they're accessed; they'll disappear in Python 2.3. `xrange` objects tried to pretend they were full sequence types by supporting slicing, sequence multiplication, and the `in` operator, but these features were rarely used and therefore buggy. The `tolist()` method and the `start`, `stop`, and `step` attributes are also being deprecated. At the C level, the fourth argument to the `PyRange_New()` function, `repeat`, has also been deprecated.
- There were a bunch of patches to the dictionary implementation, mostly to fix potential core dumps if a dictionary contains objects that sneakily changed their hash value, or mutated the dictionary they were contained in. For a while python-dev fell into a gentle rhythm of Michael Hudson finding a case that dumped core, Tim Peters fixing the bug, Michael finding another case, and round and round it went.
- On Windows, Python can now be compiled with Borland C thanks to a number of patches contributed by Stephen Hansen, though the result isn't fully functional yet. (But this *is* progress...)
- Another Windows enhancement: Wise Solutions generously offered PythonLabs use of their InstallerMaster 8.1 system. Earlier PythonLabs Windows installers used Wise 5.0a, which was beginning to show its age. (Packaged up by Tim Peters.)

- Files ending in `.pyw` can now be imported on Windows. `.pyw` is a Windows-only thing, used to indicate that a script needs to be run using `PYTHONW.EXE` instead of `PYTHON.EXE` in order to prevent a DOS console from popping up to display the output. This patch makes it possible to import such scripts, in case they're also usable as modules. (Implemented by David Bolen.)
- On platforms where Python uses the C `dlopen()` function to load extension modules, it's now possible to set the flags used by `dlopen()` using the `sys.getdlopenflags()` and `sys.setdlopenflags()` functions. (Contributed by Bram Stolk.)
- The `pow()` built-in function no longer supports 3 arguments when floating-point numbers are supplied. `pow(x, y, z)` returns `(x**y) % z`, but this is never useful for floating point numbers, and the final result varies unpredictably depending on the platform. A call such as `pow(2.0, 8.0, 7.0)` will now raise a `TypeError` exception.

What's New in Python 2.1

Author: A.M. Kuchling

Introduction

This article explains the new features in Python 2.1. While there aren't as many changes in 2.1 as there were in Python 2.0, there are still some pleasant surprises in store. 2.1 is the first release to be steered through the use of Python Enhancement Proposals, or PEPs, so most of the sizable changes have accompanying PEPs that provide more complete documentation and a design rationale for the change. This article doesn't attempt to document the new features completely, but simply provides an overview of the new features for Python programmers. Refer to the Python 2.1 documentation, or to the specific PEP, for more details about any new feature that particularly interests you.

One recent goal of the Python development team has been to accelerate the pace of new releases, with a new release coming every 6 to 9 months. 2.1 is the first release to come out at this faster pace, with the first alpha appearing in January, 3 months after the final version of 2.0 was released.

The final release of Python 2.1 was made on April 17, 2001.

PEP 227: Nested Scopes

The largest change in Python 2.1 is to Python's scoping rules. In Python 2.0, at any given time there are at most three namespaces used to look up variable names: local, module-level, and the built-in namespace. This often surprised people because it didn't match their intuitive expectations. For example, a nested recursive function definition doesn't work:

```
def f():
    ...
    def g(value):
        ...
        return g(value-1) + 1
    ...
```

The function `g()` will always raise a `NameError` exception, because the binding of the name `g` isn't in either its local namespace or in the module-level namespace. This isn't much of a problem in practice (how often do you recursively define interior functions like this?), but this also made using the `lambda` statement clumsier, and this was a problem in practice. In code which uses `lambda` you can often find local variables being copied by passing them as the default values of arguments.

```
def find(self, name):
    "Return list of any entries equal to 'name'"
    L = filter(lambda x, name=name: x == name,
              self.list_attribute)
    return L
```

The readability of Python code written in a strongly functional style suffers greatly as a result.

The most significant change to Python 2.1 is that static scoping has been added to the language to fix this problem. As a first effect, the

`name=name` default argument is now unnecessary in the above example. Put simply, when a given variable name is not assigned a value within a function (by an assignment, or the `def`, `class`, or `import` statements), references to the variable will be looked up in the local namespace of the enclosing scope. A more detailed explanation of the rules, and a dissection of the implementation, can be found in the PEP.

This change may cause some compatibility problems for code where the same variable name is used both at the module level and as a local variable within a function that contains further function definitions. This seems rather unlikely though, since such code would have been pretty confusing to read in the first place.

One side effect of the change is that the `from module import *` and `exec` statements have been made illegal inside a function scope under certain conditions. The Python reference manual has said all along that `from module import *` is only legal at the top level of a module, but the CPython interpreter has never enforced this before. As part of the implementation of nested scopes, the compiler which turns Python source into bytecodes has to generate different code to access variables in a containing scope. `from module import *` and `exec` make it impossible for the compiler to figure this out, because they add names to the local namespace that are unknowable at compile time. Therefore, if a function contains function definitions or `lambda` expressions with free variables, the compiler will flag this by raising a `SyntaxError` exception.

To make the preceding explanation a bit clearer, here's an example:

```
x = 1
def f():
    # The next line is a syntax error
    exec 'x=2'
    def g():
```

```
return x
```

Line 4 containing the `exec` statement is a syntax error, since `exec` would define a new local variable named `x` whose value should be accessed by `g()`.

This shouldn't be much of a limitation, since `exec` is rarely used in most Python code (and when it is used, it's often a sign of a poor design anyway).

Compatibility concerns have led to nested scopes being introduced gradually; in Python 2.1, they aren't enabled by default, but can be turned on within a module by using a future statement as described in PEP 236. (See the following section for further discussion of PEP 236.) In Python 2.2, nested scopes will become the default and there will be no way to turn them off, but users will have had all of 2.1's lifetime to fix any breakage resulting from their introduction.

See also:

[PEP 227 - Statically Nested Scopes](#)

Written and implemented by Jeremy Hylton.

PEP 236: `__future__` Directives

The reaction to nested scopes was widespread concern about the dangers of breaking code with the 2.1 release, and it was strong enough to make the Pythoners take a more conservative approach. This approach consists of introducing a convention for enabling optional functionality in release N that will become compulsory in release N+1.

The syntax uses a `from...import` statement using the reserved module name `__future__`. Nested scopes can be enabled by the following statement:

```
from __future__ import nested_scopes
```

While it looks like a normal `import` statement, it's not; there are strict rules on where such a future statement can be put. They can only be at the top of a module, and must precede any Python code or regular `import` statements. This is because such statements can affect how the Python bytecode compiler parses code and generates bytecode, so they must precede any statement that will result in bytecodes being produced.

See also:

PEP 236 - Back to the `__future__`

Written by Tim Peters, and primarily implemented by Jeremy Hylton.

PEP 207: Rich Comparisons

In earlier versions, Python's support for implementing comparisons on user-defined classes and extension types was quite simple. Classes could implement a `__cmp__()` method that was given two instances of a class, and could only return 0 if they were equal or +1 or -1 if they weren't; the method couldn't raise an exception or return anything other than a Boolean value. Users of Numeric Python often found this model too weak and restrictive, because in the number-crunching programs that numeric Python is used for, it would be more useful to be able to perform elementwise comparisons of two matrices, returning a matrix containing the results of a given comparison for each element. If the two matrices are of different sizes, then the compare has to be able to raise an exception to signal the error.

In Python 2.1, rich comparisons were added in order to support this need. Python classes can now individually overload each of the `<`, `<=`, `>`, `>=`, `==`, and `!=` operations. The new magic method names are:

Operation	Method name
<code><</code>	<code>__lt__()</code>
<code><=</code>	<code>__le__()</code>
<code>></code>	<code>__gt__()</code>
<code>>=</code>	<code>__ge__()</code>
<code>==</code>	<code>__eq__()</code>
<code>!=</code>	<code>__ne__()</code>

(The magic methods are named after the corresponding Fortran operators `.LT.`, `.LE.`, &c. Numeric programmers are almost certainly quite familiar with these names and will find them easy to remember.)

Each of these magic methods is of the form `method(self, other)`,

where `self` will be the object on the left-hand side of the operator, while `other` will be the object on the right-hand side. For example, the expression `A < B` will cause `A.__lt__(B)` to be called.

Each of these magic methods can return anything at all: a Boolean, a matrix, a list, or any other Python object. Alternatively they can raise an exception if the comparison is impossible, inconsistent, or otherwise meaningless.

The built-in `cmp(A,B)()` function can use the rich comparison machinery, and now accepts an optional argument specifying which comparison operation to use; this is given as one of the strings `"<"`, `"<="`, `">"`, `">="`, `"=="`, or `"!="`. If called without the optional third argument, `cmp()` will only return -1, 0, or +1 as in previous versions of Python; otherwise it will call the appropriate method and can return any Python object.

There are also corresponding changes of interest to C programmers; there's a new slot `tp_richcmp` in type objects and an API for performing a given rich comparison. I won't cover the C API here, but will refer you to PEP 207, or to 2.1's C API documentation, for the full list of related functions.

PEP 207 - Rich Comparisons

Written by Guido van Rossum, heavily based on earlier work by David Ascher, and implemented by Guido van Rossum.

PEP 230: Warning Framework

Over its 10 years of existence, Python has accumulated a certain number of obsolete modules and features along the way. It's difficult to know when a feature is safe to remove, since there's no way of knowing how much code uses it — perhaps no programs depend on the feature, or perhaps many do. To enable removing old features in a more structured way, a warning framework was added. When the Python developers want to get rid of a feature, it will first trigger a warning in the next version of Python. The following Python version can then drop the feature, and users will have had a full release cycle to remove uses of the old feature.

Python 2.1 adds the warning framework to be used in this scheme. It adds a `warnings` module that provide functions to issue warnings, and to filter out warnings that you don't want to be displayed. Third-party modules can also use this framework to deprecate old features that they no longer wish to support.

For example, in Python 2.1 the `regex` module is deprecated, so importing it causes a warning to be printed:

```
>>> import regex
__main__:1: DeprecationWarning: the regex module
          is deprecated; please use the re module
>>>
```

Warnings can be issued by calling the `warnings.warn()` function:

```
warnings.warn("feature X no longer supported")
```

The first parameter is the warning message; an additional optional parameters can be used to specify a particular warning category.

Filters can be added to disable certain warnings; a regular

expression pattern can be applied to the message or to the module name in order to suppress a warning. For example, you may have a program that uses the `regex` module and not want to spare the time to convert it to use the `re` module right now. The warning can be suppressed by calling

```
import warnings
warnings.filterwarnings(action = 'ignore',
                        message='.*regex module is deprecated',
                        category=DeprecationWarning,
                        module = '__main__')
```

This adds a filter that will apply only to warnings of the class `DeprecationWarning` triggered in the `__main__` module, and applies a regular expression to only match the message about the `regex` module being deprecated, and will cause such warnings to be ignored. Warnings can also be printed only once, printed every time the offending code is executed, or turned into exceptions that will cause the program to stop (unless the exceptions are caught in the usual way, of course).

Functions were also added to Python's C API for issuing warnings; refer to PEP 230 or to Python's API documentation for the details.

PEP 5 - Guidelines for Language Evolution

Written by Paul Prescod, to specify procedures to be followed when removing old features from Python. The policy described in this PEP hasn't been officially adopted, but the eventual policy probably won't be too different from Prescod's proposal.

PEP 230 - Warning Framework

Written and implemented by Guido van Rossum.

PEP 229: New Build System

When compiling Python, the user had to go in and edit the `Modules/Setup` file in order to enable various additional modules; the default set is relatively small and limited to modules that compile on most Unix platforms. This means that on Unix platforms with many more features, most notably Linux, Python installations often don't contain all useful modules they could.

Python 2.0 added the Distutils, a set of modules for distributing and installing extensions. In Python 2.1, the Distutils are used to compile much of the standard library of extension modules, autodetecting which ones are supported on the current machine. It's hoped that this will make Python installations easier and more featureful.

Instead of having to edit the `Modules/Setup` file in order to enable modules, a `setup.py` script in the top directory of the Python source distribution is run at build time, and attempts to discover which modules can be enabled by examining the modules and header files on the system. If a module is configured in `Modules/Setup`, the `setup.py` script won't attempt to compile that module and will defer to the `Modules/Setup` file's contents. This provides a way to specify any strange command-line flags or libraries that are required for a specific platform.

In another far-reaching change to the build mechanism, Neil Schemenauer restructured things so Python now uses a single makefile that isn't recursive, instead of makefiles in the top directory and in each of the `Python/`, `Parser/`, `Objects/`, and `Modules/` subdirectories. This makes building Python faster and also makes hacking the Makefiles clearer and simpler.

PEP 229 - Using Distutils to Build Python

Written and implemented by A.M. Kuchling.

PEP 205: Weak References

Weak references, available through the `weakref` module, are a minor but useful new data type in the Python programmer's toolbox.

Storing a reference to an object (say, in a dictionary or a list) has the side effect of keeping that object alive forever. There are a few specific cases where this behaviour is undesirable, object caches being the most common one, and another being circular references in data structures such as trees.

For example, consider a memoizing function that caches the results of another function `f(x)()` by storing the function's argument and its result in a dictionary:

```
_cache = {}
def memoize(x):
    if _cache.has_key(x):
        return _cache[x]

    retval = f(x)

    # Cache the returned object
    _cache[x] = retval

    return retval
```

This version works for simple things such as integers, but it has a side effect; the `_cache` dictionary holds a reference to the return values, so they'll never be deallocated until the Python process exits and cleans up. This isn't very noticeable for integers, but if `f()` returns an object, or a data structure that takes up a lot of memory, this can be a problem.

Weak references provide a way to implement a cache that won't keep objects alive beyond their time. If an object is only accessible

through weak references, the object will be deallocated and the weak references will now indicate that the object it referred to no longer exists. A weak reference to an object *obj* is created by calling `wr = weakref.ref(obj)`. The object being referred to is returned by calling the weak reference as if it were a function: `wr()`. It will return the referenced object, or `None` if the object no longer exists.

This makes it possible to write a `memoize()` function whose cache doesn't keep objects alive, by storing weak references in the cache.

```
_cache = {}
def memoize(x):
    if _cache.has_key(x):
        obj = _cache[x]()
        # If weak reference object still exists,
        # return it
        if obj is not None: return obj

    retval = f(x)

    # Cache a weak reference
    _cache[x] = weakref.ref(retval)

    return retval
```

The `weakref` module also allows creating proxy objects which behave like weak references — an object referenced only by proxy objects is deallocated — but instead of requiring an explicit call to retrieve the object, the proxy transparently forwards all operations to the object as long as the object still exists. If the object is deallocated, attempting to use a proxy will cause a `weakref.ReferenceError` exception to be raised.

```
proxy = weakref.proxy(obj)
proxy.attr # Equivalent to obj.attr
proxy.meth() # Equivalent to obj.meth()
del obj
proxy.attr # raises weakref.ReferenceError
```

PEP 205 - Weak References

Written and implemented by Fred L. Drake, Jr.

PEP 232: Function Attributes

In Python 2.1, functions can now have arbitrary information attached to them. People were often using docstrings to hold information about functions and methods, because the `__doc__` attribute was the only way of attaching any information to a function. For example, in the Zope Web application server, functions are marked as safe for public access by having a docstring, and in John Aycock's SPARK parsing framework, docstrings hold parts of the BNF grammar to be parsed. This overloading is unfortunate, since docstrings are really intended to hold a function's documentation; for example, it means you can't properly document functions intended for private use in Zope.

Arbitrary attributes can now be set and retrieved on functions using the regular Python syntax:

```
def f(): pass

f.publish = 1
f.secure = 1
f.grammar = "A ::= B (C D)*"
```

The dictionary containing attributes can be accessed as the function's `__dict__`. Unlike the `__dict__` attribute of class instances, in functions you can actually assign a new dictionary to `__dict__`, though the new value is restricted to a regular Python dictionary; you *can't* be tricky and set it to a `UserDict` instance, or any other random object that behaves like a mapping.

[PEP 232 - Function Attributes](#)

Written and implemented by Barry Warsaw.

PEP 235: Importing Modules on Case-Insensitive Platforms

Some operating systems have filesystems that are case-insensitive, MacOS and Windows being the primary examples; on these systems, it's impossible to distinguish the filenames `FILE.PY` and `file.py`, even though they do store the file's name in its original case (they're case-preserving, too).

In Python 2.1, the `import` statement will work to simulate case-sensitivity on case-insensitive platforms. Python will now search for the first case-sensitive match by default, raising an `ImportError` if no such file is found, so `import file` will not import a module named `FILE.PY`. Case-insensitive matching can be requested by setting the `PYTHONCASEOK` environment variable before starting the Python interpreter.

PEP 217: Interactive Display Hook

When using the Python interpreter interactively, the output of commands is displayed using the built-in `repr()` function. In Python 2.1, the variable `sys.displayhook()` can be set to a callable object which will be called instead of `repr()`. For example, you can set it to a special pretty- printing function:

```
>>> # Create a recursive data structure
... L = [1,2,3]
>>> L.append(L)
>>> L # Show Python's default output
[1, 2, 3, [...]]
>>> # Use pprint.pprint() as the display function
... import sys, pprint
>>> sys.displayhook = pprint.pprint
>>> L
[1, 2, 3, <Recursion on list with id=135143996>]
>>>
```

See also:

PEP 217 - Display Hook for Interactive Use

Written and implemented by Moshe Zadka.

PEP 208: New Coercion Model

How numeric coercion is done at the C level was significantly modified. This will only affect the authors of C extensions to Python, allowing them more flexibility in writing extension types that support numeric operations.

Extension types can now set the type flag `Py_TPFLAGS_CHECKTYPES` in their `PyTypeObject` structure to indicate that they support the new coercion model. In such extension types, the numeric slot functions can no longer assume that they'll be passed two arguments of the same type; instead they may be passed two arguments of differing types, and can then perform their own internal coercion. If the slot function is passed a type it can't handle, it can indicate the failure by returning a reference to the `Py_NotImplemented` singleton value. The numeric functions of the other type will then be tried, and perhaps they can handle the operation; if the other type also returns `Py_NotImplemented`, then a `TypeError` will be raised. Numeric methods written in Python can also return `Py_NotImplemented`, causing the interpreter to act as if the method did not exist (perhaps raising a `TypeError`, perhaps trying another object's numeric methods).

See also:

PEP 208 - Reworking the Coercion Model

Written and implemented by Neil Schemenauer, heavily based upon earlier work by Marc-André Lemburg. Read this to understand the fine points of how numeric operations will now be processed at the C level.

PEP 241: Metadata in Python Packages

A common complaint from Python users is that there's no single catalog of all the Python modules in existence. T. Middleton's Vaults of Parnassus at <http://www.vex.net/parnassus/> are the largest catalog of Python modules, but registering software at the Vaults is optional, and many people don't bother.

As a first small step toward fixing the problem, Python software packaged using the Distutils **sdist** command will include a file named `PKG-INFO` containing information about the package such as its name, version, and author (metadata, in cataloguing terminology). PEP 241 contains the full list of fields that can be present in the `PKG-INFO` file. As people began to package their software using Python 2.1, more and more packages will include metadata, making it possible to build automated cataloguing systems and experiment with them. With the result experience, perhaps it'll be possible to design a really good catalog and then build support for it into Python 2.2. For example, the Distutils **sdist** and **bdist_*** commands could support a *upload* option that would automatically upload your package to a catalog server.

You can start creating packages containing `PKG-INFO` even if you're not using Python 2.1, since a new release of the Distutils will be made for users of earlier Python versions. Version 1.0.2 of the Distutils includes the changes described in PEP 241, as well as various bugfixes and enhancements. It will be available from the Distutils SIG at <http://www.python.org/sigs/distutils-sig/>.

PEP 241 - Metadata for Python Software Packages

Written and implemented by A.M. Kuchling.

PEP 243 - Module Repository Upload Mechanism

Written by Sean Reifschneider, this draft PEP describes a proposed mechanism for uploading Python packages to a central server.

New and Improved Modules

- Ka-Ping Yee contributed two new modules: `inspect.py`, a module for getting information about live Python code, and `pydoc.py`, a module for interactively converting docstrings to HTML or text. As a bonus, `Tools/scripts/pydoc`, which is now automatically installed, uses `pydoc.py` to display documentation given a Python module, package, or class name. For example, `pydoc xml.dom` displays the following:

```
Python Library Documentation: package xml.dom in xml
NAME
    xml.dom - W3C Document Object Model implementation for
FILE
    /usr/local/lib/python2.1/xml/dom/__init__.pyc
DESCRIPTION
    The Python mapping of the Document Object Model is docu
    Python Library Reference in the section on the xml.dom
    This package contains the following modules:
    . . .
```

`pydoc` also includes a Tk-based interactive help browser. `pydoc` quickly becomes addictive; try it out!

- Two different modules for unit testing were added to the standard library. The `doctest` module, contributed by Tim Peters, provides a testing framework based on running embedded examples in docstrings and comparing the results against the expected output. PyUnit, contributed by Steve Purcell, is a unit testing framework inspired by JUnit, which was in turn an adaptation of Kent Beck's Smalltalk testing

framework. See <http://pyunit.sourceforge.net/> for more information about PyUnit.

- The `difflib` module contains a class, `SequenceMatcher`, which compares two sequences and computes the changes required to transform one sequence into the other. For example, this module can be used to write a tool similar to the Unix `diff` program, and in fact the sample program `Tools/scripts/ndiff.py` demonstrates how to write such a script.
- `curses.panel`, a wrapper for the panel library, part of ncurses and of SYSV curses, was contributed by Thomas Gellekum. The panel library provides windows with the additional feature of depth. Windows can be moved higher or lower in the depth ordering, and the panel library figures out where panels overlap and which sections are visible.
- The PyXML package has gone through a few releases since Python 2.0, and Python 2.1 includes an updated version of the `xml` package. Some of the noteworthy changes include support for Expat 1.2 and later versions, the ability for Expat parsers to handle files in any encoding supported by Python, and various bugfixes for SAX, DOM, and the `minidom` module.
- Ping also contributed another hook for handling uncaught exceptions. `sys.excepthook()` can be set to a callable object. When an exception isn't caught by any `try...except` blocks, the exception will be passed to `sys.excepthook()`, which can then do whatever it likes. At the Ninth Python Conference, Ping demonstrated an application for this hook: printing an extended traceback that not only lists the stack frames, but also lists the function arguments and the local variables for each frame.

- Various functions in the `time` module, such as `asctime()` and `localtime()`, require a floating point argument containing the time in seconds since the epoch. The most common use of these functions is to work with the current time, so the floating point argument has been made optional; when a value isn't provided, the current time will be used. For example, log file entries usually need a string containing the current time; in Python 2.1, `time.asctime()` can be used, instead of the lengthier `time.asctime(time.localtime(time.time()))` that was previously required.

This change was proposed and implemented by Thomas Wouters.

- The `ftplib` module now defaults to retrieving files in passive mode, because passive mode is more likely to work from behind a firewall. This request came from the Debian bug tracking system, since other Debian packages use `ftplib` to retrieve files and then don't work from behind a firewall. It's deemed unlikely that this will cause problems for anyone, because Netscape defaults to passive mode and few people complain, but if passive mode is unsuitable for your application or network setup, call `set_pasv(0)()` on FTP objects to disable passive mode.
- Support for raw socket access has been added to the `socket` module, contributed by Grant Edwards.
- The `pstats` module now contains a simple interactive statistics browser for displaying timing profiles for Python programs, invoked when the module is run as a script. Contributed by Eric S. Raymond.
- A new implementation-dependent function,

`sys._getframe([depth])()`, has been added to return a given frame object from the current call stack. `sys._getframe()` returns the frame at the top of the call stack; if the optional integer argument *depth* is supplied, the function returns the frame that is *depth* calls below the top of the stack. For example, `sys._getframe(1)` returns the caller's frame object.

This function is only present in CPython, not in Jython or the .NET implementation. Use it for debugging, and resist the temptation to put it into production code.

Other Changes and Fixes

There were relatively few smaller changes made in Python 2.1 due to the shorter release cycle. A search through the CVS change logs turns up 117 patches applied, and 136 bugs fixed; both figures are likely to be underestimates. Some of the more notable changes are:

- A specialized object allocator is now optionally available, that should be faster than the system `malloc()` and have less memory overhead. The allocator uses C's `malloc()` function to get large pools of memory, and then fulfills smaller memory requests from these pools. It can be enabled by providing the `--with-pymalloc` option to the **configure** script; see `objects/obmalloc.c` for the implementation details.

Authors of C extension modules should test their code with the object allocator enabled, because some incorrect code may break, causing core dumps at runtime. There are a bunch of memory allocation functions in Python's C API that have previously been just aliases for the C library's `malloc()` and `free()`, meaning that if you accidentally called mismatched functions, the error wouldn't be noticeable. When the object allocator is enabled, these functions aren't aliases of `malloc()` and `free()` any more, and calling the wrong function to free memory will get you a core dump. For example, if memory was allocated using `PyMem_New()`, it has to be freed using `PyMem_De1()`, not `free()`. A few modules included with Python fell afoul of this and had to be fixed; doubtless there are more third-party modules that will have the same problem.

The object allocator was contributed by Vladimir Marangozov.

- The speed of line-oriented file I/O has been improved because

people often complain about its lack of speed, and because it's often been used as a naïve benchmark. The `readline()` method of file objects has therefore been rewritten to be much faster. The exact amount of the speedup will vary from platform to platform depending on how slow the C library's `getc()` was, but is around 66%, and potentially much faster on some particular operating systems. Tim Peters did much of the benchmarking and coding for this change, motivated by a discussion in `comp.lang.python`.

A new module and method for file objects was also added, contributed by Jeff Epler. The new method, `xreadlines()`, is similar to the existing `xrange()` built-in. `xreadlines()` returns an opaque sequence object that only supports being iterated over, reading a line on every iteration but not reading the entire file into memory as the existing `readlines()` method does. You'd use it like this:

```
for line in sys.stdin.xreadlines():
    # ... do something for each line ...
    ...
```

For a fuller discussion of the line I/O changes, see the `python-dev` summary for January 1-15, 2001 at <http://www.python.org/dev/summary/2001-01-1/>.

- A new method, `popitem()`, was added to dictionaries to enable destructively iterating through the contents of a dictionary; this can be faster for large dictionaries because there's no need to construct a list containing all the keys or values. `D.popitem()` removes a random `(key, value)` pair from the dictionary `D` and returns it as a 2-tuple. This was implemented mostly by Tim Peters and Guido van Rossum, after a suggestion and preliminary patch by Moshe Zadka.

- Modules can now control which names are imported when `from module import *` is used, by defining an `__all__` attribute containing a list of names that will be imported. One common complaint is that if the module imports other modules such as `sys` or `string`, `from module import *` will add them to the importing module's namespace. To fix this, simply list the public names in `__all__`:

```
# List public names  
__all__ = ['Database', 'open']
```

A stricter version of this patch was first suggested and implemented by Ben Wolfson, but after some python-dev discussion, a weaker final version was checked in.

- Applying `repr()` to strings previously used octal escapes for non-printable characters; for example, a newline was `'\012'`. This was a vestigial trace of Python's C ancestry, but today octal is of very little practical use. Ka-Ping Yee suggested using hex escapes instead of octal ones, and using the `\n`, `\t`, `\r` escapes for the appropriate characters, and implemented this new formatting.
- Syntax errors detected at compile-time can now raise exceptions containing the filename and line number of the error, a pleasant side effect of the compiler reorganization done by Jeremy Hylton.
- C extensions which import other modules have been changed to use `PyImport_ImportModule()`, which means that they will use any import hooks that have been installed. This is also encouraged for third-party extensions that need to import some other module from C code.
- The size of the Unicode character database was shrunk by

another 340K thanks to Fredrik Lundh.

- Some new ports were contributed: MacOS X (by Steven Majewski), Cygwin (by Jason Tishler); RISCOS (by Dietmar Schwertberger); Unixware 7 (by Billy G. Allie).

And there's the usual list of minor bugfixes, minor memory leaks, docstring edits, and other tweaks, too lengthy to be worth itemizing; see the CVS logs for the full details if you want them.

What's New in Python 2.0

Author: A.M. Kuchling and Moshe Zadka

Introduction

A new release of Python, version 2.0, was released on October 16, 2000. This article covers the exciting new features in 2.0, highlights some other useful changes, and points out a few incompatible changes that may require rewriting code.

Python's development never completely stops between releases, and a steady flow of bug fixes and improvements are always being submitted. A host of minor fixes, a few optimizations, additional docstrings, and better error messages went into 2.0; to list them all would be impossible, but they're certainly significant. Consult the publicly-available CVS logs if you want to see the full list. This progress is due to the five developers working for PythonLabs are now getting paid to spend their days fixing bugs, and also due to the improved communication resulting from moving to SourceForge.

What About Python 1.6?

Python 1.6 can be thought of as the Contractual Obligations Python release. After the core development team left CNRI in May 2000, CNRI requested that a 1.6 release be created, containing all the work on Python that had been performed at CNRI. Python 1.6 therefore represents the state of the CVS tree as of May 2000, with the most significant new feature being Unicode support. Development continued after May, of course, so the 1.6 tree received a few fixes to ensure that it's forward-compatible with Python 2.0. 1.6 is therefore part of Python's evolution, and not a side branch.

So, should you take much interest in Python 1.6? Probably not. The 1.6final and 2.0beta1 releases were made on the same day (September 5, 2000), the plan being to finalize Python 2.0 within a month or so. If you have applications to maintain, there seems little point in breaking things by moving to 1.6, fixing them, and then having another round of breakage within a month by moving to 2.0; you're better off just going straight to 2.0. Most of the really interesting features described in this document are only in 2.0, because a lot of work was done between May and September.

New Development Process

The most important change in Python 2.0 may not be to the code at all, but to how Python is developed: in May 2000 the Python developers began using the tools made available by SourceForge for storing source code, tracking bug reports, and managing the queue of patch submissions. To report bugs or submit patches for Python 2.0, use the bug tracking and patch manager tools available from Python's [project page](http://sourceforge.net/projects/python/), located at <http://sourceforge.net/projects/python/>.

The most important of the services now hosted at SourceForge is the Python CVS tree, the version-controlled repository containing the source code for Python. Previously, there were roughly 7 or so people who had write access to the CVS tree, and all patches had to be inspected and checked in by one of the people on this short list. Obviously, this wasn't very scalable. By moving the CVS tree to SourceForge, it became possible to grant write access to more people; as of September 2000 there were 27 people able to check in changes, a fourfold increase. This makes possible large-scale changes that wouldn't be attempted if they'd have to be filtered through the small group of core developers. For example, one day Peter Schneider-Kamp took it into his head to drop K&R C compatibility and convert the C source for Python to ANSI C. After getting approval on the python-dev mailing list, he launched into a flurry of checkins that lasted about a week, other developers joined in to help, and the job was done. If there were only 5 people with write access, probably that task would have been viewed as "nice, but not worth the time and effort needed" and it would never have gotten done.

The shift to using SourceForge's services has resulted in a remarkable increase in the speed of development. Patches now get

submitted, commented on, revised by people other than the original submitter, and bounced back and forth between people until the patch is deemed worth checking in. Bugs are tracked in one central location and can be assigned to a specific person for fixing, and we can count the number of open bugs to measure progress. This didn't come without a cost: developers now have more e-mail to deal with, more mailing lists to follow, and special tools had to be written for the new environment. For example, SourceForge sends default patch and bug notification e-mail messages that are completely unhelpful, so Ka-Ping Yee wrote an HTML screen-scraper that sends more useful messages.

The ease of adding code caused a few initial growing pains, such as code was checked in before it was ready or without getting clear agreement from the developer group. The approval process that has emerged is somewhat similar to that used by the Apache group. Developers can vote +1, +0, -0, or -1 on a patch; +1 and -1 denote acceptance or rejection, while +0 and -0 mean the developer is mostly indifferent to the change, though with a slight positive or negative slant. The most significant change from the Apache model is that the voting is essentially advisory, letting Guido van Rossum, who has Benevolent Dictator For Life status, know what the general opinion is. He can still ignore the result of a vote, and approve or reject a change even if the community disagrees with him.

Producing an actual patch is the last step in adding a new feature, and is usually easy compared to the earlier task of coming up with a good design. Discussions of new features can often explode into lengthy mailing list threads, making the discussion hard to follow, and no one can read every posting to python-dev. Therefore, a relatively formal process has been set up to write Python Enhancement Proposals (PEPs), modelled on the Internet RFC process. PEPs are draft documents that describe a proposed new feature, and are continually revised until the community reaches a consensus, either accepting or rejecting the proposal. Quoting from

the introduction to PEP 1, “PEP Purpose and Guidelines”:

PEP stands for Python Enhancement Proposal. A PEP is a design document providing information to the Python community, or describing a new feature for Python. The PEP should provide a concise technical specification of the feature and a rationale for the feature.

We intend PEPs to be the primary mechanisms for proposing new features, for collecting community input on an issue, and for documenting the design decisions that have gone into Python. The PEP author is responsible for building consensus within the community and documenting dissenting opinions.

Read the rest of PEP 1 for the details of the PEP editorial process, style, and format. PEPs are kept in the Python CVS tree on SourceForge, though they’re not part of the Python 2.0 distribution, and are also available in HTML form from <http://www.python.org/peps/>. As of September 2000, there are 25 PEPs, ranging from PEP 201, “Lockstep Iteration”, to PEP 225, “Elementwise/Objectwise Operators”.

Unicode

The largest new feature in Python 2.0 is a new fundamental data type: Unicode strings. Unicode uses 16-bit numbers to represent characters instead of the 8-bit number used by ASCII, meaning that 65,536 distinct characters can be supported.

The final interface for Unicode support was arrived at through countless often- stormy discussions on the python-dev mailing list, and mostly implemented by Marc-André Lemburg, based on a Unicode string type implementation by Fredrik Lundh. A detailed explanation of the interface was written up as [PEP 100](#), “Python Unicode Integration”. This article will simply cover the most significant points about the Unicode interfaces.

In Python source code, Unicode strings are written as `u"string"`. Arbitrary Unicode characters can be written using a new escape sequence, `\uHHHH`, where *HHHH* is a 4-digit hexadecimal number from 0000 to FFFF. The existing `\xHHHH` escape sequence can also be used, and octal escapes can be used for characters up to U+01FF, which is represented by `\777`.

Unicode strings, just like regular strings, are an immutable sequence type. They can be indexed and sliced, but not modified in place. Unicode strings have an `encode([encoding])` method that returns an 8-bit string in the desired encoding. Encodings are named by strings, such as `'ascii'`, `'utf-8'`, `'iso-8859-1'`, or whatever. A codec API is defined for implementing and registering new encodings that are then available throughout a Python program. If an encoding isn't specified, the default encoding is usually 7-bit ASCII, though it can be changed for your Python installation by calling the `sys.setdefaultencoding(encoding)()` function in a customised version of `site.py`.

Combining 8-bit and Unicode strings always coerces to Unicode, using the default ASCII encoding; the result of `'a' + u'bc'` is `u'abc'`.

New built-in functions have been added, and existing built-ins modified to support Unicode:

- `unichr(ch)` returns a Unicode string 1 character long, containing the character *ch*.
- `ord(u)`, where *u* is a 1-character regular or Unicode string, returns the number of the character as an integer.
- `unicode(string [, encoding] [, errors])` creates a Unicode string from an 8-bit string. `encoding` is a string naming the encoding to use. The `errors` parameter specifies the treatment of characters that are invalid for the current encoding; passing `'strict'` as the value causes an exception to be raised on any encoding error, while `'ignore'` causes errors to be silently ignored and `'replace'` uses U+FFFD, the official replacement character, in case of any problems.
- The `exec` statement, and various built-ins such as `eval()`, `getattr()`, and `setattr()` will also accept Unicode strings as well as regular strings. (It's possible that the process of fixing this missed some built-ins; if you find a built-in function that accepts strings but doesn't accept Unicode strings at all, please report it as a bug.)

A new module, `unicodedata`, provides an interface to Unicode character properties. For example, `unicodedata.category(u'A')` returns the 2-character string 'Lu', the 'L' denoting it's a letter, and 'u' meaning that it's uppercase. `unicodedata.bidirectional(u'\u0660')` returns 'AN', meaning that U+0660 is an Arabic number.

The `codecs` module contains functions to look up existing encodings

and register new ones. Unless you want to implement a new encoding, you'll most often use the `codecs.lookup(encoding)()` function, which returns a 4-element tuple: `(encode_func, decode_func, stream_reader, stream_writer)`.

- *encode_func* is a function that takes a Unicode string, and returns a 2-tuple `(string, length)`. *string* is an 8-bit string containing a portion (perhaps all) of the Unicode string converted into the given encoding, and *length* tells you how much of the Unicode string was converted.
- *decode_func* is the opposite of *encode_func*, taking an 8-bit string and returning a 2-tuple `(ustring, length)`, consisting of the resulting Unicode string *ustring* and the integer *length* telling how much of the 8-bit string was consumed.
- *stream_reader* is a class that supports decoding input from a stream. `stream_reader(file_obj)` returns an object that supports the `read()`, `readline()`, and `readlines()` methods. These methods will all translate from the given encoding and return Unicode strings.
- *stream_writer*, similarly, is a class that supports encoding output to a stream. `stream_writer(file_obj)` returns an object that supports the `write()` and `writelines()` methods. These methods expect Unicode strings, translating them to the given encoding on output.

For example, the following code writes a Unicode string into a file, encoding it as UTF-8:

```
import codecs

unistr = u'\u0660\u2000ab ...'

(UTF8_encode, UTF8_decode,
 UTF8_streamreader, UTF8_streamwriter) = codecs.lookup('UTF-8')

output = UTF8_streamwriter( open( '/tmp/output', 'wb' ) )
```

```
output.write( unistr )
output.close()
```

The following code would then read UTF-8 input from the file:

```
input = UTF8_streamreader( open( '/tmp/output', 'rb' ) )
print repr(input.read())
input.close()
```

Unicode-aware regular expressions are available through the `re` module, which has a new underlying implementation called SRE written by Fredrik Lundh of Secret Labs AB.

A `-U` command line option was added which causes the Python compiler to interpret all string literals as Unicode string literals. This is intended to be used in testing and future-proofing your Python code, since some future version of Python may drop support for 8-bit strings and provide only Unicode strings.

List Comprehensions

Lists are a workhorse data type in Python, and many programs manipulate a list at some point. Two common operations on lists are to loop over them, and either pick out the elements that meet a certain criterion, or apply some function to each element. For example, given a list of strings, you might want to pull out all the strings containing a given substring, or strip off trailing whitespace from each line.

The existing `map()` and `filter()` functions can be used for this purpose, but they require a function as one of their arguments. This is fine if there's an existing built-in function that can be passed directly, but if there isn't, you have to create a little function to do the required work, and Python's scoping rules make the result ugly if the little function needs additional information. Take the first example in the previous paragraph, finding all the strings in the list containing a given substring. You could write the following to do it:

```
# Given the list L, make a list of all strings  
# containing the substring S.  
sublist = filter( lambda s, substring=S:  
                  string.find(s, substring) != -1,  
                  L)
```

Because of Python's scoping rules, a default argument is used so that the anonymous function created by the `lambda` statement knows what substring is being searched for. List comprehensions make this cleaner:

```
sublist = [ s for s in L if string.find(s, S) != -1 ]
```

List comprehensions have the form:

```
[ expression for expr in sequence1
```

```
for expr2 in sequence2 ...
for exprN in sequenceN
if condition ]
```

The `for...in` clauses contain the sequences to be iterated over. The sequences do not have to be the same length, because they are *not* iterated over in parallel, but from left to right; this is explained more clearly in the following paragraphs. The elements of the generated list will be the successive values of *expression*. The final `if` clause is optional; if present, *expression* is only evaluated and added to the result if *condition* is true.

To make the semantics very clear, a list comprehension is equivalent to the following Python code:

```
for expr1 in sequence1:
    for expr2 in sequence2:
        ...
        for exprN in sequenceN:
            if (condition):
                # Append the value of
                # the expression to the
                # resulting list.
```

This means that when there are multiple `for...in` clauses, the resulting list will be equal to the product of the lengths of all the sequences. If you have two lists of length 3, the output list is 9 elements long:

```
seq1 = 'abc'
seq2 = (1,2,3)
>>> [ (x,y) for x in seq1 for y in seq2]
[('a', 1), ('a', 2), ('a', 3), ('b', 1), ('b', 2), ('b', 3), ('c', 1), ('c', 2), ('c', 3)]
```

To avoid introducing an ambiguity into Python's grammar, if *expression* is creating a tuple, it must be surrounded with parentheses. The first list comprehension below is a syntax error,

while the second one is correct:

```
# Syntax error  
[ x,y for x in seq1 for y in seq2]  
# Correct  
[ (x,y) for x in seq1 for y in seq2]
```

The idea of list comprehensions originally comes from the functional programming language Haskell (<http://www.haskell.org>). Greg Ewing argued most effectively for adding them to Python and wrote the initial list comprehension patch, which was then discussed for a seemingly endless time on the python-dev mailing list and kept up-to-date by Skip Montanaro.

Augmented Assignment

Augmented assignment operators, another long-requested feature, have been added to Python 2.0. Augmented assignment operators include `+=`, `-=`, `*=`, and so forth. For example, the statement `a += 2` increments the value of the variable `a` by 2, equivalent to the slightly lengthier `a = a + 2`.

The full list of supported assignment operators is `+=`, `-=`, `*=`, `/=`, `%=`, `**=`, `&=`, `|=`, `^=`, `>>=`, and `<<=`. Python classes can override the augmented assignment operators by defining methods named `__iadd__()`, `__isub__()`, etc. For example, the following `Number` class stores a number and supports using `+=` to create a new instance with an incremented value.

```
class Number:
    def __init__(self, value):
        self.value = value
    def __iadd__(self, increment):
        return Number(self.value + increment)

n = Number(5)
n += 3
print n.value
```

The `__iadd__()` special method is called with the value of the increment, and should return a new instance with an appropriately modified value; this return value is bound as the new value of the variable on the left-hand side.

Augmented assignment operators were first introduced in the C programming language, and most C-derived languages, such as **awk**, C++, Java, Perl, and PHP also support them. The augmented assignment patch was implemented by Thomas Wouters.

String Methods

Until now string-manipulation functionality was in the `string` module, which was usually a front-end for the `strop` module written in C. The addition of Unicode posed a difficulty for the `strop` module, because the functions would all need to be rewritten in order to accept either 8-bit or Unicode strings. For functions such as `string.replace()`, which takes 3 string arguments, that means eight possible permutations, and correspondingly complicated code.

Instead, Python 2.0 pushes the problem onto the string type, making string manipulation functionality available through methods on both 8-bit strings and Unicode strings.

```
>>> 'andrew'.capitalize()
'Andrew'
>>> 'hostname'.replace('os', 'linux')
'hlinuxtname'
>>> 'moshe'.find('sh')
2
```

One thing that hasn't changed, a noteworthy April Fools' joke notwithstanding, is that Python strings are immutable. Thus, the string methods return new strings, and do not modify the string on which they operate.

The old `string` module is still around for backwards compatibility, but it mostly acts as a front-end to the new string methods.

Two methods which have no parallel in pre-2.0 versions, although they did exist in JPython for quite some time, are `startswith()` and `endswith()`. `s.startswith(t)` is equivalent to `s[:len(t)] == t`, while `s.endswith(t)` is equivalent to `s[-len(t):] == t`.

One other method which deserves special mention is `join()`. The `join()` method of a string receives one parameter, a sequence of strings, and is equivalent to the `string.join()` function from the old `string` module, with the arguments reversed. In other words, `s.join(seq)` is equivalent to the old `string.join(seq, s)`.

Garbage Collection of Cycles

The C implementation of Python uses reference counting to implement garbage collection. Every Python object maintains a count of the number of references pointing to itself, and adjusts the count as references are created or destroyed. Once the reference count reaches zero, the object is no longer accessible, since you need to have a reference to an object to access it, and if the count is zero, no references exist any longer.

Reference counting has some pleasant properties: it's easy to understand and implement, and the resulting implementation is portable, fairly fast, and reacts well with other libraries that implement their own memory handling schemes. The major problem with reference counting is that it sometimes doesn't realise that objects are no longer accessible, resulting in a memory leak. This happens when there are cycles of references.

Consider the simplest possible cycle, a class instance which has a reference to itself:

```
instance = SomeClass()
instance.myself = instance
```

After the above two lines of code have been executed, the reference count of `instance` is 2; one reference is from the variable named `'instance'`, and the other is from the `myself` attribute of the instance.

If the next line of code is `del instance`, what happens? The reference count of `instance` is decreased by 1, so it has a reference count of 1; the reference in the `myself` attribute still exists. Yet the instance is no longer accessible through Python code, and it could be deleted. Several objects can participate in a cycle if they have

references to each other, causing all of the objects to be leaked.

Python 2.0 fixes this problem by periodically executing a cycle detection algorithm which looks for inaccessible cycles and deletes the objects involved. A new `gc` module provides functions to perform a garbage collection, obtain debugging statistics, and tuning the collector's parameters.

Running the cycle detection algorithm takes some time, and therefore will result in some additional overhead. It is hoped that after we've gotten experience with the cycle collection from using 2.0, Python 2.1 will be able to minimize the overhead with careful tuning. It's not yet obvious how much performance is lost, because benchmarking this is tricky and depends crucially on how often the program creates and destroys objects. The detection of cycles can be disabled when Python is compiled, if you can't afford even a tiny speed penalty or suspect that the cycle collection is buggy, by specifying the `--without-cycle-gc` switch when running the `configure` script.

Several people tackled this problem and contributed to a solution. An early implementation of the cycle detection approach was written by Toby Kelsey. The current algorithm was suggested by Eric Tiedemann during a visit to CNRI, and Guido van Rossum and Neil Schemenauer wrote two different implementations, which were later integrated by Neil. Lots of other people offered suggestions along the way; the March 2000 archives of the python-dev mailing list contain most of the relevant discussion, especially in the threads titled "Reference cycle collection for Python" and "Finalization again".

Other Core Changes

Various minor changes have been made to Python's syntax and built-in functions. None of the changes are very far-reaching, but they're handy conveniences.

Minor Language Changes

A new syntax makes it more convenient to call a given function with a tuple of arguments and/or a dictionary of keyword arguments. In Python 1.5 and earlier, you'd use the `apply()` built-in function: `apply(f, args, kw)` calls the function `f()` with the argument tuple `args` and the keyword arguments in the dictionary `kw`. `apply()` is the same in 2.0, but thanks to a patch from Greg Ewing, `f(*args, **kw)` as a shorter and clearer way to achieve the same effect. This syntax is symmetrical with the syntax for defining functions:

```
def f(*args, **kw):  
    # args is a tuple of positional args,  
    # kw is a dictionary of keyword args  
    ...
```

The `print` statement can now have its output directed to a file-like object by following the `print` with `>> file`, similar to the redirection operator in Unix shells. Previously you'd either have to use the `write()` method of the file-like object, which lacks the convenience and simplicity of `print`, or you could assign a new value to `sys.stdout` and then restore the old value. For sending output to standard error, it's much easier to write this:

```
print >> sys.stderr, "Warning: action field not supplied"
```

Modules can now be renamed on importing them, using the syntax

```
import module as name Or from module import name as othername.
```

The patch was submitted by Thomas Wouters.

A new format style is available when using the `%` operator; `'%r'` will insert the `repr()` of its argument. This was also added from symmetry considerations, this time for symmetry with the existing `'%s'` format style, which inserts the `str()` of its argument. For example, `'%r %s' % ('abc', 'abc')` returns a string containing `'abc 'abc'`.

Previously there was no way to implement a class that overrode Python's built-in `in` operator and implemented a custom version. `obj in seq` returns true if `obj` is present in the sequence `seq`; Python computes this by simply trying every index of the sequence until either `obj` is found or an `IndexError` is encountered. Moshe Zadka contributed a patch which adds a `__contains__()` magic method for providing a custom implementation for `in`. Additionally, new built-in objects written in C can define what `in` means for them via a new slot in the sequence protocol.

Earlier versions of Python used a recursive algorithm for deleting objects. Deeply nested data structures could cause the interpreter to fill up the C stack and crash; Christian Tismer rewrote the deletion logic to fix this problem. On a related note, comparing recursive objects recursed infinitely and crashed; Jeremy Hylton rewrote the code to no longer crash, producing a useful result instead. For example, after this code:

```
a = []
b = []
a.append(a)
b.append(b)
```

The comparison `a==b` returns true, because the two recursive data

structures are isomorphic. See the thread “trashcan and PR#7” in the April 2000 archives of the python-dev mailing list for the discussion leading up to this implementation, and some useful relevant links. Note that comparisons can now also raise exceptions. In earlier versions of Python, a comparison operation such as `cmp(a,b)` would always produce an answer, even if a user-defined `__cmp__()` method encountered an error, since the resulting exception would simply be silently swallowed.

Work has been done on porting Python to 64-bit Windows on the Itanium processor, mostly by Trent Mick of ActiveState. (Confusingly, `sys.platform` is still `'win32'` on Win64 because it seems that for ease of porting, MS Visual C++ treats code as 32 bit on Itanium.) PythonWin also supports Windows CE; see the Python CE page at <http://pythonce.sourceforge.net/> for more information.

Another new platform is Darwin/MacOS X; initial support for it is in Python 2.0. Dynamic loading works, if you specify “configure `--with-dyld --with-suffix=.x`”. Consult the README in the Python source distribution for more instructions.

An attempt has been made to alleviate one of Python’s warts, the often-confusing `NameError` exception when code refers to a local variable before the variable has been assigned a value. For example, the following code raises an exception on the `print` statement in both 1.5.2 and 2.0; in 1.5.2 a `NameError` exception is raised, while 2.0 raises a new `UnboundLocalError` exception. `UnboundLocalError` is a subclass of `NameError`, so any existing code that expects `NameError` to be raised should still work.

```
def f():
    print "i=",i
    i = i + 1
f()
```

Two new exceptions, `TabError` and `IndentationError`, have been introduced. They're both subclasses of `SyntaxError`, and are raised when Python code is found to be improperly indented.

Changes to Built-in Functions

A new built-in, `zip(seq1, seq2, ...)`, has been added. `zip()` returns a list of tuples where each tuple contains the *i*-th element from each of the argument sequences. The difference between `zip()` and `map(None, seq1, seq2)` is that `map()` pads the sequences with `None` if the sequences aren't all of the same length, while `zip()` truncates the returned list to the length of the shortest argument sequence.

The `int()` and `long()` functions now accept an optional "base" parameter when the first argument is a string. `int('123', 10)` returns 123, while `int('123', 16)` returns 291. `int(123, 16)` raises a `TypeError` exception with the message "can't convert non-string with explicit base".

A new variable holding more detailed version information has been added to the `sys` module. `sys.version_info` is a tuple (`major`, `minor`, `micro`, `level`, `serial`) For example, in a hypothetical 2.0.1beta1, `sys.version_info` would be `(2, 0, 1, 'beta', 1)`. `level` is a string such as `"alpha"`, `"beta"`, or `"final"` for a final release.

Dictionaries have an odd new method, `setdefault(key, default)`, which behaves similarly to the existing `get()` method. However, if the key is missing, `setdefault()` both returns the value of `default` as `get()` would do, and also inserts it into the dictionary as the value for `key`. Thus, the following lines of code:

```
if dict.has_key( key ): return dict[key]
```

```
else:  
    dict[key] = []  
    return dict[key]
```

can be reduced to a single `return dict.setdefault(key, [])` statement.

The interpreter sets a maximum recursion depth in order to catch runaway recursion before filling the C stack and causing a core dump or GPF.. Previously this limit was fixed when you compiled Python, but in 2.0 the maximum recursion depth can be read and modified using `sys.getrecursionlimit()` and `sys.setrecursionlimit()`. The default value is 1000, and a rough maximum value for a given platform can be found by running a new script, `Misc/find_recursionlimit.py`.

Porting to 2.0

New Python releases try hard to be compatible with previous releases, and the record has been pretty good. However, some changes are considered useful enough, usually because they fix initial design decisions that turned out to be actively mistaken, that breaking backward compatibility can't always be avoided. This section lists the changes in Python 2.0 that may cause old Python code to break.

The change which will probably break the most code is tightening up the arguments accepted by some methods. Some methods would take multiple arguments and treat them as a tuple, particularly various list methods such as `append()` and `insert()`. In earlier versions of Python, if `L` is a list, `L.append(1,2)` appends the tuple `(1,2)` to the list. In Python 2.0 this causes a `TypeError` exception to be raised, with the message: 'append requires exactly 1 argument; 2 given'. The fix is to simply add an extra set of parentheses to pass both values as a tuple: `L.append((1,2))`.

The earlier versions of these methods were more forgiving because they used an old function in Python's C interface to parse their arguments; 2.0 modernizes them to use `PyArg_ParseTuple()`, the current argument parsing function, which provides more helpful error messages and treats multi-argument calls as errors. If you absolutely must use 2.0 but can't fix your code, you can edit `Objects/listobject.c` and define the preprocessor symbol `NO_STRICT_LIST_APPEND` to preserve the old behaviour; this isn't recommended.

Some of the functions in the `socket` module are still forgiving in this way. For example, `socket.connect(('hostname', 25))()` is the

correct form, passing a tuple representing an IP address, but `socket.connect('hostname', 25)()` also works. `socket.connect_ex()` and `socket.bind()` are similarly easy-going. Python 2.0alpha1 tightened these functions up, but because the documentation actually used the erroneous multiple argument form, many people wrote code which would break with the stricter checking. Guido backed out the changes in the face of public reaction, so for the `socket` module, the documentation was fixed and the multiple argument form is simply marked as deprecated; it *will* be tightened up again in a future Python version.

The `\x` escape in string literals now takes exactly 2 hex digits. Previously it would consume all the hex digits following the 'x' and take the lowest 8 bits of the result, so `\x123456` was equivalent to `\x56`.

The `AttributeError` and `NameError` exceptions have a more friendly error message, whose text will be something like `'Spam' instance has no attribute 'eggs' or name 'eggs' is not defined`. Previously the error message was just the missing attribute name `eggs`, and code written to take advantage of this fact will break in 2.0.

Some work has been done to make integers and long integers a bit more interchangeable. In 1.5.2, large-file support was added for Solaris, to allow reading files larger than 2 GiB; this made the `tell()` method of file objects return a long integer instead of a regular integer. Some code would subtract two file offsets and attempt to use the result to multiply a sequence or slice a string, but this raised a `TypeError`. In 2.0, long integers can be used to multiply or slice a sequence, and it'll behave as you'd intuitively expect it to; `3L * 'abc'` produces `'abcabcabc'`, and `(0,1,2,3)[2L:4L]` produces `(2,3)`. Long integers can also be used in various contexts where previously only integers were accepted, such as in the `seek()` method of file objects,

and in the formats supported by the `%` operator (`%d`, `%i`, `%x`, etc.). For example, `"%d" % 2L**64` will produce the string `18446744073709551616`.

The subtlest long integer change of all is that the `str()` of a long integer no longer has a trailing 'L' character, though `repr()` still includes it. The 'L' annoyed many people who wanted to print long integers that looked just like regular integers, since they had to go out of their way to chop off the character. This is no longer a problem in 2.0, but code which does `str(longval)[: -1]` and assumes the 'L' is there, will now lose the final digit.

Taking the `repr()` of a float now uses a different formatting precision than `str()`. `repr()` uses `%.17g` format string for C's `sprintf()`, while `str()` uses `%.12g` as before. The effect is that `repr()` may occasionally show more decimal places than `str()`, for certain numbers. For example, the number 8.1 can't be represented exactly in binary, so `repr(8.1)` is `'8.0999999999999996'`, while `str(8.1)` is `'8.1'`.

The `-x` command-line option, which turned all standard exceptions into strings instead of classes, has been removed; the standard exceptions will now always be classes. The `exceptions` module containing the standard exceptions was translated from Python to a built-in C module, written by Barry Warsaw and Fredrik Lundh.

Extending/Embedding Changes

Some of the changes are under the covers, and will only be apparent to people writing C extension modules or embedding a Python interpreter in a larger application. If you aren't dealing with Python's C API, you can safely skip this section.

The version number of the Python C API was incremented, so C extensions compiled for 1.5.2 must be recompiled in order to work with 2.0. On Windows, it's not possible for Python 2.0 to import a third party extension built for Python 1.5.x due to how Windows DLLs work, so Python will raise an exception and the import will fail.

Users of Jim Fulton's `ExtensionClass` module will be pleased to find out that hooks have been added so that `ExtensionClasses` are now supported by `isinstance()` and `issubclass()`. This means you no longer have to remember to write code such as `if type(obj) == myExtensionClass`, but can use the more natural `if isinstance(obj, myExtensionClass)`.

The `Python/importdl.c` file, which was a mass of `#ifdefs` to support dynamic loading on many different platforms, was cleaned up and reorganised by Greg Stein. `importdl.c` is now quite small, and platform-specific code has been moved into a bunch of `Python/dynload_*.c` files. Another cleanup: there were also a number of `my*.h` files in the `Include/` directory that held various portability hacks; they've been merged into a single file, `Include/pyport.h`.

Vladimir Marangozov's long-awaited `malloc` restructuring was completed, to make it easy to have the Python interpreter use a custom allocator instead of C's standard `malloc()`. For documentation, read the comments in `Include/pymem.h` and

`Include/objimpl.h`. For the lengthy discussions during which the interface was hammered out, see the Web archives of the 'patches' and 'python-dev' lists at python.org.

Recent versions of the GUSI development environment for MacOS support POSIX threads. Therefore, Python's POSIX threading support now works on the Macintosh. Threading support using the user-space GNU `pth` library was also contributed.

Threading support on Windows was enhanced, too. Windows supports thread locks that use kernel objects only in case of contention; in the common case when there's no contention, they use simpler functions which are an order of magnitude faster. A threaded version of Python 1.5.2 on NT is twice as slow as an unthreaded version; with the 2.0 changes, the difference is only 10%. These improvements were contributed by Yakov Markovitch.

Python 2.0's source now uses only ANSI C prototypes, so compiling Python now requires an ANSI C compiler, and can no longer be done using a compiler that only supports K&R C.

Previously the Python virtual machine used 16-bit numbers in its bytecode, limiting the size of source files. In particular, this affected the maximum size of literal lists and dictionaries in Python source; occasionally people who are generating Python code would run into this limit. A patch by Charles G. Waldman raises the limit from `216` to `232`.

Three new convenience functions intended for adding constants to a module's dictionary at module initialization time were added: `PyModule_AddObject()`, `PyModule_AddIntConstant()`, and `PyModule_AddStringConstant()`. Each of these functions takes a module object, a null-terminated C string containing the name to be added, and a third argument for the value to be assigned to the name. This third argument is, respectively, a Python object, a C long,

or a C string.

A wrapper API was added for Unix-style signal handlers. `PyOS_getsig()` gets a signal handler and `PyOS_setsig()` will set a new handler.

Distutils: Making Modules Easy to Install

Before Python 2.0, installing modules was a tedious affair – there was no way to figure out automatically where Python is installed, or what compiler options to use for extension modules. Software authors had to go through an arduous ritual of editing Makefiles and configuration files, which only really work on Unix and leave Windows and MacOS unsupported. Python users faced wildly differing installation instructions which varied between different extension packages, which made administering a Python installation something of a chore.

The SIG for distribution utilities, shepherded by Greg Ward, has created the Distutils, a system to make package installation much easier. They form the `distutils` package, a new part of Python's standard library. In the best case, installing a Python module from source will require the same steps: first you simply mean unpack the tarball or zip archive, and then run `python setup.py install`. The platform will be automatically detected, the compiler will be recognized, C extension modules will be compiled, and the distribution installed into the proper directory. Optional command-line arguments provide more control over the installation process, the `distutils` package offers many places to override defaults – separating the build from the install, building or installing in non-default directories, and more.

In order to use the Distutils, you need to write a `setup.py` script. For the simple case, when the software contains only `.py` files, a minimal `setup.py` can be just a few lines long:

```
from distutils.core import setup
setup (name = "foo", version = "1.0",
      py_modules = ["module1", "module2"])
```

The `setup.py` file isn't much more complicated if the software consists of a few packages:

```
from distutils.core import setup
setup (name = "foo", version = "1.0",
      packages = ["package", "package.subpackage"])
```

A C extension can be the most complicated case; here's an example taken from the PyXML package:

```
from distutils.core import setup, Extension

expat_extension = Extension('xml.parsers.pyexpat',
    define_macros = [('XML_NS', None)],
    include_dirs = [ 'extensions/expat/xmltok',
                    'extensions/expat/xmlparse' ],
    sources = [ 'extensions/pyexpat.c',
               'extensions/expat/xmltok/xmltok.c',
               'extensions/expat/xmltok/xmlrole.c', ]
    )
setup (name = "PyXML", version = "0.5.4",
      ext_modules =[ expat_extension ] )
```

The Distutils can also take care of creating source and binary distributions. The “sdist” command, run by “`python setup.py sdist`”, builds a source distribution such as `foo-1.0.tar.gz`. Adding new commands isn't difficult, “bdist_rpm” and “bdist_wininst” commands have already been contributed to create an RPM distribution and a Windows installer for the software, respectively. Commands to create other distribution formats such as Debian packages and Solaris `.pkg` files are in various stages of development.

All this is documented in a new manual, *Distributing Python Modules*, that joins the basic set of Python documentation.

XML Modules

Python 1.5.2 included a simple XML parser in the form of the `xml1ib` module, contributed by Sjoerd Mullender. Since 1.5.2's release, two different interfaces for processing XML have become common: SAX2 (version 2 of the Simple API for XML) provides an event-driven interface with some similarities to `xml1ib`, and the DOM (Document Object Model) provides a tree-based interface, transforming an XML document into a tree of nodes that can be traversed and modified. Python 2.0 includes a SAX2 interface and a stripped-down DOM interface as part of the `xml` package. Here we will give a brief overview of these new interfaces; consult the Python documentation or the source code for complete details. The Python XML SIG is also working on improved documentation.

SAX2 Support

SAX defines an event-driven interface for parsing XML. To use SAX, you must write a SAX handler class. Handler classes inherit from various classes provided by SAX, and override various methods that will then be called by the XML parser. For example, the `startElement()` and `endElement()` methods are called for every starting and end tag encountered by the parser, the `characters()` method is called for every chunk of character data, and so forth.

The advantage of the event-driven approach is that the whole document doesn't have to be resident in memory at any one time, which matters if you are processing really huge documents. However, writing the SAX handler class can get very complicated if you're trying to modify the document structure in some elaborate way.

For example, this little example program defines a handler that prints

a message for every starting and ending tag, and then parses the file `hamlet.xml` using it:

```
from xml import sax

class SimpleHandler(sax.ContentHandler):
    def startElement(self, name, attrs):
        print 'Start of element:', name, attrs.keys()

    def endElement(self, name):
        print 'End of element:', name

# Create a parser object
parser = sax.make_parser()

# Tell it what handler to use
handler = SimpleHandler()
parser.setContentHandler( handler )

# Parse a file!
parser.parse( 'hamlet.xml' )
```

For more information, consult the Python documentation, or the XML HOWTO at <http://pyxml.sourceforge.net/topics/howto/xml-howto.html>.

DOM Support

The Document Object Model is a tree-based representation for an XML document. A top-level `Document` instance is the root of the tree, and has a single child which is the top-level `Element` instance. This `Element` has children nodes representing character data and any sub-elements, which may have further children of their own, and so forth. Using the DOM you can traverse the resulting tree any way you like, access element and attribute values, insert and delete nodes, and convert the tree back into XML.

The DOM is useful for modifying XML documents, because you can create a DOM tree, modify it by adding new nodes or rearranging

subtrees, and then produce a new XML document as output. You can also construct a DOM tree manually and convert it to XML, which can be a more flexible way of producing XML output than simply writing `<tag1>...</tag1>` to a file.

The DOM implementation included with Python lives in the `xml.dom.minidom` module. It's a lightweight implementation of the Level 1 DOM with support for XML namespaces. The `parse()` and `parseString()` convenience functions are provided for generating a DOM tree:

```
from xml.dom import minidom
doc = minidom.parse('hamlet.xml')
```

`doc` is a `Document` instance. `Document`, like all the other DOM classes such as `Element` and `Text`, is a subclass of the `Node` base class. All the nodes in a DOM tree therefore support certain common methods, such as `toxml()` which returns a string containing the XML representation of the node and its children. Each class also has special methods of its own; for example, `Element` and `Document` instances have a method to find all child elements with a given tag name. Continuing from the previous 2-line example:

```
perslist = doc.getElementsByTagName( 'PERSONA' )
print perslist[0].toxml()
print perslist[1].toxml()
```

For the *Hamlet* XML file, the above few lines output:

```
<PERSONA>CLAUDIUS, king of Denmark. </PERSONA>
<PERSONA>HAMLET, son to the late, and nephew to the present kin
```

The root element of the document is available as `doc.documentElement`, and its children can be easily modified by deleting, adding, or removing nodes:

```
root = doc.documentElement

# Remove the first child
root.removeChild( root.childNodes[0] )

# Move the new first child to the end
root.appendChild( root.childNodes[0] )

# Insert the new first child (originally,
# the third child) before the 20th child.
root.insertBefore( root.childNodes[0], root.childNodes[20] )
```

Again, I will refer you to the Python documentation for a complete listing of the different `Node` classes and their various methods.

Relationship to PyXML

The XML Special Interest Group has been working on XML-related Python code for a while. Its code distribution, called PyXML, is available from the SIG's Web pages at <http://www.python.org/sigs/xml-sig/>. The PyXML distribution also used the package name `xml`. If you've written programs that used PyXML, you're probably wondering about its compatibility with the 2.0 `xml` package.

The answer is that Python 2.0's `xml` package isn't compatible with PyXML, but can be made compatible by installing a recent version PyXML. Many applications can get by with the XML support that is included with Python 2.0, but more complicated applications will require that the full PyXML package will be installed. When installed, PyXML versions 0.6.0 or greater will replace the `xml` package shipped with Python, and will be a strict superset of the standard package, adding a bunch of additional features. Some of the additional features in PyXML include:

- 4DOM, a full DOM implementation from FourThought, Inc.
- The `xmlproc` validating parser, written by Lars Marius Garshol.

- The `sgm1op` parser accelerator module, written by Fredrik Lundh.

Module changes

Lots of improvements and bugfixes were made to Python's extensive standard library; some of the affected modules include `readline`, `ConfigParser`, `cgi`, `calendar`, `posix`, `readline`, `xmllib`, `aifc`, `chunk`, `wave`, `random`, `shelve`, and `nntplib`. Consult the CVS logs for the exact patch-by-patch details.

Brian Gallew contributed OpenSSL support for the `socket` module. OpenSSL is an implementation of the Secure Socket Layer, which encrypts the data being sent over a socket. When compiling Python, you can edit `Modules/Setup` to include SSL support, which adds an additional function to the `socket` module: `socket.ssl(socket, keyfile, certfile)()`, which takes a socket object and returns an SSL socket. The `httplib` and `urllib` modules were also changed to support `https://` URLs, though no one has implemented FTP or SMTP over SSL.

The `httplib` module has been rewritten by Greg Stein to support HTTP/1.1. Backward compatibility with the 1.5 version of `httplib` is provided, though using HTTP/1.1 features such as pipelining will require rewriting code to use a different set of interfaces.

The `tkinter` module now supports Tcl/Tk version 8.1, 8.2, or 8.3, and support for the older 7.x versions has been dropped. The Tkinter module now supports displaying Unicode strings in Tk widgets. Also, Fredrik Lundh contributed an optimization which makes operations like `create_line` and `create_polygon` much faster, especially when using lots of coordinates.

The `curses` module has been greatly extended, starting from Oliver Andrich's enhanced version, to provide many additional functions

from ncurses and SYSV curses, such as colour, alternative character set support, pads, and mouse support. This means the module is no longer compatible with operating systems that only have BSD curses, but there don't seem to be any currently maintained OSes that fall into this category.

As mentioned in the earlier discussion of 2.0's Unicode support, the underlying implementation of the regular expressions provided by the `re` module has been changed. SRE, a new regular expression engine written by Fredrik Lundh and partially funded by Hewlett Packard, supports matching against both 8-bit strings and Unicode strings.

New modules

A number of new modules were added. We'll simply list them with brief descriptions; consult the 2.0 documentation for the details of a particular module.

- **atexit**: For registering functions to be called before the Python interpreter exits. Code that currently sets `sys.exitfunc` directly should be changed to use the **atexit** module instead, importing **atexit** and calling **atexit.register()** with the function to be called on exit. (Contributed by Skip Montanaro.)
- **codecs**, **encodings**, **unicodedata**: Added as part of the new Unicode support.
- **filecmp**: Supersedes the old **cmp**, **cmpcache** and **dircmp** modules, which have now become deprecated. (Contributed by Gordon MacMillan and Moshe Zadka.)
- **gettext**: This module provides internationalization (I18N) and localization (L10N) support for Python programs by providing an interface to the GNU gettext message catalog library. (Integrated by Barry Warsaw, from separate contributions by Martin von Löwis, Peter Funk, and James Henstridge.)
- **linuxaudiodev**: Support for the `/dev/audio` device on Linux, a twin to the existing **sunaudiodev** module. (Contributed by Peter Bosch, with fixes by Jeremy Hylton.)
- **mmap**: An interface to memory-mapped files on both Windows and Unix. A file's contents can be mapped directly into memory, at which point it behaves like a mutable string, so its contents can be read and modified. They can even be passed to functions that expect ordinary strings, such as the **re** module. (Contributed by Sam Rushing, with some extensions by A.M. Kuchling.)
- **pyexpat**: An interface to the Expat XML parser. (Contributed by

Paul Prescod.)

- **robotparser**: Parse a `robots.txt` file, which is used for writing Web spiders that politely avoid certain areas of a Web site. The parser accepts the contents of a `robots.txt` file, builds a set of rules from it, and can then answer questions about the fetchability of a given URL. (Contributed by Skip Montanaro.)
- **tabnanny**: A module/script to check Python source code for ambiguous indentation. (Contributed by Tim Peters.)
- **UserString**: A base class useful for deriving objects that behave like strings.
- **webbrowser**: A module that provides a platform independent way to launch a web browser on a specific URL. For each platform, various browsers are tried in a specific order. The user can alter which browser is launched by setting the `BROWSER` environment variable. (Originally inspired by Eric S. Raymond's patch to `urllib` which added similar functionality, but the final module comes from code originally implemented by Fred Drake as `Tools/idle/BrowserControl.py`, and adapted for the standard library by Fred.)
- **_winreg**: An interface to the Windows registry. `_winreg` is an adaptation of functions that have been part of PythonWin since 1995, but has now been added to the core distribution, and enhanced to support Unicode. `_winreg` was written by Bill Tutt and Mark Hammond.
- **zipfile**: A module for reading and writing ZIP-format archives. These are archives produced by **PKZIP** on DOS/Windows or **zip** on Unix, not to be confused with **gzip**-format files (which are supported by the `gzip` module) (Contributed by James C. Ahlstrom.)
- **imputil**: A module that provides a simpler way for writing customised import hooks, in comparison to the existing `ihooks` module. (Implemented by Greg Stein, with much discussion on python-dev along the way.)

IDLE Improvements

IDLE is the official Python cross-platform IDE, written using Tkinter. Python 2.0 includes IDLE 0.6, which adds a number of new features and improvements. A partial list:

- UI improvements and optimizations, especially in the area of syntax highlighting and auto-indentation.
- The class browser now shows more information, such as the top level functions in a module.
- Tab width is now a user settable option. When opening an existing Python file, IDLE automatically detects the indentation conventions, and adapts.
- There is now support for calling browsers on various platforms, used to open the Python documentation in a browser.
- IDLE now has a command line, which is largely similar to the vanilla Python interpreter.
- Call tips were added in many places.
- IDLE can now be installed as a package.
- In the editor window, there is now a line/column bar at the bottom.
- Three new keystroke commands: Check module (Alt-F5), Import module (F5) and Run script (Ctrl-F5).

Deleted and Deprecated Modules

A few modules have been dropped because they're obsolete, or because there are now better ways to do the same thing. The `stdwin` module is gone; it was for a platform-independent windowing toolkit that's no longer developed.

A number of modules have been moved to the `lib-old` subdirectory: `cmp`, `cmpcache`, `dircmp`, `dump`, `find`, `grep`, `packmail`, `poly`, `util`, `whatsound`, `zmod`. If you have code which relies on a module that's been moved to `lib-old`, you can simply add that directory to `sys.path` to get them back, but you're encouraged to update any code that uses these modules.

Acknowledgements

The authors would like to thank the following people for offering suggestions on various drafts of this article: David Bolen, Mark Hammond, Gregg Hauser, Jeremy Hylton, Fredrik Lundh, Detlef Lannert, Aahz Maruch, Skip Montanaro, Vladimir Marangozov, Tobias Polzin, Guido van Rossum, Neil Schemenauer, and Russ Schmidt.

1. Whetting Your Appetite

If you do much work on computers, eventually you find that there's some task you'd like to automate. For example, you may wish to perform a search-and-replace over a large number of text files, or rename and rearrange a bunch of photo files in a complicated way. Perhaps you'd like to write a small custom database, or a specialized GUI application, or a simple game.

If you're a professional software developer, you may have to work with several C/C++/Java libraries but find the usual write/compile/test/re-compile cycle is too slow. Perhaps you're writing a test suite for such a library and find writing the testing code a tedious task. Or maybe you've written a program that could use an extension language, and you don't want to design and implement a whole new language for your application.

Python is just the language for you.

You could write a Unix shell script or Windows batch files for some of these tasks, but shell scripts are best at moving around files and changing text data, not well-suited for GUI applications or games. You could write a C/C++/Java program, but it can take a lot of development time to get even a first-draft program. Python is simpler to use, available on Windows, Mac OS X, and Unix operating systems, and will help you get the job done more quickly.

Python is simple to use, but it is a real programming language, offering much more structure and support for large programs than shell scripts or batch files can offer. On the other hand, Python also offers much more error checking than C, and, being a *very-high-level language*, it has high-level data types built in, such as flexible arrays and dictionaries. Because of its more general data types Python is applicable to a much larger problem domain than Awk or even Perl,

yet many things are at least as easy in Python as in those languages.

Python allows you to split your program into modules that can be reused in other Python programs. It comes with a large collection of standard modules that you can use as the basis of your programs — or as examples to start learning to program in Python. Some of these modules provide things like file I/O, system calls, sockets, and even interfaces to graphical user interface toolkits like Tk.

Python is an interpreted language, which can save you considerable time during program development because no compilation and linking is necessary. The interpreter can be used interactively, which makes it easy to experiment with features of the language, to write throw-away programs, or to test functions during bottom-up program development. It is also a handy desk calculator.

Python enables programs to be written compactly and readably. Programs written in Python are typically much shorter than equivalent C, C++, or Java programs, for several reasons:

- the high-level data types allow you to express complex operations in a single statement;
- statement grouping is done by indentation instead of beginning and ending brackets;
- no variable or argument declarations are necessary.

Python is *extensible*: if you know how to program in C it is easy to add a new built-in function or module to the interpreter, either to perform critical operations at maximum speed, or to link Python programs to libraries that may only be available in binary form (such as a vendor-specific graphics library). Once you are really hooked, you can link the Python interpreter into an application written in C and use it as an extension or command language for that application.

By the way, the language is named after the BBC show “Monty Python’s Flying Circus” and has nothing to do with reptiles. Making references to Monty Python skits in documentation is not only allowed, it is encouraged!

Now that you are all excited about Python, you’ll want to examine it in some more detail. Since the best way to learn a language is to use it, the tutorial invites you to play with the Python interpreter as you read.

In the next chapter, the mechanics of using the interpreter are explained. This is rather mundane information, but essential for trying out the examples shown later.

The rest of the tutorial introduces various features of the Python language and system through examples, beginning with simple expressions, statements and data types, through functions and modules, and finally touching upon advanced concepts like exceptions and user-defined classes.

2. Using the Python Interpreter

2.1. Invoking the Interpreter

The Python interpreter is usually installed as `/usr/local/bin/python3.2` on those machines where it is available; putting `/usr/local/bin` in your Unix shell's search path makes it possible to start it by typing the command

```
python3.2
```

to the shell. [1] Since the choice of the directory where the interpreter lives is an installation option, other places are possible; check with your local Python guru or system administrator. (E.g., `/usr/local/python` is a popular alternative location.)

On Windows machines, the Python installation is usually placed in `C:\Python32`, though you can change this when you're running the installer. To add this directory to your path, you can type the following command into the command prompt in a DOS box:

```
set path=%path%;C:\python32
```

Typing an end-of-file character (`control-D` on Unix, `control-Z` on Windows) at the primary prompt causes the interpreter to exit with a zero exit status. If that doesn't work, you can exit the interpreter by typing the following command: `quit()`.

The interpreter's line-editing features usually aren't very sophisticated. On Unix, whoever installed the interpreter may have enabled support for the GNU readline library, which adds more elaborate interactive editing and history features. Perhaps the quickest check to see whether command line editing is supported is typing `Control-P` to the first Python prompt you get. If it beeps, you have command line editing; see Appendix *Interactive Input Editing*

and History Substitution for an introduction to the keys. If nothing appears to happen, or if `^P` is echoed, command line editing isn't available; you'll only be able to use backspace to remove characters from the current line.

The interpreter operates somewhat like the Unix shell: when called with standard input connected to a tty device, it reads and executes commands interactively; when called with a file name argument or with a file as standard input, it reads and executes a *script* from that file.

A second way of starting the interpreter is `python -c command [arg] ...`, which executes the statement(s) in *command*, analogous to the shell's `-c` option. Since Python statements often contain spaces or other characters that are special to the shell, it is usually advised to quote *command* in its entirety with single quotes.

Some Python modules are also useful as scripts. These can be invoked using `python -m module [arg] ...`, which executes the source file for *module* as if you had spelled out its full name on the command line.

When a script file is used, it is sometimes useful to be able to run the script and enter interactive mode afterwards. This can be done by passing `-i` before the script. (This does not work if the script is read from standard input, for the same reason as explained in the previous paragraph.)

2.1.1. Argument Passing

When known to the interpreter, the script name and additional arguments thereafter are turned into a list of strings and assigned to the `argv` variable in the `sys` module. You can access this list by executing `import sys`. The length of the list is at least one; when no

script and no arguments are given, `sys.argv[0]` is an empty string. When the script name is given as `'-'` (meaning standard input), `sys.argv[0]` is set to `'-'`. When `-c command` is used, `sys.argv[0]` is set to `'-c'`. When `-m module` is used, `sys.argv[0]` is set to the full name of the located module. Options found after `-c command` or `-m module` are not consumed by the Python interpreter's option processing but left in `sys.argv` for the command or module to handle.

2.1.2. Interactive Mode

When commands are read from a tty, the interpreter is said to be in *interactive mode*. In this mode it prompts for the next command with the *primary prompt*, usually three greater-than signs (`>>>`); for continuation lines it prompts with the *secondary prompt*, by default three dots (`...`). The interpreter prints a welcome message stating its version number and a copyright notice before printing the first prompt:

```
$ python3.2
Python 3.2 (py3k, Sep 12 2007, 12:21:02)
[GCC 3.4.6 20060404 (Red Hat 3.4.6-8)] on linux2
Type "help", "copyright", "credits" or "license" for more infor
>>>
```

Continuation lines are needed when entering a multi-line construct. As an example, take a look at this `if` statement:

```
>>> the_world_is_flat = 1
>>> if the_world_is_flat:
...     print("Be careful not to fall off!")
...
Be careful not to fall off!
```

2.2. The Interpreter and Its Environment

2.2.1. Error Handling

When an error occurs, the interpreter prints an error message and a stack trace. In interactive mode, it then returns to the primary prompt; when input came from a file, it exits with a nonzero exit status after printing the stack trace. (Exceptions handled by an `except` clause in a `try` statement are not errors in this context.) Some errors are unconditionally fatal and cause an exit with a nonzero exit; this applies to internal inconsistencies and some cases of running out of memory. All error messages are written to the standard error stream; normal output from executed commands is written to standard output.

Typing the interrupt character (usually Control-C or DEL) to the primary or secondary prompt cancels the input and returns to the primary prompt. [2] Typing an interrupt while a command is executing raises the `KeyboardInterrupt` exception, which may be handled by a `try` statement.

2.2.2. Executable Python Scripts

On BSD'ish Unix systems, Python scripts can be made directly executable, like shell scripts, by putting the line

```
#!/usr/bin/env python3.2
```

(assuming that the interpreter is on the user's `PATH`) at the beginning of the script and giving the file an executable mode. The `#!` must be the first two characters of the file. On some platforms, this first line must end with a Unix-style line ending (`'\n'`), not a Windows

(`'\r\n'`) line ending. Note that the hash, or pound, character, `'#'`, is used to start a comment in Python.

The script can be given an executable mode, or permission, using the **chmod** command:

```
$ chmod +x myscript.py
```

On Windows systems, there is no notion of an “executable mode”. The Python installer automatically associates `.py` files with `python.exe` so that a double-click on a Python file will run it as a script. The extension can also be `.pyw`, in that case, the console window that normally appears is suppressed.

2.2.3. Source Code Encoding

By default, Python source files are treated as encoded in UTF-8. In that encoding, characters of most languages in the world can be used simultaneously in string literals, identifiers and comments — although the standard library only uses ASCII characters for identifiers, a convention that any portable code should follow. To display all these characters properly, your editor must recognize that the file is UTF-8, and it must use a font that supports all the characters in the file.

It is also possible to specify a different encoding for source files. In order to do this, put one more special comment line right after the `#!` line to define the source file encoding:

```
# -*- coding: encoding -*-
```

With that declaration, everything in the source file will be treated as having the encoding *encoding* instead of UTF-8. The list of possible encodings can be found in the Python Library Reference, in the

section on [codecs](#).

For example, if your editor of choice does not support UTF-8 encoded files and insists on using some other encoding, say Windows-1252, you can write:

```
# -*- coding: cp-1252 -*-
```

and still use all characters in the Windows-1252 character set in the source files. The special encoding comment must be in the *first or second* line within the file.

2.2.4. The Interactive Startup File

When you use Python interactively, it is frequently handy to have some standard commands executed every time the interpreter is started. You can do this by setting an environment variable named `PYTHONSTARTUP` to the name of a file containing your start-up commands. This is similar to the `.profile` feature of the Unix shells.

This file is only read in interactive sessions, not when Python reads commands from a script, and not when `/dev/tty` is given as the explicit source of commands (which otherwise behaves like an interactive session). It is executed in the same namespace where interactive commands are executed, so that objects that it defines or imports can be used without qualification in the interactive session. You can also change the prompts `sys.ps1` and `sys.ps2` in this file.

If you want to read an additional start-up file from the current directory, you can program this in the global start-up file using code like

```
if os.path.isfile('.pythonrc.py'):
    exec(open('.pythonrc.py').read())
```

. If you want to use the startup file in a script, you must do this explicitly in the script:

```
import os
filename = os.environ.get('PYTHONSTARTUP')
if filename and os.path.isfile(filename):
    exec(open(filename).read())
```

Footnotes

[1] On Unix, the Python 3.x interpreter is by default not installed with the executable named `python`, so that it does not conflict with a simultaneously installed Python 2.x executable.

[2] A problem with the GNU Readline package may prevent this.

3. An Informal Introduction to Python

In the following examples, input and output are distinguished by the presence or absence of prompts (`>>>` and `...`): to repeat the example, you must type everything after the prompt, when the prompt appears; lines that do not begin with a prompt are output from the interpreter. Note that a secondary prompt on a line by itself in an example means you must type a blank line; this is used to end a multi-line command.

Many of the examples in this manual, even those entered at the interactive prompt, include comments. Comments in Python start with the hash character, `#`, and extend to the end of the physical line. A comment may appear at the start of a line or following whitespace or code, but not within a string literal. A hash character within a string literal is just a hash character. Since comments are to clarify code and are not interpreted by Python, they may be omitted when typing in examples.

Some examples:

```
# this is the first comment
SPAM = 1                    # and this is the second comment
                             # ... and now a third!
STRING = "# This is not a comment."
```

3.1. Using Python as a Calculator

Let's try some simple Python commands. Start the interpreter and wait for the primary prompt, `>>>`. (It shouldn't take long.)

3.1.1. Numbers

The interpreter acts as a simple calculator: you can type an expression at it and it will write the value. Expression syntax is straightforward: the operators `+`, `-`, `*` and `/` work just like in most other languages (for example, Pascal or C); parentheses can be used for grouping. For example:

```
>>> 2+2
4
>>> # This is a comment
... 2+2
4
>>> 2+2 # and a comment on the same line as code
4
>>> (50-5*6)/4
5.0
>>> 8/5 # Fractions aren't lost when dividing integers
1.6
```

Note: You might not see exactly the same result; floating point results can differ from one machine to another. We will say more later about controlling the appearance of floating point output. See also *Floating Point Arithmetic: Issues and Limitations* for a full discussion of some of the subtleties of floating point numbers and their representations.

To do integer division and get an integer result, discarding any fractional result, there is another operator, `//`:

```
>>> # Integer division returns the floor:
```

```
... 7//3
2
>>> 7//-3
-3
```

The equal sign ('=') is used to assign a value to a variable. Afterwards, no result is displayed before the next interactive prompt:

```
>>> width = 20
>>> height = 5*9
>>> width * height
900
```

A value can be assigned to several variables simultaneously:

```
>>> x = y = z = 0 # Zero x, y and z
>>> x
0
>>> y
0
>>> z
0
```

Variables must be “defined” (assigned a value) before they can be used, or an error will occur:

```
>>> # try to access an undefined variable
... n
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
NameError: name 'n' is not defined
```

There is full support for floating point; operators with mixed type operands convert the integer operand to floating point:

```
>>> 3 * 3.75 / 1.5
7.5
>>> 7.0 / 2
3.5
```

Complex numbers are also supported; imaginary numbers are written with a suffix of `j` or `J`. Complex numbers with a nonzero real component are written as `(real+imagj)`, or can be created with the `complex(real, imag)` function.

```
>>> 1j * 1J
(-1+0j)
>>> 1j * complex(0, 1)
(-1+0j)
>>> 3+1j*3
(3+3j)
>>> (3+1j)*3
(9+3j)
>>> (1+2j)/(1+1j)
(1.5+0.5j)
```

Complex numbers are always represented as two floating point numbers, the real and imaginary part. To extract these parts from a complex number `z`, use `z.real` and `z.imag`.

```
>>> a=1.5+0.5j
>>> a.real
1.5
>>> a.imag
0.5
```

The conversion functions to floating point and integer (`float()`, `int()`) don't work for complex numbers — there is not one correct way to convert a complex number to a real number. Use `abs(z)` to get its magnitude (as a float) or `z.real` to get its real part:

```
>>> a=3.0+4.0j
>>> float(a)
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
TypeError: can't convert complex to float; use abs(z)
>>> a.real
3.0
>>> a.imag
4.0
```

```
>>> abs(a) # sqrt(a.real**2 + a.imag**2)
5.0
```

In interactive mode, the last printed expression is assigned to the variable `_`. This means that when you are using Python as a desk calculator, it is somewhat easier to continue calculations, for example:

```
>>> tax = 12.5 / 100
>>> price = 100.50
>>> price * tax
12.5625
>>> price + _
113.0625
>>> round(_, 2)
113.06
```

This variable should be treated as read-only by the user. Don't explicitly assign a value to it — you would create an independent local variable with the same name masking the built-in variable with its magic behavior.

3.1.2. Strings

Besides numbers, Python can also manipulate strings, which can be expressed in several ways. They can be enclosed in single quotes or double quotes:

```
>>> 'spam eggs'
'spam eggs'
>>> 'doesn\'t'
"doesn't"
>>> "doesn't"
"doesn't"
>>> '"Yes," he said.'
'"Yes," he said.'
>>> "\"Yes,\" he said."
'"Yes," he said.'
>>> '"Isn\'t," she said.'
'"Isn\'t," she said.'
```

The interpreter prints the result of string operations in the same way as they are typed for input: inside quotes, and with quotes and other funny characters escaped by backslashes, to show the precise value. The string is enclosed in double quotes if the string contains a single quote and no double quotes, else it's enclosed in single quotes. The `print()` function produces a more readable output for such input strings.

String literals can span multiple lines in several ways. Continuation lines can be used, with a backslash as the last character on the line indicating that the next line is a logical continuation of the line:

```
hello = "This is a rather long string containing\n\  
several lines of text just as you would do in C.\n\  
    Note that whitespace at the beginning of the line is\  
    significant."  
  
print(hello)
```

Note that newlines still need to be embedded in the string using `\n` – the newline following the trailing backslash is discarded. This example would print the following:

```
This is a rather long string containing  
several lines of text just as you would do in C.  
    Note that whitespace at the beginning of the line is signif
```

Or, strings can be surrounded in a pair of matching triple-quotes: `"""` or `'''`. End of lines do not need to be escaped when using triple-quotes, but they will be included in the string. So the following uses one escape to avoid an unwanted initial blank line.

```
print("""\  
Usage: thingy [OPTIONS]  
    -h                Display this usage message  
    -H hostname       Hostname to connect to  
""")
```

produces the following output:

```
Usage: thingy [OPTIONS]
  -h                Display this usage message
  -H hostname       Hostname to connect to
```

If we make the string literal a “raw” string, `\n` sequences are not converted to newlines, but the backslash at the end of the line, and the newline character in the source, are both included in the string as data. Thus, the example:

```
hello = r"This is a rather long string containing\n\
several lines of text much as you would do in C."

print(hello)
```

would print:

```
This is a rather long string containing\n\
several lines of text much as you would do in C.
```

Strings can be concatenated (glued together) with the `+` operator, and repeated with `*`:

```
>>> word = 'Help' + 'A'
>>> word
'HelpA'
>>> '<' + word*5 + '>'
'<HelpAHelpAHelpAHelpAHelpA>'
```

Two string literals next to each other are automatically concatenated; the first line above could also have been written `word = 'Help' 'A'`; this only works with two literals, not with arbitrary string expressions:

```
>>> 'str' 'ing'                # <- This is ok
'string'
>>> 'str'.strip() + 'ing'      # <- This is ok
'string'
>>> 'str'.strip() 'ing'       # <- This is invalid
```

```
File "<stdin>", line 1, in ?
    'str'.strip() 'ing'
                ^
SyntaxError: invalid syntax
```

Strings can be subscripted (indexed); like in C, the first character of a string has subscript (index) 0. There is no separate character type; a character is simply a string of size one. As in the Icon programming language, substrings can be specified with the *slice notation*: two indices separated by a colon.

```
>>> word[4]
'A'
>>> word[0:2]
'He'
>>> word[2:4]
'lp'
```

Slice indices have useful defaults; an omitted first index defaults to zero, an omitted second index defaults to the size of the string being sliced.

```
>>> word[:2]      # The first two characters
'He'
>>> word[2:]     # Everything except the first two characters
'lpA'
```

Unlike a C string, Python strings cannot be changed. Assigning to an indexed position in the string results in an error:

```
>>> word[0] = 'x'
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
TypeError: 'str' object does not support item assignment
>>> word[:1] = 'Splat'
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
TypeError: 'str' object does not support slice assignment
```

However, creating a new string with the combined content is easy

and efficient:

```
>>> 'x' + word[1:]
'xelpA'
>>> 'Splat' + word[4]
'SplatA'
```

Here's a useful invariant of slice operations: `s[:i] + s[i:]` equals `s`.

```
>>> word[:2] + word[2:]
'HelpA'
>>> word[:3] + word[3:]
'HelpA'
```

Degenerate slice indices are handled gracefully: an index that is too large is replaced by the string size, an upper bound smaller than the lower bound returns an empty string.

```
>>> word[1:100]
'elpA'
>>> word[10:]
''
>>> word[2:1]
''
```

Indices may be negative numbers, to start counting from the right. For example:

```
>>> word[-1]      # The last character
'A'
>>> word[-2]     # The last-but-one character
'p'
>>> word[-2:]    # The last two characters
'pA'
>>> word[: -2]   # Everything except the last two characters
'Hel'
```

But note that `-0` is really the same as `0`, so it does not count from the right!

```
>>> word[-0]      # (since -0 equals 0)
'H'
```

Out-of-range negative slice indices are truncated, but don't try this for single-element (non-slice) indices:

```
>>> word[-100:]
'HelpA'
>>> word[-10]     # error
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
IndexError: string index out of range
```

One way to remember how slices work is to think of the indices as pointing *between* characters, with the left edge of the first character numbered 0. Then the right edge of the last character of a string of n characters has index n , for example:

```
+---+---+---+---+---+
| H | e | l | p | A |
+---+---+---+---+---+
0   1   2   3   4   5
-5  -4  -3  -2  -1
```

The first row of numbers gives the position of the indices 0...5 in the string; the second row gives the corresponding negative indices. The slice from i to j consists of all characters between the edges labeled i and j , respectively.

For non-negative indices, the length of a slice is the difference of the indices, if both are within bounds. For example, the length of `word[1:3]` is 2.

The built-in function `len()` returns the length of a string:

```
>>> s = 'supercalifragilisticexpialidocious'
>>> len(s)
34
```

See also:

Sequence Types — str, bytes, bytearray, list, tuple, range

Strings are examples of *sequence types*, and support the common operations supported by such types.

String Methods

Strings support a large number of methods for basic transformations and searching.

String Formatting

Information about string formatting with `str.format()` is described here.

Old String Formatting Operations

The old formatting operations invoked when strings and Unicode strings are the left operand of the `%` operator are described in more detail here.

3.1.3. About Unicode

Starting with Python 3.0 all strings support Unicode (see <http://www.unicode.org/>).

Unicode has the advantage of providing one ordinal for every character in every script used in modern and ancient texts. Previously, there were only 256 possible ordinals for script characters. Texts were typically bound to a code page which mapped the ordinals to script characters. This led to very much confusion especially with respect to internationalization (usually written as `i18n` — `'i'` + 18 characters + `'n'`) of software. Unicode solves these problems by defining one code page for all scripts.

If you want to include special characters in a string, you can do so by using the Python *Unicode-Escape* encoding. The following example

shows how:

```
>>> 'Hello\u0020World !'  
'Hello World !'
```

The escape sequence `\u0020` indicates to insert the Unicode character with the ordinal value 0x0020 (the space character) at the given position.

Other characters are interpreted by using their respective ordinal values directly as Unicode ordinals. If you have literal strings in the standard Latin-1 encoding that is used in many Western countries, you will find it convenient that the lower 256 characters of Unicode are the same as the 256 characters of Latin-1.

Apart from these standard encodings, Python provides a whole set of other ways of creating Unicode strings on the basis of a known encoding.

To convert a string into a sequence of bytes using a specific encoding, string objects provide an `encode()` method that takes one argument, the name of the encoding. Lowercase names for encodings are preferred.

```
>>> "Äpfel".encode('utf-8')  
b'\xc3\x84pfel'
```

3.1.4. Lists

Python knows a number of *compound* data types, used to group together other values. The most versatile is the *list*, which can be written as a list of comma-separated values (items) between square brackets. List items need not all have the same type.

```
>>> a = ['spam', 'eggs', 100, 1234]  
>>> a
```

```
['spam', 'eggs', 100, 1234]
```

Like string indices, list indices start at 0, and lists can be sliced, concatenated and so on:

```
>>> a[0]
'spam'
>>> a[3]
1234
>>> a[-2]
100
>>> a[1:-1]
['eggs', 100]
>>> a[:2] + ['bacon', 2*2]
['spam', 'eggs', 'bacon', 4]
>>> 3*a[:3] + ['Boo!']
['spam', 'eggs', 100, 'spam', 'eggs', 100, 'spam', 'eggs', 100,
```

All slice operations return a new list containing the requested elements. This means that the following slice returns a shallow copy of the list `a`:

```
>>> a[:]
['spam', 'eggs', 100, 1234]
```

Unlike strings, which are *immutable*, it is possible to change individual elements of a list:

```
>>> a
['spam', 'eggs', 100, 1234]
>>> a[2] = a[2] + 23
>>> a
['spam', 'eggs', 123, 1234]
```

Assignment to slices is also possible, and this can even change the size of the list or clear it entirely:

```
>>> # Replace some items:
... a[0:2] = [1, 12]
>>> a
```

```

[1, 12, 123, 1234]
>>> # Remove some:
... a[0:2] = []
>>> a
[123, 1234]
>>> # Insert some:
... a[1:1] = ['bletch', 'xyzy']
>>> a
[123, 'bletch', 'xyzy', 1234]
>>> # Insert (a copy of) itself at the beginning
>>> a[:0] = a
>>> a
[123, 'bletch', 'xyzy', 1234, 123, 'bletch', 'xyzy', 1234]
>>> # Clear the list: replace all items with an empty list
>>> a[:] = []
>>> a
[]

```

The built-in function `len()` also applies to lists:

```

>>> a = ['a', 'b', 'c', 'd']
>>> len(a)
4

```

It is possible to nest lists (create lists containing other lists), for example:

```

>>> q = [2, 3]
>>> p = [1, q, 4]
>>> len(p)
3
>>> p[1]
[2, 3]
>>> p[1][0]
2

```

You can add something to the end of the list:

```

>>> p[1].append('extra')
>>> p
[1, [2, 3, 'extra'], 4]
>>> q
[2, 3, 'extra']

```

Note that in the last example, `p[1]` and `q` really refer to the same object! We'll come back to *object semantics* later.

3.2. First Steps Towards Programming

Of course, we can use Python for more complicated tasks than adding two and two together. For instance, we can write an initial sub-sequence of the *Fibonacci* series as follows:

```
>>> # Fibonacci series:
... # the sum of two elements defines the next
... a, b = 0, 1
>>> while b < 10:
...     print(b)
...     a, b = b, a+b
...
1
1
2
3
5
8
```

This example introduces several new features.

- The first line contains a *multiple assignment*: the variables `a` and `b` simultaneously get the new values 0 and 1. On the last line this is used again, demonstrating that the expressions on the right-hand side are all evaluated first before any of the assignments take place. The right-hand side expressions are evaluated from the left to the right.
- The `while` loop executes as long as the condition (here: `b < 10`) remains true. In Python, like in C, any non-zero integer value is true; zero is false. The condition may also be a string or list value, in fact any sequence; anything with a non-zero length is true, empty sequences are false. The test used in the example is a simple comparison. The standard comparison operators are written the same as in C: `<` (less than), `>` (greater than), `==`

(equal to), `<=` (less than or equal to), `>=` (greater than or equal to) and `!=` (not equal to).

- The *body* of the loop is *indented*: indentation is Python's way of grouping statements. Python does not (yet!) provide an intelligent input line editing facility, so you have to type a tab or space(s) for each indented line. In practice you will prepare more complicated input for Python with a text editor; most text editors have an auto-indent facility. When a compound statement is entered interactively, it must be followed by a blank line to indicate completion (since the parser cannot guess when you have typed the last line). Note that each line within a basic block must be indented by the same amount.
- The `print()` function writes the value of the expression(s) it is given. It differs from just writing the expression you want to write (as we did earlier in the calculator examples) in the way it handles multiple expressions, floating point quantities, and strings. Strings are printed without quotes, and a space is inserted between items, so you can format things nicely, like this:

```
>>> i = 256*256
>>> print('The value of i is', i)
The value of i is 65536
```

The keyword *end* can be used to avoid the newline after the output, or end the output with a different string:

```
>>> a, b = 0, 1
>>> while b < 1000:
...     print(b, end=', ')
...     a, b = b, a+b
...
1, 1, 2, 3, 5, 8, 13, 21, 34, 55, 89, 144, 233, 377, 610, 987,
```

4. More Control Flow Tools

Besides the `while` statement just introduced, Python knows the usual control flow statements known from other languages, with some twists.

4.1. `if` Statements

Perhaps the most well-known statement type is the `if` statement. For example:

```
>>> x = int(input("Please enter an integer: "))
Please enter an integer: 42
>>> if x < 0:
...     x = 0
...     print('Negative changed to zero')
... elif x == 0:
...     print('Zero')
... elif x == 1:
...     print('Single')
... else:
...     print('More')
...
More
```

There can be zero or more `elif` parts, and the `else` part is optional. The keyword '`elif`' is short for 'else if', and is useful to avoid excessive indentation. An `if ... elif ... elif ...` sequence is a substitute for the `switch` or `case` statements found in other languages.

4.2. for Statements

The `for` statement in Python differs a bit from what you may be used to in C or Pascal. Rather than always iterating over an arithmetic progression of numbers (like in Pascal), or giving the user the ability to define both the iteration step and halting condition (as C), Python's `for` statement iterates over the items of any sequence (a list or a string), in the order that they appear in the sequence. For example (no pun intended):

```
>>> # Measure some strings:
... a = ['cat', 'window', 'defenestrate']
>>> for x in a:
...     print(x, len(x))
...
cat 3
window 6
defenestrate 12
```

It is not safe to modify the sequence being iterated over in the loop (this can only happen for mutable sequence types, such as lists). If you need to modify the list you are iterating over (for example, to duplicate selected items) you must iterate over a copy. The slice notation makes this particularly convenient:

```
>>> for x in a[:]: # make a slice copy of the entire list
...     if len(x) > 6: a.insert(0, x)
...
>>> a
['defenestrate', 'cat', 'window', 'defenestrate']
```

4.3. The `range()` Function

If you do need to iterate over a sequence of numbers, the built-in function `range()` comes in handy. It generates arithmetic progressions:

```
>>> for i in range(5):
...     print(i)
...
0
1
2
3
4
```

The given end point is never part of the generated sequence; `range(10)` generates 10 values, the legal indices for items of a sequence of length 10. It is possible to let the range start at another number, or to specify a different increment (even negative; sometimes this is called the 'step'):

```
range(5, 10)
    5 through 9

range(0, 10, 3)
    0, 3, 6, 9

range(-10, -100, -30)
    -10, -40, -70
```

To iterate over the indices of a sequence, you can combine `range()` and `len()` as follows:

```
>>> a = ['Mary', 'had', 'a', 'little', 'lamb']
>>> for i in range(len(a)):
...     print(i, a[i])
...
0 Mary
```

```
1 had
2 a
3 little
4 lamb
```

In most such cases, however, it is convenient to use the `enumerate()` function, see [Looping Techniques](#).

A strange thing happens if you just print a range:

```
>>> print(range(10))
range(0, 10)
```

In many ways the object returned by `range()` behaves as if it is a list, but in fact it isn't. It is an object which returns the successive items of the desired sequence when you iterate over it, but it doesn't really make the list, thus saving space.

We say such an object is *iterable*, that is, suitable as a target for functions and constructs that expect something from which they can obtain successive items until the supply is exhausted. We have seen that the `for` statement is such an *iterator*. The function `list()` is another; it creates lists from iterables:

```
>>> list(range(5))
[0, 1, 2, 3, 4]
```

Later we will see more functions that return iterables and take iterables as argument.

4.4. `break` and `continue` Statements, and `else` Clauses on Loops

The `break` statement, like in C, breaks out of the smallest enclosing `for` or `while` loop.

The `continue` statement, also borrowed from C, continues with the next iteration of the loop.

Loop statements may have an `else` clause; it is executed when the loop terminates through exhaustion of the list (with `for`) or when the condition becomes false (with `while`), but not when the loop is terminated by a `break` statement. This is exemplified by the following loop, which searches for prime numbers:

```
>>> for n in range(2, 10):
...     for x in range(2, n):
...         if n % x == 0:
...             print(n, 'equals', x, '*', n//x)
...             break
...         else:
...             # loop fell through without finding a factor
...             print(n, 'is a prime number')
...
2 is a prime number
3 is a prime number
4 equals 2 * 2
5 is a prime number
6 equals 2 * 3
7 is a prime number
8 equals 2 * 4
9 equals 3 * 3
```

4.5. `pass` Statements

The `pass` statement does nothing. It can be used when a statement is required syntactically but the program requires no action. For example:

```
>>> while True:
...     pass # Busy-wait for keyboard interrupt (Ctrl+C)
... 
```

This is commonly used for creating minimal classes:

```
>>> class MyEmptyClass:
...     pass
... 
```

Another place `pass` can be used is as a place-holder for a function or conditional body when you are working on new code, allowing you to keep thinking at a more abstract level. The `pass` is silently ignored:

```
>>> def initlog(*args):
...     pass # Remember to implement this!
... 
```

4.6. Defining Functions

We can create a function that writes the Fibonacci series to an arbitrary boundary:

```
>>> def fib(n):    # write Fibonacci series up to n
...     """Print a Fibonacci series up to n."""
...     a, b = 0, 1
...     while a < n:
...         print(a, end=' ')
...         a, b = b, a+b
...     print()
...
>>> # Now call the function we just defined:
... fib(2000)
0 1 1 2 3 5 8 13 21 34 55 89 144 233 377 610 987 1597
```

The keyword `def` introduces a function *definition*. It must be followed by the function name and the parenthesized list of formal parameters. The statements that form the body of the function start at the next line, and must be indented.

The first statement of the function body can optionally be a string literal; this string literal is the function's documentation string, or *docstring*. (More about docstrings can be found in the section [Documentation Strings](#).) There are tools which use docstrings to automatically produce online or printed documentation, or to let the user interactively browse through code; it's good practice to include docstrings in code that you write, so make a habit of it.

The *execution* of a function introduces a new symbol table used for the local variables of the function. More precisely, all variable assignments in a function store the value in the local symbol table; whereas variable references first look in the local symbol table, then in the local symbol tables of enclosing functions, then in the global symbol table, and finally in the table of built-in names. Thus, global

variables cannot be directly assigned a value within a function (unless named in a `global` statement), although they may be referenced.

The actual parameters (arguments) to a function call are introduced in the local symbol table of the called function when it is called; thus, arguments are passed using *call by value* (where the *value* is always an object *reference*, not the value of the object). [1] When a function calls another function, a new local symbol table is created for that call.

A function definition introduces the function name in the current symbol table. The value of the function name has a type that is recognized by the interpreter as a user-defined function. This value can be assigned to another name which can then also be used as a function. This serves as a general renaming mechanism:

```
>>> fib
<function fib at 10042ed0>
>>> f = fib
>>> f(100)
0 1 1 2 3 5 8 13 21 34 55 89
```

Coming from other languages, you might object that `fib` is not a function but a procedure since it doesn't return a value. In fact, even functions without a `return` statement do return a value, albeit a rather boring one. This value is called `None` (it's a built-in name). Writing the value `None` is normally suppressed by the interpreter if it would be the only value written. You can see it if you really want to using `print()`:

```
>>> fib(0)
>>> print(fib(0))
None
```

It is simple to write a function that returns a list of the numbers of the

Fibonacci series, instead of printing it:

```
>>> def fib2(n): # return Fibonacci series up to n
...     """Return a list containing the Fibonacci series up to
...     result = []
...     a, b = 0, 1
...     while a < n:
...         result.append(a)    # see below
...         a, b = b, a+b
...     return result
...
>>> f100 = fib2(100)    # call it
>>> f100                # write the result
[0, 1, 1, 2, 3, 5, 8, 13, 21, 34, 55, 89]
```

This example, as usual, demonstrates some new Python features:

- The `return` statement returns with a value from a function. `return` without an expression argument returns `None`. Falling off the end of a function also returns `None`.
- The statement `result.append(a)` calls a *method* of the list object `result`. A method is a function that 'belongs' to an object and is named `obj.methodname`, where `obj` is some object (this may be an expression), and `methodname` is the name of a method that is defined by the object's type. Different types define different methods. Methods of different types may have the same name without causing ambiguity. (It is possible to define your own object types and methods, using *classes*, see [Classes](#)) The method `append()` shown in the example is defined for list objects; it adds a new element at the end of the list. In this example it is equivalent to `result = result + [a]`, but more efficient.

4.7. More on Defining Functions

It is also possible to define functions with a variable number of arguments. There are three forms, which can be combined.

4.7.1. Default Argument Values

The most useful form is to specify a default value for one or more arguments. This creates a function that can be called with fewer arguments than it is defined to allow. For example:

```
def ask_ok(prompt, retries=4, complaint='Yes or no, please!'):
    while True:
        ok = input(prompt)
        if ok in ('y', 'ye', 'yes'):
            return True
        if ok in ('n', 'no', 'nop', 'nope'):
            return False
        retries = retries - 1
        if retries < 0:
            raise IOError('refusenik user')
        print(complaint)
```

This function can be called in several ways:

- giving only the mandatory argument: `ask_ok('Do you really want to quit?')`
- giving one of the optional arguments: `ask_ok('OK to overwrite the file?', 2)`
- or even giving all arguments: `ask_ok('OK to overwrite the file?', 2, 'Come on, only yes or no!')`

This example also introduces the `in` keyword. This tests whether or not a sequence contains a certain value.

The default values are evaluated at the point of function definition in

the *defining* scope, so that

```
i = 5

def f(arg=i):
    print(arg)

i = 6
f()
```

will print 5.

Important warning: The default value is evaluated only once. This makes a difference when the default is a mutable object such as a list, dictionary, or instances of most classes. For example, the following function accumulates the arguments passed to it on subsequent calls:

```
def f(a, L=[]):
    L.append(a)
    return L

print(f(1))
print(f(2))
print(f(3))
```

This will print

```
[1]
[1, 2]
[1, 2, 3]
```

If you don't want the default to be shared between subsequent calls, you can write the function like this instead:

```
def f(a, L=None):
    if L is None:
        L = []
    L.append(a)
    return L
```

4.7.2. Keyword Arguments

Functions can also be called using keyword arguments of the form `keyword = value`. For instance, the following function:

```
def parrot(voltage, state='a stiff', action='vroom', type='Norwe')
    print("-- This parrot wouldn't", action, end=' ')
    print("if you put", voltage, "volts through it.")
    print("-- Lovely plumage, the", type)
    print("-- It's", state, "!")
```

could be called in any of the following ways:

```
parrot(1000)
parrot(action = 'VOOOOOM', voltage = 1000000)
parrot('a thousand', state = 'pushing up the daisies')
parrot('a million', 'bereft of life', 'jump')
```

but the following calls would all be invalid:

```
parrot() # required argument missing
parrot(voltage=5.0, 'dead') # non-keyword argument following k
parrot(110, voltage=220) # duplicate value for argument
parrot(actor='John Cleese') # unknown keyword
```

In general, an argument list must have any positional arguments followed by any keyword arguments, where the keywords must be chosen from the formal parameter names. It's not important whether a formal parameter has a default value or not. No argument may receive a value more than once — formal parameter names corresponding to positional arguments cannot be used as keywords in the same calls. Here's an example that fails due to this restriction:

```
>>> def function(a):
...     pass
...
>>> function(0, a=0)
```

```
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
TypeError: function() got multiple values for keyword argument
```

When a final formal parameter of the form `**name` is present, it receives a dictionary (see *Mapping Types — dict*) containing all keyword arguments except for those corresponding to a formal parameter. This may be combined with a formal parameter of the form `*name` (described in the next subsection) which receives a tuple containing the positional arguments beyond the formal parameter list. (`*name` must occur before `**name`.) For example, if we define a function like this:

```
def cheeseshop(kind, *arguments, **keywords):
    print("-- Do you have any", kind, "?")
    print("-- I'm sorry, we're all out of", kind)
    for arg in arguments:
        print(arg)
    print("-" * 40)
    keys = sorted(keywords.keys())
    for kw in keys:
        print(kw, ":", keywords[kw])
```

It could be called like this:

```
cheeseshop("Limburger", "It's very runny, sir.",
           "It's really very, VERY runny, sir.",
           shopkeeper="Michael Palin",
           client="John Cleese",
           sketch="Cheese Shop Sketch")
```

and of course it would print:

```
-- Do you have any Limburger ?
-- I'm sorry, we're all out of Limburger
It's very runny, sir.
It's really very, VERY runny, sir.
-----
client : John Cleese
shopkeeper : Michael Palin
```

```
sketch : Cheese Shop Sketch
```

Note that the list of keyword argument names is created by sorting the result of the keywords dictionary's `keys()` method before printing its contents; if this is not done, the order in which the arguments are printed is undefined.

4.7.3. Arbitrary Argument Lists

Finally, the least frequently used option is to specify that a function can be called with an arbitrary number of arguments. These arguments will be wrapped up in a tuple (see *Tuples and Sequences*). Before the variable number of arguments, zero or more normal arguments may occur.

```
def write_multiple_items(file, separator, *args):  
    file.write(separator.join(args))
```

Normally, these `variadic` arguments will be last in the list of formal parameters, because they scoop up all remaining input arguments that are passed to the function. Any formal parameters which occur after the `*args` parameter are 'keyword-only' arguments, meaning that they can only be used as keywords rather than positional arguments.

```
>>> def concat(*args, sep="/"):  
...     return sep.join(args)  
...  
>>> concat("earth", "mars", "venus")  
'earth/mars/venus'  
>>> concat("earth", "mars", "venus", sep=".")  
'earth.mars.venus'
```

4.7.4. Unpacking Argument Lists

The reverse situation occurs when the arguments are already in a

list or tuple but need to be unpacked for a function call requiring separate positional arguments. For instance, the built-in `range()` function expects separate *start* and *stop* arguments. If they are not available separately, write the function call with the `*`-operator to unpack the arguments out of a list or tuple:

```
>>> list(range(3, 6))           # normal call with separate ar
[3, 4, 5]
>>> args = [3, 6]
>>> list(range(*args))         # call with arguments unpackage
[3, 4, 5]
```

In the same fashion, dictionaries can deliver keyword arguments with the `**`-operator:

```
>>> def parrot(voltage, state='a stiff', action='vroom'):
...     print("-- This parrot wouldn't", action, end=' ')
...     print("if you put", voltage, "volts through it.", end=' ')
...     print("E's", state, "!")
...
>>> d = {"voltage": "four million", "state": "bleedin' demised"}
>>> parrot(**d)
-- This parrot wouldn't VROOM if you put four million volts thro
```

4.7.5. Lambda Forms

By popular demand, a few features commonly found in functional programming languages like Lisp have been added to Python. With the `lambda` keyword, small anonymous functions can be created. Here's a function that returns the sum of its two arguments: `lambda a, b: a+b`. Lambda forms can be used wherever function objects are required. They are syntactically restricted to a single expression. Semantically, they are just syntactic sugar for a normal function definition. Like nested function definitions, lambda forms can reference variables from the containing scope:

```
>>> def make_incrementor(n):  
...     return lambda x: x + n  
...  
>>> f = make_incrementor(42)  
>>> f(0)  
42  
>>> f(1)  
43
```

4.7.6. Documentation Strings

Here are some conventions about the content and formatting of documentation strings.

The first line should always be a short, concise summary of the object's purpose. For brevity, it should not explicitly state the object's name or type, since these are available by other means (except if the name happens to be a verb describing a function's operation). This line should begin with a capital letter and end with a period.

If there are more lines in the documentation string, the second line should be blank, visually separating the summary from the rest of the description. The following lines should be one or more paragraphs describing the object's calling conventions, its side effects, etc.

The Python parser does not strip indentation from multi-line string literals in Python, so tools that process documentation have to strip indentation if desired. This is done using the following convention. The first non-blank line *after* the first line of the string determines the amount of indentation for the entire documentation string. (We can't use the first line since it is generally adjacent to the string's opening quotes so its indentation is not apparent in the string literal.) Whitespace "equivalent" to this indentation is then stripped from the start of all lines of the string. Lines that are indented less should not occur, but if they occur all their leading whitespace should be stripped. Equivalence of whitespace should be tested after expansion of tabs (to 8 spaces, normally).

Here is an example of a multi-line docstring:

```
>>> def my_function():
...     """Do nothing, but document it.
...
...     No, really, it doesn't do anything.
...     """
...     pass
...
>>> print(my_function.__doc__)
Do nothing, but document it.

    No, really, it doesn't do anything.
```

4.8. Intermezzo: Coding Style

Now that you are about to write longer, more complex pieces of Python, it is a good time to talk about *coding style*. Most languages can be written (or more concise, *formatted*) in different styles; some are more readable than others. Making it easy for others to read your code is always a good idea, and adopting a nice coding style helps tremendously for that.

For Python, **PEP 8** has emerged as the style guide that most projects adhere to; it promotes a very readable and eye-pleasing coding style. Every Python developer should read it at some point; here are the most important points extracted for you:

- Use 4-space indentation, and no tabs.

4 spaces are a good compromise between small indentation (allows greater nesting depth) and large indentation (easier to read). Tabs introduce confusion, and are best left out.

- Wrap lines so that they don't exceed 79 characters.

This helps users with small displays and makes it possible to have several code files side-by-side on larger displays.

- Use blank lines to separate functions and classes, and larger blocks of code inside functions.
- When possible, put comments on a line of their own.
- Use docstrings.
- Use spaces around operators and after commas, but not directly inside bracketing constructs: `a = f(1, 2) + g(3, 4)`.

- Name your classes and functions consistently; the convention is to use `CamelCase` for classes and `lower_case_with_underscores` for functions and methods. Always use `self` as the name for the first method argument (see [A First Look at Classes](#) for more on classes and methods).
- Don't use fancy encodings if your code is meant to be used in international environments. Python's default, UTF-8, or even plain ASCII work best in any case.
- Likewise, don't use non-ASCII characters in identifiers if there is only the slightest chance people speaking a different language will read or maintain the code.

Footnotes

[1] Actually, *call by object reference* would be a better description, since if a mutable object is passed, the caller will see any changes the callee makes to it (items inserted into a list).

5. Data Structures

This chapter describes some things you've learned about already in more detail, and adds some new things as well.

5.1. More on Lists

The list data type has some more methods. Here are all of the methods of list objects:

`list.append(x)`

Add an item to the end of the list; equivalent to `a[len(a):] = [x]`.

`list.extend(L)`

Extend the list by appending all the items in the given list; equivalent to `a[len(a):] = L`.

`list.insert(i, x)`

Insert an item at a given position. The first argument is the index of the element before which to insert, so `a.insert(0, x)` inserts at the front of the list, and `a.insert(len(a), x)` is equivalent to `a.append(x)`.

`list.remove(x)`

Remove the first item from the list whose value is `x`. It is an error if there is no such item.

`list.pop([i])`

Remove the item at the given position in the list, and return it. If no index is specified, `a.pop()` removes and returns the last item in the list. (The square brackets around the `i` in the method signature denote that the parameter is optional, not that you should type square brackets at that position. You will see this notation frequently in the Python Library Reference.)

`list.index(x)`

Return the index in the list of the first item whose value is `x`. It is

an error if there is no such item.

`list.count(x)`

Return the number of times `x` appears in the list.

`list.sort()`

Sort the items of the list, in place.

`list.reverse()`

Reverse the elements of the list, in place.

An example that uses most of the list methods:

```
>>> a = [66.25, 333, 333, 1, 1234.5]
>>> print(a.count(333), a.count(66.25), a.count('x'))
2 1 0
>>> a.insert(2, -1)
>>> a.append(333)
>>> a
[66.25, 333, -1, 333, 1, 1234.5, 333]
>>> a.index(333)
1
>>> a.remove(333)
>>> a
[66.25, -1, 333, 1, 1234.5, 333]
>>> a.reverse()
>>> a
[333, 1234.5, 1, 333, -1, 66.25]
>>> a.sort()
>>> a
[-1, 1, 66.25, 333, 333, 1234.5]
```

5.1.1. Using Lists as Stacks

The list methods make it very easy to use a list as a stack, where the last element added is the first element retrieved (“last-in, first-out”). To add an item to the top of the stack, use `append()`. To retrieve an item from the top of the stack, use `pop()` without an explicit index. For example:

```
>>> stack = [3, 4, 5]
>>> stack.append(6)
>>> stack.append(7)
>>> stack
[3, 4, 5, 6, 7]
>>> stack.pop()
7
>>> stack
[3, 4, 5, 6]
>>> stack.pop()
6
>>> stack.pop()
5
>>> stack
[3, 4]
```

5.1.2. Using Lists as Queues

It is also possible to use a list as a queue, where the first element added is the first element retrieved (“first-in, first-out”); however, lists are not efficient for this purpose. While appends and pops from the end of list are fast, doing inserts or pops from the beginning of a list is slow (because all of the other elements have to be shifted by one).

To implement a queue, use `collections.deque` which was designed to have fast appends and pops from both ends. For example:

```
>>> from collections import deque
>>> queue = deque(["Eric", "John", "Michael"])
>>> queue.append("Terry")           # Terry arrives
>>> queue.append("Graham")        # Graham arrives
>>> queue.popleft()               # The first to arrive now
'Eric'
>>> queue.popleft()               # The second to arrive now
'John'
>>> queue                          # Remaining queue in order
deque(['Michael', 'Terry', 'Graham'])
```

5.1.3. List Comprehensions

List comprehensions provide a concise way to create lists from sequences. Common applications are to make lists where each element is the result of some operations applied to each member of the sequence, or to create a subsequence of those elements that satisfy a certain condition.

A list comprehension consists of brackets containing an expression followed by a **for** clause, then zero or more **for** or **if** clauses. The result will be a list resulting from evaluating the expression in the context of the **for** and **if** clauses which follow it. If the expression would evaluate to a tuple, it must be parenthesized.

Here we take a list of numbers and return a list of three times each number:

```
>>> vec = [2, 4, 6]
>>> [3*x for x in vec]
[6, 12, 18]
```

Now we get a little fancier:

```
>>> [[x, x**2] for x in vec]
[[2, 4], [4, 16], [6, 36]]
```

Here we apply a method call to each item in a sequence:

```
>>> freshfruit = [' banana', ' loganberry ', 'passion fruit']
>>> [weapon.strip() for weapon in freshfruit]
['banana', 'loganberry', 'passion fruit']
```

Using the **if** clause we can filter the stream:

```
>>> [3*x for x in vec if x > 3]
[12, 18]
>>> [3*x for x in vec if x < 2]
[]
```

Tuples can often be created without their parentheses, but not here:

```
>>> [x, x**2 for x in vec] # error - parens required for tuple
File "<stdin>", line 1, in ?
    [x, x**2 for x in vec]
          ^
SyntaxError: invalid syntax
>>> [(x, x**2) for x in vec]
[(2, 4), (4, 16), (6, 36)]
```

Here are some nested for loops and other fancy behavior:

```
>>> vec1 = [2, 4, 6]
>>> vec2 = [4, 3, -9]
>>> [x*y for x in vec1 for y in vec2]
[8, 6, -18, 16, 12, -36, 24, 18, -54]
>>> [x+y for x in vec1 for y in vec2]
[6, 5, -7, 8, 7, -5, 10, 9, -3]
>>> [vec1[i]*vec2[i] for i in range(len(vec1))]
[8, 12, -54]
```

List comprehensions can be applied to complex expressions and nested functions:

```
>>> [str(round(355/113, i)) for i in range(1, 6)]
['3.1', '3.14', '3.142', '3.1416', '3.14159']
```

5.1.4. Nested List Comprehensions

If you've got the stomach for it, list comprehensions can be nested. They are a powerful tool but – like all powerful tools – they need to be used carefully, if at all.

Consider the following example of a 3x3 matrix held as a list containing three lists, one list per row:

```
>>> mat = [
...     [1, 2, 3],
...     [4, 5, 6],
```

```
...     [7, 8, 9],  
...     ]
```

Now, if you wanted to swap rows and columns, you could use a list comprehension:

```
>>> print([[row[i] for row in mat] for i in [0, 1, 2]])  
[[1, 4, 7], [2, 5, 8], [3, 6, 9]]
```

Special care has to be taken for the *nested* list comprehension:

To avoid apprehension when nesting list comprehensions, read from right to left.

A more verbose version of this snippet shows the flow explicitly:

```
for i in [0, 1, 2]:  
    for row in mat:  
        print(row[i], end="")  
    print()
```

In real world, you should prefer built-in functions to complex flow statements. The `zip()` function would do a great job for this use case:

```
>>> list(zip(*mat))  
[(1, 4, 7), (2, 5, 8), (3, 6, 9)]
```

See [Unpacking Argument Lists](#) for details on the asterisk in this line.

5.2. The `del` statement

There is a way to remove an item from a list given its index instead of its value: the `del` statement. This differs from the `pop()` method which returns a value. The `del` statement can also be used to remove slices from a list or clear the entire list (which we did earlier by assignment of an empty list to the slice). For example:

```
>>> a = [-1, 1, 66.25, 333, 333, 1234.5]
>>> del a[0]
>>> a
[1, 66.25, 333, 333, 1234.5]
>>> del a[2:4]
>>> a
[1, 66.25, 1234.5]
>>> del a[:]
>>> a
[]
```

`del` can also be used to delete entire variables:

```
>>> del a
```

Referencing the name `a` hereafter is an error (at least until another value is assigned to it). We'll find other uses for `del` later.

5.3. Tuples and Sequences

We saw that lists and strings have many common properties, such as indexing and slicing operations. They are two examples of *sequence* data types (see *Sequence Types — str, bytes, bytearray, list, tuple, range*). Since Python is an evolving language, other sequence data types may be added. There is also another standard sequence data type: the *tuple*.

A tuple consists of a number of values separated by commas, for instance:

```
>>> t = 12345, 54321, 'hello!'
>>> t[0]
12345
>>> t
(12345, 54321, 'hello!')
>>> # Tuples may be nested:
... u = t, (1, 2, 3, 4, 5)
>>> u
((12345, 54321, 'hello!'), (1, 2, 3, 4, 5))
```

As you see, on output tuples are always enclosed in parentheses, so that nested tuples are interpreted correctly; they may be input with or without surrounding parentheses, although often parentheses are necessary anyway (if the tuple is part of a larger expression).

Tuples have many uses. For example: (x, y) coordinate pairs, employee records from a database, etc. Tuples, like strings, are immutable: it is not possible to assign to the individual items of a tuple (you can simulate much of the same effect with slicing and concatenation, though). It is also possible to create tuples which contain mutable objects, such as lists.

A special problem is the construction of tuples containing 0 or 1 items: the syntax has some extra quirks to accommodate these.

Empty tuples are constructed by an empty pair of parentheses; a tuple with one item is constructed by following a value with a comma (it is not sufficient to enclose a single value in parentheses). Ugly, but effective. For example:

```
>>> empty = ()
>>> singleton = 'hello',      # <-- note trailing comma
>>> len(empty)
0
>>> len(singleton)
1
>>> singleton
('hello',)
```

The statement `t = 12345, 54321, 'hello!'` is an example of *tuple packing*: the values `12345`, `54321` and `'hello!'` are packed together in a tuple. The reverse operation is also possible:

```
>>> x, y, z = t
```

This is called, appropriately enough, *sequence unpacking* and works for any sequence on the right-hand side. Sequence unpacking requires that there are as many variables on the left side of the equals sign as there are elements in the sequence. Note that multiple assignment is really just a combination of tuple packing and sequence unpacking.

5.4. Sets

Python also includes a data type for *sets*. A set is an unordered collection with no duplicate elements. Basic uses include membership testing and eliminating duplicate entries. Set objects also support mathematical operations like union, intersection, difference, and symmetric difference.

Curly braces or the `set()` function can be used to create sets. Note: To create an empty set you have to use `set()`, not `{}`; the latter creates an empty dictionary, a data structure that we discuss in the next section.

Here is a brief demonstration:

```
>>> basket = {'apple', 'orange', 'apple', 'pear', 'orange', 'ba
>>> print(basket)                # show that duplicates h
{'orange', 'banana', 'pear', 'apple'}
>>> 'orange' in basket           # fast membership testin
True
>>> 'crabgrass' in basket
False

>>> # Demonstrate set operations on unique letters from two wor
...
>>> a = set('abracadabra')
>>> b = set('alacazam')
>>> a                               # unique letters in a
{'a', 'r', 'b', 'c', 'd'}
>>> a - b                             # letters in a but not i
{'r', 'd', 'b'}
>>> a | b                               # letters in either a or
{'a', 'c', 'r', 'd', 'b', 'm', 'z', 'l'}
>>> a & b                               # letters in both a and
{'a', 'c'}
>>> a ^ b                               # letters in a or b but
{'r', 'd', 'b', 'm', 'z', 'l'}
```

Like *for lists*, there is a set comprehension syntax:

```
>>> a = {x for x in 'abracadabra' if x not in 'abc'}
>>> a
{'r', 'd'}
```

5.5. Dictionaries

Another useful data type built into Python is the *dictionary* (see [Mapping Types — dict](#)). Dictionaries are sometimes found in other languages as “associative memories” or “associative arrays”. Unlike sequences, which are indexed by a range of numbers, dictionaries are indexed by *keys*, which can be any immutable type; strings and numbers can always be keys. Tuples can be used as keys if they contain only strings, numbers, or tuples; if a tuple contains any mutable object either directly or indirectly, it cannot be used as a key. You can’t use lists as keys, since lists can be modified in place using index assignments, slice assignments, or methods like `append()` and `extend()`.

It is best to think of a dictionary as an unordered set of *key: value* pairs, with the requirement that the keys are unique (within one dictionary). A pair of braces creates an empty dictionary: `{}`. Placing a comma-separated list of *key:value* pairs within the braces adds initial *key:value* pairs to the dictionary; this is also the way dictionaries are written on output.

The main operations on a dictionary are storing a value with some key and extracting the value given the key. It is also possible to delete a *key:value* pair with `del`. If you store using a key that is already in use, the old value associated with that key is forgotten. It is an error to extract a value using a non-existent key.

Performing `list(d.keys())` on a dictionary returns a list of all the keys used in the dictionary, in arbitrary order (if you want it sorted, just use `sorted(d.keys())` instead). [1] To check whether a single key is in the dictionary, use the `in` keyword.

Here is a small example using a dictionary:

```

>>> tel = {'jack': 4098, 'sape': 4139}
>>> tel['guido'] = 4127
>>> tel
{'sape': 4139, 'guido': 4127, 'jack': 4098}
>>> tel['jack']
4098
>>> del tel['sape']
>>> tel['irv'] = 4127
>>> tel
{'guido': 4127, 'irv': 4127, 'jack': 4098}
>>> list(tel.keys())
['irv', 'guido', 'jack']
>>> sorted(tel.keys())
['guido', 'irv', 'jack']
>>> 'guido' in tel
True
>>> 'jack' not in tel
False

```

The `dict()` constructor builds dictionaries directly from sequences of key-value pairs:

```

>>> dict([('sape', 4139), ('guido', 4127), ('jack', 4098)])
{'sape': 4139, 'jack': 4098, 'guido': 4127}

```

In addition, dict comprehensions can be used to create dictionaries from arbitrary key and value expressions:

```

>>> {x: x**2 for x in (2, 4, 6)}
{2: 4, 4: 16, 6: 36}

```

When the keys are simple strings, it is sometimes easier to specify pairs using keyword arguments:

```

>>> dict(sape=4139, guido=4127, jack=4098)
{'sape': 4139, 'jack': 4098, 'guido': 4127}

```

5.6. Looping Techniques

When looping through dictionaries, the key and corresponding value can be retrieved at the same time using the `items()` method.

```
>>> knights = {'gallahad': 'the pure', 'robin': 'the brave'}
>>> for k, v in knights.items():
...     print(k, v)
...
gallahad the pure
robin the brave
```

When looping through a sequence, the position index and corresponding value can be retrieved at the same time using the `enumerate()` function.

```
>>> for i, v in enumerate(['tic', 'tac', 'toe']):
...     print(i, v)
...
0 tic
1 tac
2 toe
```

To loop over two or more sequences at the same time, the entries can be paired with the `zip()` function.

```
>>> questions = ['name', 'quest', 'favorite color']
>>> answers = ['lancelot', 'the holy grail', 'blue']
>>> for q, a in zip(questions, answers):
...     print('What is your {0}? It is {1}.'.format(q, a))
...
What is your name? It is lancelot.
What is your quest? It is the holy grail.
What is your favorite color? It is blue.
```

To loop over a sequence in reverse, first specify the sequence in a forward direction and then call the `reversed()` function.

```
>>> for i in reversed(range(1, 10, 2)):
...     print(i)
...
9
7
5
3
1
```

To loop over a sequence in sorted order, use the `sorted()` function which returns a new sorted list while leaving the source unaltered.

```
>>> basket = ['apple', 'orange', 'apple', 'pear', 'orange', 'ba
>>> for f in sorted(set(basket)):
...     print(f)
...
apple
banana
orange
pear
```

5.7. More on Conditions

The conditions used in `while` and `if` statements can contain any operators, not just comparisons.

The comparison operators `in` and `not in` check whether a value occurs (does not occur) in a sequence. The operators `is` and `is not` compare whether two objects are really the same object; this only matters for mutable objects like lists. All comparison operators have the same priority, which is lower than that of all numerical operators.

Comparisons can be chained. For example, `a < b == c` tests whether `a` is less than `b` and moreover `b` equals `c`.

Comparisons may be combined using the Boolean operators `and` and `or`, and the outcome of a comparison (or of any other Boolean expression) may be negated with `not`. These have lower priorities than comparison operators; between them, `not` has the highest priority and `or` the lowest, so that `A and not B or C` is equivalent to `(A and (not B)) or C`. As always, parentheses can be used to express the desired composition.

The Boolean operators `and` and `or` are so-called *short-circuit* operators: their arguments are evaluated from left to right, and evaluation stops as soon as the outcome is determined. For example, if `A` and `C` are true but `B` is false, `A and B and C` does not evaluate the expression `C`. When used as a general value and not as a Boolean, the return value of a short-circuit operator is the last evaluated argument.

It is possible to assign the result of a comparison or other Boolean expression to a variable. For example,

```
>>> string1, string2, string3 = '', 'Trondheim', 'Hammer Dance'  
>>> non_null = string1 or string2 or string3  
>>> non_null  
'Trondheim'
```

Note that in Python, unlike C, assignment cannot occur inside expressions. C programmers may grumble about this, but it avoids a common class of problems encountered in C programs: typing `=` in an expression when `==` was intended.

5.8. Comparing Sequences and Other Types

Sequence objects may be compared to other objects with the same sequence type. The comparison uses *lexicographical* ordering: first the first two items are compared, and if they differ this determines the outcome of the comparison; if they are equal, the next two items are compared, and so on, until either sequence is exhausted. If two items to be compared are themselves sequences of the same type, the lexicographical comparison is carried out recursively. If all items of two sequences compare equal, the sequences are considered equal. If one sequence is an initial sub-sequence of the other, the shorter sequence is the smaller (lesser) one. Lexicographical ordering for strings uses the Unicode codepoint number to order individual characters. Some examples of comparisons between sequences of the same type:

```
(1, 2, 3) < (1, 2, 4)
[1, 2, 3] < [1, 2, 4]
'ABC' < 'C' < 'Pascal' < 'Python'
(1, 2, 3, 4) < (1, 2, 4)
(1, 2) < (1, 2, -1)
(1, 2, 3) == (1.0, 2.0, 3.0)
(1, 2, ('aa', 'ab')) < (1, 2, ('abc', 'a'), 4)
```

Note that comparing objects of different types with `<` or `>` is legal provided that the objects have appropriate comparison methods. For example, mixed numeric types are compared according to their numeric value, so `0` equals `0.0`, etc. Otherwise, rather than providing an arbitrary ordering, the interpreter will raise a `TypeError` exception.

Footnotes

Calling `d.keys()` will return a *dictionary view* object. It supports

[1] operations like membership test and iteration, but its contents are not independent of the original dictionary – it is only a *view*.

[previous](#) | [next](#) | [modules](#) | [index](#)

6. Modules

If you quit from the Python interpreter and enter it again, the definitions you have made (functions and variables) are lost. Therefore, if you want to write a somewhat longer program, you are better off using a text editor to prepare the input for the interpreter and running it with that file as input instead. This is known as creating a *script*. As your program gets longer, you may want to split it into several files for easier maintenance. You may also want to use a handy function that you've written in several programs without copying its definition into each program.

To support this, Python has a way to put definitions in a file and use them in a script or in an interactive instance of the interpreter. Such a file is called a *module*; definitions from a module can be *imported* into other modules or into the *main* module (the collection of variables that you have access to in a script executed at the top level and in calculator mode).

A module is a file containing Python definitions and statements. The file name is the module name with the suffix `.py` appended. Within a module, the module's name (as a string) is available as the value of the global variable `__name__`. For instance, use your favorite text editor to create a file called `fibonacci.py` in the current directory with the following contents:

```
# Fibonacci numbers module

def fib(n):    # write Fibonacci series up to n
    a, b = 0, 1
    while b < n:
        print(b, end=' ')
        a, b = b, a+b
    print()

def fib2(n): # return Fibonacci series up to n
```

```
result = []
a, b = 0, 1
while b < n:
    result.append(b)
    a, b = b, a+b
return result
```

Now enter the Python interpreter and import this module with the following command:

```
>>> import fibo
```

This does not enter the names of the functions defined in `fibo` directly in the current symbol table; it only enters the module name `fibo` there. Using the module name you can access the functions:

```
>>> fibo.fib(1000)
1 1 2 3 5 8 13 21 34 55 89 144 233 377 610 987
>>> fibo.fib2(100)
[1, 1, 2, 3, 5, 8, 13, 21, 34, 55, 89]
>>> fibo.__name__
'fibo'
```

If you intend to use a function often you can assign it to a local name:

```
>>> fib = fibo.fib
>>> fib(500)
1 1 2 3 5 8 13 21 34 55 89 144 233 377
```

6.1. More on Modules

A module can contain executable statements as well as function definitions. These statements are intended to initialize the module. They are executed only the *first* time the module is imported somewhere. [1]

Each module has its own private symbol table, which is used as the global symbol table by all functions defined in the module. Thus, the author of a module can use global variables in the module without worrying about accidental clashes with a user's global variables. On the other hand, if you know what you are doing you can touch a module's global variables with the same notation used to refer to its functions, `modname.itemname`.

Modules can import other modules. It is customary but not required to place all `import` statements at the beginning of a module (or script, for that matter). The imported module names are placed in the importing module's global symbol table.

There is a variant of the `import` statement that imports names from a module directly into the importing module's symbol table. For example:

```
>>> from fibo import fib, fib2
>>> fib(500)
1 1 2 3 5 8 13 21 34 55 89 144 233 377
```

This does not introduce the module name from which the imports are taken in the local symbol table (so in the example, `fibo` is not defined).

There is even a variant to import all names that a module defines:

```
>>> from fibo import *
>>> fib(500)
1 1 2 3 5 8 13 21 34 55 89 144 233 377
```

This imports all names except those beginning with an underscore (`_`). In most cases Python programmers do not use this facility since it introduces an unknown set of names into the interpreter, possibly hiding some things you have already defined.

Note that in general the practice of importing `*` from a module or package is frowned upon, since it often causes poorly readable code. However, it is okay to use it to save typing in interactive sessions.

Note: For efficiency reasons, each module is only imported once per interpreter session. Therefore, if you change your modules, you must restart the interpreter – or, if it's just one module you want to test interactively, use `imp.reload()`, e.g. `import imp; imp.reload(modulename)`.

6.1.1. Executing modules as scripts

When you run a Python module with

```
python fibo.py <arguments>
```

the code in the module will be executed, just as if you imported it, but with the `__name__` set to `"__main__"`. That means that by adding this code at the end of your module:

```
if __name__ == "__main__":
    import sys
    fib(int(sys.argv[1]))
```

you can make the file usable as a script as well as an importable

module, because the code that parses the command line only runs if the module is executed as the “main” file:

```
$ python fibo.py 50
1 1 2 3 5 8 13 21 34
```

If the module is imported, the code is not run:

```
>>> import fibo
>>>
```

This is often used either to provide a convenient user interface to a module, or for testing purposes (running the module as a script executes a test suite).

6.1.2. The Module Search Path

When a module named `spam` is imported, the interpreter searches for a file named `spam.py` in the current directory, and then in the list of directories specified by the environment variable `PYTHONPATH`. This has the same syntax as the shell variable `PATH`, that is, a list of directory names. When `PYTHONPATH` is not set, or when the file is not found there, the search continues in an installation-dependent default path; on Unix, this is usually `./usr/local/lib/python`.

Actually, modules are searched in the list of directories given by the variable `sys.path` which is initialized from the directory containing the input script (or the current directory), `PYTHONPATH` and the installation-dependent default. This allows Python programs that know what they’re doing to modify or replace the module search path. Note that because the directory containing the script being run is on the search path, it is important that the script not have the same name as a standard module, or Python will attempt to load the script as a module when that module is imported. This will generally be an error.

See section *Standard Modules* for more information.

6.1.3. “Compiled” Python files

As an important speed-up of the start-up time for short programs that use a lot of standard modules, if a file called `spam.pyc` exists in the directory where `spam.py` is found, this is assumed to contain an already-“byte-compiled” version of the module `spam`. The modification time of the version of `spam.py` used to create `spam.pyc` is recorded in `spam.pyc`, and the `.pyc` file is ignored if these don’t match.

Normally, you don’t need to do anything to create the `spam.pyc` file. Whenever `spam.py` is successfully compiled, an attempt is made to write the compiled version to `spam.pyc`. It is not an error if this attempt fails; if for any reason the file is not written completely, the resulting `spam.pyc` file will be recognized as invalid and thus ignored later. The contents of the `spam.pyc` file are platform independent, so a Python module directory can be shared by machines of different architectures.

Some tips for experts:

- When the Python interpreter is invoked with the `-O` flag, optimized code is generated and stored in `.pyo` files. The optimizer currently doesn’t help much; it only removes `assert` statements. When `-O` is used, *all bytecode* is optimized; `.pyc` files are ignored and `.py` files are compiled to optimized bytecode.
- Passing two `-O` flags to the Python interpreter (`-OO`) will cause the bytecode compiler to perform optimizations that could in some rare cases result in malfunctioning programs. Currently

only `__doc__` strings are removed from the bytecode, resulting in more compact `.pyo` files. Since some programs may rely on having these available, you should only use this option if you know what you're doing.

- A program doesn't run any faster when it is read from a `.pyc` or `.pyo` file than when it is read from a `.py` file; the only thing that's faster about `.pyc` or `.pyo` files is the speed with which they are loaded.
- When a script is run by giving its name on the command line, the bytecode for the script is never written to a `.pyc` or `.pyo` file. Thus, the startup time of a script may be reduced by moving most of its code to a module and having a small bootstrap script that imports that module. It is also possible to name a `.pyc` or `.pyo` file directly on the command line.
- It is possible to have a file called `spam.pyc` (or `spam.pyo` when `-O` is used) without a file `spam.py` for the same module. This can be used to distribute a library of Python code in a form that is moderately hard to reverse engineer.
- The module `compileall` can create `.pyc` files (or `.pyo` files when `-O` is used) for all modules in a directory.

6.2. Standard Modules

Python comes with a library of standard modules, described in a separate document, the Python Library Reference (“Library Reference” hereafter). Some modules are built into the interpreter; these provide access to operations that are not part of the core of the language but are nevertheless built in, either for efficiency or to provide access to operating system primitives such as system calls. The set of such modules is a configuration option which also depends on the underlying platform. For example, the `winreg` module is only provided on Windows systems. One particular module deserves some attention: `sys`, which is built into every Python interpreter. The variables `sys.ps1` and `sys.ps2` define the strings used as primary and secondary prompts:

```
>>> import sys
>>> sys.ps1
'>>> '
>>> sys.ps2
'... '
>>> sys.ps1 = 'C> '
C> print('Yuck!')
Yuck!
C>
```

These two variables are only defined if the interpreter is in interactive mode.

The variable `sys.path` is a list of strings that determines the interpreter’s search path for modules. It is initialized to a default path taken from the environment variable `PYTHONPATH`, or from a built-in default if `PYTHONPATH` is not set. You can modify it using standard list operations:

```
>>> import sys
```

```
>>> sys.path.append('/ufs/guido/lib/python')
```

6.3. The `dir()` Function

The built-in function `dir()` is used to find out which names a module defines. It returns a sorted list of strings:

```
>>> import fibo, sys
>>> dir(fibo)
['__name__', 'fib', 'fib2']
>>> dir(sys)
['__displayhook__', '__doc__', '__excepthook__', '__name__', '__
__stdin__', '__stdout__', '_getframe', 'api_version', 'argv',
'builtin_module_names', 'byteorder', 'callstats', 'copyright',
'displayhook', 'exc_info', 'excepthook',
'exec_prefix', 'executable', 'exit', 'getdefaultencoding', 'ge
'getrecursionlimit', 'getrefcount', 'hexversion', 'maxint', 'm
'meta_path', 'modules', 'path', 'path_hooks', 'path_importer_c
'platform', 'prefix', 'ps1', 'ps2', 'setcheckinterval', 'setdl
'setprofile', 'setrecursionlimit', 'settrace', 'stderr', 'stdi
'version', 'version_info', 'warnoptions']
```

Without arguments, `dir()` lists the names you have defined currently:

```
>>> a = [1, 2, 3, 4, 5]
>>> import fibo
>>> fib = fibo.fib
>>> dir()
['__builtins__', '__doc__', '__file__', '__name__', 'a', 'fib',
```

Note that it lists all types of names: variables, modules, functions, etc.

`dir()` does not list the names of built-in functions and variables. If you want a list of those, they are defined in the standard module `builtins`:

```
>>> import builtins
```

```
>>> dir(builtins)
```

```
['ArithmeticError', 'AssertionError', 'AttributeError', 'BaseEx  
Error', 'BytesWarning', 'DeprecationWarning', 'EOFError', 'Ellip  
ntError', 'Exception', 'False', 'FloatingPointError', 'FutureWa  
rExit', 'IOError', 'ImportError', 'ImportWarning', 'Indentation  
or', 'KeyError', 'KeyboardInterrupt', 'LookupError', 'MemoryErr  
'None', 'NotImplemented', 'NotImplementedError', 'OSError', 'O  
endingDeprecationWarning', 'ReferenceError', 'RuntimeError', 'R  
StopIteration', 'SyntaxError', 'SyntaxWarning', 'SystemError',  
bError', 'True', 'TypeError', 'UnboundLocalError', 'UnicodeDeco  
eEncodeError', 'UnicodeError', 'UnicodeTranslateError', 'Unicod  
arning', 'ValueError', 'Warning', 'ZeroDivisionError', '__build  
ug__', '__doc__', '__import__', '__name__', '__package__', 'abs  
'ascii', 'bin', 'bool', 'bytearray', 'bytes', 'chr', 'classmeth  
complex', 'copyright', 'credits', 'delattr', 'dict', 'dir', 'di  
, 'eval', 'exec', 'exit', 'filter', 'float', 'format', 'frozen  
'globals', 'hasattr', 'hash', 'help', 'hex', 'id', 'input', 'in  
'issubclass', 'iter', 'len', 'license', 'list', 'locals', 'map  
view', 'min', 'next', 'object', 'oct', 'open', 'ord', 'pow', 'p  
, 'quit', 'range', 'repr', 'reversed', 'round', 'set', 'setattr  
ed', 'staticmethod', 'str', 'sum', 'super', 'tuple', 'type', 'v
```

```
    __init__.py
    echo.py
    surround.py
    reverse.py
    ...
filters/                               Subpackage for filters
    __init__.py
    equalizer.py
    vocoder.py
    karaoke.py
    ...
```

When importing the package, Python searches through the directories on `sys.path` looking for the package subdirectory.

The `__init__.py` files are required to make Python treat the directories as containing packages; this is done to prevent directories with a common name, such as `string`, from unintentionally hiding valid modules that occur later on the module search path. In the simplest case, `__init__.py` can just be an empty file, but it can also execute initialization code for the package or set the `__all__` variable, described later.

Users of the package can import individual modules from the package, for example:

```
import sound.effects.echo
```

This loads the submodule `sound.effects.echo`. It must be referenced with its full name.

```
sound.effects.echo.echofilter(input, output, delay=0.7, atten=4
```

An alternative way of importing the submodule is:

```
from sound.effects import echo
```

This also loads the submodule `echo`, and makes it available without its package prefix, so it can be used as follows:

```
echo.echofilter(input, output, delay=0.7, atten=4)
```

Yet another variation is to import the desired function or variable directly:

```
from sound.effects.echo import echofilter
```

Again, this loads the submodule `echo`, but this makes its function `echofilter()` directly available:

```
echofilter(input, output, delay=0.7, atten=4)
```

Note that when using `from package import item`, the item can be either a submodule (or subpackage) of the package, or some other name defined in the package, like a function, class or variable. The `import` statement first tests whether the item is defined in the package; if not, it assumes it is a module and attempts to load it. If it fails to find it, an `ImportError` exception is raised.

Contrarily, when using syntax like `import item.subitem.subsubitem`, each item except for the last must be a package; the last item can be a module or a package but can't be a class or function or variable defined in the previous item.

6.4.1. Importing * From a Package

Now what happens when the user writes `from sound.effects import *`? Ideally, one would hope that this somehow goes out to the filesystem, finds which submodules are present in the package, and imports them all. This could take a long time and importing submodules might have unwanted side-effects that should only happen

when the sub-module is explicitly imported.

The only solution is for the package author to provide an explicit index of the package. The `import` statement uses the following convention: if a package's `__init__.py` code defines a list named `__all__`, it is taken to be the list of module names that should be imported when `from package import *` is encountered. It is up to the package author to keep this list up-to-date when a new version of the package is released. Package authors may also decide not to support it, if they don't see a use for importing `*` from their package. For example, the file `sounds/effects/__init__.py` could contain the following code:

```
__all__ = ["echo", "surround", "reverse"]
```

This would mean that `from sound.effects import *` would import the three named submodules of the `sound` package.

If `__all__` is not defined, the statement `from sound.effects import *` does *not* import all submodules from the package `sound.effects` into the current namespace; it only ensures that the package `sound.effects` has been imported (possibly running any initialization code in `__init__.py`) and then imports whatever names are defined in the package. This includes any names defined (and submodules explicitly loaded) by `__init__.py`. It also includes any submodules of the package that were explicitly loaded by previous `import` statements. Consider this code:

```
import sound.effects.echo
import sound.effects.surround
from sound.effects import *
```

In this example, the `echo` and `surround` modules are imported in the current namespace because they are defined in the `sound.effects`

package when the `from...import` statement is executed. (This also works when `__all__` is defined.)

Although certain modules are designed to export only names that follow certain patterns when you use `import *`, it is still considered bad practise in production code.

Remember, there is nothing wrong with using `from Package import specific_submodule!` In fact, this is the recommended notation unless the importing module needs to use submodules with the same name from different packages.

6.4.2. Intra-package References

When packages are structured into subpackages (as with the `sound` package in the example), you can use absolute imports to refer to submodules of siblings packages. For example, if the module `sound.filters.vocoder` needs to use the `echo` module in the `sound.effects` package, it can use `from sound.effects import echo`.

You can also write relative imports, with the `from module import name` form of import statement. These imports use leading dots to indicate the current and parent packages involved in the relative import. From the `surround` module for example, you might use:

```
from . import echo
from .. import formats
from ..filters import equalizer
```

Note that relative imports are based on the name of the current module. Since the name of the main module is always `"__main__"`, modules intended for use as the main module of a Python application must always use absolute imports.

6.4.3. Packages in Multiple Directories

Packages support one more special attribute, `__path__`. This is initialized to be a list containing the name of the directory holding the package's `__init__.py` before the code in that file is executed. This variable can be modified; doing so affects future searches for modules and subpackages contained in the package.

While this feature is not often needed, it can be used to extend the set of modules found in a package.

Footnotes

[1] In fact function definitions are also 'statements' that are 'executed'; the execution of a module-level function enters the function name in the module's global symbol table.

7. Input and Output

There are several ways to present the output of a program; data can be printed in a human-readable form, or written to a file for future use. This chapter will discuss some of the possibilities.

7.1. Fancier Output Formatting

So far we've encountered two ways of writing values: *expression statements* and the `print()` function. (A third way is using the `write()` method of file objects; the standard output file can be referenced as `sys.stdout`. See the Library Reference for more information on this.)

Often you'll want more control over the formatting of your output than simply printing space-separated values. There are two ways to format your output; the first way is to do all the string handling yourself; using string slicing and concatenation operations you can create any layout you can imagine. The standard module `string` contains some useful operations for padding strings to a given column width; these will be discussed shortly. The second way is to use the `str.format()` method.

The `string` module contains a class `Template` which offers yet another way to substitute values into strings.

One question remains, of course: how do you convert values to strings? Luckily, Python has ways to convert any value to a string: pass it to the `repr()` or `str()` functions.

The `str()` function is meant to return representations of values which are fairly human-readable, while `repr()` is meant to generate representations which can be read by the interpreter (or will force a `SyntaxError` if there is not equivalent syntax). For objects which don't have a particular representation for human consumption, `str()` will return the same value as `repr()`. Many values, such as numbers or structures like lists and dictionaries, have the same representation using either function. Strings and floating point numbers, in

particular, have two distinct representations.

Some examples:

```
>>> s = 'Hello, world.'
>>> str(s)
'Hello, world.'
>>> repr(s)
"'Hello, world.'"
>>> str(1.0/7.0)
'0.142857142857'
>>> repr(1.0/7.0)
'0.14285714285714285'
>>> x = 10 * 3.25
>>> y = 200 * 200
>>> s = 'The value of x is ' + repr(x) + ', and y is ' + repr(y)
>>> print(s)
The value of x is 32.5, and y is 40000...
>>> # The repr() of a string adds string quotes and backslashes
... hello = 'hello, world\n'
>>> hellos = repr(hello)
>>> print(hellos)
'hello, world\n'
>>> # The argument to repr() may be any Python object:
... repr((x, y, ('spam', 'eggs'))))
"(32.5, 40000, ('spam', 'eggs'))"
```

Here are two ways to write a table of squares and cubes:

```
>>> for x in range(1, 11):
...     print(repr(x).rjust(2), repr(x*x).rjust(3), end=' ')
...     # Note use of 'end' on previous line
...     print(repr(x*x*x).rjust(4))
...
1   1   1
2   4   8
3   9  27
4  16  64
5  25 125
6  36 216
7  49 343
8  64 512
9  81 729
10 100 1000
```

```

>>> for x in range(1, 11):
...     print('{0:2d} {1:3d} {2:4d}'.format(x, x*x, x*x*x))
...
1  1  1
2  4  8
3  9 27
4 16 64
5 25 125
6 36 216
7 49 343
8 64 512
9 81 729
10 100 1000

```

(Note that in the first example, one space between each column was added by the way `print()` works: it always adds spaces between its arguments.)

This example demonstrates the `rjust()` method of string objects, which right-justifies a string in a field of a given width by padding it with spaces on the left. There are similar methods `ljust()` and `center()`. These methods do not write anything, they just return a new string. If the input string is too long, they don't truncate it, but return it unchanged; this will mess up your column lay-out but that's usually better than the alternative, which would be lying about a value. (If you really want truncation you can always add a slice operation, as in `x.ljust(n)[:n]`.)

There is another method, `zfill()`, which pads a numeric string on the left with zeros. It understands about plus and minus signs:

```

>>> '12'.zfill(5)
'00012'
>>> '-3.14'.zfill(7)
'-003.14'
>>> '3.14159265359'.zfill(5)
'3.14159265359'

```

Basic usage of the `str.format()` method looks like this:

```
>>> print('We are the {} who say "{}!"'.format('knights', 'Ni'))
We are the knights who say "Ni!"
```

The brackets and characters within them (called format fields) are replaced with the objects passed into the `format()` method. A number in the brackets can be used to refer to the position of the object passed into the `format()` method.

```
>>> print('{0} and {1}'.format('spam', 'eggs'))
spam and eggs
>>> print('{1} and {0}'.format('spam', 'eggs'))
eggs and spam
```

If keyword arguments are used in the `format()` method, their values are referred to by using the name of the argument.

```
>>> print('This {food} is {adjective}.'.format(
...     food='spam', adjective='absolutely horrible'))
This spam is absolutely horrible.
```

Positional and keyword arguments can be arbitrarily combined:

```
>>> print('The story of {0}, {1}, and {other}.'.format('Bill',
                                                    other='G
The story of Bill, Manfred, and Georg.
```

'!a' (apply `ascii()`), '!s' (apply `str()`) and '!r' (apply `repr()`) can be used to convert the value before it is formatted:

```
>>> import math
>>> print('The value of PI is approximately {}'.format(math.pi))
The value of PI is approximately 3.14159265359.
>>> print('The value of PI is approximately {!r}'.format(math.
The value of PI is approximately 3.141592653589793.
```

An optional `':'` and format specifier can follow the field name. This allows greater control over how the value is formatted. The following example truncates Pi to three places after the decimal.

```
>>> import math
>>> print('The value of PI is approximately {:.3f}.'.format(ma
The value of PI is approximately 3.142.
```

Passing an integer after the `':'` will cause that field to be a minimum number of characters wide. This is useful for making tables pretty.

```
>>> table = {'Sjoerd': 4127, 'Jack': 4098, 'Dcab': 7678}
>>> for name, phone in table.items():
...     print('{0:10} ==> {1:10d}'.format(name, phone))
...
Jack          ==>          4098
Dcab          ==>          7678
Sjoerd        ==>          4127
```

If you have a really long format string that you don't want to split up, it would be nice if you could reference the variables to be formatted by name instead of by position. This can be done by simply passing the dict and using square brackets `'[]'` to access the keys

```
>>> table = {'Sjoerd': 4127, 'Jack': 4098, 'Dcab': 8637678}
>>> print('Jack: {0[Jack]:d}; Sjoerd: {0[Sjoerd]:d}; '
'Dcab: {0[Dcab]:d}'.format(table))
Jack: 4098; Sjoerd: 4127; Dcab: 8637678
```

This could also be done by passing the table as keyword arguments with the `**` notation.

```
>>> table = {'Sjoerd': 4127, 'Jack': 4098, 'Dcab': 8637678}
>>> print('Jack: {Jack:d}; Sjoerd: {Sjoerd:d}; Dcab: {Dcab:d}'.
Jack: 4098; Sjoerd: 4127; Dcab: 8637678
```

This is particularly useful in combination with the new built-in `vars()`

function, which returns a dictionary containing all local variables.

For a complete overview of string formatting with `str.format()`, see [Format String Syntax](#).

7.1.1. Old string formatting

The `%` operator can also be used for string formatting. It interprets the left argument much like a `sprintf()`-style format string to be applied to the right argument, and returns the string resulting from this formatting operation. For example:

```
>>> import math
>>> print('The value of PI is approximately %5.3f.' % math.pi)
The value of PI is approximately 3.142.
```

Since `str.format()` is quite new, a lot of Python code still uses the `%` operator. However, because this old style of formatting will eventually be removed from the language, `str.format()` should generally be used.

More information can be found in the [Old String Formatting Operations](#) section.

7.2. Reading and Writing Files

`open()` returns a *file object*, and is most commonly used with two arguments: `open(filename, mode)`.

```
>>> f = open('/tmp/workfile', 'w')
```

The first argument is a string containing the filename. The second argument is another string containing a few characters describing the way in which the file will be used. *mode* can be `'r'` when the file will only be read, `'w'` for only writing (an existing file with the same name will be erased), and `'a'` opens the file for appending; any data written to the file is automatically added to the end. `'r+'` opens the file for both reading and writing. The *mode* argument is optional; `'r'` will be assumed if it's omitted.

Normally, files are opened in *text mode*, that means, you read and write strings from and to the file, which are encoded in a specific encoding (the default being UTF-8). `'b'` appended to the mode opens the file in *binary mode*: now the data is read and written in the form of bytes objects. This mode should be used for all files that don't contain text.

In text mode, the default is to convert platform-specific line endings (`\n` on Unix, `\r\n` on Windows) to just `\n` on reading and `\n` back to platform-specific line endings on writing. This behind-the-scenes modification to file data is fine for text files, but will corrupt binary data like that in `JPEG` or `EXE` files. Be very careful to use binary mode when reading and writing such files.

7.2.1. Methods of File Objects

The rest of the examples in this section will assume that a file object called `f` has already been created.

To read a file's contents, call `f.read(size)`, which reads some quantity of data and returns it as a string or bytes object. `size` is an optional numeric argument. When `size` is omitted or negative, the entire contents of the file will be read and returned; it's your problem if the file is twice as large as your machine's memory. Otherwise, at most `size` bytes are read and returned. If the end of the file has been reached, `f.read()` will return an empty string (`''`).

```
>>> f.read()
'This is the entire file.\n'
>>> f.read()
''
```

`f.readline()` reads a single line from the file; a newline character (`\n`) is left at the end of the string, and is only omitted on the last line of the file if the file doesn't end in a newline. This makes the return value unambiguous; if `f.readline()` returns an empty string, the end of the file has been reached, while a blank line is represented by `\n`, a string containing only a single newline.

```
>>> f.readline()
'This is the first line of the file.\n'
>>> f.readline()
'Second line of the file\n'
>>> f.readline()
''
```

`f.readlines()` returns a list containing all the lines of data in the file. If given an optional parameter `sizehint`, it reads that many bytes from the file and enough more to complete a line, and returns the lines from that. This is often used to allow efficient reading of a large file by lines, but without having to load the entire file in memory. Only complete lines will be returned.

```
>>> f.readlines()
['This is the first line of the file.\n', 'Second line of the f
```

An alternative approach to reading lines is to loop over the file object. This is memory efficient, fast, and leads to simpler code:

```
>>> for line in f:
...     print(line, end='')
...
This is the first line of the file.
Second line of the file
```

The alternative approach is simpler but does not provide as fine-grained control. Since the two approaches manage line buffering differently, they should not be mixed.

`f.write(string)` writes the contents of *string* to the file, returning the number of characters written.

```
>>> f.write('This is a test\n')
15
```

To write something other than a string, it needs to be converted to a string first:

```
>>> value = ('the answer', 42)
>>> s = str(value)
>>> f.write(s)
18
```

`f.tell()` returns an integer giving the file object's current position in the file, measured in bytes from the beginning of the file. To change the file object's position, use `f.seek(offset, from_what)`. The position is computed from adding *offset* to a reference point; the reference point is selected by the *from_what* argument. A *from_what* value of 0 measures from the beginning of the file, 1 uses the current file position, and 2 uses the end of the file as the reference point.

`from_what` can be omitted and defaults to 0, using the beginning of the file as the reference point.

```
>>> f = open('/tmp/workfile', 'rb+')
>>> f.write(b'0123456789abcdef')
16
>>> f.seek(5)      # Go to the 6th byte in the file
5
>>> f.read(1)
b'5'
>>> f.seek(-3, 2) # Go to the 3rd byte before the end
13
>>> f.read(1)
b'd'
```

In text files (those opened without a `b` in the mode string), only seeks relative to the beginning of the file are allowed (the exception being seeking to the very file end with `seek(0, 2)`).

When you're done with a file, call `f.close()` to close it and free up any system resources taken up by the open file. After calling `f.close()`, attempts to use the file object will automatically fail.

```
>>> f.close()
>>> f.read()
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
ValueError: I/O operation on closed file
```

It is good practice to use the `with` keyword when dealing with file objects. This has the advantage that the file is properly closed after its suite finishes, even if an exception is raised on the way. It is also much shorter than writing equivalent `try-finally` blocks:

```
>>> with open('/tmp/workfile', 'r') as f:
...     read_data = f.read()
>>> f.closed
True
```

File objects have some additional methods, such as `isatty()` and `truncate()` which are less frequently used; consult the Library Reference for a complete guide to file objects.

7.2.2. The `pickle` Module

Strings can easily be written to and read from a file. Numbers take a bit more effort, since the `read()` method only returns strings, which will have to be passed to a function like `int()`, which takes a string like `'123'` and returns its numeric value `123`. However, when you want to save more complex data types like lists, dictionaries, or class instances, things get a lot more complicated.

Rather than have users be constantly writing and debugging code to save complicated data types, Python provides a standard module called `pickle`. This is an amazing module that can take almost any Python object (even some forms of Python code!), and convert it to a string representation; this process is called *pickling*. Reconstructing the object from the string representation is called *unpickling*. Between pickling and unpickling, the string representing the object may have been stored in a file or data, or sent over a network connection to some distant machine.

If you have an object `x`, and a file object `f` that's been opened for writing, the simplest way to pickle the object takes only one line of code:

```
pickle.dump(x, f)
```

To unpickle the object again, if `f` is a file object which has been opened for reading:

```
x = pickle.load(f)
```

(There are other variants of this, used when pickling many objects or when you don't want to write the pickled data to a file; consult the complete documentation for `pickle` in the Python Library Reference.)

`pickle` is the standard way to make Python objects which can be stored and reused by other programs or by a future invocation of the same program; the technical term for this is a *persistent* object. Because `pickle` is so widely used, many authors who write Python extensions take care to ensure that new data types such as matrices can be properly pickled and unpickled.

8. Errors and Exceptions

Until now error messages haven't been more than mentioned, but if you have tried out the examples you have probably seen some. There are (at least) two distinguishable kinds of errors: *syntax errors* and *exceptions*.

8.1. Syntax Errors

Syntax errors, also known as parsing errors, are perhaps the most common kind of complaint you get while you are still learning Python:

```
>>> while True print('Hello world')
      File "<stdin>", line 1, in ?
        while True print('Hello world')
                ^
SyntaxError: invalid syntax
```

The parser repeats the offending line and displays a little ‘arrow’ pointing at the earliest point in the line where the error was detected. The error is caused by (or at least detected at) the token *preceding* the arrow: in the example, the error is detected at the function `print()`, since a colon (‘:’) is missing before it. File name and line number are printed so you know where to look in case the input came from a script.

8.2. Exceptions

Even if a statement or expression is syntactically correct, it may cause an error when an attempt is made to execute it. Errors detected during execution are called *exceptions* and are not unconditionally fatal: you will soon learn how to handle them in Python programs. Most exceptions are not handled by programs, however, and result in error messages as shown here:

```
>>> 10 * (1/0)
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
ZeroDivisionError: int division or modulo by zero
>>> 4 + spam*3
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
NameError: name 'spam' is not defined
>>> '2' + 2
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
TypeError: Can't convert 'int' object to str implicitly
```

The last line of the error message indicates what happened. Exceptions come in different types, and the type is printed as part of the message: the types in the example are `ZeroDivisionError`, `NameError` and `TypeError`. The string printed as the exception type is the name of the built-in exception that occurred. This is true for all built-in exceptions, but need not be true for user-defined exceptions (although it is a useful convention). Standard exception names are built-in identifiers (not reserved keywords).

The rest of the line provides detail based on the type of exception and what caused it.

The preceding part of the error message shows the context where the exception happened, in the form of a stack traceback. In general

it contains a stack traceback listing source lines; however, it will not display lines read from standard input.

Built-in Exceptions lists the built-in exceptions and their meanings.

8.3. Handling Exceptions

It is possible to write programs that handle selected exceptions. Look at the following example, which asks the user for input until a valid integer has been entered, but allows the user to interrupt the program (using `control-C` or whatever the operating system supports); note that a user-generated interruption is signalled by raising the `KeyboardInterrupt` exception.

```
>>> while True:
...     try:
...         x = int(input("Please enter a number: "))
...         break
...     except ValueError:
...         print("Oops! That was no valid number. Try again.")
... 
```

The `try` statement works as follows.

- First, the *try clause* (the statement(s) between the `try` and `except` keywords) is executed.
- If no exception occurs, the *except clause* is skipped and execution of the `try` statement is finished.
- If an exception occurs during execution of the *try clause*, the rest of the clause is skipped. Then if its type matches the exception named after the `except` keyword, the *except clause* is executed, and then execution continues after the `try` statement.
- If an exception occurs which does not match the exception named in the *except clause*, it is passed on to outer `try` statements; if no handler is found, it is an *unhandled exception* and execution stops with a message as shown above.

A `try` statement may have more than one *except clause*, to specify

handlers for different exceptions. At most one handler will be executed. Handlers only handle exceptions that occur in the corresponding try clause, not in other handlers of the same `try` statement. An except clause may name multiple exceptions as a parenthesized tuple, for example:

```
... except (RuntimeError, TypeError, NameError):  
...     pass
```

The last except clause may omit the exception name(s), to serve as a wildcard. Use this with extreme caution, since it is easy to mask a real programming error in this way! It can also be used to print an error message and then re-raise the exception (allowing a caller to handle the exception as well):

```
import sys  
  
try:  
    f = open('myfile.txt')  
    s = f.readline()  
    i = int(s.strip())  
except IOError as err:  
    print("I/O error: {0}".format(err))  
except ValueError:  
    print("Could not convert data to an integer.")  
except:  
    print("Unexpected error:", sys.exc_info()[0])  
    raise
```

The `try ... except` statement has an optional *else clause*, which, when present, must follow all except clauses. It is useful for code that must be executed if the try clause does not raise an exception. For example:

```
for arg in sys.argv[1:]:  
    try:  
        f = open(arg, 'r')  
    except IOError:  
        print('cannot open', arg)  
    else:
```

```
print(arg, 'has', len(f.readlines()), 'lines')
f.close()
```

The use of the `else` clause is better than adding additional code to the `try` clause because it avoids accidentally catching an exception that wasn't raised by the code being protected by the `try ... except` statement.

When an exception occurs, it may have an associated value, also known as the exception's *argument*. The presence and type of the argument depend on the exception type.

The `except` clause may specify a variable after the exception name. The variable is bound to an exception instance with the arguments stored in `instance.args`. For convenience, the exception instance defines `__str__()` so the arguments can be printed directly without having to reference `.args`. One may also instantiate an exception first before raising it and add any attributes to it as desired.

```
>>> try:
...     raise Exception('spam', 'eggs')
... except Exception as inst:
...     print(type(inst))      # the exception instance
...     print(inst.args)      # arguments stored in .args
...     print(inst)           # __str__ allows args to be printed
...                             # but may be overridden in exceptio
...                             # unpack args
...     x, y = inst.args
...     print('x =', x)
...     print('y =', y)
...
<class 'Exception'>
('spam', 'eggs')
('spam', 'eggs')
x = spam
y = eggs
```

If an exception has arguments, they are printed as the last part ('detail') of the message for unhandled exceptions.

Exception handlers don't just handle exceptions if they occur immediately in the try clause, but also if they occur inside functions that are called (even indirectly) in the try clause. For example:

```
>>> def this_fails():
...     x = 1/0
...
...
>>> try:
...     this_fails()
... except ZeroDivisionError as err:
...     print('Handling run-time error:', err)
...
Handling run-time error: int division or modulo by zero
```

8.4. Raising Exceptions

The `raise` statement allows the programmer to force a specified exception to occur. For example:

```
>>> raise NameError('HiThere')
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
NameError: HiThere
```

The sole argument to `raise` indicates the exception to be raised. This must be either an exception instance or an exception class (a class that derives from `Exception`).

If you need to determine whether an exception was raised but don't intend to handle it, a simpler form of the `raise` statement allows you to re-raise the exception:

```
>>> try:
...     raise NameError('HiThere')
... except NameError:
...     print('An exception flew by!')
...     raise
...
An exception flew by!
Traceback (most recent call last):
  File "<stdin>", line 2, in ?
NameError: HiThere
```

8.5. User-defined Exceptions

Programs may name their own exceptions by creating a new exception class (see [Classes](#) for more about Python classes). Exceptions should typically be derived from the `Exception` class, either directly or indirectly. For example:

```
>>> class MyError(Exception):
...     def __init__(self, value):
...         self.value = value
...     def __str__(self):
...         return repr(self.value)
...
>>> try:
...     raise MyError(2*2)
... except MyError as e:
...     print('My exception occurred, value:', e.value)
...
My exception occurred, value: 4
>>> raise MyError('oops!')
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
__main__.MyError: 'oops!'
```

In this example, the default `__init__()` of `Exception` has been overridden. The new behavior simply creates the *value* attribute. This replaces the default behavior of creating the *args* attribute.

Exception classes can be defined which do anything any other class can do, but are usually kept simple, often only offering a number of attributes that allow information about the error to be extracted by handlers for the exception. When creating a module that can raise several distinct errors, a common practice is to create a base class for exceptions defined by that module, and subclass that to create specific exception classes for different error conditions:

```
class Error(Exception):
    """Base class for exceptions in this module."""
```

```

pass

class InputError(Error):
    """Exception raised for errors in the input.

    Attributes:
        expression -- input expression in which the error occur
        message -- explanation of the error
    """

    def __init__(self, expression, message):
        self.expression = expression
        self.message = message

class TransitionError(Error):
    """Raised when an operation attempts a state transition tha
    allowed.

    Attributes:
        previous -- state at beginning of transition
        next -- attempted new state
        message -- explanation of why the specific transition i
    """

    def __init__(self, previous, next, message):
        self.previous = previous
        self.next = next
        self.message = message

```

Most exceptions are defined with names that end in “Error,” similar to the naming of the standard exceptions.

Many standard modules define their own exceptions to report errors that may occur in functions they define. More information on classes is presented in chapter [Classes](#).

8.6. Defining Clean-up Actions

The `try` statement has another optional clause which is intended to define clean-up actions that must be executed under all circumstances. For example:

```
>>> try:
...     raise KeyboardInterrupt
... finally:
...     print('Goodbye, world!')
...
Goodbye, world!
KeyboardInterrupt
```

A *finally clause* is always executed before leaving the `try` statement, whether an exception has occurred or not. When an exception has occurred in the `try` clause and has not been handled by an `except` clause (or it has occurred in a `except` or `else` clause), it is re-raised after the `finally` clause has been executed. The `finally` clause is also executed “on the way out” when any other clause of the `try` statement is left via a `break`, `continue` or `return` statement. A more complicated example:

```
>>> def divide(x, y):
...     try:
...         result = x / y
...     except ZeroDivisionError:
...         print("division by zero!")
...     else:
...         print("result is", result)
...     finally:
...         print("executing finally clause")
...
>>> divide(2, 1)
result is 2.0
executing finally clause
>>> divide(2, 0)
division by zero!
```

```
executing finally clause
>>> divide("2", "1")
executing finally clause
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
  File "<stdin>", line 3, in divide
TypeError: unsupported operand type(s) for /: 'str' and 'str'
```

As you can see, the **finally** clause is executed in any event. The **TypeError** raised by dividing two strings is not handled by the **except** clause and therefore re-raised after the **finally** clause has been executed.

In real world applications, the **finally** clause is useful for releasing external resources (such as files or network connections), regardless of whether the use of the resource was successful.

8.7. Predefined Clean-up Actions

Some objects define standard clean-up actions to be undertaken when the object is no longer needed, regardless of whether or not the operation using the object succeeded or failed. Look at the following example, which tries to open a file and print its contents to the screen.

```
for line in open("myfile.txt"):
    print(line)
```

The problem with this code is that it leaves the file open for an indeterminate amount of time after this part of the code has finished executing. This is not an issue in simple scripts, but can be a problem for larger applications. The `with` statement allows objects like files to be used in a way that ensures they are always cleaned up promptly and correctly.

```
with open("myfile.txt") as f:
    for line in f:
        print(line)
```

After the statement is executed, the file `f` is always closed, even if a problem was encountered while processing the lines. Objects which, like files, provide predefined clean-up actions will indicate this in their documentation.

9. Classes

Compared with other programming languages, Python's class mechanism adds classes with a minimum of new syntax and semantics. It is a mixture of the class mechanisms found in C++ and Modula-3. Python classes provide all the standard features of Object Oriented Programming: the class inheritance mechanism allows multiple base classes, a derived class can override any methods of its base class or classes, and a method can call the method of a base class with the same name. Objects can contain arbitrary amounts and kinds of data. As is true for modules, classes partake of the dynamic nature of Python: they are created at runtime, and can be modified further after creation.

In C++ terminology, normally class members (including the data members) are *public* (except see below *Private Variables*), and all member functions are *virtual*. As in Modula-3, there are no shorthands for referencing the object's members from its methods: the method function is declared with an explicit first argument representing the object, which is provided implicitly by the call. As in Smalltalk, classes themselves are objects. This provides semantics for importing and renaming. Unlike C++ and Modula-3, built-in types can be used as base classes for extension by the user. Also, like in C++, most built-in operators with special syntax (arithmetic operators, subscripting etc.) can be redefined for class instances.

(Lacking universally accepted terminology to talk about classes, I will make occasional use of Smalltalk and C++ terms. I would use Modula-3 terms, since its object-oriented semantics are closer to those of Python than C++, but I expect that few readers have heard of it.)

9.1. A Word About Names and Objects

Objects have individuality, and multiple names (in multiple scopes) can be bound to the same object. This is known as aliasing in other languages. This is usually not appreciated on a first glance at Python, and can be safely ignored when dealing with immutable basic types (numbers, strings, tuples). However, aliasing has a possibly surprising effect on the semantics of Python code involving mutable objects such as lists, dictionaries, and most other types. This is usually used to the benefit of the program, since aliases behave like pointers in some respects. For example, passing an object is cheap since only a pointer is passed by the implementation; and if a function modifies an object passed as an argument, the caller will see the change — this eliminates the need for two different argument passing mechanisms as in Pascal.

9.2. Python Scopes and Namespaces

Before introducing classes, I first have to tell you something about Python's scope rules. Class definitions play some neat tricks with namespaces, and you need to know how scopes and namespaces work to fully understand what's going on. Incidentally, knowledge about this subject is useful for any advanced Python programmer.

Let's begin with some definitions.

A *namespace* is a mapping from names to objects. Most namespaces are currently implemented as Python dictionaries, but that's normally not noticeable in any way (except for performance), and it may change in the future. Examples of namespaces are: the set of built-in names (containing functions such as `abs()`, and built-in exception names); the global names in a module; and the local names in a function invocation. In a sense the set of attributes of an object also form a namespace. The important thing to know about namespaces is that there is absolutely no relation between names in different namespaces; for instance, two different modules may both define a function `maximize` without confusion — users of the modules must prefix it with the module name.

By the way, I use the word *attribute* for any name following a dot — for example, in the expression `z.real`, `real` is an attribute of the object `z`. Strictly speaking, references to names in modules are attribute references: in the expression `modname.funcname`, `modname` is a module object and `funcname` is an attribute of it. In this case there happens to be a straightforward mapping between the module's attributes and the global names defined in the module: they share the same namespace! [1]

Attributes may be read-only or writable. In the latter case,

assignment to attributes is possible. Module attributes are writable: you can write `modname.the_answer = 42`. Writable attributes may also be deleted with the `del` statement. For example, `del modname.the_answer` will remove the attribute `the_answer` from the object named by `modname`.

Namespaces are created at different moments and have different lifetimes. The namespace containing the built-in names is created when the Python interpreter starts up, and is never deleted. The global namespace for a module is created when the module definition is read in; normally, module namespaces also last until the interpreter quits. The statements executed by the top-level invocation of the interpreter, either read from a script file or interactively, are considered part of a module called `__main__`, so they have their own global namespace. (The built-in names actually also live in a module; this is called `builtins`.)

The local namespace for a function is created when the function is called, and deleted when the function returns or raises an exception that is not handled within the function. (Actually, forgetting would be a better way to describe what actually happens.) Of course, recursive invocations each have their own local namespace.

A *scope* is a textual region of a Python program where a namespace is directly accessible. “Directly accessible” here means that an unqualified reference to a name attempts to find the name in the namespace.

Although scopes are determined statically, they are used dynamically. At any time during execution, there are at least three nested scopes whose namespaces are directly accessible:

- the innermost scope, which is searched first, contains the local names
- the scopes of any enclosing functions, which are searched

starting with the nearest enclosing scope, contains non-local, but also non-global names

- the next-to-last scope contains the current module's global names
- the outermost scope (searched last) is the namespace containing built-in names

If a name is declared global, then all references and assignments go directly to the middle scope containing the module's global names. To rebind variables found outside of the innermost scope, the `nonlocal` statement can be used; if not declared nonlocal, those variables are read-only (an attempt to write to such a variable will simply create a *new* local variable in the innermost scope, leaving the identically named outer variable unchanged).

Usually, the local scope references the local names of the (textually) current function. Outside functions, the local scope references the same namespace as the global scope: the module's namespace. Class definitions place yet another namespace in the local scope.

It is important to realize that scopes are determined textually: the global scope of a function defined in a module is that module's namespace, no matter from where or by what alias the function is called. On the other hand, the actual search for names is done dynamically, at run time — however, the language definition is evolving towards static name resolution, at “compile” time, so don't rely on dynamic name resolution! (In fact, local variables are already determined statically.)

A special quirk of Python is that – if no `global` statement is in effect – assignments to names always go into the innermost scope. Assignments do not copy data — they just bind names to objects. The same is true for deletions: the statement `del x` removes the binding of `x` from the namespace referenced by the local scope. In fact, all operations that introduce new names use the local scope: in

particular, `import` statements and function definitions bind the module or function name in the local scope.

The `global` statement can be used to indicate that particular variables live in the global scope and should be rebound there; the `nonlocal` statement indicates that particular variables live in an enclosing scope and should be rebound there.

9.2.1. Scopes and Namespaces Example

This is an example demonstrating how to reference the different scopes and namespaces, and how `global` and `nonlocal` affect variable binding:

```
def scope_test():
    def do_local():
        spam = "local spam"
    def do_nonlocal():
        nonlocal spam
        spam = "nonlocal spam"
    def do_global():
        global spam
        spam = "global spam"

    spam = "test spam"
    do_local()
    print("After local assignment:", spam)
    do_nonlocal()
    print("After nonlocal assignment:", spam)
    do_global()
    print("After global assignment:", spam)

scope_test()
print("In global scope:", spam)
```

The output of the example code is:

```
After local assignment: test spam
After nonlocal assignment: nonlocal spam
After global assignment: nonlocal spam
```

In **global** scope: **global** spam

Note how the *local* assignment (which is default) didn't change *scope_test*'s binding of *spam*. The **nonlocal** assignment changed *scope_test*'s binding of *spam*, and the **global** assignment changed the module-level binding.

You can also see that there was no previous binding for *spam* before the **global** assignment.

9.3. A First Look at Classes

Classes introduce a little bit of new syntax, three new object types, and some new semantics.

9.3.1. Class Definition Syntax

The simplest form of class definition looks like this:

```
class ClassName:  
    <statement-1>  
    .  
    .  
    .  
    <statement-N>
```

Class definitions, like function definitions (`def` statements) must be executed before they have any effect. (You could conceivably place a class definition in a branch of an `if` statement, or inside a function.)

In practice, the statements inside a class definition will usually be function definitions, but other statements are allowed, and sometimes useful — we'll come back to this later. The function definitions inside a class normally have a peculiar form of argument list, dictated by the calling conventions for methods — again, this is explained later.

When a class definition is entered, a new namespace is created, and used as the local scope — thus, all assignments to local variables go into this new namespace. In particular, function definitions bind the name of the new function here.

When a class definition is left normally (via the `end`), a *class object* is created. This is basically a wrapper around the contents of the

namespace created by the class definition; we'll learn more about class objects in the next section. The original local scope (the one in effect just before the class definition was entered) is reinstated, and the class object is bound here to the class name given in the class definition header (`className` in the example).

9.3.2. Class Objects

Class objects support two kinds of operations: attribute references and instantiation.

Attribute references use the standard syntax used for all attribute references in Python: `obj.name`. Valid attribute names are all the names that were in the class's namespace when the class object was created. So, if the class definition looked like this:

```
class MyClass:
    """A simple example class"""
    i = 12345
    def f(self):
        return 'hello world'
```

then `MyClass.i` and `MyClass.f` are valid attribute references, returning an integer and a function object, respectively. Class attributes can also be assigned to, so you can change the value of `MyClass.i` by assignment. `__doc__` is also a valid attribute, returning the docstring belonging to the class: `"A simple example class"`.

Class *instantiation* uses function notation. Just pretend that the class object is a parameterless function that returns a new instance of the class. For example (assuming the above class):

```
x = MyClass()
```

creates a new *instance* of the class and assigns this object to the

local variable `x`.

The instantiation operation (“calling” a class object) creates an empty object. Many classes like to create objects with instances customized to a specific initial state. Therefore a class may define a special method named `__init__()`, like this:

```
def __init__(self):  
    self.data = []
```

When a class defines an `__init__()` method, class instantiation automatically invokes `__init__()` for the newly-created class instance. So in this example, a new, initialized instance can be obtained by:

```
x = MyClass()
```

Of course, the `__init__()` method may have arguments for greater flexibility. In that case, arguments given to the class instantiation operator are passed on to `__init__()`. For example,

```
>>> class Complex:  
...     def __init__(self, realpart, imagpart):  
...         self.r = realpart  
...         self.i = imagpart  
...  
>>> x = Complex(3.0, -4.5)  
>>> x.r, x.i  
(3.0, -4.5)
```

9.3.3. Instance Objects

Now what can we do with instance objects? The only operations understood by instance objects are attribute references. There are two kinds of valid attribute names, data attributes and methods.

data attributes correspond to “instance variables” in Smalltalk, and to

“data members” in C++. Data attributes need not be declared; like local variables, they spring into existence when they are first assigned to. For example, if `x` is the instance of `MyClass` created above, the following piece of code will print the value `16`, without leaving a trace:

```
x.counter = 1
while x.counter < 10:
    x.counter = x.counter * 2
print(x.counter)
del x.counter
```

The other kind of instance attribute reference is a *method*. A method is a function that “belongs to” an object. (In Python, the term method is not unique to class instances: other object types can have methods as well. For example, list objects have methods called `append`, `insert`, `remove`, `sort`, and so on. However, in the following discussion, we’ll use the term method exclusively to mean methods of class instance objects, unless explicitly stated otherwise.)

Valid method names of an instance object depend on its class. By definition, all attributes of a class that are function objects define corresponding methods of its instances. So in our example, `x.f` is a valid method reference, since `MyClass.f` is a function, but `x.i` is not, since `MyClass.i` is not. But `x.f` is not the same thing as `MyClass.f` — it is a *method object*, not a function object.

9.3.4. Method Objects

Usually, a method is called right after it is bound:

```
x.f()
```

In the `MyClass` example, this will return the string `'hello world'`. However, it is not necessary to call a method right away: `x.f` is a

method object, and can be stored away and called at a later time. For example:

```
xf = x.f
while True:
    print(xf())
```

will continue to print `hello world` until the end of time.

What exactly happens when a method is called? You may have noticed that `x.f()` was called without an argument above, even though the function definition for `f()` specified an argument. What happened to the argument? Surely Python raises an exception when a function that requires an argument is called without any — even if the argument isn't actually used...

Actually, you may have guessed the answer: the special thing about methods is that the object is passed as the first argument of the function. In our example, the call `x.f()` is exactly equivalent to `MyClass.f(x)`. In general, calling a method with a list of n arguments is equivalent to calling the corresponding function with an argument list that is created by inserting the method's object before the first argument.

If you still don't understand how methods work, a look at the implementation can perhaps clarify matters. When an instance attribute is referenced that isn't a data attribute, its class is searched. If the name denotes a valid class attribute that is a function object, a method object is created by packing (pointers to) the instance object and the function object just found together in an abstract object: this is the method object. When the method object is called with an argument list, a new argument list is constructed from the instance object and the argument list, and the function object is called with this new argument list.

9.4. Random Remarks

Data attributes override method attributes with the same name; to avoid accidental name conflicts, which may cause hard-to-find bugs in large programs, it is wise to use some kind of convention that minimizes the chance of conflicts. Possible conventions include capitalizing method names, prefixing data attribute names with a small unique string (perhaps just an underscore), or using verbs for methods and nouns for data attributes.

Data attributes may be referenced by methods as well as by ordinary users (“clients”) of an object. In other words, classes are not usable to implement pure abstract data types. In fact, nothing in Python makes it possible to enforce data hiding — it is all based upon convention. (On the other hand, the Python implementation, written in C, can completely hide implementation details and control access to an object if necessary; this can be used by extensions to Python written in C.)

Clients should use data attributes with care — clients may mess up invariants maintained by the methods by stamping on their data attributes. Note that clients may add data attributes of their own to an instance object without affecting the validity of the methods, as long as name conflicts are avoided — again, a naming convention can save a lot of headaches here.

There is no shorthand for referencing data attributes (or other methods!) from within methods. I find that this actually increases the readability of methods: there is no chance of confusing local variables and instance variables when glancing through a method.

Often, the first argument of a method is called `self`. This is nothing more than a convention: the name `self` has absolutely no special meaning to Python. Note, however, that by not following the

convention your code may be less readable to other Python programmers, and it is also conceivable that a *class browser* program might be written that relies upon such a convention.

Any function object that is a class attribute defines a method for instances of that class. It is not necessary that the function definition is textually enclosed in the class definition: assigning a function object to a local variable in the class is also ok. For example:

```
# Function defined outside the class
def f1(self, x, y):
    return min(x, x+y)

class C:
    f = f1
    def g(self):
        return 'hello world'
    h = g
```

Now `f`, `g` and `h` are all attributes of class `c` that refer to function objects, and consequently they are all methods of instances of `c` — `h` being exactly equivalent to `g`. Note that this practice usually only serves to confuse the reader of a program.

Methods may call other methods by using method attributes of the `self` argument:

```
class Bag:
    def __init__(self):
        self.data = []
    def add(self, x):
        self.data.append(x)
    def addtwice(self, x):
        self.add(x)
        self.add(x)
```

Methods may reference global names in the same way as ordinary functions. The global scope associated with a method is the module containing the class definition. (The class itself is never used as a

global scope.) While one rarely encounters a good reason for using global data in a method, there are many legitimate uses of the global scope: for one thing, functions and modules imported into the global scope can be used by methods, as well as functions and classes defined in it. Usually, the class containing the method is itself defined in this global scope, and in the next section we'll find some good reasons why a method would want to reference its own class.

Each value is an object, and therefore has a *class* (also called its *type*). It is stored as `object.__class__`.

9.5. Inheritance

Of course, a language feature would not be worthy of the name “class” without supporting inheritance. The syntax for a derived class definition looks like this:

```
class DerivedClassName(BaseClassName):  
    <statement-1>  
    .  
    .  
    .  
    <statement-N>
```

The name **BaseClassName** must be defined in a scope containing the derived class definition. In place of a base class name, other arbitrary expressions are also allowed. This can be useful, for example, when the base class is defined in another module:

```
class DerivedClassName(modname.BaseClassName):
```

Execution of a derived class definition proceeds the same as for a base class. When the class object is constructed, the base class is remembered. This is used for resolving attribute references: if a requested attribute is not found in the class, the search proceeds to look in the base class. This rule is applied recursively if the base class itself is derived from some other class.

There’s nothing special about instantiation of derived classes: `DerivedClassName()` creates a new instance of the class. Method references are resolved as follows: the corresponding class attribute is searched, descending down the chain of base classes if necessary, and the method reference is valid if this yields a function object.

Derived classes may override methods of their base classes.

Because methods have no special privileges when calling other methods of the same object, a method of a base class that calls another method defined in the same base class may end up calling a method of a derived class that overrides it. (For C++ programmers: all methods in Python are effectively `virtual`.)

An overriding method in a derived class may in fact want to extend rather than simply replace the base class method of the same name. There is a simple way to call the base class method directly: just call `BaseClassName.methodname(self, arguments)`. This is occasionally useful to clients as well. (Note that this only works if the base class is accessible as `BaseClassName` in the global scope.)

Python has two built-in functions that work with inheritance:

- Use `isinstance()` to check an instance's type: `isinstance(obj, int)` will be `True` only if `obj.__class__` is `int` or some class derived from `int`.
- Use `issubclass()` to check class inheritance: `issubclass(bool, int)` is `True` since `bool` is a subclass of `int`. However, `issubclass(float, int)` is `False` since `float` is not a subclass of `int`.

9.5.1. Multiple Inheritance

Python supports a form of multiple inheritance as well. A class definition with multiple base classes looks like this:

```
class DerivedClassName(Base1, Base2, Base3):
    <statement-1>
    .
    .
    .
    <statement-N>
```

For most purposes, in the simplest cases, you can think of the search for attributes inherited from a parent class as depth-first, left-to-right, not searching twice in the same class where there is an overlap in the hierarchy. Thus, if an attribute is not found in **DerivedClassName**, it is searched for in **Base1**, then (recursively) in the base classes of **Base1**, and if it was not found there, it was searched for in **Base2**, and so on.

In fact, it is slightly more complex than that; the method resolution order changes dynamically to support cooperative calls to `super()`. This approach is known in some other multiple-inheritance languages as call-next-method and is more powerful than the super call found in single-inheritance languages.

Dynamic ordering is necessary because all cases of multiple inheritance exhibit one or more diamond relationships (where at least one of the parent classes can be accessed through multiple paths from the bottommost class). For example, all classes inherit from `object`, so any case of multiple inheritance provides more than one path to reach `object`. To keep the base classes from being accessed more than once, the dynamic algorithm linearizes the search order in a way that preserves the left-to-right ordering specified in each class, that calls each parent only once, and that is monotonic (meaning that a class can be subclassed without affecting the precedence order of its parents). Taken together, these properties make it possible to design reliable and extensible classes with multiple inheritance. For more detail, see <http://www.python.org/download/releases/2.3/mro/>.

9.6. Private Variables

“Private” instance variables that cannot be accessed except from inside an object don’t exist in Python. However, there is a convention that is followed by most Python code: a name prefixed with an underscore (e.g. `_spam`) should be treated as a non-public part of the API (whether it is a function, a method or a data member). It should be considered an implementation detail and subject to change without notice.

Since there is a valid use-case for class-private members (namely to avoid name clashes of names with names defined by subclasses), there is limited support for such a mechanism, called *name mangling*. Any identifier of the form `__spam` (at least two leading underscores, at most one trailing underscore) is textually replaced with `_classname_spam`, where `classname` is the current class name with leading underscore(s) stripped. This mangling is done without regard to the syntactic position of the identifier, as long as it occurs within the definition of a class.

Note that the mangling rules are designed mostly to avoid accidents; it still is possible to access or modify a variable that is considered private. This can even be useful in special circumstances, such as in the debugger.

Notice that code passed to `exec()` or `eval()` does not consider the classname of the invoking class to be the current class; this is similar to the effect of the `global` statement, the effect of which is likewise restricted to code that is byte-compiled together. The same restriction applies to `getattr()`, `setattr()` and `delattr()`, as well as when referencing `__dict__` directly.

9.7. Odds and Ends

Sometimes it is useful to have a data type similar to the Pascal “record” or C “struct”, bundling together a few named data items. An empty class definition will do nicely:

```
class Employee:
    pass

john = Employee() # Create an empty employee record

# Fill the fields of the record
john.name = 'John Doe'
john.dept = 'computer lab'
john.salary = 1000
```

A piece of Python code that expects a particular abstract data type can often be passed a class that emulates the methods of that data type instead. For instance, if you have a function that formats some data from a file object, you can define a class with methods `read()` and `readline()` that get the data from a string buffer instead, and pass it as an argument.

Instance method objects have attributes, too: `m.__self__` is the instance object with the method `m()`, and `m.__func__` is the function object corresponding to the method.

9.8. Exceptions Are Classes Too

User-defined exceptions are identified by classes as well. Using this mechanism it is possible to create extensible hierarchies of exceptions.

There are two new valid (semantic) forms for the `raise` statement:

```
raise Class
raise Instance
```

In the first form, `class` must be an instance of `type` or of a class derived from it. The first form is a shorthand for:

```
raise Class()
```

A class in an `except` clause is compatible with an exception if it is the same class or a base class thereof (but not the other way around — an `except` clause listing a derived class is not compatible with a base class). For example, the following code will print B, C, D in that order:

```
class B(Exception):
    pass
class C(B):
    pass
class D(C):
    pass

for c in [B, C, D]:
    try:
        raise c()
    except D:
        print("D")
    except C:
        print("C")
    except B:
```

```
print("B")
```

Note that if the `except` clauses were reversed (with `except B` first), it would have printed `B, B, B` — the first matching `except` clause is triggered.

When an error message is printed for an unhandled exception, the exception's class name is printed, then a colon and a space, and finally the instance converted to a string using the built-in function `str()`.

9.9. Iterators

By now you have probably noticed that most container objects can be looped over using a `for` statement:

```
for element in [1, 2, 3]:
    print(element)
for element in (1, 2, 3):
    print(element)
for key in {'one':1, 'two':2}:
    print(key)
for char in "123":
    print(char)
for line in open("myfile.txt"):
    print(line)
```

This style of access is clear, concise, and convenient. The use of iterators pervades and unifies Python. Behind the scenes, the `for` statement calls `iter()` on the container object. The function returns an iterator object that defines the method `__next__()` which accesses elements in the container one at a time. When there are no more elements, `__next__()` raises a `StopIteration` exception which tells the `for` loop to terminate. You can call the `__next__()` method using the `next()` built-in function; this example shows how it all works:

```
>>> s = 'abc'
>>> it = iter(s)
>>> it
<iterator object at 0x00A1DB50>
>>> next(it)
'a'
>>> next(it)
'b'
>>> next(it)
'c'
>>> next(it)
```

```
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
    next(it)
StopIteration
```

Having seen the mechanics behind the iterator protocol, it is easy to add iterator behavior to your classes. Define an `__iter__()` method which returns an object with a `__next__()` method. If the class defines `__next__()`, then `__iter__()` can just return `self`:

```
class Reverse:
    "Iterator for looping over a sequence backwards"
    def __init__(self, data):
        self.data = data
        self.index = len(data)
    def __iter__(self):
        return self
    def __next__(self):
        if self.index == 0:
            raise StopIteration
        self.index = self.index - 1
        return self.data[self.index]

>>> rev = Reverse('spam')
>>> iter(rev)
<__main__.Reverse object at 0x00A1DB50>
>>> for char in rev:
...     print(char)
...
m
a
p
s
```

9.10. Generators

Generators are a simple and powerful tool for creating iterators. They are written like regular functions but use the `yield` statement whenever they want to return data. Each time `next()` is called on it, the generator resumes where it left-off (it remembers all the data values and which statement was last executed). An example shows that generators can be trivially easy to create:

```
def reverse(data):
    for index in range(len(data)-1, -1, -1):
        yield data[index]

>>> for char in reverse('golf'):
...     print(char)
...
f
l
o
g
```

Anything that can be done with generators can also be done with class based iterators as described in the previous section. What makes generators so compact is that the `__iter__()` and `__next__()` methods are created automatically.

Another key feature is that the local variables and execution state are automatically saved between calls. This made the function easier to write and much more clear than an approach using instance variables like `self.index` and `self.data`.

In addition to automatic method creation and saving program state, when generators terminate, they automatically raise `StopIteration`. In combination, these features make it easy to create iterators with no more effort than writing a regular function.

9.11. Generator Expressions

Some simple generators can be coded succinctly as expressions using a syntax similar to list comprehensions but with parentheses instead of brackets. These expressions are designed for situations where the generator is used right away by an enclosing function. Generator expressions are more compact but less versatile than full generator definitions and tend to be more memory friendly than equivalent list comprehensions.

Examples:

```
>>> sum(i*i for i in range(10))           # sum of square
285

>>> xvec = [10, 20, 30]
>>> yvec = [7, 5, 3]
>>> sum(x*y for x,y in zip(xvec, yvec))   # dot product
260

>>> from math import pi, sin
>>> sine_table = {x: sin(x*pi/180) for x in range(0, 91)}

>>> unique_words = set(word for line in page for word in line)

>>> valedictorian = max((student.gpa, student.name) for student in students)

>>> data = 'golf'
>>> list(data[i] for i in range(len(data)-1, -1, -1))
['f', 'l', 'o', 'g']
```

Footnotes

[1] Except for one thing. Module objects have a secret read-only attribute called `__dict__` which returns the dictionary used to implement the module's namespace; the name `__dict__` is an attribute but not a global name. Obviously, using this violates the abstraction of namespace implementation, and should be

restricted to things like post-mortem debuggers.

[previous](#) | [next](#) | [modules](#) | [index](#)

10. Brief Tour of the Standard Library

10.1. Operating System Interface

The `os` module provides dozens of functions for interacting with the operating system:

```
>>> import os
>>> os.getcwd()          # Return the current working directory
'C:\\Python31'
>>> os.chdir('/server/accesslogs')  # Change current working d
>>> os.system('mkdir today')  # Run the command mkdir in the s
0
```

Be sure to use the `import os` style instead of `from os import *`. This will keep `os.open()` from shadowing the built-in `open()` function which operates much differently.

The built-in `dir()` and `help()` functions are useful as interactive aids for working with large modules like `os`:

```
>>> import os
>>> dir(os)
<returns a list of all module functions>
>>> help(os)
<returns an extensive manual page created from the module's doc
```

For daily file and directory management tasks, the `shutil` module provides a higher level interface that is easier to use:

```
>>> import shutil
>>> shutil.copyfile('data.db', 'archive.db')
>>> shutil.move('/build/executables', 'installdir')
```

10.2. File Wildcards

The `glob` module provides a function for making file lists from directory wildcard searches:

```
>>> import glob
>>> glob.glob('*.py')
['primes.py', 'random.py', 'quote.py']
```

10.3. Command Line Arguments

Common utility scripts often need to process command line arguments. These arguments are stored in the `sys` module's `argv` attribute as a list. For instance the following output results from running `python demo.py one two three` at the command line:

```
>>> import sys
>>> print(sys.argv)
['demo.py', 'one', 'two', 'three']
```

The `getopt` module processes `sys.argv` using the conventions of the Unix `getopt()` function. More powerful and flexible command line processing is provided by the `argparse` module.

10.4. Error Output Redirection and Program Termination

The `sys` module also has attributes for `stdin`, `stdout`, and `stderr`. The latter is useful for emitting warnings and error messages to make them visible even when `stdout` has been redirected:

```
>>> sys.stderr.write('Warning, log file not found starting a new  
Warning, log file not found starting a new one')
```

The most direct way to terminate a script is to use `sys.exit()`.

10.5. String Pattern Matching

The `re` module provides regular expression tools for advanced string processing. For complex matching and manipulation, regular expressions offer succinct, optimized solutions:

```
>>> import re
>>> re.findall(r'\b[a-z]*', 'which foot or hand fell fastest')
['foot', 'fell', 'fastest']
>>> re.sub(r'(\b[a-z]+) \1', r'\1', 'cat in the the hat')
'cat in the hat'
```

When only simple capabilities are needed, string methods are preferred because they are easier to read and debug:

```
>>> 'tea for too'.replace('too', 'two')
'tea for two'
```

10.6. Mathematics

The `math` module gives access to the underlying C library functions for floating point math:

```
>>> import math
>>> math.cos(math.pi / 4)
0.70710678118654757
>>> math.log(1024, 2)
10.0
```

The `random` module provides tools for making random selections:

```
>>> import random
>>> random.choice(['apple', 'pear', 'banana'])
'apple'
>>> random.sample(range(100), 10) # sampling without replacement
[30, 83, 16, 4, 8, 81, 41, 50, 18, 33]
>>> random.random() # random float
0.17970987693706186
>>> random.randrange(6) # random integer chosen from range(6)
4
```

The SciPy project <<http://scipy.org>> has many other modules for numerical computations.

10.7. Internet Access

There are a number of modules for accessing the internet and processing internet protocols. Two of the simplest are `urllib.request` for retrieving data from urls and `smtplib` for sending mail:

```
>>> from urllib.request import urlopen
>>> for line in urlopen('http://tycho.usno.navy.mil/cgi-bin/tim
...     line = line.decode('utf-8') # Decoding the binary data
...     if 'EST' in line or 'EDT' in line: # look for Eastern
...         print(line)
```

```
<BR>Nov. 25, 09:43:32 PM EST
```

```
>>> import smtplib
>>> server = smtplib.SMTP('localhost')
>>> server.sendmail('soothsayer@example.org', 'jcaesar@example.
...     """To: jcaesar@example.org
...     From: soothsayer@example.org
...
...     Beware the Ides of March.
...     """)
>>> server.quit()
```

(Note that the second example needs a mailserver running on localhost.)

10.8. Dates and Times

The `datetime` module supplies classes for manipulating dates and times in both simple and complex ways. While date and time arithmetic is supported, the focus of the implementation is on efficient member extraction for output formatting and manipulation. The module also supports objects that are timezone aware.

```
>>> # dates are easily constructed and formatted
>>> from datetime import date
>>> now = date.today()
>>> now
datetime.date(2003, 12, 2)
>>> now.strftime("%m-%d-%y. %d %b %Y is a %A on the %d day of %")
'12-02-03. 02 Dec 2003 is a Tuesday on the 02 day of December.'

>>> # dates support calendar arithmetic
>>> birthday = date(1964, 7, 31)
>>> age = now - birthday
>>> age.days
14368
```

10.9. Data Compression

Common data archiving and compression formats are directly supported by modules including: `zlib`, `gzip`, `bz2`, `zipfile` and `tarfile`.

```
>>> import zlib
>>> s = b'witch which has which witches wrist watch'
>>> len(s)
41
>>> t = zlib.compress(s)
>>> len(t)
37
>>> zlib.decompress(t)
b'witch which has which witches wrist watch'
>>> zlib.crc32(s)
226805979
```

10.10. Performance Measurement

Some Python users develop a deep interest in knowing the relative performance of different approaches to the same problem. Python provides a measurement tool that answers those questions immediately.

For example, it may be tempting to use the tuple packing and unpacking feature instead of the traditional approach to swapping arguments. The `timeit` module quickly demonstrates a modest performance advantage:

```
>>> from timeit import Timer
>>> Timer('t=a; a=b; b=t', 'a=1; b=2').timeit()
0.57535828626024577
>>> Timer('a,b = b,a', 'a=1; b=2').timeit()
0.54962537085770791
```

In contrast to `timeit`'s fine level of granularity, the `profile` and `pstats` modules provide tools for identifying time critical sections in larger blocks of code.

10.11. Quality Control

One approach for developing high quality software is to write tests for each function as it is developed and to run those tests frequently during the development process.

The `doctest` module provides a tool for scanning a module and validating tests embedded in a program's docstrings. Test construction is as simple as cutting-and-pasting a typical call along with its results into the docstring. This improves the documentation by providing the user with an example and it allows the `doctest` module to make sure the code remains true to the documentation:

```
def average(values):
    """Computes the arithmetic mean of a list of numbers.

    >>> print(average([20, 30, 70]))
    40.0
    """
    return sum(values) / len(values)

import doctest
doctest.testmod() # automatically validate the embedded tests
```

The `unittest` module is not as effortless as the `doctest` module, but it allows a more comprehensive set of tests to be maintained in a separate file:

```
import unittest

class TestStatisticalFunctions(unittest.TestCase):

    def test_average(self):
        self.assertEqual(average([20, 30, 70]), 40.0)
        self.assertEqual(round(average([1, 5, 7]), 1), 4.3)
        self.assertRaises(ZeroDivisionError, average, [])
        self.assertRaises(TypeError, average, 20, 30, 70)
```

```
unittest.main() # Calling from the command line invokes all tes
```

10.12. Batteries Included

Python has a “batteries included” philosophy. This is best seen through the sophisticated and robust capabilities of its larger packages. For example:

- The `xmlrpc.client` and `xmlrpc.server` modules make implementing remote procedure calls into an almost trivial task. Despite the modules names, no direct knowledge or handling of XML is needed.
- The `email` package is a library for managing email messages, including MIME and other RFC 2822-based message documents. Unlike `smtplib` and `poplib` which actually send and receive messages, the email package has a complete toolset for building or decoding complex message structures (including attachments) and for implementing internet encoding and header protocols.
- The `xml.dom` and `xml.sax` packages provide robust support for parsing this popular data interchange format. Likewise, the `csv` module supports direct reads and writes in a common database format. Together, these modules and packages greatly simplify data interchange between Python applications and other tools.
- Internationalization is supported by a number of modules including `gettext`, `locale`, and the `codecs` package.

11. Brief Tour of the Standard Library – Part II

This second tour covers more advanced modules that support professional programming needs. These modules rarely occur in small scripts.

11.1. Output Formatting

The `reprlib` module provides a version of `repr()` customized for abbreviated displays of large or deeply nested containers:

```
>>> import reprlib
>>> reprlib.repr(set('supercalifragilisticexpialidocious'))
"set(['a', 'c', 'd', 'e', 'f', 'g', ...])"
```

The `pprint` module offers more sophisticated control over printing both built-in and user defined objects in a way that is readable by the interpreter. When the result is longer than one line, the “pretty printer” adds line breaks and indentation to more clearly reveal data structure:

```
>>> import pprint
>>> t = [[['black', 'cyan'], 'white', ['green', 'red']], [['ma
...     'yellow'], 'blue']]
...
>>> pprint.pprint(t, width=30)
[[['black', 'cyan'],
   'white',
   ['green', 'red']],
 [['magenta', 'yellow'],
  'blue']]
```

The `textwrap` module formats paragraphs of text to fit a given screen width:

```
>>> import textwrap
>>> doc = """The wrap() method is just like fill() except that
... a list of strings instead of one big string with newlines t
... the wrapped lines."""
...
>>> print(textwrap.fill(doc, width=40))
The wrap() method is just like fill()
except that it returns a list of strings
instead of one big string with newlines
```

to separate the wrapped lines.

The `locale` module accesses a database of culture specific data formats. The grouping attribute of locale's format function provides a direct way of formatting numbers with group separators:

```
>>> import locale
>>> locale.setlocale(locale.LC_ALL, 'English_United States.1252')
'English_United States.1252'
>>> conv = locale.localeconv()           # get a mapping of conv
>>> x = 1234567.8
>>> locale.format("%d", x, grouping=True)
'1,234,567'
>>> locale.format_string("%s%.*f", (conv['currency_symbol'],
...                               conv['frac_digits'], x), grouping=True)
'$1,234,567.80'
```

11.2. Templating

The `string` module includes a versatile `Template` class with a simplified syntax suitable for editing by end-users. This allows users to customize their applications without having to alter the application.

The format uses placeholder names formed by `$` with valid Python identifiers (alphanumeric characters and underscores). Surrounding the placeholder with braces allows it to be followed by more alphanumeric letters with no intervening spaces. Writing `$$` creates a single escaped `$`:

```
>>> from string import Template
>>> t = Template('${village}folk send $$10 to $cause.')
>>> t.substitute(village='Nottingham', cause='the ditch fund')
'Nottinghamfolk send $10 to the ditch fund.'
```

The `substitute()` method raises a `KeyError` when a placeholder is not supplied in a dictionary or a keyword argument. For mail-merge style applications, user supplied data may be incomplete and the `safe_substitute()` method may be more appropriate — it will leave placeholders unchanged if data is missing:

```
>>> t = Template('Return the $item to $owner.')
>>> d = dict(item='unladen swallow')
>>> t.substitute(d)
Traceback (most recent call last):
  .
  .
  .
KeyError: 'owner'
>>> t.safe_substitute(d)
'Return the unladen swallow to $owner.'
```

Template subclasses can specify a custom delimiter. For example, a batch renaming utility for a photo browser may elect to use percent signs for placeholders such as the current date, image sequence number, or file format:

```
>>> import time, os.path
>>> photofiles = ['img_1074.jpg', 'img_1076.jpg', 'img_1077.jpg']
>>> class BatchRename(Template):
...     delimiter = '%'
>>> fmt = input('Enter rename style (%d-date %n-seqnum %f-format): ')
Enter rename style (%d-date %n-seqnum %f-format): Ashley_%n%f

>>> t = BatchRename(fmt)
>>> date = time.strftime('%d%b%y')
>>> for i, filename in enumerate(photofiles):
...     base, ext = os.path.splitext(filename)
...     newname = t.substitute(d=date, n=i, f=ext)
...     print('{0} --> {1}'.format(filename, newname))

img_1074.jpg --> Ashley_0.jpg
img_1076.jpg --> Ashley_1.jpg
img_1077.jpg --> Ashley_2.jpg
```

Another application for templating is separating program logic from the details of multiple output formats. This makes it possible to substitute custom templates for XML files, plain text reports, and HTML web reports.

11.3. Working with Binary Data Record Layouts

The `struct` module provides `pack()` and `unpack()` functions for working with variable length binary record formats. The following example shows how to loop through header information in a ZIP file without using the `zipfile` module. Pack codes `"H"` and `"I"` represent two and four byte unsigned numbers respectively. The `"<"` indicates that they are standard size and in little-endian byte order:

```
import struct

data = open('myfile.zip', 'rb').read()
start = 0
for i in range(3):                                # show the first 3 file
    start += 14
    fields = struct.unpack('<IIHH', data[start:start+16])
    crc32, comp_size, uncomp_size, filenamesize, extra_size = f

    start += 16
    filename = data[start:start+filenamesize]
    start += filenamesize
    extra = data[start:start+extra_size]
    print(filename, hex(crc32), comp_size, uncomp_size)

    start += extra_size + comp_size                # skip to the next head
```

11.4. Multi-threading

Threading is a technique for decoupling tasks which are not sequentially dependent. Threads can be used to improve the responsiveness of applications that accept user input while other tasks run in the background. A related use case is running I/O in parallel with computations in another thread.

The following code shows how the high level `threading` module can run tasks in background while the main program continues to run:

```
import threading, zipfile

class AsyncZip(threading.Thread):
    def __init__(self, infile, outfile):
        threading.Thread.__init__(self)
        self.infile = infile
        self.outfile = outfile
    def run(self):
        f = zipfile.ZipFile(self.outfile, 'w', zipfile.ZIP_DEFL)
        f.write(self.infile)
        f.close()
        print('Finished background zip of:', self.infile)

background = AsyncZip('mydata.txt', 'myarchive.zip')
background.start()
print('The main program continues to run in foreground.')

background.join()    # Wait for the background task to finish
print('Main program waited until background was done.')
```

The principal challenge of multi-threaded applications is coordinating threads that share data or other resources. To that end, the threading module provides a number of synchronization primitives including locks, events, condition variables, and semaphores.

While those tools are powerful, minor design errors can result in problems that are difficult to reproduce. So, the preferred approach

to task coordination is to concentrate all access to a resource in a single thread and then use the `queue` module to feed that thread with requests from other threads. Applications using `queue` objects for inter-thread communication and coordination are easier to design, more readable, and more reliable.

11.5. Logging

The `logging` module offers a full featured and flexible logging system. At its simplest, log messages are sent to a file or to `sys.stderr`:

```
import logging
logging.debug('Debugging information')
logging.info('Informational message')
logging.warning('Warning:config file %s not found', 'server.conf')
logging.error('Error occurred')
logging.critical('Critical error -- shutting down')
```

This produces the following output:

```
WARNING:root:Warning:config file server.conf not found
ERROR:root:Error occurred
CRITICAL:root:Critical error -- shutting down
```

By default, informational and debugging messages are suppressed and the output is sent to standard error. Other output options include routing messages through email, datagrams, sockets, or to an HTTP Server. New filters can select different routing based on message priority: **DEBUG**, **INFO**, **WARNING**, **ERROR**, and **CRITICAL**.

The logging system can be configured directly from Python or can be loaded from a user editable configuration file for customized logging without altering the application.

11.6. Weak References

Python does automatic memory management (reference counting for most objects and *garbage collection* to eliminate cycles). The memory is freed shortly after the last reference to it has been eliminated.

This approach works fine for most applications but occasionally there is a need to track objects only as long as they are being used by something else. Unfortunately, just tracking them creates a reference that makes them permanent. The `weakref` module provides tools for tracking objects without creating a reference. When the object is no longer needed, it is automatically removed from a weakref table and a callback is triggered for weakref objects. Typical applications include caching objects that are expensive to create:

```
>>> import weakref, gc
>>> class A:
...     def __init__(self, value):
...         self.value = value
...     def __repr__(self):
...         return str(self.value)
...
>>> a = A(10)                                # create a reference
>>> d = weakref.WeakValueDictionary()
>>> d['primary'] = a                          # does not create a reference
>>> d['primary']                              # fetch the object if it is sti
10
>>> del a                                    # remove the one reference
>>> gc.collect()                             # run garbage collection right
0
>>> d['primary']                             # entry was automatically remov
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
    d['primary']                              # entry was automatically remov
  File "C:/python31/lib/weakref.py", line 46, in __getitem__
    o = self.data[key]()
KeyError: 'primary'
```

11.7. Tools for Working with Lists

Many data structure needs can be met with the built-in list type. However, sometimes there is a need for alternative implementations with different performance trade-offs.

The `array` module provides an `array()` object that is like a list that stores only homogeneous data and stores it more compactly. The following example shows an array of numbers stored as two byte unsigned binary numbers (typecode `"H"`) rather than the usual 16 bytes per entry for regular lists of Python int objects:

```
>>> from array import array
>>> a = array('H', [4000, 10, 700, 22222])
>>> sum(a)
26932
>>> a[1:3]
array('H', [10, 700])
```

The `collections` module provides a `deque()` object that is like a list with faster appends and pops from the left side but slower lookups in the middle. These objects are well suited for implementing queues and breadth first tree searches:

```
>>> from collections import deque
>>> d = deque(["task1", "task2", "task3"])
>>> d.append("task4")
>>> print("Handling", d.popleft())
Handling task1

unsearched = deque([starting_node])
def breadth_first_search(unsearched):
    node = unsearched.popleft()
    for m in gen_moves(node):
        if is_goal(m):
            return m
        unsearched.append(m)
```

In addition to alternative list implementations, the library also offers other tools such as the `bisect` module with functions for manipulating sorted lists:

```
>>> import bisect
>>> scores = [(100, 'perl'), (200, 'tcl'), (400, 'lua'), (500,
>>> bisect.insort(scores, (300, 'ruby'))
>>> scores
[(100, 'perl'), (200, 'tcl'), (300, 'ruby'), (400, 'lua'), (500
```

The `heapq` module provides functions for implementing heaps based on regular lists. The lowest valued entry is always kept at position zero. This is useful for applications which repeatedly access the smallest element but do not want to run a full list sort:

```
>>> from heapq import heapify, heappop, heappush
>>> data = [1, 3, 5, 7, 9, 2, 4, 6, 8, 0]
>>> heapify(data) # rearrange the list into a heap
>>> heappush(data, -5) # add a new entry
>>> [heappop(data) for i in range(3)] # fetch the three smallest
[-5, 0, 1]
```

11.8. Decimal Floating Point Arithmetic

The `decimal` module offers a `Decimal` datatype for decimal floating point arithmetic. Compared to the built-in `float` implementation of binary floating point, the class is especially helpful for

- financial applications and other uses which require exact decimal representation,
- control over precision,
- control over rounding to meet legal or regulatory requirements,
- tracking of significant decimal places, or
- applications where the user expects the results to match calculations done by hand.

For example, calculating a 5% tax on a 70 cent phone charge gives different results in decimal floating point and binary floating point. The difference becomes significant if the results are rounded to the nearest cent:

```
>>> from decimal import *
>>> round(Decimal('0.70') * Decimal('1.05'), 2)
Decimal('0.74')
>>> round(.70 * 1.05, 2)
0.73
```

The `Decimal` result keeps a trailing zero, automatically inferring four place significance from multiplicands with two place significance. `Decimal` reproduces mathematics as done by hand and avoids issues that can arise when binary floating point cannot exactly represent decimal quantities.

Exact representation enables the `Decimal` class to perform modulo calculations and equality tests that are unsuitable for binary floating point:

```
>>> Decimal('1.00') % Decimal('.10')
Decimal('0.00')
>>> 1.00 % 0.10
0.09999999999999995

>>> sum([Decimal('0.1')]*10) == Decimal('1.0')
True
>>> sum([0.1]*10) == 1.0
False
```

The `decimal` module provides arithmetic with as much precision as needed:

```
>>> getcontext().prec = 36
>>> Decimal(1) / Decimal(7)
Decimal('0.142857142857142857142857142857142857')
```

12. What Now?

Reading this tutorial has probably reinforced your interest in using Python — you should be eager to apply Python to solving your real-world problems. Where should you go to learn more?

This tutorial is part of Python's documentation set. Some other documents in the set are:

- *The Python Standard Library*:

You should browse through this manual, which gives complete (though terse) reference material about types, functions, and the modules in the standard library. The standard Python distribution includes a *lot* of additional code. There are modules to read Unix mailboxes, retrieve documents via HTTP, generate random numbers, parse command-line options, write CGI programs, compress data, and many other tasks. Skimming through the Library Reference will give you an idea of what's available.

- *Installing Python Modules* explains how to install external modules written by other Python users.
- *The Python Language Reference*: A detailed explanation of Python's syntax and semantics. It's heavy reading, but is useful as a complete guide to the language itself.

More Python resources:

- <http://www.python.org>: The major Python Web site. It contains code, documentation, and pointers to Python-related pages around the Web. This Web site is mirrored in various places around the world, such as Europe, Japan, and Australia; a mirror may be faster than the main site, depending on your

geographical location.

- <http://docs.python.org>: Fast access to Python's documentation.
- <http://pypi.python.org>: The Python Package Index, previously also nicknamed the Cheese Shop, is an index of user-created Python modules that are available for download. Once you begin releasing code, you can register it here so that others can find it.
- <http://aspn.activestate.com/ASPN/Python/Cookbook/>: The Python Cookbook is a sizable collection of code examples, larger modules, and useful scripts. Particularly notable contributions are collected in a book also titled Python Cookbook (O'Reilly & Associates, ISBN 0-596-00797-3.)
- <http://scipy.org>: The Scientific Python project includes modules for fast array computations and manipulations plus a host of packages for such things as linear algebra, Fourier transforms, non-linear solvers, random number distributions, statistical analysis and the like.

For Python-related questions and problem reports, you can post to the newsgroup *comp.lang.python*, or send them to the mailing list at python-list@python.org. The newsgroup and mailing list are gatewayed, so messages posted to one will automatically be forwarded to the other. There are around 120 postings a day (with peaks up to several hundred), asking (and answering) questions, suggesting new features, and announcing new modules. Before posting, be sure to check the list of [Frequently Asked Questions](#) (also called the FAQ), or look for it in the `Misc/` directory of the Python source distribution. Mailing list archives are available at <http://mail.python.org/pipermail/>. The FAQ answers many of the questions that come up again and again, and may already contain the solution for your problem.

13. Interactive Input Editing and History Substitution

Some versions of the Python interpreter support editing of the current input line and history substitution, similar to facilities found in the Korn shell and the GNU Bash shell. This is implemented using the [GNU Readline](#) library, which supports Emacs-style and vi-style editing. This library has its own documentation which I won't duplicate here; however, the basics are easily explained. The interactive editing and history described here are optionally available in the Unix and Cygwin versions of the interpreter.

This chapter does *not* document the editing facilities of Mark Hammond's PythonWin package or the Tk-based environment, IDLE, distributed with Python. The command line history recall which operates within DOS boxes on NT and some other DOS and Windows flavors is yet another beast.

13.1. Line Editing

If supported, input line editing is active whenever the interpreter prints a primary or secondary prompt. The current line can be edited using the conventional Emacs control characters. The most important of these are: `C-A` (Control-A) moves the cursor to the beginning of the line, `C-E` to the end, `C-B` moves it one position to the left, `C-F` to the right. Backspace erases the character to the left of the cursor, `C-D` the character to its right. `C-K` kills (erases) the rest of the line to the right of the cursor, `C-Y` yanks back the last killed string. `C-underscore` undoes the last change you made; it can be repeated for cumulative effect.

13.2. History Substitution

History substitution works as follows. All non-empty input lines issued are saved in a history buffer, and when a new prompt is given you are positioned on a new line at the bottom of this buffer. `C-P` moves one line up (back) in the history buffer, `C-N` moves one down. Any line in the history buffer can be edited; an asterisk appears in front of the prompt to mark a line as modified. Pressing the `Return` key passes the current line to the interpreter. `C-R` starts an incremental reverse search; `C-S` starts a forward search.

13.3. Key Bindings

The key bindings and some other parameters of the Readline library can be customized by placing commands in an initialization file called `~/.inputrc`. Key bindings have the form

```
key-name: function-name
```

or

```
"string": function-name
```

and options can be set with

```
set option-name value
```

For example:

```
# I prefer vi-style editing:  
set editing-mode vi  
  
# Edit using a single line:  
set horizontal-scroll-mode On  
  
# Rebind some keys:  
Meta-h: backward-kill-word  
"\C-u": universal-argument  
"\C-x\C-r": re-read-init-file
```

Note that the default binding for `Tab` in Python is to insert a `Tab` character instead of Readline's default filename completion function. If you insist, you can override this by putting

```
Tab: complete
```

in your `~/.inputrc`. (Of course, this makes it harder to type indented

continuation lines if you're accustomed to using `Tab` for that purpose.)

Automatic completion of variable and module names is optionally available. To enable it in the interpreter's interactive mode, add the following to your startup file: [1]

```
import rlcompleter, readline
readline.parse_and_bind('tab: complete')
```

This binds the `Tab` key to the completion function, so hitting the `Tab` key twice suggests completions; it looks at Python statement names, the current local variables, and the available module names. For dotted expressions such as `string.a`, it will evaluate the expression up to the final `'.'` and then suggest completions from the attributes of the resulting object. Note that this may execute application-defined code if an object with a `__getattr__()` method is part of the expression.

A more capable startup file might look like this example. Note that this deletes the names it creates once they are no longer needed; this is done since the startup file is executed in the same namespace as the interactive commands, and removing the names avoids creating side effects in the interactive environment. You may find it convenient to keep some of the imported modules, such as `os`, which turn out to be needed in most sessions with the interpreter.

```
# Add auto-completion and a stored history file of commands to
# interactive interpreter. Requires Python 2.0+, readline. Auto
# bound to the Esc key by default (you can change it - see read
#
# Store the file in ~/.pystartup, and set an environment variab
# to it: "export PYTHONSTARTUP=/home/user/.pystartup" in bash.
#
# Note that PYTHONSTARTUP does *not* expand "~", so you have to
# full path to your home directory.
```

```
import atexit
import os
import readline
import rlcompleter

historyPath = os.path.expanduser("~/pyhistory")

def save_history(historyPath=historyPath):
    import readline
    readline.write_history_file(historyPath)

if os.path.exists(historyPath):
    readline.read_history_file(historyPath)

atexit.register(save_history)
del os, atexit, readline, rlcompleter, save_history, historyPat
```

13.4. Alternatives to the Interactive Interpreter

This facility is an enormous step forward compared to earlier versions of the interpreter; however, some wishes are left: It would be nice if the proper indentation were suggested on continuation lines (the parser knows if an indent token is required next). The completion mechanism might use the interpreter's symbol table. A command to check (or even suggest) matching parentheses, quotes, etc., would also be useful.

One alternative enhanced interactive interpreter that has been around for quite some time is [IPython](#), which features tab completion, object exploration and advanced history management. It can also be thoroughly customized and embedded into other applications. Another similar enhanced interactive environment is [bpython](#).

Footnotes

[1] Python will execute the contents of a file identified by the `PYTHONSTARTUP` environment variable when you start an interactive interpreter.

14. Floating Point Arithmetic: Issues and Limitations

Floating-point numbers are represented in computer hardware as base 2 (binary) fractions. For example, the decimal fraction

0.125

has value $1/10 + 2/100 + 5/1000$, and in the same way the binary fraction

0.001

has value $0/2 + 0/4 + 1/8$. These two fractions have identical values, the only real difference being that the first is written in base 10 fractional notation, and the second in base 2.

Unfortunately, most decimal fractions cannot be represented exactly as binary fractions. A consequence is that, in general, the decimal floating-point numbers you enter are only approximated by the binary floating-point numbers actually stored in the machine.

The problem is easier to understand at first in base 10. Consider the fraction $1/3$. You can approximate that as a base 10 fraction:

0.3

or, better,

0.33

or, better,

0.333

and so on. No matter how many digits you're willing to write down, the result will never be exactly $1/3$, but will be an increasingly better approximation of $1/3$.

In the same way, no matter how many base 2 digits you're willing to use, the decimal value 0.1 cannot be represented exactly as a base 2 fraction. In base 2, $1/10$ is the infinitely repeating fraction

```
0.0001100110011001100110011001100110011001100110011001100110011...
```

Stop at any finite number of bits, and you get an approximation. On most machines today, floats are approximated using a binary fraction with the numerator using the first 53 bits starting with the most significant bit and with the denominator as a power of two. In the case of $1/10$, the binary fraction is `3602879701896397 / 2 ** 55` which is close to but not exactly equal to the true value of $1/10$.

Many users are not aware of the approximation because of the way values are displayed. Python only prints a decimal approximation to the true decimal value of the binary approximation stored by the machine. On most machines, if Python were to print the true decimal value of the binary approximation stored for 0.1, it would have to display

```
>>> 0.1
0.10000000000000000000000055511151231257827021181583404541015625
```

That is more digits than most people find useful, so Python keeps the number of digits manageable by displaying a rounded value instead

```
>>> 1 / 10
0.1
```

Just remember, even though the printed result looks like the exact value of $1/10$, the actual stored value is the nearest representable

binary fraction.

Interestingly, there are many different decimal numbers that share the same nearest approximate binary fraction. For example, the numbers `0.1` and `0.10000000000000001` and `0.1000000000000000055511151231257827021181583404541015625` are all approximated by `3602879701896397 / 2 ** 55`. Since all of these decimal values share the same approximation, any one of them could be displayed while still preserving the invariant `eval(repr(x)) == x`.

Historically, the Python prompt and built-in `repr()` function would choose the one with 17 significant digits, `0.10000000000000001`. Starting with Python 3.1, Python (on most systems) is now able to choose the shortest of these and simply display `0.1`.

Note that this is in the very nature of binary floating-point: this is not a bug in Python, and it is not a bug in your code either. You'll see the same kind of thing in all languages that support your hardware's floating-point arithmetic (although some languages may not *display* the difference by default, or in all output modes).

For more pleasant output, you may may wish to use string formatting to produce a limited number of significant digits:

```
>>> format(math.pi, '.12g') # give 12 significant digits
'3.14159265359'

>>> format(math.pi, '.2f') # give 2 digits after the point
'3.14'

>>> repr(math.pi)
'3.141592653589793'
```

It's important to realize that this is, in a real sense, an illusion: you're simply rounding the *display* of the true machine value.

One illusion may beget another. For example, since 0.1 is not exactly 1/10, summing three values of 0.1 may not yield exactly 0.3, either:

```
>>> .1 + .1 + .1 == .3
False
```

Also, since the 0.1 cannot get any closer to the exact value of 1/10 and 0.3 cannot get any closer to the exact value of 3/10, then pre-rounding with `round()` function cannot help:

```
>>> round(.1, 1) + round(.1, 1) + round(.1, 1) == round(.3, 1)
False
```

Though the numbers cannot be made closer to their intended exact values, the `round()` function can be useful for post-rounding so that results with inexact values become comparable to one another:

```
>>> round(.1 + .1 + .1, 10) == round(.3, 10)
True
```

Binary floating-point arithmetic holds many surprises like this. The problem with “0.1” is explained in precise detail below, in the “Representation Error” section. See [The Perils of Floating Point](#) for a more complete account of other common surprises.

As that says near the end, “there are no easy answers.” Still, don’t be unduly wary of floating-point! The errors in Python float operations are inherited from the floating-point hardware, and on most machines are on the order of no more than 1 part in 2^{53} per operation. That’s more than adequate for most tasks, but you do need to keep in mind that it’s not decimal arithmetic and that every float operation can suffer a new rounding error.

While pathological cases do exist, for most casual use of floating-point arithmetic you’ll see the result you expect in the end if you simply round the display of your final results to the number of

decimal digits you expect. `str()` usually suffices, and for finer control see the `str.format()` method's format specifiers in *Format String Syntax*.

For use cases which require exact decimal representation, try using the `decimal` module which implements decimal arithmetic suitable for accounting applications and high-precision applications.

Another form of exact arithmetic is supported by the `fractions` module which implements arithmetic based on rational numbers (so the numbers like $1/3$ can be represented exactly).

If you are a heavy user of floating point operations you should take a look at the Numerical Python package and many other packages for mathematical and statistical operations supplied by the SciPy project. See <http://scipy.org>.

Python provides tools that may help on those rare occasions when you really *do* want to know the exact value of a float. The `float.as_integer_ratio()` method expresses the value of a float as a fraction:

```
>>> x = 3.14159
>>> x.as_integer_ratio()
(3537115888337719, 1125899906842624)
```

Since the ratio is exact, it can be used to losslessly recreate the original value:

```
>>> x == 3537115888337719 / 1125899906842624
True
```

The `float.hex()` method expresses a float in hexadecimal (base 16), again giving the exact value stored by your computer:

```
>>> x.hex()
```

```
'0x1.921f9f01b866ep+1'
```

This precise hexadecimal representation can be used to reconstruct the float value exactly:

```
>>> x == float.fromhex('0x1.921f9f01b866ep+1')
True
```

Since the representation is exact, it is useful for reliably porting values across different versions of Python (platform independence) and exchanging data with other languages that support the same format (such as Java and C99).

Another helpful tool is the `math.fsum()` function which helps mitigate loss-of-precision during summation. It tracks “lost digits” as values are added onto a running total. That can make a difference in overall accuracy so that the errors do not accumulate to the point where they affect the final total:

```
>>> sum([0.1] * 10) == 1.0
False
>>> math.fsum([0.1] * 10) == 1.0
True
```

14.1. Representation Error

This section explains the “0.1” example in detail, and shows how you can perform an exact analysis of cases like this yourself. Basic familiarity with binary floating-point representation is assumed.

Representation error refers to the fact that some (most, actually) decimal fractions cannot be represented exactly as binary (base 2) fractions. This is the chief reason why Python (or Perl, C, C++, Java, Fortran, and many others) often won't display the exact decimal number you expect.

Why is that? $1/10$ is not exactly representable as a binary fraction. Almost all machines today (November 2000) use IEEE-754 floating point arithmetic, and almost all platforms map Python floats to IEEE-754 “double precision”. 754 doubles contain 53 bits of precision, so on input the computer strives to convert 0.1 to the closest fraction it can of the form $J/2^{**N}$ where J is an integer containing exactly 53 bits. Rewriting

$$1 / 10 \approx J / (2^{**N})$$

as

$$J \approx 2^{**N} / 10$$

and recalling that J has exactly 53 bits (is $\geq 2^{**52}$ but $< 2^{**53}$), the best value for N is 56:

```
>>> 2**52 <= 2**56 // 10 < 2**53
True
```

That is, 56 is the only value for N that leaves J with exactly 53 bits. The best possible value for J is then that quotient rounded:

decimal value
0.10000000000000000055511151231257827021181583404541015625.
Instead of displaying the full decimal value, many languages (including older versions of Python), round the result to 17 significant digits:

```
>>> format(0.1, '.17f')  
'0.10000000000000001'
```

The `fractions` and `decimal` modules make these calculations easy:

```
>>> from decimal import Decimal  
>>> from fractions import Fraction  
  
>>> Fraction.from_float(0.1)  
Fraction(3602879701896397, 36028797018963968)  
  
>>> (0.1).as_integer_ratio()  
(3602879701896397, 36028797018963968)  
  
>>> Decimal.from_float(0.1)  
Decimal('0.10000000000000000055511151231257827021181583404541015  
  
>>> format(Decimal.from_float(0.1), '.17f')  
'0.10000000000000001'
```

1. Command line and environment

The CPython interpreter scans the command line and the environment for various settings.

CPython implementation detail: Other implementations' command line schemes may differ. See [Alternate Implementations](#) for further resources.

1.1. Command line

When invoking Python, you may specify any of these options:

```
python [-bBdEhiOsSuvVwx?] [-c command | -m module-name | script
```

The most common use case is, of course, a simple invocation of a script:

```
python myscript.py
```

1.1.1. Interface options

The interpreter interface resembles that of the UNIX shell, but provides some additional methods of invocation:

- When called with standard input connected to a tty device, it prompts for commands and executes them until an EOF (an end-of-file character, you can produce that with *Ctrl-D* on UNIX or *Ctrl-Z, Enter* on Windows) is read.
- When called with a file name argument or with a file as standard input, it reads and executes a script from that file.
- When called with a directory name argument, it reads and executes an appropriately named script from that directory.
- When called with `-c command`, it executes the Python statement(s) given as *command*. Here *command* may contain multiple statements separated by newlines. Leading whitespace is significant in Python statements!
- When called with `-m module-name`, the given module is located on the Python module path and executed as a script.

In non-interactive mode, the entire input is parsed before it is executed.

An interface option terminates the list of options consumed by the interpreter, all consecutive arguments will end up in `sys.argv` – note that the first element, subscript zero (`sys.argv[0]`), is a string reflecting the program's source.

-c <command>

Execute the Python code in *command*. *command* can be one or more statements separated by newlines, with significant leading whitespace as in normal module code.

If this option is given, the first element of `sys.argv` will be `"-c"` and the current directory will be added to the start of `sys.path` (allowing modules in that directory to be imported as top level modules).

-m <module-name>

Search `sys.path` for the named module and execute its contents as the `__main__` module.

Since the argument is a *module* name, you must not give a file extension (`.py`). The `module-name` should be a valid Python module name, but the implementation may not always enforce this (e.g. it may allow you to use a name that includes a hyphen).

Package names are also permitted. When a package name is supplied instead of a normal module, the interpreter will execute `<pkg>.__main__` as the main module. This behaviour is deliberately similar to the handling of directories and zipfiles that are passed to the interpreter as the script argument.

Note: This option cannot be used with built-in modules and extension modules written in C, since they do not have Python module files. However, it can still be used for precompiled modules, even if the original source file is not available.

If this option is given, the first element of `sys.argv` will be the full path to the module file (while the module file is being located, the first element will be set to `"-m"`). As with the `-c` option, the current directory will be added to the start of `sys.path`.

Many standard library modules contain code that is invoked on their execution as a script. An example is the `timeit` module:

```
python -mtimeit -s 'setup here' 'benchmarked code here'  
python -mtimeit -h # for details
```

See also: `runpy.run_module()` Equivalent functionality directly available to Python code

PEP 338 – Executing modules as scripts

Changed in version 3.1: Supply the package name to run a `__main__` submodule.

-

Read commands from standard input (`sys.stdin`). If standard input is a terminal, `-i` is implied.

If this option is given, the first element of `sys.argv` will be `"-"` and the current directory will be added to the start of `sys.path`.

<script>

Execute the Python code contained in *script*, which must be a filesystem path (absolute or relative) referring to either a Python file, a directory containing a `__main__.py` file, or a zipfile containing a `__main__.py` file.

If this option is given, the first element of `sys.argv` will be the script name as given on the command line.

If the script name refers directly to a Python file, the directory

containing that file is added to the start of `sys.path`, and the file is executed as the `__main__` module.

If the script name refers to a directory or zipfile, the script name is added to the start of `sys.path` and the `__main__.py` file in that location is executed as the `__main__` module.

If no interface option is given, `-i` is implied, `sys.argv[0]` is an empty string (`""`) and the current directory will be added to the start of `sys.path`.

See also: *Invoking the Interpreter*

1.1.2. Generic options

-?

-h

--help

Print a short description of all command line options.

-V

--version

Print the Python version number and exit. Example output could be:

```
Python 3.0
```

1.1.3. Miscellaneous options

-b

Issue a warning when comparing str and bytes. Issue an error when the option is given twice (`-bb`).

-B

If given, Python won't try to write `.pyc` or `.pyo` files on the import

of source modules. See also `PYTHONDONTWRITEBYTECODE`.

-d

Turn on parser debugging output (for wizards only, depending on compilation options). See also `PYTHONDEBUG`.

-E

Ignore all `PYTHON*` environment variables, e.g. `PYTHONPATH` and `PYTHONHOME`, that might be set.

-i

When a script is passed as first argument or the `-c` option is used, enter interactive mode after executing the script or the command, even when `sys.stdin` does not appear to be a terminal. The `PYTHONSTARTUP` file is not read.

This can be useful to inspect global variables or a stack trace when a script raises an exception. See also `PYTHONINSPECT`.

-O

Turn on basic optimizations. This changes the filename extension for compiled (*bytecode*) files from `.pyc` to `.pyo`. See also `PYTHONOPTIMIZE`.

-OO

Discard docstrings in addition to the `-O` optimizations.

-q

Don't display the copyright and version messages even in interactive mode.

New in version 3.2.

-s

Don't add user site directory to `sys.path`

See also: [PEP 370](#) – Per user site-packages directory

-S

Disable the import of the module `site` and the site-dependent manipulations of `sys.path` that it entails.

-u

Force the binary layer of the stdin, stdout and stderr streams (which is available as their `buffer` attribute) to be unbuffered. The text I/O layer will still be line-buffered.

See also [PYTHONUNBUFFERED](#).

-v

Print a message each time a module is initialized, showing the place (filename or built-in module) from which it is loaded. When given twice (`-vv`), print a message for each file that is checked for when searching for a module. Also provides information on module cleanup at exit. See also [PYTHONVERBOSE](#).

-W arg

Warning control. Python's warning machinery by default prints warning messages to `sys.stderr`. A typical warning message has the following form:

```
file:line: category: message
```

By default, each warning is printed once for each source line where it occurs. This option controls how often warnings are printed.

Multiple `-W` options may be given; when a warning matches more than one option, the action for the last matching option is performed. Invalid `-W` options are ignored (though, a warning message is printed about invalid options when the first warning is

issued).

Warnings can also be controlled from within a Python program using the `warnings` module.

The simplest form of argument is one of the following action strings (or a unique abbreviation):

`ignore`

Ignore all warnings.

`default`

Explicitly request the default behavior (printing each warning once per source line).

`all`

Print a warning each time it occurs (this may generate many messages if a warning is triggered repeatedly for the same source line, such as inside a loop).

`module`

Print each warning only the first time it occurs in each module.

`once`

Print each warning only the first time it occurs in the program.

`error`

Raise an exception instead of printing a warning message.

The full form of argument is:

```
action:message:category:module:line
```

Here, *action* is as explained above but only applies to messages that match the remaining fields. Empty fields match all values; trailing empty fields may be omitted. The *message* field matches the start of the warning message printed; this match is case-insensitive. The *category* field matches the warning category.

This must be a class name; the match tests whether the actual warning category of the message is a subclass of the specified warning category. The full class name must be given. The *module* field matches the (fully-qualified) module name; this match is case-sensitive. The *line* field matches the line number, where zero matches all line numbers and is thus equivalent to an omitted line number.

See also: [warnings](#) – the warnings module
[PEP 230](#) – Warning framework
[PYTHONWARNINGS](#)

-x

Skip the first line of the source, allowing use of non-Unix forms of `#!cmd`. This is intended for a DOS specific hack only.

Note: The line numbers in error messages will be off by one.

-X

Reserved for various implementation-specific options. CPython currently defines none of them, but allows to pass arbitrary values and retrieve them through the `sys._xoptions` dictionary.

Changed in version 3.2: It is now allowed to pass `-X` with CPython.

1.1.4. Options you shouldn't use

-J

Reserved for use by [Jython](#).

1.2. Environment variables

These environment variables influence Python's behavior.

PYTHONHOME

Change the location of the standard Python libraries. By default, the libraries are searched in `prefix/lib/pythonversion` and `exec_prefix/lib/pythonversion`, where `prefix` and `exec_prefix` are installation-dependent directories, both defaulting to `/usr/local`.

When **PYTHONHOME** is set to a single directory, its value replaces both `prefix` and `exec_prefix`. To specify different values for these, set **PYTHONHOME** to `prefix:exec_prefix`.

PYTHONPATH

Augment the default search path for module files. The format is the same as the shell's **PATH**: one or more directory pathnames separated by `os.pathsep` (e.g. colons on Unix or semicolons on Windows). Non-existent directories are silently ignored.

In addition to normal directories, individual **PYTHONPATH** entries may refer to zipfiles containing pure Python modules (in either source or compiled form). Extension modules cannot be imported from zipfiles.

The default search path is installation dependent, but generally begins with `prefix/lib/pythonversion` (see **PYTHONHOME** above). It is *always* appended to **PYTHONPATH**.

An additional directory will be inserted in the search path in front of **PYTHONPATH** as described above under *Interface options*. The search path can be manipulated from within a Python program as

the variable `sys.path`.

PYTHONSTARTUP

If this is the name of a readable file, the Python commands in that file are executed before the first prompt is displayed in interactive mode. The file is executed in the same namespace where interactive commands are executed so that objects defined or imported in it can be used without qualification in the interactive session. You can also change the prompts `sys.ps1` and `sys.ps2` in this file.

PYTHONY2K

Set this to a non-empty string to cause the `time` module to require dates specified as strings to include 4-digit years, otherwise 2-digit years are converted based on rules described in the `time` module documentation.

PYTHONOPTIMIZE

If this is set to a non-empty string it is equivalent to specifying the `-O` option. If set to an integer, it is equivalent to specifying `-O` multiple times.

PYTHONDEBUG

If this is set to a non-empty string it is equivalent to specifying the `-d` option. If set to an integer, it is equivalent to specifying `-d` multiple times.

PYTHONINSPECT

If this is set to a non-empty string it is equivalent to specifying the `-i` option.

This variable can also be modified by Python code using `os.environ` to force inspect mode on program termination.

PYTHONUNBUFFERED

If this is set to a non-empty string it is equivalent to specifying the

`-u` option.

PYTHONVERBOSE

If this is set to a non-empty string it is equivalent to specifying the `-v` option. If set to an integer, it is equivalent to specifying `-v` multiple times.

PYTHONCASEOK

If this is set, Python ignores case in `import` statements. This only works on Windows.

PYTHONDONTWRITEBYTECODE

If this is set, Python won't try to write `.pyc` or `.pyo` files on the import of source modules.

PYTHONIOENCODING

If this is set before running the interpreter, it overrides the encoding used for `stdin/stdout/stderr`, in the syntax `encodingname:errorhandler`. The `:errorhandler` part is optional and has the same meaning as in `str.encode()`.

For `stderr`, the `:errorhandler` part is ignored; the handler will always be `'backslashreplace'`.

PYTHONNOUSERSITE

If this is set, Python won't add the user site directory to `sys.path`

See also: [PEP 370](#) – Per user site-packages directory

PYTHONUSERBASE

Sets the base directory for the user site directory

See also: [PEP 370](#) – Per user site-packages directory

PYTHONEXECUTABLE

If this environment variable is set, `sys.argv[0]` will be set to its value instead of the value got through the C runtime. Only works on Mac OS X.

PYTHONWARNINGS

This is equivalent to the `-W` option. If set to a comma separated string, it is equivalent to specifying `-W` multiple times.

1.2.1. Debug-mode variables

Setting these variables only has an effect in a debug build of Python, that is, if Python was configured with the `--with-pydebug` build option.

PYTHONTHREADDEBUG

If set, Python will print threading debug info.

PYTHONDUMPREFS

If set, Python will dump objects and reference counts still alive after shutting down the interpreter.

PYTHONMALLOCSTATS

If set, Python will print memory allocation statistics every time a new object arena is created, and on shutdown.

2. Using Python on Unix platforms

2.1. Getting and installing the latest version of Python

2.1.1. On Linux

Python comes preinstalled on most Linux distributions, and is available as a package on all others. However there are certain features you might want to use that are not available on your distro's package. You can easily compile the latest version of Python from source.

In the event that Python doesn't come preinstalled and isn't in the repositories as well, you can easily make packages for your own distro. Have a look at the following links:

See also:

<http://www.linux.com/articles/60383>

for Debian users

<http://linuxmafia.com/pub/linux/suse-linux-internals/chapter35.html>

for OpenSuse users

<http://docs.fedoraproject.org/drafts/rpm-guide-en/ch-creating-rpms.html>

for Fedora users

<http://www.slackbook.org/html/package-management-making-packages.html>

for Slackware users

2.1.2. On FreeBSD and OpenBSD

- FreeBSD users, to add the package use:

```
pkg_add -r python
```

- OpenBSD users use:

```
pkg_add ftp://ftp.openbsd.org/pub/OpenBSD/4.2/packages/<ins  
◀ | ▶
```

For example i386 users get the 2.5.1 version of Python using:

```
pkg_add ftp://ftp.openbsd.org/pub/OpenBSD/4.2/packages/i386  
◀ | ▶
```

2.1.3. On OpenSolaris

To install the newest Python versions on OpenSolaris, install blastwave (<http://www.blastwave.org/howto.html>) and type “pkg_get -i python” at the prompt.

2.2. Building Python

If you want to compile CPython yourself, first thing you should do is get the [source](#). You can download either the latest release's source or just grab a fresh [checkout](#).

The build process consists the usual

```
./configure
make
make install
```

invocations. Configuration options and caveats for specific Unix platforms are extensively documented in the [README](#) file in the root of the Python source tree.

Warning: `make install` can overwrite or masquerade the `python` binary. `make altinstall` is therefore recommended instead of `make install` since it only installs `exec_prefix/bin/pythonversion`.

2.3. Python-related paths and files

These are subject to difference depending on local installation conventions; `prefix` (`${prefix}`) and `exec_prefix` (`${exec_prefix}`) are installation-dependent and should be interpreted as for GNU software; they may be the same.

For example, on most Linux systems, the default for both is `/usr`.

File/directory	Meaning
<code>exec_prefix/bin/python</code>	Recommended location of the interpreter.
<code>prefix/lib/pythonversion,</code> <code>exec_prefix/lib/pythonversion</code>	Recommended locations of the directories containing the standard modules.
<code>prefix/include/pythonversion,</code> <code>exec_prefix/include/pythonversion</code>	Recommended locations of the directories containing the include files needed for developing Python extensions and embedding the interpreter.
<code>~/.pythonrc.py</code>	User-specific initialization file loaded by the user module; not used by default or by most applications.

2.4. Miscellaneous

To easily use Python scripts on Unix, you need to make them executable, e.g. with

```
$ chmod +x script
```

and put an appropriate Shebang line at the top of the script. A good choice is usually

```
#!/usr/bin/env python
```

which searches for the Python interpreter in the whole `PATH`. However, some Unices may not have the `env` command, so you may need to hardcode `/usr/bin/python` as the interpreter path.

To use shell commands in your Python scripts, look at the `subprocess` module.

2.5. Editors

Vim and Emacs are excellent editors which support Python very well. For more information on how to code in Python in these editors, look at:

- http://www.vim.org/scripts/script.php?script_id=790
- <http://sourceforge.net/projects/python-mode>

Geany is an excellent IDE with support for a lot of languages. For more information, read: <http://geany.uvena.de/>

Komodo edit is another extremely good IDE. It also has support for a lot of languages. For more information, read: <http://www.activestate.com/store/productdetail.aspx?prdGuid=20f4ed15-6684-4118-a78b-d37ff4058c5f>

3. Using Python on Windows

This document aims to give an overview of Windows-specific behaviour you should know about when using Python on Microsoft Windows.

3.1. Installing Python

Unlike most Unix systems and services, Windows does not require Python natively and thus does not pre-install a version of Python. However, the CPython team has compiled Windows installers (MSI packages) with every [release](#) for many years.

With ongoing development of Python, some platforms that used to be supported earlier are no longer supported (due to the lack of users or developers). Check [PEP 11](#) for details on all unsupported platforms.

- Up to 2.5, Python was still compatible with Windows 95, 98 and ME (but already raised a deprecation warning on installation). For Python 2.6 (and all following releases), this support was dropped and new releases are just expected to work on the Windows NT family.
- [Windows CE](#) is still supported.
- The [Cygwin](#) installer offers to install the [Python interpreter](#) as well; it is located under “Interpreters.” (cf. [Cygwin package source](#), [Maintainer releases](#))

See [Python for Windows \(and DOS\)](#) for detailed information about platforms with precompiled installers.

2003

3.2. Alternative bundles

Besides the standard CPython distribution, there are modified packages including additional functionality. The following is a list of popular versions and their key features:

ActivePython

Installer with multi-platform compatibility, documentation, PyWin32

Enthought Python Distribution

Popular modules (such as PyWin32) with their respective documentation, tool suite for building extensible Python applications

Notice that these packages are likely to install *older* versions of Python.

3.3. Configuring Python

In order to run Python flawlessly, you might have to change certain environment settings in Windows.

3.3.1. Excursus: Setting environment variables

Windows has a built-in dialog for changing environment variables (following guide applies to XP classical view): Right-click the icon for your machine (usually located on your Desktop and called “My Computer”) and choose *Properties* there. Then, open the *Advanced* tab and click the *Environment Variables* button.

In short, your path is:

My Computer ▶ *Properties* ▶ *Advanced* ▶ *Environment Variables*

In this dialog, you can add or modify User and System variables. To change System variables, you need non-restricted access to your machine (i.e. Administrator rights).

Another way of adding variables to your environment is using the **set** command:

```
set PYTHONPATH=%PYTHONPATH%;C:\My_python_lib
```

To make this setting permanent, you could add the corresponding command line to your `autoexec.bat`. **msconfig** is a graphical interface to this file.

Viewing environment variables can also be done more straightforward: The command prompt will expand strings wrapped into percent signs automatically:

```
echo %PATH%
```

Consult **set /?** for details on this behaviour.

How To Manage Environment Variables in Windows XP

<http://www.chem.gla.ac.uk/~louis/software/faq/q1.html>

Setting Environment variables, Louis J. Farrugia

3.3.2. Finding the Python executable

Besides using the automatically created start menu entry for the Python interpreter, you might want to start Python in the DOS prompt. To make this work, you need to set your `%PATH%` environment variable to include the directory of your Python distribution, delimited by a semicolon from other entries. An example variable could look like this (assuming the first two entries are Windows' default):

```
C:\WINDOWS\system32;C:\WINDOWS;C:\Python25
```

Typing **python** on your command prompt will now fire up the Python interpreter. Thus, you can also execute your scripts with command line options, see *Command line* documentation.

3.3.3. Finding modules

Python usually stores its library (and thereby your site-packages folder) in the installation directory. So, if you had installed Python to `c:\Python\`, the default library would reside in `c:\Python\Lib\` and

third-party modules should be stored in `C:\Python\Lib\site-packages\`.

This is how `sys.path` is populated on Windows:

- An empty entry is added at the start, which corresponds to the current directory.
- If the environment variable `PYTHONPATH` exists, as described in *Environment variables*, its entries are added next. Note that on Windows, paths in this variable must be separated by semicolons, to distinguish them from the colon used in drive identifiers (`C:\` etc.).
- Additional “application paths” can be added in the registry as subkeys of `\SOFTWARE\Python\PythonCore\version\PythonPath` under both the `HKEY_CURRENT_USER` and `HKEY_LOCAL_MACHINE` hives. Subkeys which have semicolon-delimited path strings as their default value will cause each path to be added to `sys.path`. (Note that all known installers only use HKLM, so HKCU is typically empty.)
- If the environment variable `PYTHONHOME` is set, it is assumed as “Python Home”. Otherwise, the path of the main Python executable is used to locate a “landmark file” (`Lib\os.py`) to deduce the “Python Home”. If a Python home is found, the relevant sub-directories added to `sys.path` (`Lib`, `plat-win`, etc) are based on that folder. Otherwise, the core Python path is constructed from the `PythonPath` stored in the registry.
- If the Python Home cannot be located, no `PYTHONPATH` is specified in the environment, and no registry entries can be found, a default path with relative entries is used (e.g. `.\Lib;.\plat-win`, etc).

The end result of all this is:

- When running `python.exe`, or any other `.exe` in the main Python directory (either an installed version, or directly from the PCbuild directory), the core path is deduced, and the core paths in the registry are ignored. Other “application paths” in the registry are always read.
- When Python is hosted in another `.exe` (different directory, embedded via COM, etc), the “Python Home” will not be deduced, so the core path from the registry is used. Other “application paths” in the registry are always read.
- If Python can’t find its home and there is no registry (eg, frozen `.exe`, some very strange installation setup) you get a path with some default, but relative, paths.

3.3.4. Executing scripts

Python scripts (files with the extension `.py`) will be executed by **python.exe** by default. This executable opens a terminal, which stays open even if the program uses a GUI. If you do not want this to happen, use the extension `.pyw` which will cause the script to be executed by **pythonw.exe** by default (both executables are located in the top-level of your Python installation directory). This suppresses the terminal window on startup.

You can also make all `.py` scripts execute with **pythonw.exe**, setting this through the usual facilities, for example (might require administrative rights):

1. Launch a command prompt.
2. Associate the correct file group with `.py` scripts:

```
assoc .py=Python.File
```

3. Redirect all Python files to the new executable:

```
ftype Python.File=C:\Path\to\pythonw.exe "%1" %*
```

3.4. Additional modules

Even though Python aims to be portable among all platforms, there are features that are unique to Windows. A couple of modules, both in the standard library and external, and snippets exist to use these features.

The Windows-specific standard modules are documented in *MS Windows Specific Services*.

3.4.1. PyWin32

The `PyWin32` module by Mark Hammond is a collection of modules for advanced Windows-specific support. This includes utilities for:

- [Component Object Model \(COM\)](#)
- Win32 API calls
- Registry
- Event log
- [Microsoft Foundation Classes \(MFC\)](#) user interfaces

`PythonWin` is a sample MFC application shipped with `PyWin32`. It is an embeddable IDE with a built-in debugger.

See also:

Win32 How Do I...?

by Tim Golden

Python and COM

by David and Paul Boddie

3.4.2. Py2exe

`Py2exe` is a `distutils` extension (see *Extending Distutils*) which wraps Python scripts into executable Windows programs (`*.exe` files). When you have done this, you can distribute your application without requiring your users to install Python.

3.4.3. WConio

Since Python's advanced terminal handling layer, `curses`, is restricted to Unix-like systems, there is a library exclusive to Windows as well: Windows Console I/O for Python.

`WConio` is a wrapper for Turbo-C's `CONIO.H`, used to create text user interfaces.

3.5. Compiling Python on Windows

If you want to compile CPython yourself, first thing you should do is get the [source](#). You can download either the latest release's source or just grab a fresh [checkout](#).

For Microsoft Visual C++, which is the compiler with which official Python releases are built, the source tree contains solutions/project files. View the `readme.txt` in their respective directories:

Directory	MSVC version	Visual Studio version
PC/VC6/	6.0	97
PC/VS7.1/	7.1	2003
PC/VS8.0/	8.0	2005
PCbuild/	9.0	2008

Note that not all of these build directories are fully supported. Read the release notes to see which compiler version the official releases for your version are built with.

Check `PC/readme.txt` for general information on the build process.

For extension modules, consult *[Building C and C++ Extensions on Windows](#)*.

A Python for Windows Tutorial

by Amanda Birmingham, 2004

4. Using Python on a Macintosh

Author: Bob Savage <bobsavage@mac.com>

Python on a Macintosh running Mac OS X is in principle very similar to Python on any other Unix platform, but there are a number of additional features such as the IDE and the Package Manager that are worth pointing out.

4.1. Getting and Installing MacPython

Mac OS X 10.5 comes with Python 2.5.1 pre-installed by Apple. If you wish, you are invited to install the most recent version of Python from the Python website (<http://www.python.org>). A current “universal binary” build of Python, which runs natively on the Mac’s new Intel and legacy PPC CPU’s, is available there.

What you get after installing is a number of things:

- A `MacPython 2.5` folder in your `Applications` folder. In here you find IDLE, the development environment that is a standard part of official Python distributions; `PythonLauncher`, which handles double-clicking Python scripts from the Finder; and the “Build Applet” tool, which allows you to package Python scripts as standalone applications on your system.
- A framework `/Library/Frameworks/Python.framework`, which includes the Python executable and libraries. The installer adds this location to your shell path. To uninstall MacPython, you can simply remove these three things. A symlink to the Python executable is placed in `/usr/local/bin/`.

The Apple-provided build of Python is installed in `/System/Library/Frameworks/Python.framework` and `/usr/bin/python`, respectively. You should never modify or delete these, as they are Apple-controlled and are used by Apple- or third-party software. Remember that if you choose to install a newer Python version from `python.org`, you will have two different but functional Python installations on your computer, so it will be important that your paths and usages are consistent with what you want to do.

IDLE includes a help menu that allows you to access Python

documentation. If you are completely new to Python you should start reading the tutorial introduction in that document.

If you are familiar with Python on other Unix platforms you should read the section on running Python scripts from the Unix shell.

4.1.1. How to run a Python script

Your best way to get started with Python on Mac OS X is through the IDLE integrated development environment, see section *The IDE* and use the Help menu when the IDE is running.

If you want to run Python scripts from the Terminal window command line or from the Finder you first need an editor to create your script. Mac OS X comes with a number of standard Unix command line editors, **vim** and **emacs** among them. If you want a more Mac-like editor, **BBEdit** or **TextWrangler** from Bare Bones Software (see <http://www.barebones.com/products/bbedit/index.shtml>) are good choices, as is **TextMate** (see <http://macromates.com/>). Other editors include **Gvim** (<http://macvim.org>) and **Aquamacs** (<http://aquamacs.org/>).

To run your script from the Terminal window you must make sure that `/usr/local/bin` is in your shell search path.

To run your script from the Finder you have two options:

- Drag it to **PythonLauncher**
- Select **PythonLauncher** as the default application to open your script (or any `.py` script) through the finder Info window and double-click it. **PythonLauncher** has various preferences to control how your script is launched. Option-dragging allows you to change these for one invocation, or use its Preferences menu to change things globally.

4.1.2. Running scripts with a GUI

With older versions of Python, there is one Mac OS X quirk that you need to be aware of: programs that talk to the Aqua window manager (in other words, anything that has a GUI) need to be run in a special way. Use **pythonw** instead of **python** to start such scripts.

With Python 2.5, you can use either **python** or **pythonw**.

4.1.3. Configuration

Python on OS X honors all standard Unix environment variables such as **PYTHONPATH**, but setting these variables for programs started from the Finder is non-standard as the Finder does not read your `.profile` or `.cshrc` at startup. You need to create a file `~/MacOSX/environment.plist`. See Apple's Technical Document QA1067 for details.

For more information on installation Python packages in MacPython, see section *Installing Additional Python Packages*.

4.2. The IDE

MacPython ships with the standard IDLE development environment. A good introduction to using IDLE can be found at http://hkn.eecs.berkeley.edu/~dyoo/python/idle_intro/index.html.

4.3. Installing Additional Python Packages

There are several methods to install additional Python packages:

- <http://pythonmac.org/packages/> contains selected compiled packages for Python 2.5, 2.4, and 2.3.
- Packages can be installed via the standard Python distutils mode (`python setup.py install`).
- Many packages can also be installed via the **setuptools** extension.

4.4. GUI Programming on the Mac

There are several options for building GUI applications on the Mac with Python.

PyObjC is a Python binding to Apple's Objective-C/Cocoa framework, which is the foundation of most modern Mac development. Information on PyObjC is available from <http://pyobjc.sourceforge.net>.

The standard Python GUI toolkit is `tkinter`, based on the cross-platform Tk toolkit (<http://www.tcl.tk>). An Aqua-native version of Tk is bundled with OS X by Apple, and the latest version can be downloaded and installed from <http://www.activestate.com>; it can also be built from source.

wxPython is another popular cross-platform GUI toolkit that runs natively on Mac OS X. Packages and documentation are available from <http://www.wxpython.org>.

PyQt is another popular cross-platform GUI toolkit that runs natively on Mac OS X. More information can be found at <http://www.riverbankcomputing.co.uk/software/pyqt/intro>.

4.5. Distributing Python Applications on the Mac

The “Build Applet” tool that is placed in the MacPython 2.5 folder is fine for packaging small Python scripts on your own machine to run as a standard Mac application. This tool, however, is not robust enough to distribute Python applications to other users.

The standard tool for deploying standalone Python applications on the Mac is **py2app**. More information on installing and using py2app can be found at <http://undefined.org/python/#py2app>.

4.6. Application Scripting

Python can also be used to script other Mac applications via Apple's Open Scripting Architecture (OSA); see <http://appscript.sourceforge.net>. Appscript is a high-level, user-friendly Apple event bridge that allows you to control scriptable Mac OS X applications using ordinary Python scripts. Appscript makes Python a serious alternative to Apple's own *AppleScript* language for automating your Mac. A related package, *PyOSA*, is an OSA language component for the Python scripting language, allowing Python code to be executed by any OSA-enabled application (Script Editor, Mail, iTunes, etc.). PyOSA makes Python a full peer to AppleScript.

4.7. Other Resources

The MacPython mailing list is an excellent support resource for Python users and developers on the Mac:

<http://www.python.org/community/sigs/current/pythonmac-sig/>

Another useful resource is the MacPython wiki:

<http://wiki.python.org/moin/MacPython>

1. Introduction

This reference manual describes the Python programming language. It is not intended as a tutorial.

While I am trying to be as precise as possible, I chose to use English rather than formal specifications for everything except syntax and lexical analysis. This should make the document more understandable to the average reader, but will leave room for ambiguities. Consequently, if you were coming from Mars and tried to re-implement Python from this document alone, you might have to guess things and in fact you would probably end up implementing quite a different language. On the other hand, if you are using Python and wonder what the precise rules about a particular area of the language are, you should definitely be able to find them here. If you would like to see a more formal definition of the language, maybe you could volunteer your time — or invent a cloning machine :-).

It is dangerous to add too many implementation details to a language reference document — the implementation may change, and other implementations of the same language may work differently. On the other hand, CPython is the one Python implementation in widespread use (although alternate implementations continue to gain support), and its particular quirks are sometimes worth being mentioned, especially where the implementation imposes additional limitations. Therefore, you'll find short “implementation notes” sprinkled throughout the text.

Every Python implementation comes with a number of built-in and standard modules. These are documented in *The Python Standard Library*. A few built-in modules are mentioned when they interact in a significant way with the language definition.

1.1. Alternate Implementations

Though there is one Python implementation which is by far the most popular, there are some alternate implementations which are of particular interest to different audiences.

Known implementations include:

CPython

This is the original and most-maintained implementation of Python, written in C. New language features generally appear here first.

Jython

Python implemented in Java. This implementation can be used as a scripting language for Java applications, or can be used to create applications using the Java class libraries. It is also often used to create tests for Java libraries. More information can be found at [the Jython website](#).

Python for .NET

This implementation actually uses the CPython implementation, but is a managed .NET application and makes .NET libraries available. It was created by Brian Lloyd. For more information, see the [Python for .NET home page](#).

IronPython

An alternate Python for .NET. Unlike Python.NET, this is a complete Python implementation that generates IL, and compiles Python code directly to .NET assemblies. It was created by Jim Hugunin, the original creator of Jython. For more information, see [the IronPython website](#).

PyPy

An implementation of Python written completely in Python. It supports several advanced features not found in other

implementations like stackless support and a Just in Time compiler. One of the goals of the project is to encourage experimentation with the language itself by making it easier to modify the interpreter (since it is written in Python). Additional information is available on [the PyPy project's home page](#).

Each of these implementations varies in some way from the language as documented in this manual, or introduces specific information beyond what's covered in the standard Python documentation. Please refer to the implementation-specific documentation to determine what else you need to know about the specific implementation you're using.

1.2. Notation

The descriptions of lexical analysis and syntax use a modified BNF grammar notation. This uses the following style of definition:

```
name      ::= lc_letter (lc_letter | "_")*  
lc_letter ::= "a"..."z"
```

The first line says that a `name` is an `lc_letter` followed by a sequence of zero or more `lc_letters` and underscores. An `lc_letter` in turn is any of the single characters 'a' through 'z'. (This rule is actually adhered to for the names defined in lexical and grammar rules in this document.)

Each rule begins with a name (which is the name defined by the rule) and `::=`. A vertical bar (`|`) is used to separate alternatives; it is the least binding operator in this notation. A star (`*`) means zero or more repetitions of the preceding item; likewise, a plus (`+`) means one or more repetitions, and a phrase enclosed in square brackets (`[]`) means zero or one occurrences (in other words, the enclosed phrase is optional). The `*` and `+` operators bind as tightly as possible; parentheses are used for grouping. Literal strings are enclosed in quotes. White space is only meaningful to separate tokens. Rules are normally contained on a single line; rules with many alternatives may be formatted alternatively with each line after the first beginning with a vertical bar.

In lexical definitions (as the example above), two more conventions are used: Two literal characters separated by three dots mean a choice of any single character in the given (inclusive) range of ASCII characters. A phrase between angular brackets (`<...>`) gives an informal description of the symbol defined; e.g., this could be used to describe the notion of 'control character' if needed.

Even though the notation used is almost the same, there is a big difference between the meaning of lexical and syntactic definitions: a lexical definition operates on the individual characters of the input source, while a syntax definition operates on the stream of tokens generated by the lexical analysis. All uses of BNF in the next chapter (“Lexical Analysis”) are lexical definitions; uses in subsequent chapters are syntactic definitions.

2. Lexical analysis

A Python program is read by a *parser*. Input to the parser is a stream of *tokens*, generated by the *lexical analyzer*. This chapter describes how the lexical analyzer breaks a file into tokens.

Python reads program text as Unicode code points; the encoding of a source file can be given by an encoding declaration and defaults to UTF-8, see [PEP 3120](#) for details. If the source file cannot be decoded, a `SyntaxError` is raised.

2.1. Line structure

A Python program is divided into a number of *logical lines*.

2.1.1. Logical lines

The end of a logical line is represented by the token NEWLINE. Statements cannot cross logical line boundaries except where NEWLINE is allowed by the syntax (e.g., between statements in compound statements). A logical line is constructed from one or more *physical lines* by following the explicit or implicit *line joining* rules.

2.1.2. Physical lines

A physical line is a sequence of characters terminated by an end-of-line sequence. In source files, any of the standard platform line termination sequences can be used - the Unix form using ASCII LF (linefeed), the Windows form using the ASCII sequence CR LF (return followed by linefeed), or the old Macintosh form using the ASCII CR (return) character. All of these forms can be used equally, regardless of platform.

When embedding Python, source code strings should be passed to Python APIs using the standard C conventions for newline characters (the `\n` character, representing ASCII LF, is the line terminator).

2.1.3. Comments

A comment starts with a hash character (`#`) that is not part of a string literal, and ends at the end of the physical line. A comment signifies the end of the logical line unless the implicit line joining rules are

invoked. Comments are ignored by the syntax; they are not tokens.

2.1.4. Encoding declarations

If a comment in the first or second line of the Python script matches the regular expression `coding[=:]\s*([-\\w.]+)`, this comment is processed as an encoding declaration; the first group of this expression names the encoding of the source code file. The recommended forms of this expression are

```
# -*- coding: <encoding-name> -*-
```

which is recognized also by GNU Emacs, and

```
# vim:fileencoding=<encoding-name>
```

which is recognized by Bram Moolenaar's VIM.

If no encoding declaration is found, the default encoding is UTF-8. In addition, if the first bytes of the file are the UTF-8 byte-order mark (`b'\xef\xbb\xbf'`), the declared file encoding is UTF-8 (this is supported, among others, by Microsoft's **notepad**).

If an encoding is declared, the encoding name must be recognized by Python. The encoding is used for all lexical analysis, including string literals, comments and identifiers. The encoding declaration must appear on a line of its own.

2.1.5. Explicit line joining

Two or more physical lines may be joined into logical lines using backslash characters (`\`), as follows: when a physical line ends in a backslash that is not part of a string literal or comment, it is joined with the following forming a single logical line, deleting the backslash and the following end-of-line character. For example:

```
if 1900 < year < 2100 and 1 <= month <= 12 \  
    and 1 <= day <= 31 and 0 <= hour < 24 \  
    and 0 <= minute < 60 and 0 <= second < 60:    # Looks like a  
    return 1
```

A line ending in a backslash cannot carry a comment. A backslash does not continue a comment. A backslash does not continue a token except for string literals (i.e., tokens other than string literals cannot be split across physical lines using a backslash). A backslash is illegal elsewhere on a line outside a string literal.

2.1.6. Implicit line joining

Expressions in parentheses, square brackets or curly braces can be split over more than one physical line without using backslashes. For example:

```
month_names = ['Januari', 'Februari', 'Maart',      # These are  
              'April',   'Mei',      'Juni',      # Dutch nam  
              'Juli',    'Augustus', 'September', # for the m  
              'Oktober', 'November', 'December'] # of the ye
```

Implicitly continued lines can carry comments. The indentation of the continuation lines is not important. Blank continuation lines are allowed. There is no NEWLINE token between implicit continuation lines. Implicitly continued lines can also occur within triple-quoted strings (see below); in that case they cannot carry comments.

2.1.7. Blank lines

A logical line that contains only spaces, tabs, formfeeds and possibly a comment, is ignored (i.e., no NEWLINE token is generated). During interactive input of statements, handling of a blank line may differ depending on the implementation of the read-eval-print loop. In the standard interactive interpreter, an entirely blank logical line (i.e.

one containing not even whitespace or a comment) terminates a multi-line statement.

2.1.8. Indentation

Leading whitespace (spaces and tabs) at the beginning of a logical line is used to compute the indentation level of the line, which in turn is used to determine the grouping of statements.

Tabs are replaced (from left to right) by one to eight spaces such that the total number of characters up to and including the replacement is a multiple of eight (this is intended to be the same rule as used by Unix). The total number of spaces preceding the first non-blank character then determines the line's indentation. Indentation cannot be split over multiple physical lines using backslashes; the whitespace up to the first backslash determines the indentation.

Indentation is rejected as inconsistent if a source file mixes tabs and spaces in a way that makes the meaning dependent on the worth of a tab in spaces; a `TabError` is raised in that case.

Cross-platform compatibility note: because of the nature of text editors on non-UNIX platforms, it is unwise to use a mixture of spaces and tabs for the indentation in a single source file. It should also be noted that different platforms may explicitly limit the maximum indentation level.

A formfeed character may be present at the start of the line; it will be ignored for the indentation calculations above. Formfeed characters occurring elsewhere in the leading whitespace have an undefined effect (for instance, they may reset the space count to zero).

The indentation levels of consecutive lines are used to generate INDENT and DEDENT tokens, using a stack, as follows.

Before the first line of the file is read, a single zero is pushed on the stack; this will never be popped off again. The numbers pushed on the stack will always be strictly increasing from bottom to top. At the beginning of each logical line, the line's indentation level is compared to the top of the stack. If it is equal, nothing happens. If it is larger, it is pushed on the stack, and one INDENT token is generated. If it is smaller, it *must* be one of the numbers occurring on the stack; all numbers on the stack that are larger are popped off, and for each number popped off a DEDENT token is generated. At the end of the file, a DEDENT token is generated for each number remaining on the stack that is larger than zero.

Here is an example of a correctly (though confusingly) indented piece of Python code:

```
def perm(l):
    # Compute the list of all permutations of l
    if len(l) <= 1:
        return [l]
    r = []
    for i in range(len(l)):
        s = l[:i] + l[i+1:]
        p = perm(s)
        for x in p:
            r.append(l[i:i+1] + x)
    return r
```

The following example shows various indentation errors:

```
def perm(l):
for i in range(len(l)):
    s = l[:i] + l[i+1:]
    p = perm(l[:i] + l[i+1:])
    for x in p:
        r.append(l[i:i+1] + x)
    return r
```

error: first line indented
error: not indented
error: unexpected indent
error: inconsistent dedent

(Actually, the first three errors are detected by the parser; only the

last error is found by the lexical analyzer — the indentation of `return` `r` does not match a level popped off the stack.)

2.1.9. Whitespace between tokens

Except at the beginning of a logical line or in string literals, the whitespace characters space, tab and formfeed can be used interchangeably to separate tokens. Whitespace is needed between two tokens only if their concatenation could otherwise be interpreted as a different token (e.g., `ab` is one token, but `a b` is two tokens).

2.2. Other tokens

Besides NEWLINE, INDENT and DEDENT, the following categories of tokens exist: *identifiers*, *keywords*, *literals*, *operators*, and *delimiters*. Whitespace characters (other than line terminators, discussed earlier) are not tokens, but serve to delimit tokens. Where ambiguity exists, a token comprises the longest possible string that forms a legal token, when read from left to right.

2.3. Identifiers and keywords

Identifiers (also referred to as *names*) are described by the following lexical definitions.

The syntax of identifiers in Python is based on the Unicode standard annex UAX-31, with elaboration and changes as defined below; see also [PEP 3131](#) for further details.

Within the ASCII range (U+0001..U+007F), the valid characters for identifiers are the same as in Python 2.x: the uppercase and lowercase letters `A` through `z`, the underscore `_` and, except for the first character, the digits `0` through `9`.

Python 3.0 introduces additional characters from outside the ASCII range (see [PEP 3131](#)). For these characters, the classification uses the version of the Unicode Character Database as included in the `unicodedata` module.

Identifiers are unlimited in length. Case is significant.

```
identifier ::= xid_start xid_continue*
id_start   ::= <all characters in general categories Lu, Ll,
id_continue ::= <all characters in id_start, plus characters
xid_start  ::= <all characters in id_start whose NFKC normal
xid_continue ::= <all characters in id_continue whose NFKC nor
```

The Unicode category codes mentioned above stand for:

- *Lu* - uppercase letters
- *Ll* - lowercase letters
- *Lt* - titlecase letters
- *Lm* - modifier letters
- *Lo* - other letters

- *Nl* - letter numbers
- *Mn* - nonspacing marks
- *Mc* - spacing combining marks
- *Nd* - decimal numbers
- *Pc* - connector punctuations
- *Other_ID_Start* - explicit list of characters in [PropList.txt](#) to support backwards compatibility
- *Other_ID_Continue* - likewise

All identifiers are converted into the normal form NFKC while parsing; comparison of identifiers is based on NFKC.

A non-normative HTML file listing all valid identifier characters for Unicode 4.1 can be found at <http://www.dcl.hpi.uni-potsdam.de/home/loewis/table-3131.html>.

2.3.1. Keywords

The following identifiers are used as reserved words, or *keywords* of the language, and cannot be used as ordinary identifiers. They must be spelled exactly as written here:

False	class	finally	is	return
None	continue	for	lambda	try
True	def	from	nonlocal	while
and	del	global	not	with
as	elif	if	or	yield
assert	else	import	pass	
break	except	in	raise	

2.3.2. Reserved classes of identifiers

Certain classes of identifiers (besides keywords) have special meanings. These classes are identified by the patterns of leading and trailing underscore characters:

`_*`

Not imported by `from module import *`. The special identifier `_` is used in the interactive interpreter to store the result of the last evaluation; it is stored in the `builtins` module. When not in interactive mode, `_` has no special meaning and is not defined. See section *The import statement*.

Note: The name `_` is often used in conjunction with internationalization; refer to the documentation for the `gettext` module for more information on this convention.

`__*`

System-defined names. These names are defined by the interpreter and its implementation (including the standard library). Current system names are discussed in the *Special method names* section and elsewhere. More will likely be defined in future versions of Python. Any use of `__*` names, in any context, that does not follow explicitly documented use, is subject to breakage without warning.

`__*`

Class-private names. Names in this category, when used within the context of a class definition, are re-written to use a mangled form to help avoid name clashes between “private” attributes of base and derived classes. See section *Identifiers (Names)*.

2.4. Literals

Literals are notations for constant values of some built-in types.

2.4.1. String and Bytes literals

String literals are described by the following lexical definitions:

```
stringliteral ::= [stringprefix](shortstring | longstring)
stringprefix ::= "r" | "R"
shortstring  ::= "'" shortstringitem* "'" | '"' shortstring
longstring   ::= "'" longstringitem* "'" | '"' longst
shortstringitem ::= shortstringchar | stringescapeseq
longstringitem  ::= longstringchar | stringescapeseq
shortstringchar ::= <any source character except "\" or newlin
longstringchar  ::= <any source character except "\">
stringescapeseq ::= "\" <any source character>
```

```
bytesliteral ::= bytesprefix(shortbytes | longbytes)
bytesprefix  ::= "b" | "B" | "br" | "Br" | "bR" | "BR"
shortbytes   ::= "'" shortbytesitem* "'" | '"' shortbytesite
longbytes    ::= "'" longbytesitem* "'" | '"' longbyte
shortbytesitem ::= shortbyteschar | bytesescapeseq
longbytesitem  ::= longbyteschar | bytesescapeseq
shortbyteschar ::= <any ASCII character except "\" or newline
longbyteschar  ::= <any ASCII character except "\">
bytesescapeseq ::= "\" <any ASCII character>
```

One syntactic restriction not indicated by these productions is that whitespace is not allowed between the `stringprefix` or `bytesprefix` and the rest of the literal. The source character set is defined by the encoding declaration; it is UTF-8 if no encoding declaration is given in the source file; see section [Encoding declarations](#).

In plain English: Both types of literals can be enclosed in matching single quotes (') or double quotes ("). They can also be enclosed in

matching groups of three single or double quotes (these are generally referred to as *triple-quoted strings*). The backslash (`\`) character is used to escape characters that otherwise have a special meaning, such as newline, backslash itself, or the quote character.

Bytes literals are always prefixed with `'b'` or `'B'`; they produce an instance of the `bytes` type instead of the `str` type. They may only contain ASCII characters; bytes with a numeric value of 128 or greater must be expressed with escapes.

Both string and bytes literals may optionally be prefixed with a letter `'r'` or `'R'`; such strings are called *raw strings* and treat backslashes as literal characters. As a result, in string literals, `'\u'` and `'\u'` escapes in raw strings are not treated specially.

In triple-quoted strings, unescaped newlines and quotes are allowed (and are retained), except that three unescaped quotes in a row terminate the string. (A “quote” is the character used to open the string, i.e. either `'` or `"`.)

Unless an `'r'` or `'R'` prefix is present, escape sequences in strings are interpreted according to rules similar to those used by Standard C. The recognized escape sequences are:

Escape Sequence	Meaning	Notes
<code>\newline</code>	Backslash and newline ignored	
<code>\\</code>	Backslash (<code>\</code>)	
<code>\'</code>	Single quote (<code>'</code>)	
<code>\"</code>	Double quote (<code>"</code>)	
<code>\a</code>	ASCII Bell (BEL)	
<code>\b</code>	ASCII Backspace (BS)	
<code>\f</code>	ASCII Formfeed (FF)	
<code>\n</code>	ASCII Linefeed (LF)	
<code>\r</code>	ASCII Carriage Return (CR)	

<code>\t</code>	ASCII Horizontal Tab (TAB)	
<code>\v</code>	ASCII Vertical Tab (VT)	
<code>\ooo</code>	Character with octal value <i>ooo</i>	(1,3)
<code>\xhh</code>	Character with hex value <i>hh</i>	(2,3)

Escape sequences only recognized in string literals are:

Escape Sequence	Meaning	Notes
<code>\N{name}</code>	Character named <i>name</i> in the Unicode database	
<code>\uxxxx</code>	Character with 16-bit hex value <i>xxxx</i>	(4)
<code>\Uxxxxxxxx</code>	Character with 32-bit hex value <i>xxxxxxxx</i>	(5)

Notes:

1. As in Standard C, up to three octal digits are accepted.
2. Unlike in Standard C, exactly two hex digits are required.
3. In a bytes literal, hexadecimal and octal escapes denote the byte with the given value. In a string literal, these escapes denote a Unicode character with the given value.
4. Individual code units which form parts of a surrogate pair can be encoded using this escape sequence. Exactly four hex digits are required.
5. Any Unicode character can be encoded this way, but characters outside the Basic Multilingual Plane (BMP) will be encoded using a surrogate pair if Python is compiled to use 16-bit code units (the default). Exactly eight hex digits are required.

Unlike Standard C, all unrecognized escape sequences are left in the string unchanged, i.e., *the backslash is left in the string*. (This behavior is useful when debugging: if an escape sequence is mistyped, the resulting output is more easily recognized as broken.) It is also important to note that the escape sequences only recognized in string literals fall into the category of unrecognized

escapes for bytes literals.

Even in a raw string, string quotes can be escaped with a backslash, but the backslash remains in the string; for example, `r"\"` is a valid string literal consisting of two characters: a backslash and a double quote; `r"\` is not a valid string literal (even a raw string cannot end in an odd number of backslashes). Specifically, *a raw string cannot end in a single backslash* (since the backslash would escape the following quote character). Note also that a single backslash followed by a newline is interpreted as those two characters as part of the string, *not* as a line continuation.

2.4.2. String literal concatenation

Multiple adjacent string or bytes literals (delimited by whitespace), possibly using different quoting conventions, are allowed, and their meaning is the same as their concatenation. Thus, `"hello" 'world'` is equivalent to `"hello world"`. This feature can be used to reduce the number of backslashes needed, to split long strings conveniently across long lines, or even to add comments to parts of strings, for example:

```
re.compile("[A-Za-z_]"          # letter or underscore
           "[A-Za-z0-9_]*"      # letter, digit or underscore
           )
```

Note that this feature is defined at the syntactical level, but implemented at compile time. The '+' operator must be used to concatenate string expressions at run time. Also note that literal concatenation can use different quoting styles for each component (even mixing raw strings and triple quoted strings).

2.4.3. Numeric literals

There are three types of numeric literals: integers, floating point

numbers, and imaginary numbers. There are no complex literals (complex numbers can be formed by adding a real number and an imaginary number).

Note that numeric literals do not include a sign; a phrase like `-1` is actually an expression composed of the unary operator `'-'` and the literal `1`.

2.4.4. Integer literals

Integer literals are described by the following lexical definitions:

```
integer      ::= decimalinteger | octinteger | hexinteger |
decimalinteger ::= nonzerodigit digit* | "0"+
nonzerodigit ::= "1"..."9"
digit        ::= "0"..."9"
octinteger   ::= "0" ("o" | "O") octdigit+
hexinteger   ::= "0" ("x" | "X") hexdigit+
bininteger   ::= "0" ("b" | "B") bindigit+
octdigit     ::= "0"..."7"
hexdigit     ::= digit | "a"..."f" | "A"..."F"
bindigit     ::= "0" | "1"
```

There is no limit for the length of integer literals apart from what can be stored in available memory.

Note that leading zeros in a non-zero decimal number are not allowed. This is for disambiguation with C-style octal literals, which Python used before version 3.0.

Some examples of integer literals:

7	2147483647	0o177	0b100110111
3	79228162514264337593543950336	0o377	0x100000000
	79228162514264337593543950336		0xdeadbeef

2.4.5. Floating point literals

Floating point literals are described by the following lexical definitions:

```
floatnumber ::= pointfloat | exponentfloat
pointfloat  ::= [intpart] fraction | intpart "."
exponentfloat ::= (intpart | pointfloat) exponent
intpart     ::= digit+
fraction    ::= "." digit+
exponent    ::= ("e" | "E") ["+" | "-"] digit+
```

Note that the integer and exponent parts are always interpreted using radix 10. For example, `077e010` is legal, and denotes the same number as `77e10`. The allowed range of floating point literals is implementation-dependent. Some examples of floating point literals:

```
3.14    10.    .001    1e100    3.14e-10    0e0
```

Note that numeric literals do not include a sign; a phrase like `-1` is actually an expression composed of the unary operator `-` and the literal `1`.

2.4.6. Imaginary literals

Imaginary literals are described by the following lexical definitions:

```
imagnumber ::= (floatnumber | intpart) ("j" | "J")
```

An imaginary literal yields a complex number with a real part of 0.0. Complex numbers are represented as a pair of floating point numbers and have the same restrictions on their range. To create a complex number with a nonzero real part, add a floating point number to it, e.g., `(3+4j)`. Some examples of imaginary literals:

```
3.14j    10.j    10j    .001j    1e100j    3.14e-10j
```

2.5. Operators

The following tokens are operators:

+	-	*	**	/	//	%
<<	>>	&		^	~	
<	>	<=	>=	==	!=	

2.6. Delimiters

The following tokens serve as delimiters in the grammar:

```
(      )      [      ]      {      }  
,      :      .      ;      @      =  
+=     -=     *=     /=     //=    %=  
&=    |=     ^=     >>=   <<=    **=
```

The period can also occur in floating-point and imaginary literals. A sequence of three periods has a special meaning as an ellipsis literal. The second half of the list, the augmented assignment operators, serve lexically as delimiters, but also perform an operation.

The following printing ASCII characters have special meaning as part of other tokens or are otherwise significant to the lexical analyzer:

```
'      "      #      \
```

The following printing ASCII characters are not used in Python. Their occurrence outside string literals and comments is an unconditional error:

```
$      ?      `
```

3. Data model

3.1. Objects, values and types

Objects are Python's abstraction for data. All data in a Python program is represented by objects or by relations between objects. (In a sense, and in conformance to Von Neumann's model of a "stored program computer," code is also represented by objects.)

Every object has an identity, a type and a value. An object's *identity* never changes once it has been created; you may think of it as the object's address in memory. The `'is'` operator compares the identity of two objects; the `id()` function returns an integer representing its identity (currently implemented as its address). An object's *type* is also unchangeable. [1] An object's type determines the operations that the object supports (e.g., "does it have a length?") and also defines the possible values for objects of that type. The `type()` function returns an object's type (which is an object itself). The *value* of some objects can change. Objects whose value can change are said to be *mutable*; objects whose value is unchangeable once they are created are called *immutable*. (The value of an immutable container object that contains a reference to a mutable object can change when the latter's value is changed; however the container is still considered immutable, because the collection of objects it contains cannot be changed. So, immutability is not strictly the same as having an unchangeable value, it is more subtle.) An object's mutability is determined by its type; for instance, numbers, strings and tuples are immutable, while dictionaries and lists are mutable.

Objects are never explicitly destroyed; however, when they become unreachable they may be garbage-collected. An implementation is allowed to postpone garbage collection or omit it altogether — it is a matter of implementation quality how garbage collection is implemented, as long as no objects are collected that are still reachable.

CPython implementation detail: CPython currently uses a reference-counting scheme with (optional) delayed detection of cyclically linked garbage, which collects most objects as soon as they become unreachable, but is not guaranteed to collect garbage containing circular references. See the documentation of the `gc` module for information on controlling the collection of cyclic garbage. Other implementations act differently and CPython may change.

Note that the use of the implementation's tracing or debugging facilities may keep objects alive that would normally be collectable. Also note that catching an exception with a `try...except` statement may keep objects alive.

Some objects contain references to “external” resources such as open files or windows. It is understood that these resources are freed when the object is garbage-collected, but since garbage collection is not guaranteed to happen, such objects also provide an explicit way to release the external resource, usually a `close()` method. Programs are strongly recommended to explicitly close such objects. The `try...finally` statement and the `with` statement provide convenient ways to do this.

Some objects contain references to other objects; these are called *containers*. Examples of containers are tuples, lists and dictionaries. The references are part of a container's value. In most cases, when we talk about the value of a container, we imply the values, not the identities of the contained objects; however, when we talk about the mutability of a container, only the identities of the immediately contained objects are implied. So, if an immutable container (like a tuple) contains a reference to a mutable object, its value changes if that mutable object is changed.

Types affect almost all aspects of object behavior. Even the importance of object identity is affected in some sense: for immutable types, operations that compute new values may actually return a reference to any existing object with the same type and value, while for mutable objects this is not allowed. E.g., after `a = 1;`
`b = 1,` `a` and `b` may or may not refer to the same object with the value one, depending on the implementation, but after `c = [];`
`d = [],` `c` and `d` are guaranteed to refer to two different, unique, newly created empty lists. (Note that `c = d = []` assigns the same object to both `c` and `d`.)

3.2. The standard type hierarchy

Below is a list of the types that are built into Python. Extension modules (written in C, Java, or other languages, depending on the implementation) can define additional types. Future versions of Python may add types to the type hierarchy (e.g., rational numbers, efficiently stored arrays of integers, etc.), although such additions will often be provided via the standard library instead.

Some of the type descriptions below contain a paragraph listing ‘special attributes.’ These are attributes that provide access to the implementation and are not intended for general use. Their definition may change in the future.

None

This type has a single value. There is a single object with this value. This object is accessed through the built-in name `None`. It is used to signify the absence of a value in many situations, e.g., it is returned from functions that don’t explicitly return anything. Its truth value is false.

NotImplemented

This type has a single value. There is a single object with this value. This object is accessed through the built-in name `NotImplemented`. Numeric methods and rich comparison methods may return this value if they do not implement the operation for the operands provided. (The interpreter will then try the reflected operation, or some other fallback, depending on the operator.) Its truth value is true.

Ellipsis

This type has a single value. There is a single object with this value. This object is accessed through the literal `...` or the built-

in name `Ellipsis`. Its truth value is true.

`numbers.Number`

These are created by numeric literals and returned as results by arithmetic operators and arithmetic built-in functions. Numeric objects are immutable; once created their value never changes. Python numbers are of course strongly related to mathematical numbers, but subject to the limitations of numerical representation in computers.

Python distinguishes between integers, floating point numbers, and complex numbers:

`numbers.Integral`

These represent elements from the mathematical set of integers (positive and negative).

There are two types of integers:

Integers (`int`)

These represent numbers in an unlimited range, subject to available (virtual) memory only. For the purpose of shift and mask operations, a binary representation is assumed, and negative numbers are represented in a variant of 2's complement which gives the illusion of an infinite string of sign bits extending to the left.

Booleans (`bool`)

These represent the truth values False and True. The two objects representing the values False and True are the only Boolean objects. The Boolean type is a subtype of the integer type, and Boolean values behave like the values 0 and 1, respectively, in almost all contexts, the exception being that when converted to a string, the strings `"False"`

or `"True"` are returned, respectively.

The rules for integer representation are intended to give the most meaningful interpretation of shift and mask operations involving negative integers.

`numbers.Real (float)`

These represent machine-level double precision floating point numbers. You are at the mercy of the underlying machine architecture (and C or Java implementation) for the accepted range and handling of overflow. Python does not support single-precision floating point numbers; the savings in processor and memory usage that are usually the reason for using these is dwarfed by the overhead of using objects in Python, so there is no reason to complicate the language with two kinds of floating point numbers.

`numbers.Complex (complex)`

These represent complex numbers as a pair of machine-level double precision floating point numbers. The same caveats apply as for floating point numbers. The real and imaginary parts of a complex number `z` can be retrieved through the read-only attributes `z.real` and `z.imag`.

Sequences

These represent finite ordered sets indexed by non-negative numbers. The built-in function `len()` returns the number of items of a sequence. When the length of a sequence is n , the index set contains the numbers $0, 1, \dots, n-1$. Item i of sequence `a` is selected by `a[i]`.

Sequences also support slicing: `a[i:j]` selects all items with index k such that $i \leq k < j$. When used as an expression, a slice is a sequence of the same type. This implies that the index set is

renumbered so that it starts at 0.

Some sequences also support “extended slicing” with a third “step” parameter: `a[i:j:k]` selects all items of `a` with index `x` where `x = i + n*k`, `n >= 0` and `i <= x < j`.

Sequences are distinguished according to their mutability:

Immutable sequences

An object of an immutable sequence type cannot change once it is created. (If the object contains references to other objects, these other objects may be mutable and may be changed; however, the collection of objects directly referenced by an immutable object cannot change.)

The following types are immutable sequences:

Strings

The items of a string object are Unicode code units. A Unicode code unit is represented by a string object of one item and can hold either a 16-bit or 32-bit value representing a Unicode ordinal (the maximum value for the ordinal is given in `sys.maxunicode`, and depends on how Python is configured at compile time). Surrogate pairs may be present in the Unicode object, and will be reported as two separate items. The built-in functions `chr()` and `ord()` convert between code units and nonnegative integers representing the Unicode ordinals as defined in the Unicode Standard 3.0. Conversion from and to other encodings are possible through the string method `encode()`.

Tuples

The items of a tuple are arbitrary Python objects. Tuples of two or more items are formed by comma-separated lists of

expressions. A tuple of one item (a 'singleton') can be formed by affixing a comma to an expression (an expression by itself does not create a tuple, since parentheses must be usable for grouping of expressions). An empty tuple can be formed by an empty pair of parentheses.

Bytes

A bytes object is an immutable array. The items are 8-bit bytes, represented by integers in the range $0 \leq x < 256$. Bytes literals (like `b'abc'` and the built-in function `bytes()`) can be used to construct bytes objects. Also, bytes objects can be decoded to strings via the `decode()` method.

Mutable sequences

Mutable sequences can be changed after they are created. The subscription and slicing notations can be used as the target of assignment and `del` (delete) statements.

There are currently two intrinsic mutable sequence types:

Lists

The items of a list are arbitrary Python objects. Lists are formed by placing a comma-separated list of expressions in square brackets. (Note that there are no special cases needed to form lists of length 0 or 1.)

Byte Arrays

A bytearray object is a mutable array. They are created by the built-in `bytearray()` constructor. Aside from being mutable (and hence unhashable), byte arrays otherwise provide the same interface and functionality as immutable bytes objects.

The extension module `array` provides an additional example of a mutable sequence type, as does the `collections` module.

Set types

These represent unordered, finite sets of unique, immutable objects. As such, they cannot be indexed by any subscript. However, they can be iterated over, and the built-in function `len()` returns the number of items in a set. Common uses for sets are fast membership testing, removing duplicates from a sequence, and computing mathematical operations such as intersection, union, difference, and symmetric difference.

For set elements, the same immutability rules apply as for dictionary keys. Note that numeric types obey the normal rules for numeric comparison: if two numbers compare equal (e.g., `1` and `1.0`), only one of them can be contained in a set.

There are currently two intrinsic set types:

Sets

These represent a mutable set. They are created by the built-in `set()` constructor and can be modified afterwards by several methods, such as `add()`.

Frozen sets

These represent an immutable set. They are created by the built-in `frozenset()` constructor. As a frozenset is immutable and *hashable*, it can be used again as an element of another set, or as a dictionary key.

Mappings

These represent finite sets of objects indexed by arbitrary index sets. The subscript notation `a[k]` selects the item indexed by `k` from the mapping `a`; this can be used in expressions and as the

target of assignments or `del` statements. The built-in function `len()` returns the number of items in a mapping.

There is currently a single intrinsic mapping type:

Dictionaries

These represent finite sets of objects indexed by nearly arbitrary values. The only types of values not acceptable as keys are values containing lists or dictionaries or other mutable types that are compared by value rather than by object identity, the reason being that the efficient implementation of dictionaries requires a key's hash value to remain constant. Numeric types used for keys obey the normal rules for numeric comparison: if two numbers compare equal (e.g., `1` and `1.0`) then they can be used interchangeably to index the same dictionary entry.

Dictionaries are mutable; they can be created by the `{...}` notation (see section *Dictionary displays*).

The extension modules `dbm.ndbm` and `dbm.gnu` provide additional examples of mapping types, as does the `collections` module.

Callable types

These are the types to which the function call operation (see section *Calls*) can be applied:

User-defined functions

A user-defined function object is created by a function definition (see section *Function definitions*). It should be called with an argument list containing the same number of items as the function's formal parameter list.

Special attributes:

Attribute	Meaning	
<code>__doc__</code>	The function's documentation string, or None if unavailable	Writable
<code>__name__</code>	The function's name	Writable
<code>__module__</code>	The name of the module the function was defined in, or None if unavailable.	Writable
<code>__defaults__</code>	A tuple containing default argument values for those arguments that have defaults, or None if no arguments have a default value	Writable
<code>__code__</code>	The code object representing the compiled function body.	Writable
<code>__globals__</code>	A reference to the dictionary that holds the function's global variables — the global namespace of the module in which the function was defined.	Read-only
<code>__dict__</code>	The namespace supporting arbitrary function attributes.	Writable
<code>__closure__</code>	None or a tuple of cells that contain bindings for the function's free variables.	Read-only
<code>__annotations__</code>	A dict containing annotations of parameters. The keys of the dict are the parameter names, or 'return' for the return annotation, if provided.	Writable
<code>__kwdefaults__</code>	A dict containing defaults for keyword-only	Writable

parameters.

Most of the attributes labelled “Writable” check the type of the assigned value.

Function objects also support getting and setting arbitrary attributes, which can be used, for example, to attach metadata to functions. Regular attribute dot-notation is used to get and set such attributes. *Note that the current implementation only supports function attributes on user-defined functions. Function attributes on built-in functions may be supported in the future.*

Additional information about a function’s definition can be retrieved from its code object; see the description of internal types below.

Instance methods

An instance method object combines a class, a class instance and any callable object (normally a user-defined function).

Special read-only attributes: `__self__` is the class instance object, `__func__` is the function object; `__doc__` is the method’s documentation (same as `__func__.__doc__`); `__name__` is the method name (same as `__func__.__name__`); `__module__` is the name of the module the method was defined in, or `None` if unavailable.

Methods also support accessing (but not setting) the arbitrary function attributes on the underlying function object.

User-defined method objects may be created when getting an attribute of a class (perhaps via an instance of that class), if that attribute is a user-defined function object or a class method object.

When an instance method object is created by retrieving a user-defined function object from a class via one of its instances, its `__self__` attribute is the instance, and the method object is said to be bound. The new method's `__func__` attribute is the original function object.

When a user-defined method object is created by retrieving another method object from a class or instance, the behaviour is the same as for a function object, except that the `__func__` attribute of the new instance is not the original method object but its `__func__` attribute.

When an instance method object is created by retrieving a class method object from a class or instance, its `__self__` attribute is the class itself, and its `__func__` attribute is the function object underlying the class method.

When an instance method object is called, the underlying function (`__func__`) is called, inserting the class instance (`__self__`) in front of the argument list. For instance, when `c` is a class which contains a definition for a function `f()`, and `x` is an instance of `c`, calling `x.f(1)` is equivalent to calling `c.f(x, 1)`.

When an instance method object is derived from a class method object, the “class instance” stored in `__self__` will actually be the class itself, so that calling either `x.f(1)` or `c.f(1)` is equivalent to calling `f(c,1)` where `f` is the underlying function.

Note that the transformation from function object to instance method object happens each time the attribute is retrieved from the instance. In some cases, a fruitful optimization is to assign the attribute to a local variable and call that local

variable. Also notice that this transformation only happens for user-defined functions; other callable objects (and all non-callable objects) are retrieved without transformation. It is also important to note that user-defined functions which are attributes of a class instance are not converted to bound methods; this *only* happens when the function is an attribute of the class.

Generator functions

A function or method which uses the `yield` statement (see section *The yield statement*) is called a *generator function*. Such a function, when called, always returns an iterator object which can be used to execute the body of the function: calling the iterator's `__next__()` method will cause the function to execute until it provides a value using the `yield` statement. When the function executes a `return` statement or falls off the end, a `StopIteration` exception is raised and the iterator will have reached the end of the set of values to be returned.

Built-in functions

A built-in function object is a wrapper around a C function. Examples of built-in functions are `len()` and `math.sin()` (`math` is a standard built-in module). The number and type of the arguments are determined by the C function. Special read-only attributes: `__doc__` is the function's documentation string, or `None` if unavailable; `__name__` is the function's name; `__self__` is set to `None` (but see the next item); `__module__` is the name of the module the function was defined in or `None` if unavailable.

Built-in methods

This is really a different disguise of a built-in function, this time containing an object passed to the C function as an implicit

extra argument. An example of a built-in method is `alist.append()`, assuming `alist` is a list object. In this case, the special read-only attribute `__self__` is set to the object denoted by `alist`.

Classes

Classes are callable. These objects normally act as factories for new instances of themselves, but variations are possible for class types that override `__new__()`. The arguments of the call are passed to `__new__()` and, in the typical case, to `__init__()` to initialize the new instance.

Class Instances

Instances of arbitrary classes can be made callable by defining a `__call__()` method in their class.

Modules

Modules are imported by the `import` statement (see section *The import statement*). A module object has a namespace implemented by a dictionary object (this is the dictionary referenced by the `__globals__` attribute of functions defined in the module). Attribute references are translated to lookups in this dictionary, e.g., `m.x` is equivalent to `m.__dict__["x"]`. A module object does not contain the code object used to initialize the module (since it isn't needed once the initialization is done).

Attribute assignment updates the module's namespace dictionary, e.g., `m.x = 1` is equivalent to `m.__dict__["x"] = 1`.

Special read-only attribute: `__dict__` is the module's namespace as a dictionary object.

CPython implementation detail: Because of the way CPython clears module dictionaries, the module dictionary will be

cleared when the module falls out of scope even if the dictionary still has live references. To avoid this, copy the dictionary or keep the module around while using its dictionary directly.

Predefined (writable) attributes: `__name__` is the module's name; `__doc__` is the module's documentation string, or `None` if unavailable; `__file__` is the pathname of the file from which the module was loaded, if it was loaded from a file. The `__file__` attribute is not present for C modules that are statically linked into the interpreter; for extension modules loaded dynamically from a shared library, it is the pathname of the shared library file.

Custom classes

Custom class types are typically created by class definitions (see section [Class definitions](#)). A class has a namespace implemented by a dictionary object. Class attribute references are translated to lookups in this dictionary, e.g., `c.x` is translated to `c.__dict__["x"]` (although there are a number of hooks which allow for other means of locating attributes). When the attribute name is not found there, the attribute search continues in the base classes. This search of the base classes uses the C3 method resolution order which behaves correctly even in the presence of 'diamond' inheritance structures where there are multiple inheritance paths leading back to a common ancestor. Additional details on the C3 MRO used by Python can be found in the documentation accompanying the 2.3 release at <http://www.python.org/download/releases/2.3/mro/>.

When a class attribute reference (for class `c`, say) would yield a class method object, it is transformed into an instance method object whose `__self__` attribute is `c`. When it would yield a static method object, it is transformed into the object wrapped by the

static method object. See section *Implementing Descriptors* for another way in which attributes retrieved from a class may differ from those actually contained in its `__dict__`.

Class attribute assignments update the class's dictionary, never the dictionary of a base class.

A class object can be called (see above) to yield a class instance (see below).

Special attributes: `__name__` is the class name; `__module__` is the module name in which the class was defined; `__dict__` is the dictionary containing the class's namespace; `__bases__` is a tuple (possibly empty or a singleton) containing the base classes, in the order of their occurrence in the base class list; `__doc__` is the class's documentation string, or None if undefined.

Class instances

A class instance is created by calling a class object (see above). A class instance has a namespace implemented as a dictionary which is the first place in which attribute references are searched. When an attribute is not found there, and the instance's class has an attribute by that name, the search continues with the class attributes. If a class attribute is found that is a user-defined function object, it is transformed into an instance method object whose `__self__` attribute is the instance. Static method and class method objects are also transformed; see above under "Classes". See section *Implementing Descriptors* for another way in which attributes of a class retrieved via its instances may differ from the objects actually stored in the class's `__dict__`. If no class attribute is found, and the object's class has a `__getattr__()` method, that is called to satisfy the lookup.

Attribute assignments and deletions update the instance's

dictionary, never a class's dictionary. If the class has a `__setattr__()` or `__delattr__()` method, this is called instead of updating the instance dictionary directly.

Class instances can pretend to be numbers, sequences, or mappings if they have methods with certain special names. See section *Special method names*.

Special attributes: `__dict__` is the attribute dictionary; `__class__` is the instance's class.

I/O objects (also known as file objects)

A *file object* represents an open file. Various shortcuts are available to create file objects: the `open()` built-in function, and also `os.popen()`, `os.fdopen()`, and the `makefile()` method of socket objects (and perhaps by other functions or methods provided by extension modules).

The objects `sys.stdin`, `sys.stdout` and `sys.stderr` are initialized to file objects corresponding to the interpreter's standard input, output and error streams; they are all open in text mode and therefore follow the interface defined by the `io.TextIOBase` abstract class.

Internal types

A few types used internally by the interpreter are exposed to the user. Their definitions may change with future versions of the interpreter, but they are mentioned here for completeness.

Code objects

Code objects represent *byte-compiled* executable Python code, or *bytecode*. The difference between a code object and a function object is that the function object contains an explicit reference to the function's globals (the module in which it was defined), while a code object contains no context; also the

default argument values are stored in the function object, not in the code object (because they represent values calculated at run-time). Unlike function objects, code objects are immutable and contain no references (directly or indirectly) to mutable objects.

Special read-only attributes: `co_name` gives the function name; `co_argcount` is the number of positional arguments (including arguments with default values); `co_nlocals` is the number of local variables used by the function (including arguments); `co_varnames` is a tuple containing the names of the local variables (starting with the argument names); `co_cellvars` is a tuple containing the names of local variables that are referenced by nested functions; `co_freevars` is a tuple containing the names of free variables; `co_code` is a string representing the sequence of bytecode instructions; `co_consts` is a tuple containing the literals used by the bytecode; `co_names` is a tuple containing the names used by the bytecode; `co_filename` is the filename from which the code was compiled; `co_firstlineno` is the first line number of the function; `co_lnotab` is a string encoding the mapping from bytecode offsets to line numbers (for details see the source code of the interpreter); `co_stacksize` is the required stack size (including local variables); `co_flags` is an integer encoding a number of flags for the interpreter.

The following flag bits are defined for `co_flags`: bit `0x04` is set if the function uses the `*arguments` syntax to accept an arbitrary number of positional arguments; bit `0x08` is set if the function uses the `**keywords` syntax to accept arbitrary keyword arguments; bit `0x20` is set if the function is a generator.

Future feature declarations (`from __future__ import division`) also use bits in `co_flags` to indicate whether a code object was compiled with a particular feature enabled: bit `0x2000` is set if the function was compiled with future division enabled; bits `0x10` and `0x1000` were used in earlier versions of Python.

Other bits in `co_flags` are reserved for internal use.

If a code object represents a function, the first item in `co_consts` is the documentation string of the function, or `None` if undefined.

Frame objects

Frame objects represent execution frames. They may occur in traceback objects (see below).

Special read-only attributes: `f_back` is to the previous stack frame (towards the caller), or `None` if this is the bottom stack frame; `f_code` is the code object being executed in this frame; `f_locals` is the dictionary used to look up local variables; `f_globals` is used for global variables; `f_builtins` is used for built-in (intrinsic) names; `f_lasti` gives the precise instruction (this is an index into the bytecode string of the code object).

Special writable attributes: `f_trace`, if not `None`, is a function called at the start of each source code line (this is used by the debugger); `f_lineno` is the current line number of the frame — writing to this from within a trace function jumps to the given line (only for the bottom-most frame). A debugger can implement a Jump command (aka Set Next Statement) by writing to `f_lineno`.

Traceback objects

Traceback objects represent a stack trace of an exception. A traceback object is created when an exception occurs. When the search for an exception handler unwinds the execution stack, at each unwound level a traceback object is inserted in front of the current traceback. When an exception handler is entered, the stack trace is made available to the program. (See section *The try statement*.) It is accessible as the third item of the tuple returned by `sys.exc_info()`. When the program contains no suitable handler, the stack trace is written (nicely formatted) to the standard error stream; if the interpreter is interactive, it is also made available to the user as `sys.last_traceback`.

Special read-only attributes: `tb_next` is the next level in the stack trace (towards the frame where the exception occurred), or `None` if there is no next level; `tb_frame` points to the execution frame of the current level; `tb_lineno` gives the line number where the exception occurred; `tb_lasti` indicates the precise instruction. The line number and last instruction in the traceback may differ from the line number of its frame object if the exception occurred in a `try` statement with no matching `except` clause or with a `finally` clause.

Slice objects

Slice objects are used to represent slices for `__getitem__()` methods. They are also created by the built-in `slice()` function.

Special read-only attributes: `start` is the lower bound; `stop` is the upper bound; `step` is the step value; each is `None` if omitted. These attributes can have any type.

Slice objects support one method:

`slice.indices(self, length)`

This method takes a single integer argument *length* and computes information about the slice that the slice object would describe if applied to a sequence of *length* items. It returns a tuple of three integers; respectively these are the *start* and *stop* indices and the *step* or stride length of the slice. Missing or out-of-bounds indices are handled in a manner consistent with regular slices.

Static method objects

Static method objects provide a way of defeating the transformation of function objects to method objects described above. A static method object is a wrapper around any other object, usually a user-defined method object. When a static method object is retrieved from a class or a class instance, the object actually returned is the wrapped object, which is not subject to any further transformation. Static method objects are not themselves callable, although the objects they wrap usually are. Static method objects are created by the built-in `staticmethod()` constructor.

Class method objects

A class method object, like a static method object, is a wrapper around another object that alters the way in which that object is retrieved from classes and class instances. The behaviour of class method objects upon such retrieval is described above, under “User-defined methods”. Class method objects are created by the built-in `classmethod()` constructor.

3.3. Special method names

A class can implement certain operations that are invoked by special syntax (such as arithmetic operations or subscripting and slicing) by defining methods with special names. This is Python's approach to *operator overloading*, allowing classes to define their own behavior with respect to language operators. For instance, if a class defines a method named `__getitem__()`, and `x` is an instance of this class, then `x[i]` is roughly equivalent to `type(x).__getitem__(x, i)`. Except where mentioned, attempts to execute an operation raise an exception when no appropriate method is defined (typically `AttributeError` or `TypeError`).

When implementing a class that emulates any built-in type, it is important that the emulation only be implemented to the degree that it makes sense for the object being modelled. For example, some sequences may work well with retrieval of individual elements, but extracting a slice may not make sense. (One example of this is the `NodeList` interface in the W3C's Document Object Model.)

3.3.1. Basic customization

`object.__new__(cls[, ...])`

Called to create a new instance of class `cls`. `__new__()` is a static method (special-cased so you need not declare it as such) that takes the class of which an instance was requested as its first argument. The remaining arguments are those passed to the object constructor expression (the call to the class). The return value of `__new__()` should be the new object instance (usually an instance of `cls`).

Typical implementations create a new instance of the class by

invoking the superclass's `__new__()` method using `super(currentclass, cls).__new__(cls[, ...])` with appropriate arguments and then modifying the newly-created instance as necessary before returning it.

If `__new__()` returns an instance of `cls`, then the new instance's `__init__()` method will be invoked like `__init__(self[, ...])`, where `self` is the new instance and the remaining arguments are the same as were passed to `__new__()`.

If `__new__()` does not return an instance of `cls`, then the new instance's `__init__()` method will not be invoked.

`__new__()` is intended mainly to allow subclasses of immutable types (like `int`, `str`, or `tuple`) to customize instance creation. It is also commonly overridden in custom metaclasses in order to customize class creation.

object.`__init__(self[, ...])`

Called when the instance is created. The arguments are those passed to the class constructor expression. If a base class has an `__init__()` method, the derived class's `__init__()` method, if any, must explicitly call it to ensure proper initialization of the base class part of the instance; for example: `BaseClass.__init__(self, [args...])`. As a special constraint on constructors, no value may be returned; doing so will cause a `TypeError` to be raised at runtime.

object.`__del__(self)`

Called when the instance is about to be destroyed. This is also called a destructor. If a base class has a `__del__()` method, the derived class's `__del__()` method, if any, must explicitly call it to ensure proper deletion of the base class part of the instance.

Note that it is possible (though not recommended!) for the `__del__()` method to postpone destruction of the instance by creating a new reference to it. It may then be called at a later time when this new reference is deleted. It is not guaranteed that `__del__()` methods are called for objects that still exist when the interpreter exits.

Note: `del x` doesn't directly call `x.__del__()` — the former decrements the reference count for `x` by one, and the latter is only called when `x`'s reference count reaches zero. Some common situations that may prevent the reference count of an object from going to zero include: circular references between objects (e.g., a doubly-linked list or a tree data structure with parent and child pointers); a reference to the object on the stack frame of a function that caught an exception (the traceback stored in `sys.exc_info()[2]` keeps the stack frame alive); or a reference to the object on the stack frame that raised an unhandled exception in interactive mode (the traceback stored in `sys.last_traceback` keeps the stack frame alive). The first situation can only be remedied by explicitly breaking the cycles; the latter two situations can be resolved by storing `None` in `sys.last_traceback`. Circular references which are garbage are detected when the option cycle detector is enabled (it's on by default), but can only be cleaned up if there are no Python-level `__del__()` methods involved. Refer to the documentation for the `gc` module for more information about how `__del__()` methods are handled by the cycle detector, particularly the description of the `garbage` value.

Warning: Due to the precarious circumstances under which `__del__()` methods are invoked, exceptions that occur during their execution are ignored, and a warning is printed to

`sys.stderr` instead. Also, when `__del__()` is invoked in response to a module being deleted (e.g., when execution of the program is done), other globals referenced by the `__del__()` method may already have been deleted or in the process of being torn down (e.g. the import machinery shutting down). For this reason, `__del__()` methods should do the absolute minimum needed to maintain external invariants. Starting with version 1.5, Python guarantees that globals whose name begins with a single underscore are deleted from their module before other globals are deleted; if no other references to such globals exist, this may help in assuring that imported modules are still available at the time when the `__del__()` method is called.

object.`__repr__(self)`

Called by the `repr()` built-in function to compute the “official” string representation of an object. If at all possible, this should look like a valid Python expression that could be used to recreate an object with the same value (given an appropriate environment). If this is not possible, a string of the form `<...some useful description...>` should be returned. The return value must be a string object. If a class defines `__repr__()` but not `__str__()`, then `__repr__()` is also used when an “informal” string representation of instances of that class is required.

This is typically used for debugging, so it is important that the representation is information-rich and unambiguous.

object.`__str__(self)`

Called by the `str()` built-in function and by the `print()` function to compute the “informal” string representation of an object. This differs from `__repr__()` in that it does not have to be a valid Python expression: a more convenient or concise representation

may be used instead. The return value must be a string object.

`object.__format__(self, format_spec)`

Called by the `format()` built-in function (and by extension, the `format()` method of class `str`) to produce a “formatted” string representation of an object. The `format_spec` argument is a string that contains a description of the formatting options desired. The interpretation of the `format_spec` argument is up to the type implementing `__format__()`, however most classes will either delegate formatting to one of the built-in types, or use a similar formatting option syntax.

See *Format Specification Mini-Language* for a description of the standard formatting syntax.

The return value must be a string object.

`object.__lt__(self, other)`

`object.__le__(self, other)`

`object.__eq__(self, other)`

`object.__ne__(self, other)`

`object.__gt__(self, other)`

`object.__ge__(self, other)`

These are the so-called “rich comparison” methods. The correspondence between operator symbols and method names is as follows: `x<y` calls `x.__lt__(y)`, `x<=y` calls `x.__le__(y)`, `x==y` calls `x.__eq__(y)`, `x!=y` calls `x.__ne__(y)`, `x>y` calls `x.__gt__(y)`, and `x>=y` calls `x.__ge__(y)`.

A rich comparison method may return the singleton `NotImplemented` if it does not implement the operation for a given pair of arguments. By convention, `False` and `True` are returned for a successful comparison. However, these methods can return any value, so if the comparison operator is used in a Boolean

context (e.g., in the condition of an `if` statement), Python will call `bool()` on the value to determine if the result is true or false.

There are no implied relationships among the comparison operators. The truth of `x==y` does not imply that `x!=y` is false. Accordingly, when defining `__eq__()`, one should also define `__ne__()` so that the operators will behave as expected. See the paragraph on `__hash__()` for some important notes on creating *hashable* objects which support custom comparison operations and are usable as dictionary keys.

There are no swapped-argument versions of these methods (to be used when the left argument does not support the operation but the right argument does); rather, `__lt__()` and `__gt__()` are each other's reflection, `__le__()` and `__ge__()` are each other's reflection, and `__eq__()` and `__ne__()` are their own reflection.

Arguments to rich comparison methods are never coerced.

To automatically generate ordering operations from a single root operation, see `functools.total_ordering()`.

object. `__hash__(self)`

Called by built-in function `hash()` and for operations on members of hashed collections including `set`, `frozenset`, and `dict`. `__hash__()` should return an integer. The only required property is that objects which compare equal have the same hash value; it is advised to somehow mix together (e.g. using exclusive or) the hash values for the components of the object that also play a part in comparison of objects.

If a class does not define an `__eq__()` method it should not define a `__hash__()` operation either; if it defines `__eq__()` but not `__hash__()`, its instances will not be usable as items in hashable

collections. If a class defines mutable objects and implements an `__eq__()` method, it should not implement `__hash__()`, since the implementation of hashable collections requires that a key's hash value is immutable (if the object's hash value changes, it will be in the wrong hash bucket).

User-defined classes have `__eq__()` and `__hash__()` methods by default; with them, all objects compare unequal (except with themselves) and `x.__hash__()` returns `id(x)`.

Classes which inherit a `__hash__()` method from a parent class but change the meaning of `__eq__()` such that the hash value returned is no longer appropriate (e.g. by switching to a value-based concept of equality instead of the default identity based equality) can explicitly flag themselves as being unhashable by setting `__hash__ = None` in the class definition. Doing so means that not only will instances of the class raise an appropriate `TypeError` when a program attempts to retrieve their hash value, but they will also be correctly identified as unhashable when checking `isinstance(obj, collections.Hashable)` (unlike classes which define their own `__hash__()` to explicitly raise `TypeError`).

If a class that overrides `__eq__()` needs to retain the implementation of `__hash__()` from a parent class, the interpreter must be told this explicitly by setting `__hash__ = <ParentClass>.__hash__`. Otherwise the inheritance of `__hash__()` will be blocked, just as if `__hash__` had been explicitly set to `None`.

`object.__bool__(self)`

Called to implement truth value testing and the built-in operation `bool()`; should return `False` or `True`. When this method is not defined, `__len__()` is called, if it is defined, and the object is considered true if its result is nonzero. If a class defines neither

`__len__()` nor `__bool__()`, all its instances are considered true.

3.3.2. Customizing attribute access

The following methods can be defined to customize the meaning of attribute access (use of, assignment to, or deletion of `x.name`) for class instances.

`object.__getattr__(self, name)`

Called when an attribute lookup has not found the attribute in the usual places (i.e. it is not an instance attribute nor is it found in the class tree for `self`). `name` is the attribute name. This method should return the (computed) attribute value or raise an `AttributeError` exception.

Note that if the attribute is found through the normal mechanism, `__getattr__()` is not called. (This is an intentional asymmetry between `__getattr__()` and `__setattr__()`.) This is done both for efficiency reasons and because otherwise `__getattr__()` would have no way to access other attributes of the instance. Note that at least for instance variables, you can fake total control by not inserting any values in the instance attribute dictionary (but instead inserting them in another object). See the `__getattribute__()` method below for a way to actually get total control over attribute access.

`object.__getattribute__(self, name)`

Called unconditionally to implement attribute accesses for instances of the class. If the class also defines `__getattr__()`, the latter will not be called unless `__getattribute__()` either calls it explicitly or raises an `AttributeError`. This method should return the (computed) attribute value or raise an `AttributeError` exception. In order to avoid infinite recursion in this method, its

implementation should always call the base class method with the same name to access any attributes it needs, for example, `object.__getattr__(self, name)`.

Note: This method may still be bypassed when looking up special methods as the result of implicit invocation via language syntax or built-in functions. See [Special method lookup](#).

`object.__setattr__(self, name, value)`

Called when an attribute assignment is attempted. This is called instead of the normal mechanism (i.e. store the value in the instance dictionary). *name* is the attribute name, *value* is the value to be assigned to it.

If `__setattr__()` wants to assign to an instance attribute, it should call the base class method with the same name, for example, `object.__setattr__(self, name, value)`.

`object.__delattr__(self, name)`

Like `__setattr__()` but for attribute deletion instead of assignment. This should only be implemented if `del obj.name` is meaningful for the object.

`object.__dir__(self)`

Called when `dir()` is called on the object. A list must be returned.

3.3.2.1. Implementing Descriptors

The following methods only apply when an instance of the class containing the method (a so-called *descriptor* class) appears in the class dictionary of another class, known as the *owner* class. In the examples below, “the attribute” refers to the attribute whose name is the key of the property in the owner class’ `__dict__`.

`object.__get__(self, instance, owner)`

Called to get the attribute of the owner class (class attribute access) or of an instance of that class (instance attribute access). *owner* is always the owner class, while *instance* is the instance that the attribute was accessed through, or `None` when the attribute is accessed through the *owner*. This method should return the (computed) attribute value or raise an `AttributeError` exception.

`object.__set__(self, instance, value)`

Called to set the attribute on an instance *instance* of the owner class to a new value, *value*.

`object.__delete__(self, instance)`

Called to delete the attribute on an instance *instance* of the owner class.

3.3.2.2. Invoking Descriptors

In general, a descriptor is an object attribute with “binding behavior”, one whose attribute access has been overridden by methods in the descriptor protocol: `__get__()`, `__set__()`, and `__delete__()`. If any of those methods are defined for an object, it is said to be a descriptor.

The default behavior for attribute access is to get, set, or delete the attribute from an object’s dictionary. For instance, `a.x` has a lookup chain starting with `a.__dict__['x']`, then `type(a).__dict__['x']`, and continuing through the base classes of `type(a)` excluding metaclasses.

However, if the looked-up value is an object defining one of the descriptor methods, then Python may override the default behavior and invoke the descriptor method instead. Where this occurs in the

precedence chain depends on which descriptor methods were defined and how they were called.

The starting point for descriptor invocation is a binding, `a.x`. How the arguments are assembled depends on `a`:

Direct Call

The simplest and least common call is when user code directly invokes a descriptor method: `x.__get__(a)`.

Instance Binding

If binding to an object instance, `a.x` is transformed into the call: `type(a).__dict__['x'].__get__(a, type(a))`.

Class Binding

If binding to a class, `A.x` is transformed into the call: `A.__dict__['x'].__get__(None, A)`.

Super Binding

If `a` is an instance of `super`, then the binding `super(B, obj).m()` searches `obj.__class__.__mro__` for the base class `A` immediately preceding `B` and then invokes the descriptor with the call: `A.__dict__['m'].__get__(obj, A)`.

For instance bindings, the precedence of descriptor invocation depends on the which descriptor methods are defined. A descriptor can define any combination of `__get__()`, `__set__()` and `__delete__()`. If it does not define `__get__()`, then accessing the attribute will return the descriptor object itself unless there is a value in the object's instance dictionary. If the descriptor defines `__set__()` and/or `__delete__()`, it is a data descriptor; if it defines neither, it is a non-data descriptor. Normally, data descriptors define both `__get__()` and `__set__()`, while non-data descriptors have just the `__get__()` method. Data descriptors with `__set__()` and `__get__()` defined always override a redefinition in an instance dictionary. In

contrast, non-data descriptors can be overridden by instances.

Python methods (including `staticmethod()` and `classmethod()`) are implemented as non-data descriptors. Accordingly, instances can redefine and override methods. This allows individual instances to acquire behaviors that differ from other instances of the same class.

The `property()` function is implemented as a data descriptor. Accordingly, instances cannot override the behavior of a property.

3.3.2.3. `__slots__`

By default, instances of classes have a dictionary for attribute storage. This wastes space for objects having very few instance variables. The space consumption can become acute when creating large numbers of instances.

The default can be overridden by defining `__slots__` in a class definition. The `__slots__` declaration takes a sequence of instance variables and reserves just enough space in each instance to hold a value for each variable. Space is saved because `__dict__` is not created for each instance.

object. `__slots__`

This class variable can be assigned a string, iterable, or sequence of strings with variable names used by instances. If defined in a class, `__slots__` reserves space for the declared variables and prevents the automatic creation of `__dict__` and `__weakref__` for each instance.

3.3.2.3.1. Notes on using `__slots__`

- When inheriting from a class without `__slots__`, the `__dict__` attribute of that class will always be accessible, so a `__slots__` definition in the subclass is meaningless.

- Without a `__dict__` variable, instances cannot be assigned new variables not listed in the `__slots__` definition. Attempts to assign to an unlisted variable name raises `AttributeError`. If dynamic assignment of new variables is desired, then add `'__dict__'` to the sequence of strings in the `__slots__` declaration.
- Without a `__weakref__` variable for each instance, classes defining `__slots__` do not support weak references to its instances. If weak reference support is needed, then add `'__weakref__'` to the sequence of strings in the `__slots__` declaration.
- `__slots__` are implemented at the class level by creating descriptors (*Implementing Descriptors*) for each variable name. As a result, class attributes cannot be used to set default values for instance variables defined by `__slots__`; otherwise, the class attribute would overwrite the descriptor assignment.
- The action of a `__slots__` declaration is limited to the class where it is defined. As a result, subclasses will have a `__dict__` unless they also define `__slots__` (which must only contain names of any *additional* slots).
- If a class defines a slot also defined in a base class, the instance variable defined by the base class slot is inaccessible (except by retrieving its descriptor directly from the base class). This renders the meaning of the program undefined. In the future, a check may be added to prevent this.
- Nonempty `__slots__` does not work for classes derived from “variable-length” built-in types such as `int`, `str` and `tuple`.
- Any non-string iterable may be assigned to `__slots__`. Mappings may also be used; however, in the future, special meaning may be assigned to the values corresponding to each key.
- `__class__` assignment works only if both classes have the same `__slots__`.

3.3.3. Customizing class creation

By default, classes are constructed using `type()`. A class definition is read into a separate namespace and the value of class name is bound to the result of `type(name, bases, dict)`.

When the class definition is read, if a callable `metaclass` keyword argument is passed after the bases in the class definition, the callable given will be called instead of `type()`. If other keyword arguments are passed, they will also be passed to the metaclass. This allows classes or functions to be written which monitor or alter the class creation process:

- Modifying the class dictionary prior to the class being created.
- Returning an instance of another class – essentially performing the role of a factory function.

These steps will have to be performed in the metaclass's `__new__()` method – `type.__new__()` can then be called from this method to create a class with different properties. This example adds a new element to the class dictionary before creating the class:

```
class metaccls(type):
    def __new__(mcs, name, bases, dict):
        dict['foo'] = 'metaccls was here'
        return type.__new__(mcs, name, bases, dict)
```

You can of course also override other class methods (or add new methods); for example defining a custom `__call__()` method in the metaclass allows custom behavior when the class is called, e.g. not always creating a new instance.

If the metaclass has a `__prepare__()` attribute (usually implemented as a class or static method), it is called before the class body is evaluated with the name of the class and a tuple of its bases for arguments. It should return an object that supports the mapping

interface that will be used to store the namespace of the class. The default is a plain dictionary. This could be used, for example, to keep track of the order that class attributes are declared in by returning an ordered dictionary.

The appropriate metaclass is determined by the following precedence rules:

- If the `metaclass` keyword argument is passed with the bases, it is used.
- Otherwise, if there is at least one base class, its metaclass is used.
- Otherwise, the default metaclass (`type`) is used.

The potential uses for metaclasses are boundless. Some ideas that have been explored including logging, interface checking, automatic delegation, automatic property creation, proxies, frameworks, and automatic resource locking/synchronization.

Here is an example of a metaclass that uses an `collections.OrderedDict` to remember the order that class members were defined:

```
class OrderedClass(type):

    @classmethod
    def __prepare__(metacls, name, bases, **kwds):
        return collections.OrderedDict()

    def __new__(cls, name, bases, classdict):
        result = type.__new__(cls, name, bases, dict(classdict))
        result.members = tuple(classdict)
        return result

class A(metaclass=OrderedClass):
    def one(self): pass
    def two(self): pass
    def three(self): pass
    def four(self): pass
```

```
>>> A.members
(' __module__', 'one', 'two', 'three', 'four')
```

When the class definition for *A* gets executed, the process begins with calling the metaclass's `__prepare__()` method which returns an empty `collections.OrderedDict`. That mapping records the methods and attributes of *A* as they are defined within the body of the class statement. Once those definitions are executed, the ordered dictionary is fully populated and the metaclass's `__new__()` method gets invoked. That method builds the new type and it saves the ordered dictionary keys in an attribute called `members`.

3.3.4. Customizing instance and subclass checks

The following methods are used to override the default behavior of the `isinstance()` and `issubclass()` built-in functions.

In particular, the metaclass `abc.ABCMeta` implements these methods in order to allow the addition of Abstract Base Classes (ABCs) as “virtual base classes” to any class or type (including built-in types), including other ABCs.

```
class.__instancecheck__(self, instance)
```

Return true if *instance* should be considered a (direct or indirect) instance of *class*. If defined, called to implement `isinstance(instance, class)`.

```
class.__subclasscheck__(self, subclass)
```

Return true if *subclass* should be considered a (direct or indirect) subclass of *class*. If defined, called to implement `issubclass(subclass, class)`.

Note that these methods are looked up on the type (metaclass) of a

class. They cannot be defined as class methods in the actual class. This is consistent with the lookup of special methods that are called on instances, only in this case the instance is itself a class.

See also:

PEP 3119 - Introducing Abstract Base Classes

Includes the specification for customizing `isinstance()` and `issubclass()` behavior through `__instancecheck__()` and `__subclasscheck__()`, with motivation for this functionality in the context of adding Abstract Base Classes (see the `abc` module) to the language.

3.3.5. Emulating callable objects

`object.__call__(self[, args...])`

Called when the instance is “called” as a function; if this method is defined, `x(arg1, arg2, ...)` is a shorthand for `x.__call__(arg1, arg2, ...)`.

3.3.6. Emulating container types

The following methods can be defined to implement container objects. Containers usually are sequences (such as lists or tuples) or mappings (like dictionaries), but can represent other containers as well. The first set of methods is used either to emulate a sequence or to emulate a mapping; the difference is that for a sequence, the allowable keys should be the integers k for which $0 \leq k < N$ where N is the length of the sequence, or slice objects, which define a range of items. It is also recommended that mappings provide the methods `keys()`, `values()`, `items()`, `get()`, `clear()`, `setdefault()`, `pop()`, `popitem()`, `copy()`, and `update()` behaving similar to those for

Python's standard dictionary objects. The `collections` module provides a `MutableMapping` abstract base class to help create those methods from a base set of `__getitem__()`, `__setitem__()`, `__delitem__()`, and `keys()`. Mutable sequences should provide methods `append()`, `count()`, `index()`, `extend()`, `insert()`, `pop()`, `remove()`, `reverse()` and `sort()`, like Python standard list objects. Finally, sequence types should implement addition (meaning concatenation) and multiplication (meaning repetition) by defining the methods `__add__()`, `__radd__()`, `__iadd__()`, `__mul__()`, `__rmul__()` and `__imul__()` described below; they should not define other numerical operators. It is recommended that both mappings and sequences implement the `__contains__()` method to allow efficient use of the `in` operator; for mappings, `in` should search the mapping's keys; for sequences, it should search through the values. It is further recommended that both mappings and sequences implement the `__iter__()` method to allow efficient iteration through the container; for mappings, `__iter__()` should be the same as `keys()`; for sequences, it should iterate through the values.

object. `__len__(self)`

Called to implement the built-in function `len()`. Should return the length of the object, an integer `>= 0`. Also, an object that doesn't define a `__bool__()` method and whose `__len__()` method returns zero is considered to be false in a Boolean context.

Note: Slicing is done exclusively with the following three methods. A call like

```
a[1:2] = b
```

is translated to

```
a[slice(1, 2, None)] = b
```

and so forth. Missing slice items are always filled in with **None**.

object. **__getitem__**(*self, key*)

Called to implement evaluation of `self[key]`. For sequence types, the accepted keys should be integers and slice objects. Note that the special interpretation of negative indexes (if the class wishes to emulate a sequence type) is up to the **__getitem__()** method. If *key* is of an inappropriate type, **TypeError** may be raised; if of a value outside the set of indexes for the sequence (after any special interpretation of negative values), **IndexError** should be raised. For mapping types, if *key* is missing (not in the container), **KeyError** should be raised.

Note: `for` loops expect that an **IndexError** will be raised for illegal indexes to allow proper detection of the end of the sequence.

object. **__setitem__**(*self, key, value*)

Called to implement assignment to `self[key]`. Same note as for **__getitem__()**. This should only be implemented for mappings if the objects support changes to the values for keys, or if new keys can be added, or for sequences if elements can be replaced. The same exceptions should be raised for improper *key* values as for the **__getitem__()** method.

object. **__delitem__**(*self, key*)

Called to implement deletion of `self[key]`. Same note as for **__getitem__()**. This should only be implemented for mappings if the objects support removal of keys, or for sequences if elements can be removed from the sequence. The same exceptions should be raised for improper *key* values as for the **__getitem__()** method.

object. **__iter__**(*self*)

This method is called when an iterator is required for a container. This method should return a new iterator object that can iterate over all the objects in the container. For mappings, it should iterate over the keys of the container, and should also be made available as the method `keys()`.

Iterator objects also need to implement this method; they are required to return themselves. For more information on iterator objects, see *Iterator Types*.

object. **__reversed__**(*self*)

Called (if present) by the `reversed()` built-in to implement reverse iteration. It should return a new iterator object that iterates over all the objects in the container in reverse order.

If the `__reversed__()` method is not provided, the `reversed()` built-in will fall back to using the sequence protocol (`__len__()` and `__getitem__()`). Objects that support the sequence protocol should only provide `__reversed__()` if they can provide an implementation that is more efficient than the one provided by `reversed()`.

The membership test operators (`in` and `not in`) are normally implemented as an iteration through a sequence. However, container objects can supply the following special method with a more efficient implementation, which also does not require the object be a sequence.

object. **__contains__**(*self*, *item*)

Called to implement membership test operators. Should return true if *item* is in *self*, false otherwise. For mapping objects, this should consider the keys of the mapping rather than the values or the key-item pairs.

For objects that don't define `__contains__()`, the membership test first tries iteration via `__iter__()`, then the old sequence iteration protocol via `__getitem__()`, see [this section in the language reference](#).

3.3.7. Emulating numeric types

The following methods can be defined to emulate numeric objects. Methods corresponding to operations that are not supported by the particular kind of number implemented (e.g., bitwise operations for non-integral numbers) should be left undefined.

```
object.__add__(self, other)
object.__sub__(self, other)
object.__mul__(self, other)
object.__truediv__(self, other)
object.__floordiv__(self, other)
object.__mod__(self, other)
object.__divmod__(self, other)
object.__pow__(self, other[, modulo])
object.__lshift__(self, other)
object.__rshift__(self, other)
object.__and__(self, other)
object.__xor__(self, other)
object.__or__(self, other)
```

These methods are called to implement the binary arithmetic operations (`+`, `-`, `*`, `/`, `//`, `%`, `divmod()`, `pow()`, `**`, `<<`, `>>`, `&`, `^`, `|`). For instance, to evaluate the expression `x + y`, where `x` is an instance of a class that has an `__add__()` method, `x.__add__(y)` is called. The `__divmod__()` method should be the equivalent to using `__floordiv__()` and `__mod__()`; it should not be related to `__truediv__()`. Note that `__pow__()` should be defined to accept

an optional third argument if the ternary version of the built-in `pow()` function is to be supported.

If one of those methods does not support the operation with the supplied arguments, it should return `NotImplemented`.

```
object.__radd__(self, other)
object.__rsub__(self, other)
object.__rmul__(self, other)
object.__rtruediv__(self, other)
object.__rfloordiv__(self, other)
object.__rmod__(self, other)
object.__rdivmod__(self, other)
object.__rpow__(self, other)
object.__rlshift__(self, other)
object.__rrshift__(self, other)
object.__rand__(self, other)
object.__rxor__(self, other)
object.__ror__(self, other)
```

These methods are called to implement the binary arithmetic operations (`+`, `-`, `*`, `/`, `//`, `%`, `divmod()`, `pow()`, `**`, `<<`, `>>`, `&`, `^`, `|`) with reflected (swapped) operands. These functions are only called if the left operand does not support the corresponding operation and the operands are of different types. [2] For instance, to evaluate the expression `x - y`, where `y` is an instance of a class that has an `__rsub__()` method, `y.__rsub__(x)` is called if `x.__sub__(y)` returns `NotImplemented`.

Note that ternary `pow()` will not try calling `__rpow__()` (the coercion rules would become too complicated).

Note: If the right operand's type is a subclass of the left operand's type and that subclass provides the reflected method

for the operation, this method will be called before the left operand's non-reflected method. This behavior allows subclasses to override their ancestors' operations.

```
object.__iadd__(self, other)
object.__isub__(self, other)
object.__imul__(self, other)
object.__itruediv__(self, other)
object.__ifloordiv__(self, other)
object.__imod__(self, other)
object.__ipow__(self, other[, modulo])
object.__ilshift__(self, other)
object.__irshift__(self, other)
object.__iand__(self, other)
object.__ixor__(self, other)
object.__ior__(self, other)
```

These methods are called to implement the augmented arithmetic assignments (`+=`, `-=`, `*=`, `/=`, `//=`, `%=`, `**=`, `<<=`, `>>=`, `&=`, `^=`, `|=`). These methods should attempt to do the operation in-place (modifying *self*) and return the result (which could be, but does not have to be, *self*). If a specific method is not defined, the augmented assignment falls back to the normal methods. For instance, to execute the statement `x += y`, where *x* is an instance of a class that has an `__iadd__()` method, `x.__iadd__(y)` is called. If *x* is an instance of a class that does not define a `__iadd__()` method, `x.__add__(y)` and `y.__radd__(x)` are considered, as with the evaluation of `x + y`.

```
object.__neg__(self)
object.__pos__(self)
object.__abs__(self)
object.__invert__(self)
```

Called to implement the unary arithmetic operations (`-`, `+`, `abs()` and `~`).

`object.__complex__(self)`

`object.__int__(self)`

`object.__float__(self)`

`object.__round__(self[, n])`

Called to implement the built-in functions `complex()`, `int()`, `float()` and `round()`. Should return a value of the appropriate type.

`object.__index__(self)`

Called to implement `operator.index()`. Also called whenever Python needs an integer object (such as in slicing, or in the built-in `bin()`, `hex()` and `oct()` functions). Must return an integer.

3.3.8. With Statement Context Managers

A *context manager* is an object that defines the runtime context to be established when executing a `with` statement. The context manager handles the entry into, and the exit from, the desired runtime context for the execution of the block of code. Context managers are normally invoked using the `with` statement (described in section [The with statement](#)), but can also be used by directly invoking their methods.

Typical uses of context managers include saving and restoring various kinds of global state, locking and unlocking resources, closing opened files, etc.

For more information on context managers, see [Context Manager Types](#).

`object.__enter__(self)`

Enter the runtime context related to this object. The `with` statement will bind this method's return value to the target(s) specified in the `as` clause of the statement, if any.

`object.__exit__(self, exc_type, exc_value, traceback)`

Exit the runtime context related to this object. The parameters describe the exception that caused the context to be exited. If the context was exited without an exception, all three arguments will be `None`.

If an exception is supplied, and the method wishes to suppress the exception (i.e., prevent it from being propagated), it should return a true value. Otherwise, the exception will be processed normally upon exit from this method.

Note that `__exit__()` methods should not reraise the passed-in exception; this is the caller's responsibility.

See also:

PEP 0343 - The “with” statement

The specification, background, and examples for the Python `with` statement.

3.3.9. Special method lookup

For custom classes, implicit invocations of special methods are only guaranteed to work correctly if defined on an object's type, not in the object's instance dictionary. That behaviour is the reason why the following code raises an exception:

```
>>> class C:
...     pass
...
>>> c = C()
```

```
>>> c.__len__ = lambda: 5
>>> len(c)
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
TypeError: object of type 'C' has no len()
```

The rationale behind this behaviour lies with a number of special methods such as `__hash__()` and `__repr__()` that are implemented by all objects, including type objects. If the implicit lookup of these methods used the conventional lookup process, they would fail when invoked on the type object itself:

```
>>> 1.__hash__() == hash(1)
True
>>> int.__hash__() == hash(int)
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
TypeError: descriptor '__hash__' of 'int' object needs an argument
```

Incorrectly attempting to invoke an unbound method of a class in this way is sometimes referred to as ‘metaclass confusion’, and is avoided by bypassing the instance when looking up special methods:

```
>>> type(1).__hash__(1) == hash(1)
True
>>> type(int).__hash__(int) == hash(int)
True
```

In addition to bypassing any instance attributes in the interest of correctness, implicit special method lookup generally also bypasses the `__getattr__()` method even of the object’s metaclass:

```
>>> class Meta(type):
...     def __getattr__(*args):
...         print("Metaclass getattr invoked")
...         return type.__getattr__(*args)
...
>>> class C(object, metaclass=Meta):
```

```

...     def __len__(self):
...         return 10
...     def __getattr__(*args):
...         print("Class getattr invoked")
...         return object.__getattr__(*args)
...
>>> c = C()
>>> c.__len__()                # Explicit lookup via instance
Class getattr invoked
10
>>> type(c).__len__(c)        # Explicit lookup via type
Metaclass getattr invoked
10
>>> len(c)                    # Implicit lookup
10

```

Bypassing the `__getattr__()` machinery in this fashion provides significant scope for speed optimisations within the interpreter, at the cost of some flexibility in the handling of special methods (the special method *must* be set on the class object itself in order to be consistently invoked by the interpreter).

Footnotes

[1] It is possible in some cases to change an object's type, under certain controlled conditions. It generally isn't a good idea though, since it can lead to some very strange behaviour if it is handled incorrectly.

[2] For operands of the same type, it is assumed that if the non-reflected method (such as `__add__()`) fails the operation is not supported, which is why the reflected method is not called.

4. Execution model

4.1. Naming and binding

Names refer to objects. Names are introduced by name binding operations. Each occurrence of a name in the program text refers to the *binding* of that name established in the innermost function block containing the use.

A *block* is a piece of Python program text that is executed as a unit. The following are blocks: a module, a function body, and a class definition. Each command typed interactively is a block. A script file (a file given as standard input to the interpreter or specified on the interpreter command line the first argument) is a code block. A script command (a command specified on the interpreter command line with the `-c` option) is a code block. The string argument passed to the built-in functions `eval()` and `exec()` is a code block.

A code block is executed in an *execution frame*. A frame contains some administrative information (used for debugging) and determines where and how execution continues after the code block's execution has completed.

A *scope* defines the visibility of a name within a block. If a local variable is defined in a block, its scope includes that block. If the definition occurs in a function block, the scope extends to any blocks contained within the defining one, unless a contained block introduces a different binding for the name. The scope of names defined in a class block is limited to the class block; it does not extend to the code blocks of methods – this includes comprehensions and generator expressions since they are implemented using a function scope. This means that the following will fail:

```
class A:  
    a = 42
```

```
b = list(a + i for i in range(10))
```

When a name is used in a code block, it is resolved using the nearest enclosing scope. The set of all such scopes visible to a code block is called the block's *environment*.

If a name is bound in a block, it is a local variable of that block, unless declared as `nonlocal`. If a name is bound at the module level, it is a global variable. (The variables of the module code block are local and global.) If a variable is used in a code block but not defined there, it is a *free variable*.

When a name is not found at all, a `NameError` exception is raised. If the name refers to a local variable that has not been bound, a `UnboundLocalError` exception is raised. `UnboundLocalError` is a subclass of `NameError`.

The following constructs bind names: formal parameters to functions, `import` statements, class and function definitions (these bind the class or function name in the defining block), and targets that are identifiers if occurring in an assignment, `for` loop header, or after `as` in a `with` statement or `except` clause. The `import` statement of the form `from ... import *` binds all names defined in the imported module, except those beginning with an underscore. This form may only be used at the module level.

A target occurring in a `del` statement is also considered bound for this purpose (though the actual semantics are to unbind the name). It is illegal to unbind a name that is referenced by an enclosing scope; the compiler will report a `SyntaxError`.

Each assignment or import statement occurs within a block defined by a class or function definition or at the module level (the top-level code block).

If a name binding operation occurs anywhere within a code block, all uses of the name within the block are treated as references to the current block. This can lead to errors when a name is used within a block before it is bound. This rule is subtle. Python lacks declarations and allows name binding operations to occur anywhere within a code block. The local variables of a code block can be determined by scanning the entire text of the block for name binding operations.

If the `global` statement occurs within a block, all uses of the name specified in the statement refer to the binding of that name in the top-level namespace. Names are resolved in the top-level namespace by searching the global namespace, i.e. the namespace of the module containing the code block, and the builtins namespace, the namespace of the module `builtins`. The global namespace is searched first. If the name is not found there, the builtins namespace is searched. The global statement must precede all uses of the name.

The builtins namespace associated with the execution of a code block is actually found by looking up the name `__builtins__` in its global namespace; this should be a dictionary or a module (in the latter case the module's dictionary is used). By default, when in the `__main__` module, `__builtins__` is the built-in module `builtins`; when in any other module, `__builtins__` is an alias for the dictionary of the `builtins` module itself. `__builtins__` can be set to a user-created dictionary to create a weak form of restricted execution.

CPython implementation detail: Users should not touch `__builtins__`; it is strictly an implementation detail. Users wanting to override values in the builtins namespace should `import` the `builtins` module and modify its attributes appropriately.

The namespace for a module is automatically created the first time a module is imported. The main module for a script is always called `__main__`.

The `global` statement has the same scope as a name binding operation in the same block. If the nearest enclosing scope for a free variable contains a global statement, the free variable is treated as a global.

A class definition is an executable statement that may use and define names. These references follow the normal rules for name resolution. The namespace of the class definition becomes the attribute dictionary of the class. Names defined at the class scope are not visible in methods.

4.1.1. Interaction with dynamic features

There are several cases where Python statements are illegal when used in conjunction with nested scopes that contain free variables.

If a variable is referenced in an enclosing scope, it is illegal to delete the name. An error will be reported at compile time.

If the wild card form of import — `import *` — is used in a function and the function contains or is a nested block with free variables, the compiler will raise a `SyntaxError`.

The `eval()` and `exec()` functions do not have access to the full environment for resolving names. Names may be resolved in the local and global namespaces of the caller. Free variables are not resolved in the nearest enclosing namespace, but in the global namespace. [1] The `exec()` and `eval()` functions have optional arguments to override the global and local namespace. If only one namespace is specified, it is used for both.

4.2. Exceptions

Exceptions are a means of breaking out of the normal flow of control of a code block in order to handle errors or other exceptional conditions. An exception is *raised* at the point where the error is detected; it may be *handled* by the surrounding code block or by any code block that directly or indirectly invoked the code block where the error occurred.

The Python interpreter raises an exception when it detects a runtime error (such as division by zero). A Python program can also explicitly raise an exception with the `raise` statement. Exception handlers are specified with the `try ... except` statement. The `finally` clause of such a statement can be used to specify cleanup code which does not handle the exception, but is executed whether an exception occurred or not in the preceding code.

Python uses the “termination” model of error handling: an exception handler can find out what happened and continue execution at an outer level, but it cannot repair the cause of the error and retry the failing operation (except by re-entering the offending piece of code from the top).

When an exception is not handled at all, the interpreter terminates execution of the program, or returns to its interactive main loop. In either case, it prints a stack backtrace, except when the exception is `SystemExit`.

Exceptions are identified by class instances. The `except` clause is selected depending on the class of the instance: it must reference the class of the instance or a base class thereof. The instance can be received by the handler and can carry additional information about the exceptional condition.

Note: Exception messages are not part of the Python API. Their contents may change from one version of Python to the next without warning and should not be relied on by code which will run under multiple versions of the interpreter.

See also the description of the `try` statement in section *The try statement* and `raise` statement in section *The raise statement*.

Footnotes

[1] This limitation occurs because the code that is executed by these operations is not available at the time the module is compiled.

5. Expressions

This chapter explains the meaning of the elements of expressions in Python.

Syntax Notes: In this and the following chapters, extended BNF notation will be used to describe syntax, not lexical analysis. When (one alternative of) a syntax rule has the form

```
name ::= othername
```

and no semantics are given, the semantics of this form of `name` are the same as for `othername`.

5.1. Arithmetic conversions

When a description of an arithmetic operator below uses the phrase “the numeric arguments are converted to a common type,” this means that the operator implementation for built-in types works that way:

- If either argument is a complex number, the other is converted to complex;
- otherwise, if either argument is a floating point number, the other is converted to floating point;
- otherwise, both must be integers and no conversion is necessary.

Some additional rules apply for certain operators (e.g., a string left argument to the ‘%’ operator). Extensions must define their own conversion behavior.

5.2. Atoms

Atoms are the most basic elements of expressions. The simplest atoms are identifiers or literals. Forms enclosed in parentheses, brackets or braces are also categorized syntactically as atoms. The syntax for atoms is:

```
atom      ::= identifier | literal | enclosure
enclosure ::= parenth_form | list_display | dict_display | set_display
           | generator_expression | yield_atom
```

5.2.1. Identifiers (Names)

An identifier occurring as an atom is a name. See section *Identifiers and keywords* for lexical definition and section *Naming and binding* for documentation of naming and binding.

When the name is bound to an object, evaluation of the atom yields that object. When a name is not bound, an attempt to evaluate it raises a `NameError` exception.

Private name mangling: When an identifier that textually occurs in a class definition begins with two or more underscore characters and does not end in two or more underscores, it is considered a *private name* of that class. Private names are transformed to a longer form before code is generated for them. The transformation inserts the class name in front of the name, with leading underscores removed, and a single underscore inserted in front of the class name. For example, the identifier `__spam` occurring in a class named `Ham` will be transformed to `_Ham__spam`. This transformation is independent of the syntactical context in which the identifier is used. If the transformed name is extremely long (longer than 255 characters), implementation defined truncation may happen. If the class name consists only of

underscores, no transformation is done.

5.2.2. Literals

Python supports string and bytes literals and various numeric literals:

```
literal ::= stringliteral | bytesliteral  
         | integer | floatnumber | imagnumber
```

Evaluation of a literal yields an object of the given type (string, bytes, integer, floating point number, complex number) with the given value. The value may be approximated in the case of floating point and imaginary (complex) literals. See section *Literals* for details.

With the exception of bytes literals, these all correspond to immutable data types, and hence the object's identity is less important than its value. Multiple evaluations of literals with the same value (either the same occurrence in the program text or a different occurrence) may obtain the same object or a different object with the same value.

5.2.3. Parenthesized forms

A parenthesized form is an optional expression list enclosed in parentheses:

```
parenth_form ::= "(" [expression_list] ")"
```

A parenthesized expression list yields whatever that expression list yields: if the list contains at least one comma, it yields a tuple; otherwise, it yields the single expression that makes up the expression list.

An empty pair of parentheses yields an empty tuple object. Since tuples are immutable, the rules for literals apply (i.e., two

occurrences of the empty tuple may or may not yield the same object).

Note that tuples are not formed by the parentheses, but rather by use of the comma operator. The exception is the empty tuple, for which parentheses *are* required — allowing unparenthesized “nothing” in expressions would cause ambiguities and allow common typos to pass uncaught.

5.2.4. Displays for lists, sets and dictionaries

For constructing a list, a set or a dictionary Python provides special syntax called “displays”, each of them in two flavors:

- either the container contents are listed explicitly, or
- they are computed via a set of looping and filtering instructions, called a *comprehension*.

Common syntax elements for comprehensions are:

```
comprehension ::= expression comp_for
comp_for      ::= "for" target_list "in" or_test [comp_iter]
comp_iter     ::= comp_for | comp_if
comp_if       ::= "if" expression_nocond [comp_iter]
```

The comprehension consists of a single expression followed by at least one **for** clause and zero or more **for** or **if** clauses. In this case, the elements of the new container are those that would be produced by considering each of the **for** or **if** clauses a block, nesting from left to right, and evaluating the expression to produce an element each time the innermost block is reached.

Note that the comprehension is executed in a separate scope, so names assigned to in the target list don’t “leak” in the enclosing scope.

5.2.5. List displays

A list display is a possibly empty series of expressions enclosed in square brackets:

```
list_display ::= "[" [expression_list | comprehension] "]"
```

A list display yields a new list object, the contents being specified by either a list of expressions or a comprehension. When a comma-separated list of expressions is supplied, its elements are evaluated from left to right and placed into the list object in that order. When a comprehension is supplied, the list is constructed from the elements resulting from the comprehension.

5.2.6. Set displays

A set display is denoted by curly braces and distinguishable from dictionary displays by the lack of colons separating keys and values:

```
set_display ::= "{" (expression_list | comprehension) "}"
```

A set display yields a new mutable set object, the contents being specified by either a sequence of expressions or a comprehension. When a comma-separated list of expressions is supplied, its elements are evaluated from left to right and added to the set object. When a comprehension is supplied, the set is constructed from the elements resulting from the comprehension.

An empty set cannot be constructed with `{}`; this literal constructs an empty dictionary.

5.2.7. Dictionary displays

A dictionary display is a possibly empty series of key/datum pairs

enclosed in curly braces:

```
dict_display      ::= "{" [key_datum_list | dict_comprehensio
key_datum_list   ::= key_datum ("," key_datum)* ["," ]
key_datum        ::= expression ":" expression
dict_comprehension ::= expression ":" expression comp_for
```

A dictionary display yields a new dictionary object.

If a comma-separated sequence of key/datum pairs is given, they are evaluated from left to right to define the entries of the dictionary: each key object is used as a key into the dictionary to store the corresponding datum. This means that you can specify the same key multiple times in the key/datum list, and the final dictionary's value for that key will be the last one given.

A dict comprehension, in contrast to list and set comprehensions, needs two expressions separated with a colon followed by the usual “for” and “if” clauses. When the comprehension is run, the resulting key and value elements are inserted in the new dictionary in the order they are produced.

Restrictions on the types of the key values are listed earlier in section *The standard type hierarchy*. (To summarize, the key type should be *hashable*, which excludes all mutable objects.) Clashes between duplicate keys are not detected; the last datum (textually rightmost in the display) stored for a given key value prevails.

5.2.8. Generator expressions

A generator expression is a compact generator notation in parentheses:

```
generator_expression ::= "(" expression comp_for ")"
```

A generator expression yields a new generator object. Its syntax is the same as for comprehensions, except that it is enclosed in parentheses instead of brackets or curly braces.

Variables used in the generator expression are evaluated lazily when the `__next__()` method is called for generator object (in the same fashion as normal generators). However, the leftmost `for` clause is immediately evaluated, so that an error produced by it can be seen before any other possible error in the code that handles the generator expression. Subsequent `for` clauses cannot be evaluated immediately since they may depend on the previous `for` loop. For example: `(x*y for x in range(10) for y in bar(x))`.

The parentheses can be omitted on calls with only one argument. See section [Calls](#) for the detail.

5.2.9. Yield expressions

```
yield_atom      ::= "(" yield_expression ")"  
yield_expression ::= "yield" [expression_list]
```

The `yield` expression is only used when defining a generator function, and can only be used in the body of a function definition. Using a `yield` expression in a function definition is sufficient to cause that definition to create a generator function instead of a normal function.

When a generator function is called, it returns an iterator known as a generator. That generator then controls the execution of a generator function. The execution starts when one of the generator's methods is called. At that time, the execution proceeds to the first `yield` expression, where it is suspended again, returning the value of `expression_list` to generator's caller. By suspended we mean that all local state is retained, including the current bindings of local

variables, the instruction pointer, and the internal evaluation stack. When the execution is resumed by calling one of the generator's methods, the function can proceed exactly as if the `yield` expression was just another external call. The value of the `yield` expression after resuming depends on the method which resumed the execution.

All of this makes generator functions quite similar to coroutines; they yield multiple times, they have more than one entry point and their execution can be suspended. The only difference is that a generator function cannot control where should the execution continue after it yields; the control is always transferred to the generator's caller.

The `yield` statement is allowed in the `try` clause of a `try ... finally` construct. If the generator is not resumed before it is finalized (by reaching a zero reference count or by being garbage collected), the generator-iterator's `close()` method will be called, allowing any pending `finally` clauses to execute.

The following generator's methods can be used to control the execution of a generator function:

`generator.__next__()`

Starts the execution of a generator function or resumes it at the last executed `yield` expression. When a generator function is resumed with a `__next__()` method, the current `yield` expression always evaluates to `None`. The execution then continues to the next `yield` expression, where the generator is suspended again, and the value of the `expression_list` is returned to `next()`'s caller. If the generator exits without yielding another value, a `StopIteration` exception is raised.

This method is normally called implicitly, e.g. by a `for` loop, or by the built-in `next()` function.

`generator.send(value)`

Resumes the execution and “sends” a value into the generator function. The `value` argument becomes the result of the current `yield` expression. The `send()` method returns the next value yielded by the generator, or raises `StopIteration` if the generator exits without yielding another value. When `send()` is called to start the generator, it must be called with `None` as the argument, because there is no `yield` expression that could receive the value.

`generator.throw(type[, value[, traceback]])`

Raises an exception of type `type` at the point where generator was paused, and returns the next value yielded by the generator function. If the generator exits without yielding another value, a `StopIteration` exception is raised. If the generator function does not catch the passed-in exception, or raises a different exception, then that exception propagates to the caller.

`generator.close()`

Raises a `GeneratorExit` at the point where the generator function was paused. If the generator function then raises `StopIteration` (by exiting normally, or due to already being closed) or `GeneratorExit` (by not catching the exception), `close` returns to its caller. If the generator yields a value, a `RuntimeError` is raised. If the generator raises any other exception, it is propagated to the caller. `close()` does nothing if the generator has already exited due to an exception or normal exit.

Here is a simple example that demonstrates the behavior of generators and generator functions:

```
>>> def echo(value=None):
...     print("Execution starts when 'next()' is called for the
```

```
...     try:
...         while True:
...             try:
...                 value = (yield value)
...             except Exception as e:
...                 value = e
...         finally:
...             print("Don't forget to clean up when 'close()' is c
...
>>> generator = echo(1)
>>> print(next(generator))
Execution starts when 'next()' is called for the first time.
1
>>> print(next(generator))
None
>>> print(generator.send(2))
2
>>> generator.throw(TypeError, "spam")
TypeError('spam',)
>>> generator.close()
Don't forget to clean up when 'close()' is called.
```

The proposal for adding generators and the `yield` statement to Python.

PEP 0342 - Coroutines via Enhanced Generators

The proposal to enhance the API and syntax of generators, making them usable as simple coroutines.

5.3. Primaries

Primaries represent the most tightly bound operations of the language. Their syntax is:

```
primary ::= atom | attributeref | subscription | slicing | ca.
```

5.3.1. Attribute references

An attribute reference is a primary followed by a period and a name:

```
attributeref ::= primary "." identifier
```

The primary must evaluate to an object of a type that supports attribute references, which most objects do. This object is then asked to produce the attribute whose name is the identifier (which can be customized by overriding the `__getattr__()` method). If this attribute is not available, the exception `AttributeError` is raised. Otherwise, the type and value of the object produced is determined by the object. Multiple evaluations of the same attribute reference may yield different objects.

5.3.2. Subscriptions

A subscription selects an item of a sequence (string, tuple or list) or mapping (dictionary) object:

```
subscription ::= primary "[" expression_list "]"
```

The primary must evaluate to an object that supports subscription, e.g. a list or dictionary. User-defined objects can support subscription by defining a `__getitem__()` method.

For built-in objects, there are two types of objects that support subscription:

If the primary is a mapping, the expression list must evaluate to an object whose value is one of the keys of the mapping, and the subscription selects the value in the mapping that corresponds to that key. (The expression list is a tuple except if it has exactly one item.)

If the primary is a sequence, the expression (list) must evaluate to an integer or a slice (as discussed in the following section).

The formal syntax makes no special provision for negative indices in sequences; however, built-in sequences all provide a `__getitem__()` method that interprets negative indices by adding the length of the sequence to the index (so that `x[-1]` selects the last item of `x`). The resulting value must be a nonnegative integer less than the number of items in the sequence, and the subscription selects the item whose index is that value (counting from zero). Since the support for negative indices and slicing occurs in the object's `__getitem__()` method, subclasses overriding this method will need to explicitly add that support.

A string's items are characters. A character is not a separate data type but a string of exactly one character.

5.3.3. Slicings

A slicing selects a range of items in a sequence object (e.g., a string, tuple or list). Slicings may be used as expressions or as targets in assignment or `del` statements. The syntax for a slicing:

```
slicing      ::= primary "[" slice_list "]"
slice_list   ::= slice_item ("," slice_item)* [","]
slice_item   ::= expression | proper_slice
proper_slice ::= [lower_bound] ":" [upper_bound] [ ":" [stride]
```

```
lower_bound ::= expression
upper_bound ::= expression
stride      ::= expression
```

There is ambiguity in the formal syntax here: anything that looks like an expression list also looks like a slice list, so any subscription can be interpreted as a slicing. Rather than further complicating the syntax, this is disambiguated by defining that in this case the interpretation as a subscription takes priority over the interpretation as a slicing (this is the case if the slice list contains no proper slice).

The semantics for a slicing are as follows. The primary must evaluate to a mapping object, and it is indexed (using the same `__getitem__()` method as normal subscription) with a key that is constructed from the slice list, as follows. If the slice list contains at least one comma, the key is a tuple containing the conversion of the slice items; otherwise, the conversion of the lone slice item is the key. The conversion of a slice item that is an expression is that expression. The conversion of a proper slice is a slice object (see section *The standard type hierarchy*) whose `start`, `stop` and `step` attributes are the values of the expressions given as lower bound, upper bound and stride, respectively, substituting `None` for missing expressions.

5.3.4. Calls

A call calls a callable object (e.g., a function) with a possibly empty series of arguments:

```
call ::= primary "(" [argument_list [",,"] | cc
argument_list ::= positional_arguments [",," keyword_arg
                [",," "*" expression] [",," keyword_a
                [",," "*" expression]
                | keyword_arguments [",," "*" expressi
                [",," keyword_arguments] [",," "*" e
                | "*" expression [",," keyword_argumen
```

```
positional_arguments ::= | "*" expression  
                      expression ("," expression)*  
keyword_arguments   ::= keyword_item ("," keyword_item)*  
keyword_item        ::= identifier "=" expression
```

A trailing comma may be present after the positional and keyword arguments but does not affect the semantics.

The primary must evaluate to a callable object (user-defined functions, built-in functions, methods of built-in objects, class objects, methods of class instances, and all objects having a `__call__()` method are callable). All argument expressions are evaluated before the call is attempted. Please refer to section *Function definitions* for the syntax of formal parameter lists.

If keyword arguments are present, they are first converted to positional arguments, as follows. First, a list of unfilled slots is created for the formal parameters. If there are N positional arguments, they are placed in the first N slots. Next, for each keyword argument, the identifier is used to determine the corresponding slot (if the identifier is the same as the first formal parameter name, the first slot is used, and so on). If the slot is already filled, a `TypeError` exception is raised. Otherwise, the value of the argument is placed in the slot, filling it (even if the expression is `None`, it fills the slot). When all arguments have been processed, the slots that are still unfilled are filled with the corresponding default value from the function definition. (Default values are calculated, once, when the function is defined; thus, a mutable object such as a list or dictionary used as default value will be shared by all calls that don't specify an argument value for the corresponding slot; this should usually be avoided.) If there are any unfilled slots for which no default value is specified, a `TypeError` exception is raised. Otherwise, the list of filled slots is used as the argument list for the call.

CPython implementation detail: An implementation may provide built-in functions whose positional parameters do not have names, even if they are ‘named’ for the purpose of documentation, and which therefore cannot be supplied by keyword. In CPython, this is the case for functions implemented in C that use `PyArg_ParseTuple()` to parse their arguments.

If there are more positional arguments than there are formal parameter slots, a `TypeError` exception is raised, unless a formal parameter using the syntax `*identifier` is present; in this case, that formal parameter receives a tuple containing the excess positional arguments (or an empty tuple if there were no excess positional arguments).

If any keyword argument does not correspond to a formal parameter name, a `TypeError` exception is raised, unless a formal parameter using the syntax `**identifier` is present; in this case, that formal parameter receives a dictionary containing the excess keyword arguments (using the keywords as keys and the argument values as corresponding values), or a (new) empty dictionary if there were no excess keyword arguments.

If the syntax `*expression` appears in the function call, `expression` must evaluate to a sequence. Elements from this sequence are treated as if they were additional positional arguments; if there are positional arguments x_1, \dots, x_N , and `expression` evaluates to a sequence y_1, \dots, y_M , this is equivalent to a call with $M+N$ positional arguments $x_1, \dots, x_N, y_1, \dots, y_M$.

A consequence of this is that although the `*expression` syntax may appear *after* some keyword arguments, it is processed *before* the keyword arguments (and the `**expression` argument, if any – see

below). So:

```
>>> def f(a, b):
...     print(a, b)
...
>>> f(b=1, *(2,))
2 1
>>> f(a=1, *(2,))
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
TypeError: f() got multiple values for keyword argument 'a'
>>> f(1, *(2,))
1 2
```

It is unusual for both keyword arguments and the `*expression` syntax to be used in the same call, so in practice this confusion does not arise.

If the syntax `**expression` appears in the function call, `expression` must evaluate to a mapping, the contents of which are treated as additional keyword arguments. In the case of a keyword appearing in both `expression` and as an explicit keyword argument, a `TypeError` exception is raised.

Formal parameters using the syntax `*identifier` or `**identifier` cannot be used as positional argument slots or as keyword argument names.

A call always returns some value, possibly `None`, unless it raises an exception. How this value is computed depends on the type of the callable object.

If it is—

a user-defined function:

The code block for the function is executed, passing it the argument list. The first thing the code block will do is bind the formal parameters to the arguments; this is described in section

Function definitions. When the code block executes a `return` statement, this specifies the return value of the function call.

a built-in function or method:

The result is up to the interpreter; see *Built-in Functions* for the descriptions of built-in functions and methods.

a class object:

A new instance of that class is returned.

a class instance method:

The corresponding user-defined function is called, with an argument list that is one longer than the argument list of the call: the instance becomes the first argument.

a class instance:

The class must define a `__call__()` method; the effect is then the same as if that method was called.

5.4. The power operator

The power operator binds more tightly than unary operators on its left; it binds less tightly than unary operators on its right. The syntax is:

```
power ::= primary ["**" u_expr]
```

Thus, in an unparenthesized sequence of power and unary operators, the operators are evaluated from right to left (this does not constrain the evaluation order for the operands): `-1**2` results in `-1`.

The power operator has the same semantics as the built-in `pow()` function, when called with two arguments: it yields its left argument raised to the power of its right argument. The numeric arguments are first converted to a common type, and the result is of that type.

For int operands, the result has the same type as the operands unless the second argument is negative; in that case, all arguments are converted to float and a float result is delivered. For example, `10**2` returns `100`, but `10** -2` returns `0.01`.

Raising `0.0` to a negative power results in a `ZeroDivisionError`. Raising a negative number to a fractional power results in a `complex` number. (In earlier versions it raised a `ValueError`.)

5.5. Unary arithmetic and bitwise operations

All unary arithmetic and bitwise operations have the same priority:

```
u_expr ::= power | "-" u_expr | "+" u_expr | "~" u_expr
```

The unary `-` (minus) operator yields the negation of its numeric argument.

The unary `+` (plus) operator yields its numeric argument unchanged.

The unary `~` (invert) operator yields the bitwise inversion of its integer argument. The bitwise inversion of `x` is defined as `-(x+1)`. It only applies to integral numbers.

In all three cases, if the argument does not have the proper type, a `TypeError` exception is raised.

5.6. Binary arithmetic operations

The binary arithmetic operations have the conventional priority levels. Note that some of these operations also apply to certain non-numeric types. Apart from the power operator, there are only two levels, one for multiplicative operators and one for additive operators:

```
m_expr ::= u_expr | m_expr "*" u_expr | m_expr "/" u_expr |  
          | m_expr "%" u_expr  
a_expr ::= m_expr | a_expr "+" m_expr | a_expr "-" m_expr
```

The `*` (multiplication) operator yields the product of its arguments. The arguments must either both be numbers, or one argument must be an integer and the other must be a sequence. In the former case, the numbers are converted to a common type and then multiplied together. In the latter case, sequence repetition is performed; a negative repetition factor yields an empty sequence.

The `/` (division) and `//` (floor division) operators yield the quotient of their arguments. The numeric arguments are first converted to a common type. Integer division yields a float, while floor division of integers results in an integer; the result is that of mathematical division with the ‘floor’ function applied to the result. Division by zero raises the `ZeroDivisionError` exception.

The `%` (modulo) operator yields the remainder from the division of the first argument by the second. The numeric arguments are first converted to a common type. A zero right argument raises the `ZeroDivisionError` exception. The arguments may be floating point numbers, e.g., `3.14%0.7` equals `0.34` (since `3.14` equals `4*0.7 + 0.34`.) The modulo operator always yields a result with the same sign as its second operand (or zero); the absolute value of the result is

strictly smaller than the absolute value of the second operand [1].

The floor division and modulo operators are connected by the following identity: $x == (x//y)*y + (x\%y)$. Floor division and modulo are also connected with the built-in function `divmod()`: `divmod(x, y) == (x//y, x%y)`. [2].

In addition to performing the modulo operation on numbers, the `%` operator is also overloaded by string objects to perform old-style string formatting (also known as interpolation). The syntax for string formatting is described in the Python Library Reference, section *Old String Formatting Operations*.

The floor division operator, the modulo operator, and the `divmod()` function are not defined for complex numbers. Instead, convert to a floating point number using the `abs()` function if appropriate.

The `+` (addition) operator yields the sum of its arguments. The arguments must either both be numbers or both sequences of the same type. In the former case, the numbers are converted to a common type and then added together. In the latter case, the sequences are concatenated.

The `-` (subtraction) operator yields the difference of its arguments. The numeric arguments are first converted to a common type.

5.7. Shifting operations

The shifting operations have lower priority than the arithmetic operations:

```
shift_expr ::= a_expr | shift_expr ( "<<" | ">>" ) a_expr
```

These operators accept integers as arguments. They shift the first argument to the left or right by the number of bits given by the second argument.

A right shift by n bits is defined as division by `pow(2, n)`. A left shift by n bits is defined as multiplication with `pow(2, n)`.

Note: In the current implementation, the right-hand operand is required to be at most `sys.maxsize`. If the right-hand operand is larger than `sys.maxsize` an `OverflowError` exception is raised.

5.8. Binary bitwise operations

Each of the three bitwise operations has a different priority level:

```
and_expr ::= shift_expr | and_expr "&" shift_expr
xor_expr ::= and_expr | xor_expr "^" and_expr
or_expr  ::= xor_expr | or_expr "|" xor_expr
```

The `&` operator yields the bitwise AND of its arguments, which must be integers.

The `^` operator yields the bitwise XOR (exclusive OR) of its arguments, which must be integers.

The `|` operator yields the bitwise (inclusive) OR of its arguments, which must be integers.

5.9. Comparisons

Unlike C, all comparison operations in Python have the same priority, which is lower than that of any arithmetic, shifting or bitwise operation. Also unlike C, expressions like `a < b < c` have the interpretation that is conventional in mathematics:

```
comparison ::= or_expr ( comp_operator or_expr )*
comp_operator ::= "<" | ">" | "==" | ">=" | "<=" | "!="
               | "is" ["not"] | ["not"] "in"
```

Comparisons yield boolean values: `True` or `False`.

Comparisons can be chained arbitrarily, e.g., `x < y <= z` is equivalent to `x < y` and `y <= z`, except that `y` is evaluated only once (but in both cases `z` is not evaluated at all when `x < y` is found to be false).

Formally, if `a, b, c, ..., y, z` are expressions and `op1, op2, ..., opN` are comparison operators, then `a op1 b op2 c ... y opN z` is equivalent to `a op1 b` and `b op2 c` and `... y opN z`, except that each expression is evaluated at most once.

Note that `a op1 b op2 c` doesn't imply any kind of comparison between `a` and `c`, so that, e.g., `x < y > z` is perfectly legal (though perhaps not pretty).

The operators `<`, `>`, `==`, `>=`, `<=`, and `!=` compare the values of two objects. The objects need not have the same type. If both are numbers, they are converted to a common type. Otherwise, the `==` and `!=` operators *always* consider objects of different types to be unequal, while the `<`, `>`, `>=` and `<=` operators raise a `TypeError` when comparing objects of different types that do not implement these

operators for the given pair of types. You can control comparison behavior of objects of non-built-in types by defining rich comparison methods like `__gt__()`, described in section *Basic customization*.

Comparison of objects of the same type depends on the type:

- Numbers are compared arithmetically.
- The values `float('NaN')` and `Decimal('NaN')` are special. They are identical to themselves, `x is x` but are not equal to themselves, `x != x`. Additionally, comparing any value to a not-a-number value will return `False`. For example, both `3 < float('NaN')` and `float('NaN') < 3` will return `False`.
- Bytes objects are compared lexicographically using the numeric values of their elements.
- Strings are compared lexicographically using the numeric equivalents (the result of the built-in function `ord()`) of their characters. [3] String and bytes object can't be compared!
- Tuples and lists are compared lexicographically using comparison of corresponding elements. This means that to compare equal, each element must compare equal and the two sequences must be of the same type and have the same length.

If not equal, the sequences are ordered the same as their first differing elements. For example, `[1,2,x] <= [1,2,y]` has the same value as `x <= y`. If the corresponding element does not exist, the shorter sequence is ordered first (for example, `[1,2] < [1,2,3]`).

- Mappings (dictionaries) compare equal if and only if they have the same `(key, value)` pairs. Order comparisons `'<'`, `'<='`,

`'>=', '>')` raise `TypeError`.

- Sets and frozensets define comparison operators to mean subset and superset tests. Those relations do not define total orderings (the two sets `{1,2}` and `{2,3}` are not equal, nor subsets of one another, nor supersets of one another). Accordingly, sets are not appropriate arguments for functions which depend on total ordering. For example, `min()`, `max()`, and `sorted()` produce undefined results given a list of sets as inputs.
- Most other objects of built-in types compare unequal unless they are the same object; the choice whether one object is considered smaller or larger than another one is made arbitrarily but consistently within one execution of a program.

Comparison of objects of the differing types depends on whether either of the types provide explicit support for the comparison. Most numeric types can be compared with one another, but comparisons of `float` and `Decimal` are not supported to avoid the inevitable confusion arising from representation issues such as `float('1.1')` being inexactly represented and therefore not exactly equal to `Decimal('1.1')` which is. When cross-type comparison is not supported, the comparison method returns `NotImplemented`. This can create the illusion of non-transitivity between supported cross-type comparisons and unsupported comparisons. For example, `Decimal(2) == 2` and `2 == float(2)` but `Decimal(2) != float(2)`.

The operators `in` and `not in` test for membership. `x in s` evaluates to true if `x` is a member of `s`, and false otherwise. `x not in s` returns the negation of `x in s`. All built-in sequences and set types support this as well as dictionary, for which `in` tests whether a the dictionary has a given key. For container types such as list, tuple, set, frozenset, dict, or `collections.deque`, the expression `x in y` is

equivalent to `any(x is e or x == e for e in y)`.

For the string and bytes types, `x in y` is true if and only if `x` is a substring of `y`. An equivalent test is `y.find(x) != -1`. Empty strings are always considered to be a substring of any other string, so `"" in "abc"` will return `True`.

For user-defined classes which define the `__contains__()` method, `x in y` is true if and only if `y.__contains__(x)` is true.

For user-defined classes which do not define `__contains__()` but do define `__iter__()`, `x in y` is true if some value `z` with `x == z` is produced while iterating over `y`. If an exception is raised during the iteration, it is as if `in` raised that exception.

Lastly, the old-style iteration protocol is tried: if a class defines `__getitem__()`, `x in y` is true if and only if there is a non-negative integer index `i` such that `x == y[i]`, and all lower integer indices do not raise `IndexError` exception. (If any other exception is raised, it is as if `in` raised that exception).

The operator `not in` is defined to have the inverse true value of `in`.

The operators `is` and `is not` test for object identity: `x is y` is true if and only if `x` and `y` are the same object. `x is not y` yields the inverse truth value. [4]

5.10. Boolean operations

```
or_test ::= and_test | or_test "or" and_test
and_test ::= not_test | and_test "and" not_test
not_test ::= comparison | "not" not_test
```

In the context of Boolean operations, and also when expressions are used by control flow statements, the following values are interpreted as false: `False`, `None`, numeric zero of all types, and empty strings and containers (including strings, tuples, lists, dictionaries, sets and frozensets). All other values are interpreted as true. User-defined objects can customize their truth value by providing a `__bool__()` method.

The operator `not` yields `True` if its argument is false, `False` otherwise.

The expression `x and y` first evaluates `x`; if `x` is false, its value is returned; otherwise, `y` is evaluated and the resulting value is returned.

The expression `x or y` first evaluates `x`; if `x` is true, its value is returned; otherwise, `y` is evaluated and the resulting value is returned.

(Note that neither `and` nor `or` restrict the value and type they return to `False` and `True`, but rather return the last evaluated argument. This is sometimes useful, e.g., if `s` is a string that should be replaced by a default value if it is empty, the expression `s or 'foo'` yields the desired value. Because `not` has to invent a value anyway, it does not bother to return a value of the same type as its argument, so e.g., `not 'foo'` yields `False`, not `''`.)

5.11. Conditional expressions

```
conditional_expression ::= or_test ["if" or_test "else" expres  
expression            ::= conditional_expression | lambda_for  
expression_nocond     ::= or_test | lambda_form_nocond
```

Conditional expressions (sometimes called a “ternary operator”) have the lowest priority of all Python operations.

The expression `x if C else y` first evaluates the condition, *C* (*not* *x*); if *C* is true, *x* is evaluated and its value is returned; otherwise, *y* is evaluated and its value is returned.

See [PEP 308](#) for more details about conditional expressions.

5.12. Lambdas

```
lambda_form      ::= "lambda" [parameter_list]: expression  
lambda_form_nocond ::= "lambda" [parameter_list]: expression_n
```

Lambda forms (lambda expressions) have the same syntactic position as expressions. They are a shorthand to create anonymous functions; the expression `lambda arguments: expression` yields a function object. The unnamed object behaves like a function object defined with

```
def <lambda>(arguments):  
    return expression
```

See section [Function definitions](#) for the syntax of parameter lists. Note that functions created with lambda forms cannot contain statements or annotations.

5.13. Expression lists

```
expression_list ::= expression ( "," expression )* [ ",", "]"
```

An expression list containing at least one comma yields a tuple. The length of the tuple is the number of expressions in the list. The expressions are evaluated from left to right.

The trailing comma is required only to create a single tuple (a.k.a. a *singleton*); it is optional in all other cases. A single expression without a trailing comma doesn't create a tuple, but rather yields the value of that expression. (To create an empty tuple, use an empty pair of parentheses: `()`.)

5.14. Evaluation order

Python evaluates expressions from left to right. Notice that while evaluating an assignment, the right-hand side is evaluated before the left-hand side.

In the following lines, expressions will be evaluated in the arithmetic order of their suffixes:

```
expr1, expr2, expr3, expr4
(expr1, expr2, expr3, expr4)
{expr1: expr2, expr3: expr4}
expr1 + expr2 * (expr3 - expr4)
expr1(expr2, expr3, *expr4, **expr5)
expr3, expr4 = expr1, expr2
```

5.15. Summary

The following table summarizes the operator precedences in Python, from lowest precedence (least binding) to highest precedence (most binding). Operators in the same box have the same precedence. Unless the syntax is explicitly given, operators are binary. Operators in the same box group left to right (except for comparisons, including tests, which all have the same precedence and chain from left to right — see section [Comparisons](#) — and exponentiation, which groups from right to left).

Operator	Description
<code>lambda</code>	Lambda expression
<code>if – else</code>	Conditional expression
<code>or</code>	Boolean OR
<code>and</code>	Boolean AND
<code>not X</code>	Boolean NOT
<code>in, not in, is, is not, <, <=, >, >=, !=, ==</code>	Comparisons, including membership tests and identity tests,
<code> </code>	Bitwise OR
<code>^</code>	Bitwise XOR
<code>&</code>	Bitwise AND
<code><<, >></code>	Shifts
<code>+, -</code>	Addition and subtraction
<code>*, /, //, %</code>	Multiplication, division, remainder [5]
<code>+x, -x, ~x</code>	Positive, negative, bitwise NOT
<code>**</code>	Exponentiation [6]
<code>x[index], x[index:index], x(arguments...), x.attribute</code>	Subscription, slicing, call, attribute reference

<code>(expressions...), [expressions...], {key:datum...}, {expressions...}</code>	Binding or tuple display, list display, dictionary display, set display
---	---

Footnotes

[1] While `abs(x%y) < abs(y)` is true mathematically, for floats it may not be true numerically due to roundoff. For example, and assuming a platform on which a Python float is an IEEE 754 double-precision number, in order that `-1e-100 % 1e100` have the same sign as `1e100`, the computed result is `-1e-100 + 1e100`, which is numerically exactly equal to `1e100`. The function `math.fmod()` returns a result whose sign matches the sign of the first argument instead, and so returns `-1e-100` in this case. Which approach is more appropriate depends on the application.

[2] If `x` is very close to an exact integer multiple of `y`, it's possible for `x//y` to be one larger than `(x-x%y)//y` due to rounding. In such cases, Python returns the latter result, in order to preserve that `divmod(x,y)[0] * y + x % y` be very close to `x`.

[3] While comparisons between strings make sense at the byte level, they may be counter-intuitive to users. For example, the strings `"\u00c7"` and `"\u0327\u0043"` compare differently, even though they both represent the same unicode character (LATIN CAPITAL LETTER C WITH CEDILLA). To compare strings in a human recognizable way, compare using `unicodedata.normalize()`.

[4] Due to automatic garbage-collection, free lists, and the dynamic nature of descriptors, you may notice seemingly unusual behaviour in certain uses of the `is` operator, like those involving comparisons between instance methods, or constants. Check their documentation for more info.

[5] The `%` operator is also used for string formatting; the same precedence applies.

[6] The power operator `**` binds less tightly than an arithmetic or bitwise unary operator on its right, that is, `2**-1` is `0.5`.

6. Simple statements

Simple statements are comprised within a single logical line. Several simple statements may occur on a single line separated by semicolons. The syntax for simple statements is:

```
simple_stmt ::= expression_stmt
             | assert_stmt
             | assignment_stmt
             | augmented_assignment_stmt
             | pass_stmt
             | del_stmt
             | return_stmt
             | yield_stmt
             | raise_stmt
             | break_stmt
             | continue_stmt
             | import_stmt
             | global_stmt
             | nonlocal_stmt
```

6.1. Expression statements

Expression statements are used (mostly interactively) to compute and write a value, or (usually) to call a procedure (a function that returns no meaningful result; in Python, procedures return the value `None`). Other uses of expression statements are allowed and occasionally useful. The syntax for an expression statement is:

```
expression_stmt ::= expression_list
```

An expression statement evaluates the expression list (which may be a single expression).

In interactive mode, if the value is not `None`, it is converted to a string using the built-in `repr()` function and the resulting string is written to standard output on a line by itself (except if the result is `None`, so that procedure calls do not cause any output.)

6.2. Assignment statements

Assignment statements are used to (re)bind names to values and to modify attributes or items of mutable objects:

```
assignment_stmt ::= (target_list "=")+ (expression_list | yield)
target_list     ::= target ("," target)* [","]
target         ::= identifier
                | "(" target_list ")"
                | "[" target_list "]"
                | attributeref
                | subscription
                | slicing
                | "*" target
```

(See section *Primitives* for the syntax definitions for the last three symbols.)

An assignment statement evaluates the expression list (remember that this can be a single expression or a comma-separated list, the latter yielding a tuple) and assigns the single resulting object to each of the target lists, from left to right.

Assignment is defined recursively depending on the form of the target (list). When a target is part of a mutable object (an attribute reference, subscription or slicing), the mutable object must ultimately perform the assignment and decide about its validity, and may raise an exception if the assignment is unacceptable. The rules observed by various types and the exceptions raised are given with the definition of the object types (see section *The standard type hierarchy*).

Assignment of an object to a target list, optionally enclosed in parentheses or square brackets, is recursively defined as follows.

- If the target list is a single target: The object is assigned to that

target.

- If the target list is a comma-separated list of targets: The object must be an iterable with the same number of items as there are targets in the target list, and the items are assigned, from left to right, to the corresponding targets. (This rule is relaxed as of Python 1.5; in earlier versions, the object had to be a tuple. Since strings are sequences, an assignment like `a, b = "xy"` is now legal as long as the string has the right length.)
 - If the target list contains one target prefixed with an asterisk, called a “starred” target: The object must be a sequence with at least as many items as there are targets in the target list, minus one. The first items of the sequence are assigned, from left to right, to the targets before the starred target. The final items of the sequence are assigned to the targets after the starred target. A list of the remaining items in the sequence is then assigned to the starred target (the list can be empty).
 - Else: The object must be a sequence with the same number of items as there are targets in the target list, and the items are assigned, from left to right, to the corresponding targets.

Assignment of an object to a single target is recursively defined as follows.

- If the target is an identifier (name):
 - If the name does not occur in a `global` or `nonlocal` statement in the current code block: the name is bound to the object in the current local namespace.
 - Otherwise: the name is bound to the object in the global namespace or the outer namespace determined by `nonlocal`, respectively.

The name is rebound if it was already bound. This may cause

the reference count for the object previously bound to the name to reach zero, causing the object to be deallocated and its destructor (if it has one) to be called.

- If the target is a target list enclosed in parentheses or in square brackets: The object must be an iterable with the same number of items as there are targets in the target list, and its items are assigned, from left to right, to the corresponding targets.
- If the target is an attribute reference: The primary expression in the reference is evaluated. It should yield an object with assignable attributes; if this is not the case, `TypeError` is raised. That object is then asked to assign the assigned object to the given attribute; if it cannot perform the assignment, it raises an exception (usually but not necessarily `AttributeError`).

Note: If the object is a class instance and the attribute reference occurs on both sides of the assignment operator, the RHS expression, `a.x` can access either an instance attribute or (if no instance attribute exists) a class attribute. The LHS target `a.x` is always set as an instance attribute, creating it if necessary. Thus, the two occurrences of `a.x` do not necessarily refer to the same attribute: if the RHS expression refers to a class attribute, the LHS creates a new instance attribute as the target of the assignment:

```
class Cls:
    x = 3          # class variable
inst = Cls()
inst.x = inst.x + 1  # writes inst.x as 4 leaving Cls.x as
```

This description does not necessarily apply to descriptor attributes, such as properties created with `property()`.

- If the target is a subscription: The primary expression in the

reference is evaluated. It should yield either a mutable sequence object (such as a list) or a mapping object (such as a dictionary). Next, the subscript expression is evaluated.

If the primary is a mutable sequence object (such as a list), the subscript must yield an integer. If it is negative, the sequence's length is added to it. The resulting value must be a nonnegative integer less than the sequence's length, and the sequence is asked to assign the assigned object to its item with that index. If the index is out of range, `IndexError` is raised (assignment to a subscripted sequence cannot add new items to a list).

If the primary is a mapping object (such as a dictionary), the subscript must have a type compatible with the mapping's key type, and the mapping is then asked to create a key/datum pair which maps the subscript to the assigned object. This can either replace an existing key/value pair with the same key value, or insert a new key/value pair (if no key with the same value existed).

For user-defined objects, the `__setitem__()` method is called with appropriate arguments.

- If the target is a slicing: The primary expression in the reference is evaluated. It should yield a mutable sequence object (such as a list). The assigned object should be a sequence object of the same type. Next, the lower and upper bound expressions are evaluated, insofar they are present; defaults are zero and the sequence's length. The bounds should evaluate to integers. If either bound is negative, the sequence's length is added to it. The resulting bounds are clipped to lie between zero and the sequence's length, inclusive. Finally, the sequence object is asked to replace the slice with the items of the assigned sequence. The length of the slice may be different from the length of the assigned sequence, thus changing the length of

the target sequence, if the object allows it.

CPython implementation detail: In the current implementation, the syntax for targets is taken to be the same as for expressions, and invalid syntax is rejected during the code generation phase, causing less detailed error messages.

WARNING: Although the definition of assignment implies that overlaps between the left-hand side and the right-hand side are 'safe' (for example `a, b = b, a` swaps two variables), overlaps *within* the collection of assigned-to variables are not safe! For instance, the following program prints `[0, 2]`:

```
x = [0, 1]
i = 0
i, x[i] = 1, 2
print(x)
```

PEP 3132 - Extended Iterable Unpacking

The specification for the `*target` feature.

6.2.1. Augmented assignment statements

Augmented assignment is the combination, in a single statement, of a binary operation and an assignment statement:

```
augmented_assignment_stmt ::= augtarget augop (expression_list
augtarget                  ::= identifier | attributeref | subs
augop                      ::= "+=" | "-=" | "*=" | "/=" | "//="
                             | ">>=" | "<<=" | "&=" | "^=" |
```

(See section *Primaries* for the syntax definitions for the last three symbols.)

An augmented assignment evaluates the target (which, unlike normal assignment statements, cannot be an unpacking) and the expression list, performs the binary operation specific to the type of assignment on the two operands, and assigns the result to the original target. The target is only evaluated once.

An augmented assignment expression like `x += 1` can be rewritten as `x = x + 1` to achieve a similar, but not exactly equal effect. In the augmented version, `x` is only evaluated once. Also, when possible, the actual operation is performed *in-place*, meaning that rather than creating a new object and assigning that to the target, the old object is modified instead.

With the exception of assigning to tuples and multiple targets in a single statement, the assignment done by augmented assignment statements is handled the same way as normal assignments. Similarly, with the exception of the possible *in-place* behavior, the binary operation performed by augmented assignment is the same as the normal binary operations.

For targets which are attribute references, the same *caveat about class and instance attributes* applies as for regular assignments.

6.3. The `assert` statement

Assert statements are a convenient way to insert debugging assertions into a program:

```
assert_stmt ::= "assert" expression ["," expression]
```

The simple form, `assert expression`, is equivalent to

```
if __debug__:  
    if not expression: raise AssertionError
```

The extended form, `assert expression1, expression2`, is equivalent to

```
if __debug__:  
    if not expression1: raise AssertionError(expression2)
```

These equivalences assume that `__debug__` and `AssertionError` refer to the built-in variables with those names. In the current implementation, the built-in variable `__debug__` is `True` under normal circumstances, `False` when optimization is requested (command line option `-O`). The current code generator emits no code for an assert statement when optimization is requested at compile time. Note that it is unnecessary to include the source code for the expression that failed in the error message; it will be displayed as part of the stack trace.

Assignments to `__debug__` are illegal. The value for the built-in variable is determined when the interpreter starts.

6.4. The `pass` statement

```
pass_stmt ::= "pass"
```

`pass` is a null operation — when it is executed, nothing happens. It is useful as a placeholder when a statement is required syntactically, but no code needs to be executed, for example:

```
def f(arg): pass      # a function that does nothing (yet)
class C: pass        # a class with no methods (yet)
```

6.5. The `del` statement

```
del_stmt ::= "del" target_list
```

Deletion is recursively defined very similar to the way assignment is defined. Rather than spelling it out in full details, here are some hints.

Deletion of a target list recursively deletes each target, from left to right.

Deletion of a name removes the binding of that name from the local or global namespace, depending on whether the name occurs in a `global` statement in the same code block. If the name is unbound, a `NameError` exception will be raised.

Deletion of attribute references, subscriptions and slicings is passed to the primary object involved; deletion of a slicing is in general equivalent to assignment of an empty slice of the right type (but even this is determined by the sliced object).

Changed in version 3.2.

6.6. The `return` statement

```
return_stmt ::= "return" [expression_list]
```

`return` may only occur syntactically nested in a function definition, not within a nested class definition.

If an expression list is present, it is evaluated, else `None` is substituted.

`return` leaves the current function call with the expression list (or `None`) as return value.

When `return` passes control out of a `try` statement with a `finally` clause, that `finally` clause is executed before really leaving the function.

In a generator function, the `return` statement is not allowed to include an `expression_list`. In that context, a bare `return` indicates that the generator is done and will cause `StopIteration` to be raised.

6.7. The `yield` statement

```
yield_stmt ::= yield_expression
```

The `yield` statement is only used when defining a generator function, and is only used in the body of the generator function. Using a `yield` statement in a function definition is sufficient to cause that definition to create a generator function instead of a normal function. When a generator function is called, it returns an iterator known as a generator iterator, or more commonly, a generator. The body of the generator function is executed by calling the `next()` function on the generator repeatedly until it raises an exception.

When a `yield` statement is executed, the state of the generator is frozen and the value of `expression_list` is returned to `next()`'s caller. By “frozen” we mean that all local state is retained, including the current bindings of local variables, the instruction pointer, and the internal evaluation stack: enough information is saved so that the next time `next()` is invoked, the function can proceed exactly as if the `yield` statement were just another external call.

The `yield` statement is allowed in the `try` clause of a `try ... finally` construct. If the generator is not resumed before it is finalized (by reaching a zero reference count or by being garbage collected), the generator-iterator's `close()` method will be called, allowing any pending `finally` clauses to execute.

See also:

PEP 0255 - Simple Generators

The proposal for adding generators and the `yield` statement to Python.

PEP 0342 - Coroutines via Enhanced Generators

The proposal that, among other generator enhancements, proposed allowing `yield` to appear inside a `try ... finally` block.

6.8. The `raise` statement

```
raise_stmt ::= "raise" [expression ["from" expression]]
```

If no expressions are present, `raise` re-raises the last exception that was active in the current scope. If no exception is active in the current scope, a `TypeError` exception is raised indicating that this is an error (if running under IDLE, a `queue.Empty` exception is raised instead).

Otherwise, `raise` evaluates the first expression as the exception object. It must be either a subclass or an instance of `BaseException`. If it is a class, the exception instance will be obtained when needed by instantiating the class with no arguments.

The *type* of the exception is the exception instance's class, the *value* is the instance itself.

A traceback object is normally created automatically when an exception is raised and attached to it as the `__traceback__` attribute, which is writable. You can create an exception and set your own traceback in one step using the `with_traceback()` exception method (which returns the same exception instance, with its traceback set to its argument), like so:

```
raise Exception("foo occurred").with_traceback(tracebackobj)
```

The `from` clause is used for exception chaining: if given, the second *expression* must be another exception class or instance, which will then be attached to the raised exception as the `__cause__` attribute (which is writable). If the raised exception is not handled, both exceptions will be printed:

```
>>> try:
...     print(1 / 0)
... except Exception as exc:
...     raise RuntimeError("Something bad happened") from exc..
```

```
Traceback (most recent call last):
  File "<stdin>", line 2, in <module>
ZeroDivisionError: int division or modulo by zero
```

The above exception was the direct cause of the following exception

```
Traceback (most recent call last):
  File "<stdin>", line 4, in <module>
RuntimeError: Something bad happened
```

A similar mechanism works implicitly if an exception is raised inside an exception handler: the previous exception is then attached as the new exception's `__context__` attribute:

```
>>> try:
...     print(1 / 0)
... except:
...     raise RuntimeError("Something bad happened")
... 
```

```
Traceback (most recent call last):
  File "<stdin>", line 2, in <module>
ZeroDivisionError: int division or modulo by zero
```

During handling of the above exception, another exception occurred

```
Traceback (most recent call last):
  File "<stdin>", line 4, in <module>
RuntimeError: Something bad happened
```

Additional information on exceptions can be found in section [Exceptions](#), and information about handling exceptions is in section [The try statement](#).

6.9. The `break` statement

```
break_stmt ::= "break"
```

`break` may only occur syntactically nested in a `for` or `while` loop, but not nested in a function or class definition within that loop.

It terminates the nearest enclosing loop, skipping the optional `else` clause if the loop has one.

If a `for` loop is terminated by `break`, the loop control target keeps its current value.

When `break` passes control out of a `try` statement with a `finally` clause, that `finally` clause is executed before really leaving the loop.

6.10. The `continue` statement

```
continue_stmt ::= "continue"
```

`continue` may only occur syntactically nested in a `for` or `while` loop, but not nested in a function or class definition or `finally` clause within that loop. It continues with the next cycle of the nearest enclosing loop.

When `continue` passes control out of a `try` statement with a `finally` clause, that `finally` clause is executed before really starting the next loop cycle.

6.11. The `import` statement

```
import_stmt ::= "import" module ["as" name] ( "," module |
              | "from" relative_module "import" identifi
              ( "," identifier ["as" name] ) *
              | "from" relative_module "import" "(" iden
              ( "," identifier ["as" name] ) * [ "," ] ")"
              | "from" module "import" "*"
module       ::= ( identifier "." ) * identifier
relative_module ::= "." * module | "." +
name        ::= identifier
```

Import statements are executed in two steps: (1) find a module, and initialize it if necessary; (2) define a name or names in the local namespace (of the scope where the `import` statement occurs). The statement comes in two forms differing on whether it uses the `from` keyword. The first form (without `from`) repeats these steps for each identifier in the list. The form with `from` performs step (1) once, and then performs step (2) repeatedly. For a reference implementation of step (1), see the `importlib` module.

To understand how step (1) occurs, one must first understand how Python handles hierarchical naming of modules. To help organize modules and provide a hierarchy in naming, Python has a concept of packages. A package can contain other packages and modules while modules cannot contain other modules or packages. From a file system perspective, packages are directories and modules are files. The original [specification for packages](#) is still available to read, although minor details have changed since the writing of that document.

Once the name of the module is known (unless otherwise specified, the term “module” will refer to both packages and modules), searching for the module or package can begin. The first place

checked is `sys.modules`, the cache of all modules that have been imported previously. If the module is found there then it is used in step (2) of import unless `None` is found in `sys.modules`, in which case `ImportError` is raised.

If the module is not found in the cache, then `sys.meta_path` is searched (the specification for `sys.meta_path` can be found in [PEP 302](#)). The object is a list of *finder* objects which are queried in order as to whether they know how to load the module by calling their `find_module()` method with the name of the module. If the module happens to be contained within a package (as denoted by the existence of a dot in the name), then a second argument to `find_module()` is given as the value of the `__path__` attribute from the parent package (everything up to the last dot in the name of the module being imported). If a finder can find the module it returns a *loader* (discussed later) or returns `None`.

If none of the finders on `sys.meta_path` are able to find the module then some implicitly defined finders are queried. Implementations of Python vary in what implicit meta path finders are defined. The one they all do define, though, is one that handles `sys.path_hooks`, `sys.path_importer_cache`, and `sys.path`.

The implicit finder searches for the requested module in the “paths” specified in one of two places (“paths” do not have to be file system paths). If the module being imported is supposed to be contained within a package then the second argument passed to `find_module()`, `__path__` on the parent package, is used as the source of paths. If the module is not contained in a package then `sys.path` is used as the source of paths.

Once the source of paths is chosen it is iterated over to find a finder that can handle that path. The dict at `sys.path_importer_cache`

caches finders for paths and is checked for a finder. If the path does not have a finder cached then `sys.path_hooks` is searched by calling each object in the list with a single argument of the path, returning a finder or raises `ImportError`. If a finder is returned then it is cached in `sys.path_importer_cache` and then used for that path entry. If no finder can be found but the path exists then a value of `None` is stored in `sys.path_importer_cache` to signify that an implicit, file-based finder that handles modules stored as individual files should be used for that path. If the path does not exist then a finder which always returns `None` is placed in the cache for the path.

If no finder can find the module then `ImportError` is raised. Otherwise some finder returned a loader whose `load_module()` method is called with the name of the module to load (see [PEP 302](#) for the original definition of loaders). A loader has several responsibilities to perform on a module it loads. First, if the module already exists in `sys.modules` (a possibility if the loader is called outside of the import machinery) then it is to use that module for initialization and not a new module. But if the module does not exist in `sys.modules` then it is to be added to that dict before initialization begins. If an error occurs during loading of the module and it was added to `sys.modules` it is to be removed from the dict. If an error occurs but the module was already in `sys.modules` it is left in the dict.

The loader must set several attributes on the module. `__name__` is to be set to the name of the module. `__file__` is to be the “path” to the file unless the module is built-in (and thus listed in `sys.builtin_module_names`) in which case the attribute is not set. If what is being imported is a package then `__path__` is to be set to a list of paths to be searched when looking for modules and packages contained within the package being imported. `__package__` is optional but should be set to the name of package that contains the module or package (the empty string is used for module not contained in a

package). `__loader__` is also optional but should be set to the loader object that is loading the module.

If an error occurs during loading then the loader raises `ImportError` if some other exception is not already being propagated. Otherwise the loader returns the module that was loaded and initialized.

When step (1) finishes without raising an exception, step (2) can begin.

The first form of `import` statement binds the module name in the local namespace to the module object, and then goes on to import the next identifier, if any. If the module name is followed by `as`, the name following `as` is used as the local name for the module.

The `from` form does not bind the module name: it goes through the list of identifiers, looks each one of them up in the module found in step (1), and binds the name in the local namespace to the object thus found. As with the first form of `import`, an alternate local name can be supplied by specifying “`as localname`”. If a name is not found, `ImportError` is raised. If the list of identifiers is replaced by a star (`'*'`), all public names defined in the module are bound in the local namespace of the `import` statement.

The *public names* defined by a module are determined by checking the module’s namespace for a variable named `__all__`; if defined, it must be a sequence of strings which are names defined or imported by that module. The names given in `__all__` are all considered public and are required to exist. If `__all__` is not defined, the set of public names includes all names found in the module’s namespace which do not begin with an underscore character (`'_'`). `__all__` should contain the entire public API. It is intended to avoid accidentally exporting items that are not part of the API (such as library modules which were imported and used within the module).

The `from` form with `*` may only occur in a module scope. The wildcard form of import — `import *` — is only allowed at the module level. Attempting to use it in class or function definitions will raise a `SyntaxError`.

When specifying what module to import you do not have to specify the absolute name of the module. When a module or package is contained within another package it is possible to make a relative import within the same top package without having to mention the package name. By using leading dots in the specified module or package after `from` you can specify how high to traverse up the current package hierarchy without specifying exact names. One leading dot means the current package where the module making the import exists. Two dots means up one package level. Three dots is up two levels, etc. So if you execute `from . import mod` from a module in the `pkg` package then you will end up importing `pkg.mod`. If you execute `from ..subpkg2 import mod` from within `pkg.subpkg1` you will import `pkg.subpkg2.mod`. The specification for relative imports is contained within [PEP 328](#).

`importlib.import_module()` is provided to support applications that determine which modules need to be loaded dynamically.

6.11.1. Future statements

A *future statement* is a directive to the compiler that a particular module should be compiled using syntax or semantics that will be available in a specified future release of Python. The future statement is intended to ease migration to future versions of Python that introduce incompatible changes to the language. It allows use of the new features on a per-module basis before the release in which the feature becomes standard.

```
future_statement ::= "from" "__future__" "import" feature ["as
```

```
        ("," feature ["as" name])*
        | "from" "__future__" "import" "(" featur
        ("," feature ["as" name])* [","] ")"
feature      ::= identifier
name         ::= identifier
```

A future statement must appear near the top of the module. The only lines that can appear before a future statement are:

- the module docstring (if any),
- comments,
- blank lines, and
- other future statements.

The features recognized by Python 3.0 are `absolute_import`, `division`, `generators`, `unicode_literals`, `print_function`, `nested_scopes` and `with_statement`. They are all redundant because they are always enabled, and only kept for backwards compatibility.

A future statement is recognized and treated specially at compile time: Changes to the semantics of core constructs are often implemented by generating different code. It may even be the case that a new feature introduces new incompatible syntax (such as a new reserved word), in which case the compiler may need to parse the module differently. Such decisions cannot be pushed off until runtime.

For any given release, the compiler knows which feature names have been defined, and raises a compile-time error if a future statement contains a feature not known to it.

The direct runtime semantics are the same as for any import statement: there is a standard module `__future__`, described later, and it will be imported in the usual way at the time the future statement is executed.

The interesting runtime semantics depend on the specific feature enabled by the future statement.

Note that there is nothing special about the statement:

```
import __future__ [as name]
```

That is not a future statement; it's an ordinary import statement with no special semantics or syntax restrictions.

Code compiled by calls to the built-in functions `exec()` and `compile()` that occur in a module `m` containing a future statement will, by default, use the new syntax or semantics associated with the future statement. This can be controlled by optional arguments to `compile()` — see the documentation of that function for details.

A future statement typed at an interactive interpreter prompt will take effect for the rest of the interpreter session. If an interpreter is started with the `-i` option, is passed a script name to execute, and the script includes a future statement, it will be in effect in the interactive session started after the script is executed.

PEP 236 - Back to the `__future__`

The original proposal for the `__future__` mechanism.

6.12. The `global` statement

```
global_stmt ::= "global" identifier ("," identifier)*
```

The `global` statement is a declaration which holds for the entire current code block. It means that the listed identifiers are to be interpreted as globals. It would be impossible to assign to a global variable without `global`, although free variables may refer to globals without being declared global.

Names listed in a `global` statement must not be used in the same code block textually preceding that `global` statement.

Names listed in a `global` statement must not be defined as formal parameters or in a `for` loop control target, `class` definition, function definition, or `import` statement.

CPython implementation detail: The current implementation does not enforce the latter two restrictions, but programs should not abuse this freedom, as future implementations may enforce them or silently change the meaning of the program.

Programmer's note: the `global` is a directive to the parser. It applies only to code parsed at the same time as the `global` statement. In particular, a `global` statement contained in a string or code object supplied to the built-in `exec()` function does not affect the code block *containing* the function call, and code contained in such a string is unaffected by `global` statements in the code containing the function call. The same applies to the `eval()` and `compile()` functions.

6.13. The `nonlocal` statement

```
nonlocal_stmt ::= "nonlocal" identifier ("," identifier)*
```

The `nonlocal` statement causes the listed identifiers to refer to previously bound variables in the nearest enclosing scope. This is important because the default behavior for binding is to search the local namespace first. The statement allows encapsulated code to rebind variables outside of the local scope besides the global (module) scope.

Names listed in a `nonlocal` statement, unlike to those listed in a `global` statement, must refer to pre-existing bindings in an enclosing scope (the scope in which a new binding should be created cannot be determined unambiguously).

Names listed in a `nonlocal` statement must not collide with pre-existing bindings in the local scope.

See also:

PEP 3104 - Access to Names in Outer Scopes

The specification for the `nonlocal` statement.

Footnotes

[1] It may occur within an `except` or `else` clause. The restriction on occurring in the `try` clause is implementor's laziness and will eventually be lifted.

7. Compound statements

Compound statements contain (groups of) other statements; they affect or control the execution of those other statements in some way. In general, compound statements span multiple lines, although in simple incarnations a whole compound statement may be contained in one line.

The `if`, `while` and `for` statements implement traditional control flow constructs. `try` specifies exception handlers and/or cleanup code for a group of statements, while the `with` statement allows the execution of initialization and finalization code around a block of code. Function and class definitions are also syntactically compound statements.

Compound statements consist of one or more ‘clauses.’ A clause consists of a header and a ‘suite.’ The clause headers of a particular compound statement are all at the same indentation level. Each clause header begins with a uniquely identifying keyword and ends with a colon. A suite is a group of statements controlled by a clause. A suite can be one or more semicolon-separated simple statements on the same line as the header, following the header’s colon, or it can be one or more indented statements on subsequent lines. Only the latter form of suite can contain nested compound statements; the following is illegal, mostly because it wouldn’t be clear to which `if` clause a following `else` clause would belong:

```
if test1: if test2: print(x)
```

Also note that the semicolon binds tighter than the colon in this context, so that in the following example, either all or none of the `print()` calls are executed:

```
if x < y < z: print(x); print(y); print(z)
```

Summarizing:

```
compound_stmt ::= if_stmt
                | while_stmt
                | for_stmt
                | try_stmt
                | with_stmt
                | funcdef
                | classdef
suite          ::= stmt_list NEWLINE | NEWLINE INDENT statement
statement     ::= stmt_list NEWLINE | compound_stmt
stmt_list     ::= simple_stmt ";"* [";"]
```

Note that statements always end in a `NEWLINE` possibly followed by a `DEDENT`. Also note that optional continuation clauses always begin with a keyword that cannot start a statement, thus there are no ambiguities (the ‘dangling `else`’ problem is solved in Python by requiring nested `if` statements to be indented).

The formatting of the grammar rules in the following sections places each clause on a separate line for clarity.

7.1. The `if` statement

The `if` statement is used for conditional execution:

```
if_stmt ::= "if" expression ":" suite
          ( "elif" expression ":" suite )*
          ["else" ":" suite]
```

It selects exactly one of the suites by evaluating the expressions one by one until one is found to be true (see section *Boolean operations* for the definition of true and false); then that suite is executed (and no other part of the `if` statement is executed or evaluated). If all expressions are false, the suite of the `else` clause, if present, is executed.

7.2. The `while` statement

The `while` statement is used for repeated execution as long as an expression is true:

```
while_stmt ::= "while" expression ":" suite  
            ["else" ":" suite]
```

This repeatedly tests the expression and, if it is true, executes the first suite; if the expression is false (which may be the first time it is tested) the suite of the `else` clause, if present, is executed and the loop terminates.

A `break` statement executed in the first suite terminates the loop without executing the `else` clause's suite. A `continue` statement executed in the first suite skips the rest of the suite and goes back to testing the expression.

7.3. The `for` statement

The `for` statement is used to iterate over the elements of a sequence (such as a string, tuple or list) or other iterable object:

```
for_stmt ::= "for" target_list "in" expression_list ":" suite
           ["else" ":" suite]
```

The expression list is evaluated once; it should yield an iterable object. An iterator is created for the result of the `expression_list`. The suite is then executed once for each item provided by the iterator, in the order of ascending indices. Each item in turn is assigned to the target list using the standard rules for assignments (see *Assignment statements*), and then the suite is executed. When the items are exhausted (which is immediately when the sequence is empty or an iterator raises a `StopIteration` exception), the suite in the `else` clause, if present, is executed, and the loop terminates.

A `break` statement executed in the first suite terminates the loop without executing the `else` clause's suite. A `continue` statement executed in the first suite skips the rest of the suite and continues with the next item, or with the `else` clause if there was no next item.

The suite may assign to the variable(s) in the target list; this does not affect the next item assigned to it.

Names in the target list are not deleted when the loop is finished, but if the sequence is empty, it will not have been assigned to at all by the loop. Hint: the built-in function `range()` returns an iterator of integers suitable to emulate the effect of Pascal's `for i := a to b do`; e.g., `list(range(3))` returns the list `[0, 1, 2]`.

Note: There is a subtlety when the sequence is being modified by the loop (this can only occur for mutable sequences, i.e. lists). An internal counter is used to keep track of which item is used next, and this is incremented on each iteration. When this counter has reached the length of the sequence the loop terminates. This means that if the suite deletes the current (or a previous) item from the sequence, the next item will be skipped (since it gets the index of the current item which has already been treated). Likewise, if the suite inserts an item in the sequence before the current item, the current item will be treated again the next time through the loop. This can lead to nasty bugs that can be avoided by making a temporary copy using a slice of the whole sequence, e.g.,

```
for x in a[:]:  
    if x < 0: a.remove(x)
```

7.4. The `try` statement

The `try` statement specifies exception handlers and/or cleanup code for a group of statements:

```
try_stmt ::= try1_stmt | try2_stmt
try1_stmt ::= "try" ":" suite
              ("except" [expression ["as" target]] ":" suite)+
              ["else" ":" suite]
              ["finally" ":" suite]
try2_stmt ::= "try" ":" suite
              "finally" ":" suite
```

The `except` clause(s) specify one or more exception handlers. When no exception occurs in the `try` clause, no exception handler is executed. When an exception occurs in the `try` suite, a search for an exception handler is started. This search inspects the `except` clauses in turn until one is found that matches the exception. An expression-less `except` clause, if present, must be last; it matches any exception. For an `except` clause with an expression, that expression is evaluated, and the clause matches the exception if the resulting object is “compatible” with the exception. An object is compatible with an exception if it is the class or a base class of the exception object or a tuple containing an item compatible with the exception.

If no `except` clause matches the exception, the search for an exception handler continues in the surrounding code and on the invocation stack. [1]

If the evaluation of an expression in the header of an `except` clause raises an exception, the original search for a handler is canceled and a search starts for the new exception in the surrounding code and on the call stack (it is treated as if the entire `try` statement raised the

exception).

When a matching except clause is found, the exception is assigned to the target specified after the `as` keyword in that except clause, if present, and the except clause's suite is executed. All except clauses must have an executable block. When the end of this block is reached, execution continues normally after the entire try statement. (This means that if two nested handlers exist for the same exception, and the exception occurs in the try clause of the inner handler, the outer handler will not handle the exception.)

When an exception has been assigned using `as target`, it is cleared at the end of the except clause. This is as if

```
except E as N:  
    foo
```

was translated to

```
except E as N:  
    try:  
        foo  
    finally:  
        del N
```

This means the exception must be assigned to a different name to be able to refer to it after the except clause. Exceptions are cleared because with the traceback attached to them, they form a reference cycle with the stack frame, keeping all locals in that frame alive until the next garbage collection occurs.

Before an except clause's suite is executed, details about the exception are stored in the `sys` module and can be accessed via `sys.exc_info()`. `sys.exc_info()` returns a 3-tuple consisting of the exception class, the exception instance and a traceback object (see section *The standard type hierarchy*) identifying the point in the

program where the exception occurred. `sys.exc_info()` values are restored to their previous values (before the call) when returning from a function that handled an exception.

The optional `else` clause is executed if and when control flows off the end of the `try` clause. [2] Exceptions in the `else` clause are not handled by the preceding `except` clauses.

If `finally` is present, it specifies a 'cleanup' handler. The `try` clause is executed, including any `except` and `else` clauses. If an exception occurs in any of the clauses and is not handled, the exception is temporarily saved. The `finally` clause is executed. If there is a saved exception, it is re-raised at the end of the `finally` clause. If the `finally` clause raises another exception or executes a `return` or `break` statement, the saved exception is lost. The exception information is not available to the program during execution of the `finally` clause.

When a `return`, `break` or `continue` statement is executed in the `try` suite of a `try...finally` statement, the `finally` clause is also executed 'on the way out.' A `continue` statement is illegal in the `finally` clause. (The reason is a problem with the current implementation — this restriction may be lifted in the future).

Additional information on exceptions can be found in section [Exceptions](#), and information on using the `raise` statement to generate exceptions may be found in section [The raise statement](#).

7.5. The `with` statement

The `with` statement is used to wrap the execution of a block with methods defined by a context manager (see section *With Statement Context Managers*). This allows common `try...except...finally` usage patterns to be encapsulated for convenient reuse.

```
with_stmt ::= "with" with_item ("," with_item)* ":" suite
with_item ::= expression ["as" target]
```

The execution of the `with` statement with one “item” proceeds as follows:

1. The context expression (the expression given in the `with_item`) is evaluated to obtain a context manager.
2. The context manager’s `__exit__()` is loaded for later use.
3. The context manager’s `__enter__()` method is invoked.
4. If a target was included in the `with` statement, the return value from `__enter__()` is assigned to it.

Note: The `with` statement guarantees that if the `__enter__()` method returns without an error, then `__exit__()` will always be called. Thus, if an error occurs during the assignment to the target list, it will be treated the same as an error occurring within the suite would be. See step 6 below.

5. The suite is executed.
6. The context manager’s `__exit__()` method is invoked. If an exception caused the suite to be exited, its type, value, and

traceback are passed as arguments to `__exit__()`. Otherwise, three `None` arguments are supplied.

If the suite was exited due to an exception, and the return value from the `__exit__()` method was false, the exception is reraised. If the return value was true, the exception is suppressed, and execution continues with the statement following the `with` statement.

If the suite was exited for any reason other than an exception, the return value from `__exit__()` is ignored, and execution proceeds at the normal location for the kind of exit that was taken.

With more than one item, the context managers are processed as if multiple `with` statements were nested:

```
with A() as a, B() as b:  
    suite
```

is equivalent to

```
with A() as a:  
    with B() as b:  
        suite
```

Changed in version 3.1: Support for multiple context expressions.

PEP 0343 - The “with” statement

The specification, background, and examples for the Python `with` statement.

7.6. Function definitions

A function definition defines a user-defined function object (see section *The standard type hierarchy*):

```
funcdef      ::= [decorators] "def" funcname "(" [parameter_
decorators   ::= decorator+
decorator    ::= "@" dotted_name "(" [argument_list [","]]
dotted_name  ::= identifier "." identifier)*
parameter_list ::= (defparameter ",")*
              (  "*" [parameter] ("," defparameter)*
              [, "*" parameter
              | "*" parameter
              | defparameter [","] )
parameter    ::= identifier [":" expression]
defparameter ::= parameter ["=" expression]
funcname     ::= identifier
```

A function definition is an executable statement. Its execution binds the function name in the current local namespace to a function object (a wrapper around the executable code for the function). This function object contains a reference to the current global namespace as the global namespace to be used when the function is called.

The function definition does not execute the function body; this gets executed only when the function is called. [3]

A function definition may be wrapped by one or more *decorator* expressions. Decorator expressions are evaluated when the function is defined, in the scope that contains the function definition. The result must be a callable, which is invoked with the function object as the only argument. The returned value is bound to the function name instead of the function object. Multiple decorators are applied in nested fashion. For example, the following code

```
@f1(arg)
```

```
@f2
def func(): pass
```

is equivalent to

```
def func(): pass
func = f1(arg)(f2(func))
```

When one or more parameters have the form *parameter* = *expression*, the function is said to have “default parameter values.” For a parameter with a default value, the corresponding argument may be omitted from a call, in which case the parameter’s default value is substituted. If a parameter has a default value, all following parameters up until the “*” must also have a default value — this is a syntactic restriction that is not expressed by the grammar.

Default parameter values are evaluated when the function definition is executed. This means that the expression is evaluated once, when the function is defined, and that that same “pre-computed” value is used for each call. This is especially important to understand when a default parameter is a mutable object, such as a list or a dictionary: if the function modifies the object (e.g. by appending an item to a list), the default value is in effect modified. This is generally not what was intended. A way around this is to use `None` as the default, and explicitly test for it in the body of the function, e.g.:

```
def whats_on_the_telly(penguin=None):
    if penguin is None:
        penguin = []
    penguin.append("property of the zoo")
    return penguin
```

Function call semantics are described in more detail in section [Calls](#). A function call always assigns values to all parameters mentioned in the parameter list, either from position arguments, from keyword

arguments, or from default values. If the form “`*identifier`” is present, it is initialized to a tuple receiving any excess positional parameters, defaulting to the empty tuple. If the form “`**identifier`” is present, it is initialized to a new dictionary receiving any excess keyword arguments, defaulting to a new empty dictionary. Parameters after “`*`” or “`*identifier`” are keyword-only parameters and may only be passed used keyword arguments.

Parameters may have annotations of the form “`: expression`” following the parameter name. Any parameter may have an annotation even those of the form `*identifier` or `**identifier`. Functions may have “return” annotation of the form “`-> expression`” after the parameter list. These annotations can be any valid Python expression and are evaluated when the function definition is executed. Annotations may be evaluated in a different order than they appear in the source code. The presence of annotations does not change the semantics of a function. The annotation values are available as values of a dictionary keyed by the parameters’ names in the `__annotations__` attribute of the function object.

It is also possible to create anonymous functions (functions not bound to a name), for immediate use in expressions. This uses lambda forms, described in section [Lambdas](#). Note that the lambda form is merely a shorthand for a simplified function definition; a function defined in a “`def`” statement can be passed around or assigned to another name just like a function defined by a lambda form. The “`def`” form is actually more powerful since it allows the execution of multiple statements and annotations.

Programmer’s note: Functions are first-class objects. A “`def`” form executed inside a function definition defines a local function that can be returned or passed around. Free variables used in the nested function can access the local variables of the function containing the `def`. See section [Naming and binding](#) for details.

7.7. Class definitions

A class definition defines a class object (see section *The standard type hierarchy*):

```
classdef ::= [decorators] "class" classname [inheritance] '  
inheritance ::= "(" [argument_list [","] | comprehension] ")"  
classname ::= identifier
```

A class definition is an executable statement. The inheritance list usually gives a list of base classes (see *Customizing class creation* for more advanced uses), so each item in the list should evaluate to a class object which allows subclassing. Classes without an inheritance list inherit, by default, from the base class `object`; hence,

```
class Foo:  
    pass
```

is equivalent to

```
class Foo(object):  
    pass
```

The class's suite is then executed in a new execution frame (see *Naming and binding*), using a newly created local namespace and the original global namespace. (Usually, the suite contains mostly function definitions.) When the class's suite finishes execution, its execution frame is discarded but its local namespace is saved. [4] A class object is then created using the inheritance list for the base classes and the saved local namespace for the attribute dictionary. The class name is bound to this class object in the original local namespace.

Class creation can be customized heavily using *metaclasses*.

Classes can also be decorated: just like when decorating functions,

```
@f1(arg)
@f2
class Foo: pass
```

is equivalent to

```
class Foo: pass
Foo = f1(arg)(f2(Foo))
```

The evaluation rules for the decorator expressions are the same as for function decorators. The result must be a class object, which is then bound to the class name.

Programmer's note: Variables defined in the class definition are class attributes; they are shared by instances. Instance attributes can be set in a method with `self.name = value`. Both class and instance attributes are accessible through the notation “`self.name`”, and an instance attribute hides a class attribute with the same name when accessed in this way. Class attributes can be used as defaults for instance attributes, but using mutable values there can lead to unexpected results. *Descriptors* can be used to create instance variables with different implementation details.

Footnotes

- [1] The exception is propagated to the invocation stack only if there is no `finally` clause that negates the exception. Currently, control “flows off the end” except in the case of an
- [2] exception or the execution of a `return`, `continue`, or `break` statement.

[3] A string literal appearing as the first statement in the function body is transformed into the function's `__doc__` attribute and therefore the function's *docstring*.

[4] A string literal appearing as the first statement in the class body is transformed into the namespace's `__doc__` item and therefore the class's *docstring*.

8. Top-level components

The Python interpreter can get its input from a number of sources: from a script passed to it as standard input or as program argument, typed in interactively, from a module source file, etc. This chapter gives the syntax used in these cases.

8.1. Complete Python programs

While a language specification need not prescribe how the language interpreter is invoked, it is useful to have a notion of a complete Python program. A complete Python program is executed in a minimally initialized environment: all built-in and standard modules are available, but none have been initialized, except for `sys` (various system services), `builtins` (built-in functions, exceptions and `None`) and `__main__`. The latter is used to provide the local and global namespace for execution of the complete program.

The syntax for a complete Python program is that for file input, described in the next section.

The interpreter may also be invoked in interactive mode; in this case, it does not read and execute a complete program but reads and executes one statement (possibly compound) at a time. The initial environment is identical to that of a complete program; each statement is executed in the namespace of `__main__`.

Under Unix, a complete program can be passed to the interpreter in three forms: with the `-c string` command line option, as a file passed as the first command line argument, or as standard input. If the file or standard input is a tty device, the interpreter enters interactive mode; otherwise, it executes the file as a complete program.

8.2. File input

All input read from non-interactive files has the same form:

```
file_input ::= (NEWLINE | statement)*
```

This syntax is used in the following situations:

- when parsing a complete Python program (from a file or from a string);
- when parsing a module;
- when parsing a string passed to the `exec()` function;

8.3. Interactive input

Input in interactive mode is parsed using the following grammar:

```
interactive_input ::= [stmt_list] NEWLINE | compound_stmt NEWL
```

Note that a (top-level) compound statement must be followed by a blank line in interactive mode; this is needed to help the parser detect the end of the input.

8.4. Expression input

There are two forms of expression input. Both ignore leading whitespace. The string argument to `eval()` must have the following form:

```
eval_input ::= expression_list NEWLINE*
```

Note: to read ‘raw’ input line without interpretation, you can use the `readline()` method of file objects, including `sys.stdin`.

9. Full Grammar specification

This is the full Python grammar, as it is read by the parser generator and used to parse Python source files:

```
# Grammar for Python

# Note: Changing the grammar specified in this file will most
#       require corresponding changes in the parser module
#       (../Modules/parsermodule.c). If you can't make the ch
#       that module yourself, please co-ordinate the required
#       with someone who can; ask around on python-dev for hel
#       Drake <fdrake@acm.org> will probably be listening ther

# NOTE WELL: You should also follow all the steps listed in PEP
# "How to Change Python's Grammar"

# Start symbols for the grammar:
#     single_input is a single interactive statement;
#     file_input is a module or sequence of commands read fro
#     eval_input is the input for the eval() and input() func
# NB: compound_stmt in single_input is followed by extra NEWLIN

1. Introduction

The “Python library” contains several different kinds of components.

It contains data types that would normally be considered part of the “core” of a language, such as numbers and lists. For these types, the Python language core defines the form of literals and places some constraints on their semantics, but does not fully define the semantics. (On the other hand, the language core does define syntactic properties like the spelling and priorities of operators.)

The library also contains built-in functions and exceptions — objects that can be used by all Python code without the need of an `import` statement. Some of these are defined by the core language, but many are not essential for the core semantics and are only described here.

The bulk of the library, however, consists of a collection of modules. There are many ways to dissect this collection. Some modules are written in C and built in to the Python interpreter; others are written in Python and imported in source form. Some modules provide interfaces that are highly specific to Python, like printing a stack trace; some provide interfaces that are specific to particular operating systems, such as access to specific hardware; others provide interfaces that are specific to a particular application domain, like the World Wide Web. Some modules are available in all versions and ports of Python; others are only available when the underlying system supports or requires them; yet others are available only when a particular configuration option was chosen at the time when Python was compiled and installed.

This manual is organized “from the inside out:” it first describes the built-in data types, then the built-in functions and exceptions, and finally the modules, grouped in chapters of related modules. The

ordering of the chapters as well as the ordering of the modules within each chapter is roughly from most relevant to least important.

This means that if you start reading this manual from the start, and skip to the next chapter when you get bored, you will get a reasonable overview of the available modules and application areas that are supported by the Python library. Of course, you don't *have* to read it like a novel — you can also browse the table of contents (in front of the manual), or look for a specific function, module or term in the index (in the back). And finally, if you enjoy learning about random subjects, you choose a random page number (see module [random](#)) and read a section or two. Regardless of the order in which you read the sections of this manual, it helps to start with chapter [Built-in Functions](#), as the remainder of the manual assumes familiarity with this material.

Let the show begin!

2. Built-in Functions

The Python interpreter has a number of functions and types built into it that are always available. They are listed here in alphabetical order.

Built-in Functions				
<code>abs()</code>	<code>dict()</code>	<code>help()</code>	<code>min()</code>	<code>setattr()</code>
<code>all()</code>	<code>dir()</code>	<code>hex()</code>	<code>next()</code>	<code>slice()</code>
<code>any()</code>	<code>divmod()</code>	<code>id()</code>	<code>object()</code>	<code>sorted()</code>
<code>ascii()</code>	<code>enumerate()</code>	<code>input()</code>	<code>oct()</code>	<code>staticmethod()</code>
<code>bin()</code>	<code>eval()</code>	<code>int()</code>	<code>open()</code>	<code>str()</code>
<code>bool()</code>	<code>exec()</code>	<code>isinstance()</code>	<code>ord()</code>	<code>sum()</code>
<code>bytearray()</code>	<code>filter()</code>	<code>issubclass()</code>	<code>pow()</code>	<code>super()</code>
<code>bytes()</code>	<code>float()</code>	<code>iter()</code>	<code>print()</code>	<code>tuple()</code>
<code>callable()</code>	<code>format()</code>	<code>len()</code>	<code>property()</code>	<code>type()</code>
<code>chr()</code>	<code>frozenset()</code>	<code>list()</code>	<code>range()</code>	<code>vars()</code>
<code>classmethod()</code>	<code>getattr()</code>	<code>locals()</code>	<code>repr()</code>	<code>zip()</code>
<code>compile()</code>	<code>globals()</code>	<code>map()</code>	<code>reversed()</code>	<code>__import__()</code>
<code>complex()</code>	<code>hasattr()</code>	<code>max()</code>	<code>round()</code>	
<code>delattr()</code>	<code>hash()</code>	<code>memoryview()</code>	<code>set()</code>	

`abs(x)`

Return the absolute value of a number. The argument may be an integer or a floating point number. If the argument is a complex number, its magnitude is returned.

`all(iterable)`

Return True if all elements of the *iterable* are true (or if the iterable is empty). Equivalent to:

```
def all(iterable):
    for element in iterable:
        if not element:
            return False
```

```
return True
```

any(*iterable*)

Return True if any element of the *iterable* is true. If the iterable is empty, return False. Equivalent to:

```
def any(iterable):  
    for element in iterable:  
        if element:  
            return True  
    return False
```

ascii(*object*)

As `repr()`, return a string containing a printable representation of an object, but escape the non-ASCII characters in the string returned by `repr()` using `\x`, `\u` or `\U` escapes. This generates a string similar to that returned by `repr()` in Python 2.

bin(*x*)

Convert an integer number to a binary string. The result is a valid Python expression. If *x* is not a Python `int` object, it has to define an `__index__()` method that returns an integer.

bool(*[x]*)

Convert a value to a Boolean, using the standard truth testing procedure. If *x* is false or omitted, this returns `False`; otherwise it returns `True`. `bool` is also a class, which is a subclass of `int`. Class `bool` cannot be subclassed further. Its only instances are `False` and `True`.

bytearray(*[source[, encoding[, errors]]]*)

Return a new array of bytes. The `bytearray` type is a mutable sequence of integers in the range $0 \leq x < 256$. It has most of the usual methods of mutable sequences, described in *Mutable*

Sequence Types, as well as most methods that the `bytes` type has, see *Bytes and Byte Array Methods*.

The optional *source* parameter can be used to initialize the array in a few different ways:

- If it is a *string*, you must also give the *encoding* (and optionally, *errors*) parameters; `bytearray()` then converts the string to bytes using `str.encode()`.
- If it is an *integer*, the array will have that size and will be initialized with null bytes.
- If it is an object conforming to the *buffer* interface, a read-only buffer of the object will be used to initialize the bytes array.
- If it is an *iterable*, it must be an iterable of integers in the range `0 <= x < 256`, which are used as the initial contents of the array.

Without an argument, an array of size 0 is created.

`bytes([source[, encoding[, errors]])`

Return a new “bytes” object, which is an immutable sequence of integers in the range `0 <= x < 256`. `bytes` is an immutable version of `bytearray` – it has the same non-mutating methods and the same indexing and slicing behavior.

Accordingly, constructor arguments are interpreted as for `bytearray()`.

Bytes objects can also be created with literals, see *String and Bytes literals*.

`callable(object)`

Return `True` if the *object* argument appears callable, `False` if not. If this returns true, it is still possible that a call fails, but if it is

false, calling *object* will never succeed. Note that classes are callable (calling a class returns a new instance); instances are callable if their class has a `__call__()` method.

New in version 3.2: This function was first removed in Python 3.0 and then brought back in Python 3.2.

`chr(i)`

Return the string representing a character whose Unicode codepoint is the integer *i*. For example, `chr(97)` returns the string `'a'`. This is the inverse of `ord()`. The valid range for the argument is from 0 through 1,114,111 (0x10FFFF in base 16). `ValueError` will be raised if *i* is outside that range.

Note that on narrow Unicode builds, the result is a string of length two for *i* greater than 65,535 (0xFFFF in hexadecimal).

`classmethod(function)`

Return a class method for *function*.

A class method receives the class as implicit first argument, just like an instance method receives the instance. To declare a class method, use this idiom:

```
class C:
    @classmethod
    def f(cls, arg1, arg2, ...): ...
```

The `@classmethod` form is a function *decorator* – see the description of function definitions in *Function definitions* for details.

It can be called either on the class (such as `c.f()`) or on an instance (such as `c().f()`). The instance is ignored except for its class. If a class method is called for a derived class, the derived

class object is passed as the implied first argument.

Class methods are different than C++ or Java static methods. If you want those, see `staticmethod()` in this section.

For more information on class methods, consult the documentation on the standard type hierarchy in [The standard type hierarchy](#).

`compile(source, filename, mode, flags=0, dont_inherit=False, optimize=-1)`

Compile the *source* into a code or AST object. Code objects can be executed by `exec()` or `eval()`. *source* can either be a string or an AST object. Refer to the `ast` module documentation for information on how to work with AST objects.

The *filename* argument should give the file from which the code was read; pass some recognizable value if it wasn't read from a file ('<string>' is commonly used).

The *mode* argument specifies what kind of code must be compiled; it can be 'exec' if *source* consists of a sequence of statements, 'eval' if it consists of a single expression, or 'single' if it consists of a single interactive statement (in the latter case, expression statements that evaluate to something other than `None` will be printed).

The optional arguments *flags* and *dont_inherit* control which future statements (see [PEP 236](#)) affect the compilation of *source*. If neither is present (or both are zero) the code is compiled with those future statements that are in effect in the code that is calling `compile`. If the *flags* argument is given and *dont_inherit* is not (or is zero) then the future statements specified by the *flags* argument are used in addition to those that would be used

anyway. If *dont_inherit* is a non-zero integer then the *flags* argument is it – the future statements in effect around the call to compile are ignored.

Future statements are specified by bits which can be bitwise ORed together to specify multiple statements. The bitfield required to specify a given feature can be found as the `compiler_flag` attribute on the `_Feature` instance in the `__future__` module.

The argument *optimize* specifies the optimization level of the compiler; the default value of `-1` selects the optimization level of the interpreter as given by `-O` options. Explicit levels are `0` (no optimization; `__debug__` is true), `1` (asserts are removed, `__debug__` is false) or `2` (docstrings are removed too).

This function raises `SyntaxError` if the compiled source is invalid, and `TypeError` if the source contains null bytes.

Note: When compiling a string with multi-line code in 'single' or 'eval' mode, input must be terminated by at least one newline character. This is to facilitate detection of incomplete and complete statements in the `code` module.

Changed in version 3.2: Allowed use of Windows and Mac newlines. Also input in 'exec' mode does not have to end in a newline anymore. Added the *optimize* parameter.

complex([*real*[, *imag*]])

Create a complex number with the value *real* + *imag**j or convert a string or number to a complex number. If the first parameter is a string, it will be interpreted as a complex number and the function must be called without a second parameter. The second parameter can never be a string. Each argument may be any

numeric type (including complex). If *imag* is omitted, it defaults to zero and the function serves as a numeric conversion function like `int()` and `float()`. If both arguments are omitted, returns `0j`.

The complex type is described in *Numeric Types — int, float, complex*.

`delattr(object, name)`

This is a relative of `setattr()`. The arguments are an object and a string. The string must be the name of one of the object's attributes. The function deletes the named attribute, provided the object allows it. For example, `delattr(x, 'foobar')` is equivalent to `del x.foobar`.

`dict([arg])`

Create a new data dictionary, optionally with items taken from *arg*. The dictionary type is described in *Mapping Types — dict*.

For other containers see the built in `list`, `set`, and `tuple` classes, and the `collections` module.

`dir([object])`

Without arguments, return the list of names in the current local scope. With an argument, attempt to return a list of valid attributes for that object.

If the object has a method named `__dir__()`, this method will be called and must return the list of attributes. This allows objects that implement a custom `__getattr__()` or `__getattribute__()` function to customize the way `dir()` reports their attributes.

If the object does not provide `__dir__()`, the function tries its best to gather information from the object's `__dict__` attribute, if defined, and from its type object. The resulting list is not

necessarily complete, and may be inaccurate when the object has a custom `__getattr__()`.

The default `dir()` mechanism behaves differently with different types of objects, as it attempts to produce the most relevant, rather than complete, information:

- If the object is a module object, the list contains the names of the module's attributes.
- If the object is a type or class object, the list contains the names of its attributes, and recursively of the attributes of its bases.
- Otherwise, the list contains the object's attributes' names, the names of its class's attributes, and recursively of the attributes of its class's base classes.

The resulting list is sorted alphabetically. For example:

```
>>> import struct
>>> dir()
['__builtins__', '__doc__', '__name__', 'struct']
>>> dir(struct)
['Struct', '__builtins__', '__doc__', '__file__', '__name__',
 '__package__', '_clearcache', 'calcsize', 'error', 'pack',
 'unpack', 'unpack_from']
>>> class Foo:
...     def __dir__(self):
...         return ["kan", "ga", "roo"]
...
>>> f = Foo()
>>> dir(f)
['ga', 'kan', 'roo']
```

Note: Because `dir()` is supplied primarily as a convenience for use at an interactive prompt, it tries to supply an interesting set of names more than it tries to supply a rigorously or consistently defined set of names, and its detailed behavior may change across releases. For example, metaclass

attributes are not in the result list when the argument is a class.

divmod(a, b)

Take two (non complex) numbers as arguments and return a pair of numbers consisting of their quotient and remainder when using integer division. With mixed operand types, the rules for binary arithmetic operators apply. For integers, the result is the same as `(a // b, a % b)`. For floating point numbers the result is `(q, a % b)`, where `q` is usually `math.floor(a / b)` but may be 1 less than that. In any case `q * b + a % b` is very close to `a`, if `a % b` is non-zero it has the same sign as `b`, and `0 <= abs(a % b) < abs(b)`.

enumerate(iterable, start=0)

Return an enumerate object. *iterable* must be a sequence, an *iterator*, or some other object which supports iteration. The `__next__()` method of the iterator returned by `enumerate()` returns a tuple containing a count (from *start* which defaults to 0) and the corresponding value obtained from iterating over *iterable*. `enumerate()` is useful for obtaining an indexed series: `(0, seq[0]), (1, seq[1]), (2, seq[2]), ...` For example:

```
>>> for i, season in enumerate(['Spring', 'Summer', 'Fall',
...                             print(i, season)
0 Spring
1 Summer
2 Fall
3 Winter
```

eval(expression, globals=None, locals=None)

The arguments are a string and optional globals and locals. If provided, *globals* must be a dictionary. If provided, *locals* can be any mapping object.

The *expression* argument is parsed and evaluated as a Python

expression (technically speaking, a condition list) using the *globals* and *locals* dictionaries as global and local namespace. If the *globals* dictionary is present and lacks `'__builtins__'`, the current globals are copied into *globals* before *expression* is parsed. This means that *expression* normally has full access to the standard `builtins` module and restricted environments are propagated. If the *locals* dictionary is omitted it defaults to the *globals* dictionary. If both dictionaries are omitted, the expression is executed in the environment where `eval()` is called. The return value is the result of the evaluated expression. Syntax errors are reported as exceptions. Example:

```
>>> x = 1
>>> eval('x+1')
2
```

This function can also be used to execute arbitrary code objects (such as those created by `compile()`). In this case pass a code object instead of a string. If the code object has been compiled with `'exec'` as the *mode* argument, `eval()`'s return value will be **None**.

Hints: dynamic execution of statements is supported by the `exec()` function. The `globals()` and `locals()` functions returns the current global and local dictionary, respectively, which may be useful to pass around for use by `eval()` or `exec()`.

See `ast.literal_eval()` for a function that can safely evaluate strings with expressions containing only literals.

`exec(object[, globals[, locals]])`

This function supports dynamic execution of Python code. *object* must be either a string or a code object. If it is a string, the string is parsed as a suite of Python statements which is then executed

(unless a syntax error occurs). [1] If it is a code object, it is simply executed. In all cases, the code that's executed is expected to be valid as file input (see the section "File input" in the Reference Manual). Be aware that the `return` and `yield` statements may not be used outside of function definitions even within the context of code passed to the `exec()` function. The return value is `None`.

In all cases, if the optional parts are omitted, the code is executed in the current scope. If only *globals* is provided, it must be a dictionary, which will be used for both the global and the local variables. If *globals* and *locals* are given, they are used for the global and local variables, respectively. If provided, *locals* can be any mapping object.

If the *globals* dictionary does not contain a value for the key `__builtins__`, a reference to the dictionary of the built-in module `builtins` is inserted under that key. That way you can control what builtins are available to the executed code by inserting your own `__builtins__` dictionary into *globals* before passing it to `exec()`.

Note: The built-in functions `globals()` and `locals()` return the current global and local dictionary, respectively, which may be useful to pass around for use as the second and third argument to `exec()`.

Note: The default *locals* act as described for function `locals()` below: modifications to the default *locals* dictionary should not be attempted. Pass an explicit *locals* dictionary if you need to see effects of the code on *locals* after function `exec()` returns.

filter(*function*, *iterable*)

Construct an iterator from those elements of *iterable* for which

function returns true. *iterable* may be either a sequence, a container which supports iteration, or an iterator. If *function* is **None**, the identity function is assumed, that is, all elements of *iterable* that are false are removed.

Note that `filter(function, iterable)` is equivalent to the generator expression `(item for item in iterable if function(item))` if *function* is not **None** and `(item for item in iterable if item)` if *function* is **None**.

See `itertools.filterfalse()` for the complementary function that returns elements of *iterable* for which *function* returns false.

`float([x])`

Convert a string or a number to floating point.

If the argument is a string, it should contain a decimal number, optionally preceded by a sign, and optionally embedded in whitespace. The optional sign may be '+' or '-'; a '+' sign has no effect on the value produced. The argument may also be a string representing a NaN (not-a-number), or a positive or negative infinity. More precisely, the input must conform to the following grammar after leading and trailing whitespace characters are removed:

```
sign          ::= "+" | "-"
infinity      ::= "Infinity" | "inf"
nan           ::= "nan"
numeric_value ::= floatnumber | infinity | nan
numeric_string ::= [sign] numeric_value
```

Here `floatnumber` is the form of a Python floating-point literal, described in *Floating point literals*. Case is not significant, so, for example, “inf”, “Inf”, “INFINITY” and “iNfINity” are all acceptable spellings for positive infinity.

Otherwise, if the argument is an integer or a floating point number, a floating point number with the same value (within Python's floating point precision) is returned. If the argument is outside the range of a Python float, an `OverflowError` will be raised.

For a general Python object `x`, `float(x)` delegates to `x.__float__()`.

If no argument is given, `0.0` is returned.

Examples:

```
>>> float('+1.23')
1.23
>>> float('  -12345\n')
-12345.0
>>> float('1e-003')
0.001
>>> float('+1E6')
1000000.0
>>> float('-Infinity')
-inf
```

The float type is described in [Numeric Types — int, float, complex](#).

format(value[, format_spec])

Convert a *value* to a “formatted” representation, as controlled by *format_spec*. The interpretation of *format_spec* will depend on the type of the *value* argument, however there is a standard formatting syntax that is used by most built-in types: [Format Specification Mini-Language](#).

Note: `format(value, format_spec)` merely calls `value.__format__(format_spec)`.

frozenset(*[iterable]*)

Return a frozenset object, optionally with elements taken from *iterable*. The frozenset type is described in [Set Types — set, frozenset](#).

For other containers see the built in [dict](#), [list](#), and [tuple](#) classes, and the [collections](#) module.

getattr(*object, name*[, *default*])

Return the value of the named attribute of *object*. *name* must be a string. If the string is the name of one of the object's attributes, the result is the value of that attribute. For example, `getattr(x, 'foobar')` is equivalent to `x.foobar`. If the named attribute does not exist, *default* is returned if provided, otherwise [AttributeError](#) is raised.

globals()

Return a dictionary representing the current global symbol table. This is always the dictionary of the current module (inside a function or method, this is the module where it is defined, not the module from which it is called).

hasattr(*object, name*)

The arguments are an object and a string. The result is `True` if the string is the name of one of the object's attributes, `False` if not. (This is implemented by calling `getattr(object, name)` and seeing whether it raises an [AttributeError](#) or not.)

hash(*object*)

Return the hash value of the object (if it has one). Hash values are integers. They are used to quickly compare dictionary keys during a dictionary lookup. Numeric values that compare equal have the same hash value (even if they are of different types, as

is the case for 1 and 1.0).

`help([object])`

Invoke the built-in help system. (This function is intended for interactive use.) If no argument is given, the interactive help system starts on the interpreter console. If the argument is a string, then the string is looked up as the name of a module, function, class, method, keyword, or documentation topic, and a help page is printed on the console. If the argument is any other kind of object, a help page on the object is generated.

This function is added to the built-in namespace by the `site` module.

`hex(x)`

Convert an integer number to a hexadecimal string. The result is a valid Python expression. If `x` is not a Python `int` object, it has to define an `__index__()` method that returns an integer.

Note: To obtain a hexadecimal string representation for a float, use the `float.hex()` method.

`id(object)`

Return the “identity” of an object. This is an integer which is guaranteed to be unique and constant for this object during its lifetime. Two objects with non-overlapping lifetimes may have the same `id()` value.

CPython implementation detail: This is the address of the object.

`input([prompt])`

If the *prompt* argument is present, it is written to standard output without a trailing newline. The function then reads a line from input, converts it to a string (stripping a trailing newline), and returns that. When EOF is read, `EOFError` is raised. Example:

```
>>> s = input('--> ')
--> Monty Python's Flying Circus
>>> s
"Monty Python's Flying Circus"
```

If the `readline` module was loaded, then `input()` will use it to provide elaborate line editing and history features.

`int([number | string [, base]])`

Convert a number or string to an integer. If no arguments are given, return 0. If a number is given, return `number.__int__()`. Conversion of floating point numbers to integers truncates towards zero. A string must be a base-radix integer literal optionally preceded by '+' or '-' (with no space in between) and optionally surrounded by whitespace. A base-n literal consists of the digits 0 to n-1, with 'a' to 'z' (or 'A' to 'Z') having values 10 to 35. The default *base* is 10. The allowed values are 0 and 2-36. Base-2, -8, and -16 literals can be optionally prefixed with `0b/0B`, `0o/0O`, or `0x/0X`, as with integer literals in code. Base 0 means to interpret exactly as a code literal, so that the actual base is 2, 8, 10, or 16, and so that `int('010', 0)` is not legal, while `int('010')` is, as well as `int('010', 8)`.

The integer type is described in *Numeric Types — int, float, complex*.

`isinstance(object, classinfo)`

Return true if the *object* argument is an instance of the *classinfo* argument, or of a (direct or indirect) subclass thereof. If *object* is not an object of the given type, the function always returns false.

If *classinfo* is not a class (type object), it may be a tuple of type objects, or may recursively contain other such tuples (other sequence types are not accepted). If *classinfo* is not a type or tuple of types and such tuples, a **TypeError** exception is raised.

issubclass(*class*, *classinfo*)

Return true if *class* is a subclass (direct or indirect) of *classinfo*. A class is considered a subclass of itself. *classinfo* may be a tuple of class objects, in which case every entry in *classinfo* will be checked. In any other case, a **TypeError** exception is raised.

iter(*object*[, *sentinel*])

Return an *iterator* object. The first argument is interpreted very differently depending on the presence of the second argument. Without a second argument, *object* must be a collection object which supports the iteration protocol (the `__iter__()` method), or it must support the sequence protocol (the `__getitem__()` method with integer arguments starting at 0). If it does not support either of those protocols, **TypeError** is raised. If the second argument, *sentinel*, is given, then *object* must be a callable object. The iterator created in this case will call *object* with no arguments for each call to its `__next__()` method; if the value returned is equal to *sentinel*, **StopIteration** will be raised, otherwise the value will be returned.

One useful application of the second form of `iter()` is to read lines of a file until a certain line is reached. The following example reads a file until "STOP" is reached:

```
with open("mydata.txt") as fp:
    for line in iter(fp.readline, "STOP"):
        process_line(line)
```

len(*s*)

Return the length (the number of items) of an object. The argument may be a sequence (string, tuple or list) or a mapping (dictionary).

`list([iterable])`

Return a list whose items are the same and in the same order as *iterable*'s items. *iterable* may be either a sequence, a container that supports iteration, or an iterator object. If *iterable* is already a list, a copy is made and returned, similar to `iterable[:]`. For instance, `list('abc')` returns `['a', 'b', 'c']` and `list((1, 2, 3))` returns `[1, 2, 3]`. If no argument is given, returns a new empty list, `[]`.

`list` is a mutable sequence type, as documented in *Sequence Types — str, bytes, bytearray, list, tuple, range*.

`locals()`

Update and return a dictionary representing the current local symbol table. Free variables are returned by `locals()` when it is called in function blocks, but not in class blocks.

Note: The contents of this dictionary should not be modified; changes may not affect the values of local and free variables used by the interpreter.

`map(function, iterable, ...)`

Return an iterator that applies *function* to every item of *iterable*, yielding the results. If additional *iterable* arguments are passed, *function* must take that many arguments and is applied to the items from all iterables in parallel. With multiple iterables, the iterator stops when the shortest iterable is exhausted. For cases where the function inputs are already arranged into argument tuples, see `itertools.starmap()`.

max(*iterable*[, *args...*], *, [, *key*])

With a single argument *iterable*, return the largest item of a non-empty iterable (such as a string, tuple or list). With more than one argument, return the largest of the arguments.

The optional keyword-only *key* argument specifies a one-argument ordering function like that used for `list.sort()`.

If multiple items are maximal, the function returns the first one encountered. This is consistent with other sort-stability preserving tools such as `sorted(iterable, key=keyfunc, reverse=True)[0]` and `heapq.nlargest(1, iterable, key=keyfunc)`.

memoryview(*obj*)

Return a “memory view” object created from the given argument. See [memoryview type](#) for more information.

min(*iterable*[, *args...*], *, [, *key*])

With a single argument *iterable*, return the smallest item of a non-empty iterable (such as a string, tuple or list). With more than one argument, return the smallest of the arguments.

The optional keyword-only *key* argument specifies a one-argument ordering function like that used for `list.sort()`.

If multiple items are minimal, the function returns the first one encountered. This is consistent with other sort-stability preserving tools such as `sorted(iterable, key=keyfunc)[0]` and `heapq.nsmallest(1, iterable, key=keyfunc)`.

next(*iterator*[, *default*])

Retrieve the next item from the *iterator* by calling its `__next__()` method. If *default* is given, it is returned if the iterator is exhausted, otherwise `StopIteration` is raised.

`object()`

Return a new featureless object. `object` is a base for all classes. It has the methods that are common to all instances of Python classes. This function does not accept any arguments.

Note: `object` does *not* have a `__dict__`, so you can't assign arbitrary attributes to an instance of the `object` class.

`oct(x)`

Convert an integer number to an octal string. The result is a valid Python expression. If `x` is not a Python `int` object, it has to define an `__index__()` method that returns an integer.

`open(file, mode='r', buffering=-1, encoding=None, errors=None, newline=None, closefd=True)`

Open `file` and return a corresponding stream. If the file cannot be opened, an `IOError` is raised.

`file` is either a string or bytes object giving the pathname (absolute or relative to the current working directory) of the file to be opened or an integer file descriptor of the file to be wrapped. (If a file descriptor is given, it is closed when the returned I/O object is closed, unless `closefd` is set to `False`.)

`mode` is an optional string that specifies the mode in which the file is opened. It defaults to `'r'` which means open for reading in text mode. Other common values are `'w'` for writing (truncating the file if it already exists), and `'a'` for appending (which on *some* Unix systems, means that *all* writes append to the end of the file regardless of the current seek position). In text mode, if `encoding` is not specified the encoding used is platform dependent. (For reading and writing raw bytes use binary mode and leave

encoding unspecified.) The available modes are:

Character	Meaning
'r'	open for reading (default)
'w'	open for writing, truncating the file first
'a'	open for writing, appending to the end of the file if it exists
'b'	binary mode
't'	text mode (default)
'+'	open a disk file for updating (reading and writing)
'U'	universal newline mode (for backwards compatibility; should not be used in new code)

The default mode is `'r'` (open for reading text, synonym of `'rt'`). For binary read-write access, the mode `'w+b'` opens and truncates the file to 0 bytes. `'r+b'` opens the file without truncation.

As mentioned in the [Overview](#), Python distinguishes between binary and text I/O. Files opened in binary mode (including `'b'` in the *mode* argument) return contents as `bytes` objects without any decoding. In text mode (the default, or when `'t'` is included in the *mode* argument), the contents of the file are returned as `str`, the bytes having been first decoded using a platform-dependent encoding or using the specified *encoding* if given.

Note: Python doesn't depend on the underlying operating system's notion of text files; all the the processing is done by Python itself, and is therefore platform-independent.

buffering is an optional integer used to set the buffering policy. Pass 0 to switch buffering off (only allowed in binary mode), 1 to select line buffering (only usable in text mode), and an integer > 1 to indicate the size of a fixed-size chunk buffer. When no

buffering argument is given, the default buffering policy works as follows:

- Binary files are buffered in fixed-size chunks; the size of the buffer is chosen using a heuristic trying to determine the underlying device's "block size" and falling back on `io.DEFAULT_BUFFER_SIZE`. On many systems, the buffer will typically be 4096 or 8192 bytes long.
- "Interactive" text files (files for which `isatty()` returns True) use line buffering. Other text files use the policy described above for binary files.

encoding is the name of the encoding used to decode or encode the file. This should only be used in text mode. The default encoding is platform dependent (whatever `locale.getpreferredencoding()` returns), but any encoding supported by Python can be used. See the `codecs` module for the list of supported encodings.

errors is an optional string that specifies how encoding and decoding errors are to be handled—this cannot be used in binary mode. Pass `'strict'` to raise a `ValueError` exception if there is an encoding error (the default of `None` has the same effect), or pass `'ignore'` to ignore errors. (Note that ignoring encoding errors can lead to data loss.) `'replace'` causes a replacement marker (such as `'?'`) to be inserted where there is malformed data. When writing, `'xmlcharrefreplace'` (replace with the appropriate XML character reference) or `'backslashreplace'` (replace with backslashed escape sequences) can be used. Any other error handling name that has been registered with `codecs.register_error()` is also valid.

newline controls how universal newlines works (it only applies to text mode). It can be `None`, `''`, `'\n'`, `'\r'`, and `'\r\n'`. It works as

follows:

- On input, if *newline* is `None`, universal newlines mode is enabled. Lines in the input can end in `'\n'`, `'\r'`, or `'\r\n'`, and these are translated into `'\n'` before being returned to the caller. If it is `''`, universal newline mode is enabled, but line endings are returned to the caller untranslated. If it has any of the other legal values, input lines are only terminated by the given string, and the line ending is returned to the caller untranslated.
- On output, if *newline* is `None`, any `'\n'` characters written are translated to the system default line separator, `os.linesep`. If *newline* is `''`, no translation takes place. If *newline* is any of the other legal values, any `'\n'` characters written are translated to the given string.

If *closefd* is `False` and a file descriptor rather than a filename was given, the underlying file descriptor will be kept open when the file is closed. If a filename is given *closefd* has no effect and must be `True` (the default).

The type of file object returned by the `open()` function depends on the mode. When `open()` is used to open a file in a text mode (`'w'`, `'r'`, `'wt'`, `'rt'`, etc.), it returns a subclass of `io.TextIOBase` (specifically `io.TextIOWrapper`). When used to open a file in a binary mode with buffering, the returned class is a subclass of `io.BufferedIOBase`. The exact class varies: in read binary mode, it returns a `io.BufferedReader`; in write binary and append binary modes, it returns a `io.BufferedWriter`, and in read/write mode, it returns a `io.BufferedReader`. When buffering is disabled, the raw stream, a subclass of `io.RawIOBase`, `io.FileIO`, is returned.

See also the file handling modules, such as, `fileinput`, `io`

(where `open()` is declared), `os`, `os.path`, `tempfile`, and `shutil`.

`ord(c)`

Given a string representing one Unicode character, return an integer representing the Unicode code point of that character. For example, `ord('a')` returns the integer `97` and `ord('\u2020')` returns `8224`. This is the inverse of `chr()`.

On wide Unicode builds, if the argument length is not one, a `TypeError` will be raised. On narrow Unicode builds, strings of length two are accepted when they form a UTF-16 surrogate pair.

`pow(x, y[, z])`

Return x to the power y ; if z is present, return x to the power y , modulo z (computed more efficiently than `pow(x, y) % z`). The two-argument form `pow(x, y)` is equivalent to using the power operator: `x**y`.

The arguments must have numeric types. With mixed operand types, the coercion rules for binary arithmetic operators apply. For `int` operands, the result has the same type as the operands (after coercion) unless the second argument is negative; in that case, all arguments are converted to float and a float result is delivered. For example, `10**2` returns `100`, but `10**-2` returns `0.01`. If the second argument is negative, the third argument must be omitted. If z is present, x and y must be of integer types, and y must be non-negative.

`print([object, ...], *, sep=' ', end='\n', file=sys.stdout)`

Print *object(s)* to the stream *file*, separated by *sep* and followed by *end*. *sep*, *end* and *file*, if present, must be given as keyword arguments.

All non-keyword arguments are converted to strings like `str()` does and written to the stream, separated by `sep` and followed by `end`. Both `sep` and `end` must be strings; they can also be `None`, which means to use the default values. If no `object` is given, `print()` will just write `end`.

The `file` argument must be an object with a `write(string)` method; if it is not present or `None`, `sys.stdout` will be used.

`property(fget=None, fset=None, fdel=None, doc=None)`

Return a property attribute.

`fget` is a function for getting an attribute value, likewise `fset` is a function for setting, and `fdel` a function for del'ing, an attribute. Typical use is to define a managed attribute `x`:

```
class C:
    def __init__(self):
        self._x = None

    def getx(self):
        return self._x
    def setx(self, value):
        self._x = value
    def delx(self):
        del self._x
    x = property(getx, setx, delx, "I'm the 'x' property.")
```

If then `c` is an instance of `C`, `c.x` will invoke the getter, `c.x = value` will invoke the setter and `del c.x` the deleter.

If given, `doc` will be the docstring of the property attribute. Otherwise, the property will copy `fget`'s docstring (if it exists). This makes it possible to create read-only properties easily using `property()` as a *decorator*:

```
class Parrot:
    def __init__(self):
```

```

        self._voltage = 100000

    @property
    def voltage(self):
        """Get the current voltage."""
        return self._voltage

```

turns the `voltage()` method into a “getter” for a read-only attribute with the same name.

A property object has `getter`, `setter`, and `deleter` methods usable as decorators that create a copy of the property with the corresponding accessor function set to the decorated function. This is best explained with an example:

```

class C:
    def __init__(self):
        self._x = None

    @property
    def x(self):
        """I'm the 'x' property."""
        return self._x

    @x.setter
    def x(self, value):
        self._x = value

    @x.deleter
    def x(self):
        del self._x

```

This code is exactly equivalent to the first example. Be sure to give the additional functions the same name as the original property (`x` in this case.)

The returned property also has the attributes `fget`, `fset`, and `fdel` corresponding to the constructor arguments.

`range([start], stop[, step])`

This is a versatile function to create iterables yielding arithmetic progressions. It is most often used in `for` loops. The arguments must be integers. If the `step` argument is omitted, it defaults to `1`. If the `start` argument is omitted, it defaults to `0`. The full form returns an iterable of integers `[start, start + step, start + 2 * step, ...]`. If `step` is positive, the last element is the largest `start + i * step` less than `stop`; if `step` is negative, the last element is the smallest `start + i * step` greater than `stop`. `step` must not be zero (or else `ValueError` is raised). Example:

```
>>> list(range(10))
[0, 1, 2, 3, 4, 5, 6, 7, 8, 9]
>>> list(range(1, 11))
[1, 2, 3, 4, 5, 6, 7, 8, 9, 10]
>>> list(range(0, 30, 5))
[0, 5, 10, 15, 20, 25]
>>> list(range(0, 10, 3))
[0, 3, 6, 9]
>>> list(range(0, -10, -1))
[0, -1, -2, -3, -4, -5, -6, -7, -8, -9]
>>> list(range(0))
[]
>>> list(range(1, 0))
[]
```

Range objects implement the `collections.Sequence` ABC, and provide features such as containment tests, element index lookup, slicing and support for negative indices:

```
>>> r = range(0, 20, 2)
>>> r
range(0, 20, 2)
>>> 11 in r
False
>>> 10 in r
True
>>> r.index(10)
5
>>> r[5]
10
```

```
>>> r[:5]
range(0, 10, 2)
>>> r[-1]
18
```

Ranges containing absolute values larger than `sys.maxsize` are permitted but some features (such as `len()`) will raise `OverflowError`.

Changed in version 3.2: Implement the Sequence ABC. Support slicing and negative indices. Test integers for membership in constant time instead of iterating through all items.

`repr(object)`

Return a string containing a printable representation of an object. For many types, this function makes an attempt to return a string that would yield an object with the same value when passed to `eval()`, otherwise the representation is a string enclosed in angle brackets that contains the name of the type of the object together with additional information often including the name and address of the object. A class can control what this function returns for its instances by defining a `__repr__()` method.

`reversed(seq)`

Return a reverse *iterator*. `seq` must be an object which has a `__reversed__()` method or supports the sequence protocol (the `__len__()` method and the `__getitem__()` method with integer arguments starting at 0).

`round(x[, n])`

Return the floating point value `x` rounded to `n` digits after the decimal point. If `n` is omitted, it defaults to zero. Delegates to `x.__round__(n)`.

For the built-in types supporting `round()`, values are rounded to

the closest multiple of 10 to the power minus n ; if two multiples are equally close, rounding is done toward the even choice (so, for example, both `round(0.5)` and `round(-0.5)` are 0, and `round(1.5)` is 2). The return value is an integer if called with one argument, otherwise of the same type as x .

Note: The behavior of `round()` for floats can be surprising: for example, `round(2.675, 2)` gives 2.67 instead of the expected 2.68. This is not a bug: it's a result of the fact that most decimal fractions can't be represented exactly as a float. See [Floating Point Arithmetic: Issues and Limitations](#) for more information.

`set([iterable])`

Return a new set, optionally with elements taken from *iterable*. The set type is described in [Set Types — set, frozenset](#).

`setattr(object, name, value)`

This is the counterpart of `getattr()`. The arguments are an object, a string and an arbitrary value. The string may name an existing attribute or a new attribute. The function assigns the value to the attribute, provided the object allows it. For example, `setattr(x, 'foobar', 123)` is equivalent to `x.foobar = 123`.

`slice([start], stop[, step])`

Return a *slice* object representing the set of indices specified by `range(start, stop, step)`. The *start* and *step* arguments default to `None`. Slice objects have read-only data attributes `start`, `stop` and `step` which merely return the argument values (or their default). They have no other explicit functionality; however they are used by Numerical Python and other third party extensions. Slice objects are also generated when extended indexing syntax is used. For example: `a[start:stop:step]` or `a[start:stop, i]`.

See `itertools.islice()` for an alternate version that returns an iterator.

sorted(*iterable*[, *key*][, *reverse*])

Return a new sorted list from the items in *iterable*.

Has two optional arguments which must be specified as keyword arguments.

key specifies a function of one argument that is used to extract a comparison key from each list element: `key=str.lower`. The default value is `None` (compare the elements directly).

reverse is a boolean value. If set to `True`, then the list elements are sorted as if each comparison were reversed.

Use `functools.cmp_to_key()` to convert an old-style *cmp* function to a *key* function.

For sorting examples and a brief sorting tutorial, see [Sorting HowTo](#).

staticmethod(*function*)

Return a static method for *function*.

A static method does not receive an implicit first argument. To declare a static method, use this idiom:

```
class C:
    @staticmethod
    def f(arg1, arg2, ...): ...
```

The `@staticmethod` form is a function *decorator* – see the description of function definitions in [Function definitions](#) for details.

It can be called either on the class (such as `c.f()`) or on an instance (such as `c().f()`). The instance is ignored except for its class.

Static methods in Python are similar to those found in Java or C++. For a more advanced concept, see `classmethod()` in this section.

For more information on static methods, consult the documentation on the standard type hierarchy in *The standard type hierarchy*.

`str([object[, encoding[, errors]]])`

Return a string version of an object, using one of the following modes:

If *encoding* and/or *errors* are given, `str()` will decode the *object* which can either be a byte string or a character buffer using the codec for *encoding*. The *encoding* parameter is a string giving the name of an encoding; if the encoding is not known, `LookupError` is raised. Error handling is done according to *errors*; this specifies the treatment of characters which are invalid in the input encoding. If *errors* is `'strict'` (the default), a `ValueError` is raised on errors, while a value of `'ignore'` causes errors to be silently ignored, and a value of `'replace'` causes the official Unicode replacement character, U+FFFD, to be used to replace input characters which cannot be decoded. See also the `codecs` module.

When only *object* is given, this returns its nicely printable representation. For strings, this is the string itself. The difference with `repr(object)` is that `str(object)` does not always attempt to return a string that is acceptable to `eval()`; its goal is to return a printable string. With no arguments, this returns the empty string.

Objects can specify what `str(object)` returns by defining a `__str__()` special method.

For more information on strings see *Sequence Types — str, bytes, bytearray, list, tuple, range* which describes sequence functionality (strings are sequences), and also the string-specific methods described in the *String Methods* section. To output formatted strings, see the *String Formatting* section. In addition see the *String Services* section.

`sum(iterable[, start])`

Sums *start* and the items of an *iterable* from left to right and returns the total. *start* defaults to `0`. The *iterable*'s items are normally numbers, and the start value is not allowed to be a string.

For some use cases, there are good alternatives to `sum()`. The preferred, fast way to concatenate a sequence of strings is by calling `''.join(sequence)`. To add floating point values with extended precision, see `math.fsum()`. To concatenate a series of iterables, consider using `itertools.chain()`.

`super([type[, object-or-type]])`

Return a proxy object that delegates method calls to a parent or sibling class of *type*. This is useful for accessing inherited methods that have been overridden in a class. The search order is same as that used by `getattr()` except that the *type* itself is skipped.

The `__mro__` attribute of the *type* lists the method resolution search order used by both `getattr()` and `super()`. The attribute is dynamic and can change whenever the inheritance hierarchy is updated.

If the second argument is omitted, the super object returned is unbound. If the second argument is an object, `isinstance(obj, type)` must be true. If the second argument is a type, `issubclass(type2, type)` must be true (this is useful for classmethods).

There are two typical use cases for *super*. In a class hierarchy with single inheritance, *super* can be used to refer to parent classes without naming them explicitly, thus making the code more maintainable. This use closely parallels the use of *super* in other programming languages.

The second use case is to support cooperative multiple inheritance in a dynamic execution environment. This use case is unique to Python and is not found in statically compiled languages or languages that only support single inheritance. This makes it possible to implement “diamond diagrams” where multiple base classes implement the same method. Good design dictates that this method have the same calling signature in every case (because the order of calls is determined at runtime, because that order adapts to changes in the class hierarchy, and because that order can include sibling classes that are unknown prior to runtime).

For both use cases, a typical superclass call looks like this:

```
class C(B):
    def method(self, arg):
        super().method(arg)      # This does the same thing as
                                # super(C, self).method(arg)
```

Note that `super()` is implemented as part of the binding process for explicit dotted attribute lookups such as `super().__getitem__(name)`. It does so by implementing its own `__getattr__()` method for searching classes in a

predictable order that supports cooperative multiple inheritance. Accordingly, `super()` is undefined for implicit lookups using statements or operators such as `super()[name]`.

Also note that `super()` is not limited to use inside methods. The two argument form specifies the arguments exactly and makes the appropriate references. The zero argument form automatically searches the stack frame for the class (`__class__`) and the first argument.

`tuple([iterable])`

Return a tuple whose items are the same and in the same order as *iterable*'s items. *iterable* may be a sequence, a container that supports iteration, or an iterator object. If *iterable* is already a tuple, it is returned unchanged. For instance, `tuple('abc')` returns `('a', 'b', 'c')` and `tuple([1, 2, 3])` returns `(1, 2, 3)`. If no argument is given, returns a new empty tuple, `()`.

`tuple` is an immutable sequence type, as documented in *Sequence Types — str, bytes, bytearray, list, tuple, range*.

`type(object)`

Return the type of an *object*. The return value is a type object and generally the same object as returned by `object.__class__`.

The `isinstance()` built-in function is recommended for testing the type of an object, because it takes subclasses into account.

With three arguments, `type()` functions as a constructor as detailed below.

`type(name, bases, dict)`

Return a new type object. This is essentially a dynamic form of the `class` statement. The *name* string is the class name and

becomes the `__name__` attribute; the *bases* tuple itemizes the base classes and becomes the `__bases__` attribute; and the *dict* dictionary is the namespace containing definitions for class body and becomes the `__dict__` attribute. For example, the following two statements create identical `type` objects:

```
>>> class X:
...     a = 1
...
>>> X = type('X', (object,), dict(a=1))
```

`vars([object])`

Without an argument, act like `locals()`.

With a module, class or class instance object as argument (or anything else that has a `__dict__` attribute), return that attribute.

Note: The returned dictionary should not be modified: the effects on the corresponding symbol table are undefined. [2]

`zip(*iterables)`

Make an iterator that aggregates elements from each of the iterables.

Returns an iterator of tuples, where the *i*-th tuple contains the *i*-th element from each of the argument sequences or iterables. The iterator stops when the shortest input iterable is exhausted. With a single iterable argument, it returns an iterator of 1-tuples. With no arguments, it returns an empty iterator. Equivalent to:

```
def zip(*iterables):
    # zip('ABCD', 'xy') --> Ax By
    sentinel = object()
    iterables = [iter(it) for it in iterables]
    while iterables:
        result = []
```

```

for it in iterables:
    elem = next(it, sentinel)
    if elem is sentinel:
        return
    result.append(elem)
yield tuple(result)

```

The left-to-right evaluation order of the iterables is guaranteed. This makes possible an idiom for clustering a data series into n-length groups using `zip(*[iter(s)]*n)`.

`zip()` should only be used with unequal length inputs when you don't care about trailing, unmatched values from the longer iterables. If those values are important, use `itertools.zip_longest()` instead.

`zip()` in conjunction with the `*` operator can be used to unzip a list:

```

>>> x = [1, 2, 3]
>>> y = [4, 5, 6]
>>> zipped = zip(x, y)
>>> list(zipped)
[(1, 4), (2, 5), (3, 6)]
>>> x2, y2 = zip(*zip(x, y))
>>> x == list(x2) and y == list(y2)
True

```

`__import__(name, globals={}, locals={}, fromlist=[], level=0)`

Note: This is an advanced function that is not needed in everyday Python programming.

This function is invoked by the `import` statement. It can be replaced (by importing the `builtins` module and assigning to `builtins.__import__`) in order to change semantics of the `import` statement, but nowadays it is usually simpler to use import hooks (see [PEP 302](#)). Direct use of `__import__()` is rare, except in

cases where you want to import a module whose name is only known at runtime.

The function imports the module *name*, potentially using the given *globals* and *locals* to determine how to interpret the name in a package context. The *fromlist* gives the names of objects or submodules that should be imported from the module given by *name*. The standard implementation does not use its *locals* argument at all, and uses its *globals* only to determine the package context of the `import` statement.

level specifies whether to use absolute or relative imports. `0` (the default) means only perform absolute imports. Positive values for *level* indicate the number of parent directories to search relative to the directory of the module calling `__import__()`.

When the *name* variable is of the form `package.module`, normally, the top-level package (the name up till the first dot) is returned, *not* the module named by *name*. However, when a non-empty *fromlist* argument is given, the module named by *name* is returned.

For example, the statement `import spam` results in bytecode resembling the following code:

```
spam = __import__('spam', globals(), locals(), [], 0)
```

The statement `import spam.ham` results in this call:

```
spam = __import__('spam.ham', globals(), locals(), [], 0)
```

Note how `__import__()` returns the toplevel module here because this is the object that is bound to a name by the `import` statement.

On the other hand, the statement `from spam.ham import eggs, sausage as saus` results in

```
_temp = __import__('spam.ham', globals(), locals(), ['eggs',  
eggs = _temp.eggs  
saus = _temp.sausage
```

Here, the `spam.ham` module is returned from `__import__()`. From this object, the names to import are retrieved and assigned to their respective names.

If you simply want to import a module (potentially within a package) by name, you can call `__import__()` and then look it up in `sys.modules`:

```
>>> import sys  
>>> name = 'foo.bar.baz'  
>>> __import__(name)  
<module 'foo' from ...>  
>>> baz = sys.modules[name]  
>>> baz  
<module 'foo.bar.baz' from ...>
```

Footnotes

[1] Note that the parser only accepts the Unix-style end of line convention. If you are reading the code from a file, make sure to use newline conversion mode to convert Windows or Mac-style newlines.

[2] In the current implementation, local variable bindings cannot normally be affected this way, but variables retrieved from other scopes (such as modules) can be. This may change.

3. Built-in Constants

A small number of constants live in the built-in namespace. They are:

False

The false value of the `bool` type. Assignments to `False` are illegal and raise a `SyntaxError`.

True

The true value of the `bool` type. Assignments to `True` are illegal and raise a `SyntaxError`.

None

The sole value of `types.NoneType`. `None` is frequently used to represent the absence of a value, as when default arguments are not passed to a function. Assignments to `None` are illegal and raise a `SyntaxError`.

NotImplemented

Special value which can be returned by the “rich comparison” special methods (`__eq__()`, `__lt__()`, and friends), to indicate that the comparison is not implemented with respect to the other type.

Ellipsis

The same as `...`. Special value used mostly in conjunction with extended slicing syntax for user-defined container data types.

`__debug__`

This constant is true if Python was not started with an `-O` option. See also the `assert` statement.

Note: The names `None`, `False`, `True` and `__debug__` cannot be reassigned (assignments to them, even as an attribute name, raise

`SyntaxError`), so they can be considered “true” constants.

3.1. Constants added by the `site` module

The `site` module (which is imported automatically during startup, except if the `-S` command-line option is given) adds several constants to the built-in namespace. They are useful for the interactive interpreter shell and should not be used in programs.

`quit(code=None)`

`exit(code=None)`

Objects that when printed, print a message like “Use `quit()` or Ctrl-D (i.e. EOF) to exit”, and when called, raise `SystemExit` with the specified exit code.

`copyright`

`license`

`credits`

Objects that when printed, print a message like “Type `license()` to see the full license text”, and when called, display the corresponding text in a pager-like fashion (one screen at a time).

4. Built-in Types

The following sections describe the standard types that are built into the interpreter.

The principal built-in types are numerics, sequences, mappings, classes, instances and exceptions.

Some operations are supported by several object types; in particular, practically all objects can be compared, tested for truth value, and converted to a string (with the `repr()` function or the slightly different `str()` function). The latter function is implicitly used when an object is written by the `print()` function.

4.1. Truth Value Testing

Any object can be tested for truth value, for use in an `if` or `while` condition or as operand of the Boolean operations below. The following values are considered false:

- `None`
- `False`
- zero of any numeric type, for example, `0`, `0.0`, `0j`.
- any empty sequence, for example, `''`, `()`, `[]`.
- any empty mapping, for example, `{}`.
- instances of user-defined classes, if the class defines a `__bool__()` or `__len__()` method, when that method returns the integer zero or `bool` value `False`. [1]

All other values are considered true — so objects of many types are always true.

Operations and built-in functions that have a Boolean result always return `0` or `False` for false and `1` or `True` for true, unless otherwise stated. (Important exception: the Boolean operations `or` and `and` always return one of their operands.)

4.2. Boolean Operations — and, or, not

These are the Boolean operations, ordered by ascending priority:

Operation	Result	Notes
<code>x or y</code>	if <code>x</code> is false, then <code>y</code> , else <code>x</code>	(1)
<code>x and y</code>	if <code>x</code> is false, then <code>x</code> , else <code>y</code>	(2)
<code>not x</code>	if <code>x</code> is false, then <code>True</code> , else <code>False</code>	(3)

Notes:

1. This is a short-circuit operator, so it only evaluates the second argument if the first one is `False`.
2. This is a short-circuit operator, so it only evaluates the second argument if the first one is `True`.
3. `not` has a lower priority than non-Boolean operators, so `not a == b` is interpreted as `not (a == b)`, and `a == not b` is a syntax error.

4.3. Comparisons

There are eight comparison operations in Python. They all have the same priority (which is higher than that of the Boolean operations). Comparisons can be chained arbitrarily; for example, `x < y <= z` is equivalent to `x < y` and `y <= z`, except that `y` is evaluated only once (but in both cases `z` is not evaluated at all when `x < y` is found to be false).

This table summarizes the comparison operations:

Operation	Meaning
<code><</code>	strictly less than
<code><=</code>	less than or equal
<code>></code>	strictly greater than
<code>>=</code>	greater than or equal
<code>==</code>	equal
<code>!=</code>	not equal
<code>is</code>	object identity
<code>is not</code>	negated object identity

Objects of different types, except different numeric types, never compare equal. Furthermore, some types (for example, function objects) support only a degenerate notion of comparison where any two objects of that type are unequal. The `<`, `<=`, `>` and `>=` operators will raise a `TypeError` exception when comparing a complex number with another built-in numeric type, when the objects are of different types that cannot be compared, or in other cases where there is no defined ordering.

Non-identical instances of a class normally compare as non-equal unless the class defines the `__eq__()` method.

Instances of a class cannot be ordered with respect to other instances of the same class, or other types of object, unless the class defines enough of the methods `__lt__()`, `__le__()`, `__gt__()`, and `__ge__()` (in general, `__lt__()` and `__eq__()` are sufficient, if you want the conventional meanings of the comparison operators).

The behavior of the `is` and `is not` operators cannot be customized; also they can be applied to any two objects and never raise an exception.

Two more operations with the same syntactic priority, `in` and `not in`, are supported only by sequence types (below).

4.4. Numeric Types — `int`, `float`, `complex`

There are three distinct numeric types: *integers*, *floating point numbers*, and *complex numbers*. In addition, Booleans are a subtype of integers. Integers have unlimited precision. Floating point numbers are usually implemented using `double` in C; information about the precision and internal representation of floating point numbers for the machine on which your program is running is available in `sys.float_info`. Complex numbers have a real and imaginary part, which are each a floating point number. To extract these parts from a complex number `z`, use `z.real` and `z.imag`. (The standard library includes additional numeric types, `fractions` that hold rationals, and `decimal` that hold floating-point numbers with user-definable precision.)

Numbers are created by numeric literals or as the result of built-in functions and operators. Unadorned integer literals (including hex, octal and binary numbers) yield integers. Numeric literals containing a decimal point or an exponent sign yield floating point numbers. Appending `'j'` or `'J'` to a numeric literal yields an imaginary number (a complex number with a zero real part) which you can add to an integer or float to get a complex number with real and imaginary parts.

Python fully supports mixed arithmetic: when a binary arithmetic operator has operands of different numeric types, the operand with the “narrower” type is widened to that of the other, where integer is narrower than floating point, which is narrower than complex. Comparisons between numbers of mixed type use the same rule. [2] The constructors `int()`, `float()`, and `complex()` can be used to produce numbers of a specific type.

All numeric types (except `complex`) support the following operations,

sorted by ascending priority (operations in the same box have the same priority; all numeric operations have a higher priority than comparison operations):

Operation	Result	Notes	Full documentation
<code>x + y</code>	sum of <code>x</code> and <code>y</code>		
<code>x - y</code>	difference of <code>x</code> and <code>y</code>		
<code>x * y</code>	product of <code>x</code> and <code>y</code>		
<code>x / y</code>	quotient of <code>x</code> and <code>y</code>		
<code>x // y</code>	floored quotient of <code>x</code> and <code>y</code>	(1)	
<code>x % y</code>	remainder of <code>x / y</code>	(2)	
<code>-x</code>	<code>x</code> negated		
<code>+x</code>	<code>x</code> unchanged		
<code>abs(x)</code>	absolute value or magnitude of <code>x</code>		<code>abs()</code>
<code>int(x)</code>	<code>x</code> converted to integer	(3)	<code>int()</code>
<code>float(x)</code>	<code>x</code> converted to floating point	(4)	<code>float()</code>
<code>complex(re, im)</code>	a complex number with real part <i>re</i> , imaginary part <i>im</i> . <i>im</i> defaults to zero.		<code>complex()</code>
<code>c.conjugate()</code>	conjugate of the complex number <code>c</code>		
<code>divmod(x, y)</code>	the pair <code>(x // y, x % y)</code>	(2)	<code>divmod()</code>
<code>pow(x, y)</code>	<code>x</code> to the power <code>y</code>	(5)	<code>pow()</code>
<code>x ** y</code>	<code>x</code> to the power <code>y</code>	(5)	

Notes:

1. Also referred to as integer division. The resultant value is a whole integer, though the result's type is not necessarily `int`. The

result is always rounded towards minus infinity: `1//2` is `0`, `(-1)//2` is `-1`, `1//(-2)` is `-1`, and `(-1)//(-2)` is `0`.

2. Not for complex numbers. Instead convert to floats using `abs()` if appropriate.
3. Conversion from floating point to integer may round or truncate as in C; see functions `floor()` and `ceil()` in the `math` module for well-defined conversions.
4. float also accepts the strings “nan” and “inf” with an optional prefix “+” or “-” for Not a Number (NaN) and positive or negative infinity.
5. Python defines `pow(0, 0)` and `0 ** 0` to be `1`, as is common for programming languages.

All `numbers.Real` types (`int` and `float`) also include the following operations:

Operation	Result	Notes
<code>math.trunc(x)</code>	<code>x</code> truncated to Integral	
<code>round(x[, n])</code>	<code>x</code> rounded to <code>n</code> digits, rounding half to even. If <code>n</code> is omitted, it defaults to 0.	
<code>math.floor(x)</code>	the greatest integral float $\leq x$	
<code>math.ceil(x)</code>	the least integral float $\geq x$	

For additional numeric operations see the `math` and `cmath` modules.

4.4.1. Bit-string Operations on Integer Types

Integers support additional operations that make sense only for bit-strings. Negative numbers are treated as their 2's complement value (this assumes a sufficiently large number of bits that no overflow occurs during the operation).

The priorities of the binary bitwise operations are all lower than the numeric operations and higher than the comparisons; the unary operation `~` has the same priority as the other unary numeric operations (`+` and `-`).

This table lists the bit-string operations sorted in ascending priority (operations in the same box have the same priority):

Operation	Result	Notes
<code>x y</code>	bitwise <i>or</i> of <code>x</code> and <code>y</code>	
<code>x ^ y</code>	bitwise <i>exclusive or</i> of <code>x</code> and <code>y</code>	
<code>x & y</code>	bitwise <i>and</i> of <code>x</code> and <code>y</code>	
<code>x << n</code>	<code>x</code> shifted left by <code>n</code> bits	(1)(2)
<code>x >> n</code>	<code>x</code> shifted right by <code>n</code> bits	(1)(3)
<code>~x</code>	the bits of <code>x</code> inverted	

Notes:

1. Negative shift counts are illegal and cause a `ValueError` to be raised.
2. A left shift by `n` bits is equivalent to multiplication by `pow(2, n)` without overflow check.
3. A right shift by `n` bits is equivalent to division by `pow(2, n)` without overflow check.

4.4.2. Additional Methods on Integer Types

`int.bit_length()`

Return the number of bits necessary to represent an integer in binary, excluding the sign and leading zeros:

```
>>> n = -37
>>> bin(n)
'-0b100101'
>>> n.bit_length()
```

More precisely, if `x` is nonzero, then `x.bit_length()` is the unique positive integer `k` such that `2**(k-1) <= abs(x) < 2**k`. Equivalently, when `abs(x)` is small enough to have a correctly rounded logarithm, then `k = 1 + int(log(abs(x), 2))`. If `x` is zero, then `x.bit_length()` returns 0.

Equivalent to:

```
def bit_length(self):
    s = bin(self)          # binary representation: bin(-37) -
    s = s.lstrip('-0b')   # remove leading zeros and minus sig
    return len(s)         # len('100101') --> 6
```

New in version 3.1.

`int.to_bytes(length, byteorder, *, signed=False)`

Return an array of bytes representing an integer.

```
>>> (1024).to_bytes(2, byteorder='big')
b'\x04\x00'
>>> (1024).to_bytes(10, byteorder='big')
b'\x00\x00\x00\x00\x00\x00\x00\x00\x04\x00'
>>> (-1024).to_bytes(10, byteorder='big', signed=True)
b'\xff\xff\xff\xff\xff\xff\xff\xff\xffc\x00'
>>> x = 1000
>>> x.to_bytes((x.bit_length() // 8) + 1, byteorder='little')
b'\xe8\x03'
```

The integer is represented using `length` bytes. An `OverflowError` is raised if the integer is not representable with the given number of bytes.

The `byteorder` argument determines the byte order used to represent the integer. If `byteorder` is `"big"`, the most significant byte is at the beginning of the byte array. If `byteorder` is `"little"`,

the most significant byte is at the end of the byte array. To request the native byte order of the host system, use `sys.byteorder` as the byte order value.

The *signed* argument determines whether two's complement is used to represent the integer. If *signed* is `False` and a negative integer is given, an `OverflowError` is raised. The default value for *signed* is `False`.

New in version 3.2.

classmethod `int.from_bytes(bytes, byteorder, *, signed=False)`

Return the integer represented by the given array of bytes.

```
>>> int.from_bytes(b'\x00\x10', byteorder='big')
16
>>> int.from_bytes(b'\x00\x10', byteorder='little')
4096
>>> int.from_bytes(b'\xfc\x00', byteorder='big', signed=True)
-1024
>>> int.from_bytes(b'\xfc\x00', byteorder='big', signed=False)
64512
>>> int.from_bytes([255, 0, 0], byteorder='big')
16711680
```

The argument *bytes* must either support the buffer protocol or be an iterable producing bytes. `bytes` and `bytearray` are examples of built-in objects that support the buffer protocol.

The *byteorder* argument determines the byte order used to represent the integer. If *byteorder* is `"big"`, the most significant byte is at the beginning of the byte array. If *byteorder* is `"little"`, the most significant byte is at the end of the byte array. To request the native byte order of the host system, use `sys.byteorder` as the byte order value.

The *signed* argument indicates whether two's complement is used to represent the integer.

New in version 3.2.

4.4.3. Additional Methods on Float

The float type has some additional methods.

`float.as_integer_ratio()`

Return a pair of integers whose ratio is exactly equal to the original float and with a positive denominator. Raises `OverflowError` on infinities and a `ValueError` on NaNs.

`float.is_integer()`

Return `True` if the float instance is finite with integral value, and `False` otherwise:

```
>>> (-2.0).is_integer()
True
>>> (3.2).is_integer()
False
```

Two methods support conversion to and from hexadecimal strings. Since Python's floats are stored internally as binary numbers, converting a float to or from a *decimal* string usually involves a small rounding error. In contrast, hexadecimal strings allow exact representation and specification of floating-point numbers. This can be useful when debugging, and in numerical work.

`float.hex()`

Return a representation of a floating-point number as a hexadecimal string. For finite floating-point numbers, this representation will always include a leading `0x` and a trailing `p` and exponent.

classmethod `float.fromhex(s)`

Class method to return the float represented by a hexadecimal string `s`. The string `s` may have leading and trailing whitespace.

Note that `float.hex()` is an instance method, while `float.fromhex()` is a class method.

A hexadecimal string takes the form:

```
[sign] ['0x'] integer ['.' fraction] ['p' exponent]
```

where the optional `sign` may be either `+` or `-`, `integer` and `fraction` are strings of hexadecimal digits, and `exponent` is a decimal integer with an optional leading sign. Case is not significant, and there must be at least one hexadecimal digit in either the integer or the fraction. This syntax is similar to the syntax specified in section 6.4.4.2 of the C99 standard, and also to the syntax used in Java 1.5 onwards. In particular, the output of `float.hex()` is usable as a hexadecimal floating-point literal in C or Java code, and hexadecimal strings produced by C's `%a` format character or Java's `Double.toHexString` are accepted by `float.fromhex()`.

Note that the exponent is written in decimal rather than hexadecimal, and that it gives the power of 2 by which to multiply the coefficient. For example, the hexadecimal string `0x3.a7p10` represents the floating-point number $(3 + 10./16 + 7./16^{**2}) * 2.0^{**10}$, or `3740.0`:

```
>>> float.fromhex('0x3.a7p10')
3740.0
```

Applying the reverse conversion to `3740.0` gives a different hexadecimal string representing the same number:

```
>>> float.hex(3740.0)
```

```
'0x1.d380000000000p+11'
```

4.4.4. Hashing of numeric types

For numbers `x` and `y`, possibly of different types, it's a requirement that `hash(x) == hash(y)` whenever `x == y` (see the `__hash__()` method documentation for more details). For ease of implementation and efficiency across a variety of numeric types (including `int`, `float`, `decimal.Decimal` and `fractions.Fraction`) Python's hash for numeric types is based on a single mathematical function that's defined for any rational number, and hence applies to all instances of `int` and `fractions.Fraction`, and all finite instances of `float` and `decimal.Decimal`. Essentially, this function is given by reduction modulo `P` for a fixed prime `P`. The value of `P` is made available to Python as the `modulus` attribute of `sys.hash_info`.

CPython implementation detail: Currently, the prime used is `P = 2**31 - 1` on machines with 32-bit C longs and `P = 2**61 - 1` on machines with 64-bit C longs.

Here are the rules in detail:

- If `x = m / n` is a nonnegative rational number and `n` is not divisible by `P`, define `hash(x)` as `m * invmod(n, P) % P`, where `invmod(n, P)` gives the inverse of `n` modulo `P`.
- If `x = m / n` is a nonnegative rational number and `n` is divisible by `P` (but `m` is not) then `n` has no inverse modulo `P` and the rule above doesn't apply; in this case define `hash(x)` to be the constant value `sys.hash_info.inf`.
- If `x = m / n` is a negative rational number define `hash(x)` as `-hash(-x)`. If the resulting hash is `-1`, replace it with `-2`.

- The particular values `sys.hash_info.inf`, `-sys.hash_info.inf` and `sys.hash_info.nan` are used as hash values for positive infinity, negative infinity, or nans (respectively). (All hashable nans have the same hash value.)
- For a **complex** number `z`, the hash values of the real and imaginary parts are combined by computing `hash(z.real) + sys.hash_info.imag * hash(z.imag)`, reduced modulo `2**sys.hash_info.width` so that it lies in `range(-2**(sys.hash_info.width - 1), 2**(sys.hash_info.width - 1))`. Again, if the result is `-1`, it's replaced with `-2`.

To clarify the above rules, here's some example Python code, equivalent to the builtin hash, for computing the hash of a rational number, **float**, or **complex**:

```
import sys, math

def hash_fraction(m, n):
    """Compute the hash of a rational number m / n.

    Assumes m and n are integers, with n positive.
    Equivalent to hash(fractions.Fraction(m, n)).

    """
    P = sys.hash_info.modulus
    # Remove common factors of P. (Unnecessary if m and n already
    while m % P == n % P == 0:
        m, n = m // P, n // P

    if n % P == 0:
        hash_ = sys.hash_info.inf
    else:
        # Fermat's Little Theorem: pow(n, P-1, P) is 1, so
        # pow(n, P-2, P) gives the inverse of n modulo P.
        hash_ = (abs(m) % P) * pow(n, P - 2, P) % P
    if m < 0:
        hash_ = -hash_
    if hash_ == -1:
        hash_ = -2
```

```
    return hash_

def hash_float(x):
    """Compute the hash of a float x."""

    if math.isnan(x):
        return sys.hash_info.nan
    elif math.isinf(x):
        return sys.hash_info.inf if x > 0 else -sys.hash_info.i
    else:
        return hash_fraction(*x.as_integer_ratio())

def hash_complex(z):
    """Compute the hash of a complex number z."""

    hash_ = hash_float(z.real) + sys.hash_info.imag * hash_floa
    # do a signed reduction modulo 2**sys.hash_info.width
    M = 2**(sys.hash_info.width - 1)
    hash_ = (hash_ & (M - 1)) - (hash_ & M)
    if hash_ == -1:
        hash_ == -2
    return hash_
```

4.5. Iterator Types

Python supports a concept of iteration over containers. This is implemented using two distinct methods; these are used to allow user-defined classes to support iteration. Sequences, described below in more detail, always support the iteration methods.

One method needs to be defined for container objects to provide iteration support:

`container.__iter__()`

Return an iterator object. The object is required to support the iterator protocol described below. If a container supports different types of iteration, additional methods can be provided to specifically request iterators for those iteration types. (An example of an object supporting multiple forms of iteration would be a tree structure which supports both breadth-first and depth-first traversal.) This method corresponds to the `tp_iter` slot of the type structure for Python objects in the Python/C API.

The iterator objects themselves are required to support the following two methods, which together form the *iterator protocol*:

`iterator.__iter__()`

Return the iterator object itself. This is required to allow both containers and iterators to be used with the `for` and `in` statements. This method corresponds to the `tp_iter` slot of the type structure for Python objects in the Python/C API.

`iterator.__next__()`

Return the next item from the container. If there are no further items, raise the `StopIteration` exception. This method corresponds to the `tp_iternext` slot of the type structure for

Python objects in the Python/C API.

Python defines several iterator objects to support iteration over general and specific sequence types, dictionaries, and other more specialized forms. The specific types are not important beyond their implementation of the iterator protocol.

Once an iterator's `__next__()` method raises `StopIteration`, it must continue to do so on subsequent calls. Implementations that do not obey this property are deemed broken.

4.5.1. Generator Types

Python's *generators* provide a convenient way to implement the iterator protocol. If a container object's `__iter__()` method is implemented as a generator, it will automatically return an iterator object (technically, a generator object) supplying the `__iter__()` and `__next__()` methods. More information about generators can be found in *the documentation for the yield expression*.

4.6. Sequence Types — `str`, `bytes`, `bytearray`, `list`, `tuple`, `range`

There are six sequence types: strings, byte sequences (`bytes` objects), byte arrays (`bytearray` objects), lists, tuples, and range objects. For other containers see the built in `dict` and `set` classes, and the `collections` module.

Strings contain Unicode characters. Their literals are written in single or double quotes: `'xyzzy'`, `"frobozz"`. See *String and Bytes literals* for more about string literals. In addition to the functionality described here, there are also string-specific methods described in the *String Methods* section.

Bytes and `bytearray` objects contain single bytes – the former is immutable while the latter is a mutable sequence. Bytes objects can be constructed the constructor, `bytes()`, and from literals; use a `b` prefix with normal string syntax: `b'xyzzy'`. To construct byte arrays, use the `bytearray()` function.

While string objects are sequences of characters (represented by strings of length 1), bytes and `bytearray` objects are sequences of *integers* (between 0 and 255), representing the ASCII value of single bytes. That means that for a bytes or `bytearray` object `b`, `b[0]` will be an integer, while `b[0:1]` will be a bytes or `bytearray` object of length 1. The representation of bytes objects uses the literal format (`b'...'`) since it is generally more useful than e.g. `bytes([50, 19, 100])`. You can always convert a bytes object into a list of integers using `list(b)`.

Also, while in previous Python versions, byte strings and Unicode strings could be exchanged for each other rather freely (barring

encoding issues), strings and bytes are now completely separate concepts. There's no implicit en-/decoding if you pass an object of the wrong type. A string always compares unequal to a bytes or bytearray object.

Lists are constructed with square brackets, separating items with commas: `[a, b, c]`. Tuples are constructed by the comma operator (not within square brackets), with or without enclosing parentheses, but an empty tuple must have the enclosing parentheses, such as `a, b, c` or `()`. A single item tuple must have a trailing comma, such as `(d,)`.

Objects of type range are created using the `range()` function. They don't support concatenation or repetition, and using `min()` or `max()` on them is inefficient.

Most sequence types support the following operations. The `in` and `not in` operations have the same priorities as the comparison operations. The `+` and `*` operations have the same priority as the corresponding numeric operations. [3] Additional methods are provided for *Mutable Sequence Types*.

This table lists the sequence operations sorted in ascending priority (operations in the same box have the same priority). In the table, `s` and `t` are sequences of the same type; `n`, `i`, `j` and `k` are integers.

Operation	Result	Notes
<code>x in s</code>	True if an item of <code>s</code> is equal to <code>x</code> , else False	(1)
<code>x not in s</code>	False if an item of <code>s</code> is equal to <code>x</code> , else True	(1)
<code>s + t</code>	the concatenation of <code>s</code> and <code>t</code>	(6)
<code>s * n, n * s</code>	<code>n</code> shallow copies of <code>s</code> concatenated	(2)
<code>s[i]</code>	<code>i</code> 'th item of <code>s</code> , origin 0	(3)

<code>s[i:j]</code>	slice of <code>s</code> from <code>i</code> to <code>j</code>	(3)(4)
<code>s[i:j:k]</code>	slice of <code>s</code> from <code>i</code> to <code>j</code> with step <code>k</code>	(3)(5)
<code>len(s)</code>	length of <code>s</code>	
<code>min(s)</code>	smallest item of <code>s</code>	
<code>max(s)</code>	largest item of <code>s</code>	
<code>s.index(i)</code>	index of the first occurrence of <code>i</code> in <code>s</code>	
<code>s.count(i)</code>	total number of occurrences of <code>i</code> in <code>s</code>	

Sequence types also support comparisons. In particular, tuples and lists are compared lexicographically by comparing corresponding elements. This means that to compare equal, every element must compare equal and the two sequences must be of the same type and have the same length. (For full details see [Comparisons](#) in the language reference.)

Notes:

1. When `s` is a string object, the `in` and `not in` operations act like a substring test.
2. Values of `n` less than `0` are treated as `0` (which yields an empty sequence of the same type as `s`). Note also that the copies are shallow; nested structures are not copied. This often haunts new Python programmers; consider:

```
>>> lists = [[]] * 3
>>> lists
[[], [], []]
>>> lists[0].append(3)
>>> lists
[[3], [3], [3]]
```

What has happened is that `[[]]` is a one-element list containing an empty list, so all three elements of `[[]] * 3` are (pointers to) this single empty list. Modifying any of the elements of `lists`

modifies this single list. You can create a list of different lists this way:

```
>>> lists = [[] for i in range(3)]
>>> lists[0].append(3)
>>> lists[1].append(5)
>>> lists[2].append(7)
>>> lists
[[3], [5], [7]]
```

3. If i or j is negative, the index is relative to the end of the string: $\text{len}(s) + i$ or $\text{len}(s) + j$ is substituted. But note that -0 is still 0 .
4. The slice of s from i to j is defined as the sequence of items with index k such that $i \leq k < j$. If i or j is greater than $\text{len}(s)$, use $\text{len}(s)$. If i is omitted or `None`, use 0 . If j is omitted or `None`, use $\text{len}(s)$. If i is greater than or equal to j , the slice is empty.
5. The slice of s from i to j with step k is defined as the sequence of items with index $x = i + n*k$ such that $0 \leq n < (j-i)/k$. In other words, the indices are i , $i+k$, $i+2*k$, $i+3*k$ and so on, stopping when j is reached (but never including j). If i or j is greater than $\text{len}(s)$, use $\text{len}(s)$. If i or j are omitted or `None`, they become “end” values (which end depends on the sign of k). Note, k cannot be zero. If k is `None`, it is treated like 1 .
6. **CPython implementation detail:** If s and t are both strings, some Python implementations such as CPython can usually perform an in-place optimization for assignments of the form $s = s + t$ or $s += t$. When applicable, this optimization makes quadratic run-time much less likely. This optimization is both version and implementation dependent. For performance sensitive code, it is preferable to use the `str.join()` method

which assures consistent linear concatenation performance across versions and implementations.

4.6.1. String Methods

String objects support the methods listed below.

In addition, Python's strings support the sequence type methods described in the *Sequence Types — str, bytes, bytearray, list, tuple, range* section. To output formatted strings, see the *String Formatting* section. Also, see the `re` module for string functions based on regular expressions.

`str.capitalize()`

Return a copy of the string with its first character capitalized and the rest lowercased.

`str.center(width[, fillchar])`

Return centered in a string of length *width*. Padding is done using the specified *fillchar* (default is a space).

`str.count(sub[, start[, end]])`

Return the number of non-overlapping occurrences of substring *sub* in the range [*start*, *end*]. Optional arguments *start* and *end* are interpreted as in slice notation.

`str.encode(encoding="utf-8", errors="strict")`

Return an encoded version of the string as a bytes object. Default encoding is `'utf-8'`. *errors* may be given to set a different error handling scheme. The default for *errors* is `'strict'`, meaning that encoding errors raise a `UnicodeError`. Other possible values are `'ignore'`, `'replace'`, `'xmlcharrefreplace'`, `'backslashreplace'`

and any other name registered via `codecs.register_error()`, see section *Codec Base Classes*. For a list of possible encodings, see section *Standard Encodings*.

Changed in version 3.1: Support for keyword arguments added.

`str.endswith(suffix[, start[, end]])`

Return `True` if the string ends with the specified *suffix*, otherwise return `False`. *suffix* can also be a tuple of suffixes to look for. With optional *start*, test beginning at that position. With optional *end*, stop comparing at that position.

`str.expandtabs([tabsize])`

Return a copy of the string where all tab characters are replaced by one or more spaces, depending on the current column and the given tab size. The column number is reset to zero after each newline occurring in the string. If *tabsize* is not given, a tab size of `8` characters is assumed. This doesn't understand other non-printing characters or escape sequences.

`str.find(sub[, start[, end]])`

Return the lowest index in the string where substring *sub* is found, such that *sub* is contained in the slice `s[start:end]`. Optional arguments *start* and *end* are interpreted as in slice notation. Return `-1` if *sub* is not found.

`str.format(*args, **kwargs)`

Perform a string formatting operation. The string on which this method is called can contain literal text or replacement fields delimited by braces `{}`. Each replacement field contains either the numeric index of a positional argument, or the name of a keyword argument. Returns a copy of the string where each replacement field is replaced with the string value of the

corresponding argument.

```
>>> "The sum of 1 + 2 is {0}".format(1+2)
'The sum of 1 + 2 is 3'
```

See *Format String Syntax* for a description of the various formatting options that can be specified in format strings.

`str.format_map(mapping)`

Similar to `str.format(**mapping)`, except that `mapping` is used directly and not copied to a `dict`. This is useful if for example `mapping` is a dict subclass:

```
>>> class Default(dict):
...     def __missing__(self, key):
...         return key
...
>>> '{name} was born in {country}'.format_map(Default(name='
'Guido was born in country'
```

New in version 3.2.

`str.index(sub[, start[, end]])`

Like `find()`, but raise `ValueError` when the substring is not found.

`str.isalnum()`

Return true if all characters in the string are alphanumeric and there is at least one character, false otherwise. A character `c` is alphanumeric if one of the following returns `True`: `c.isalpha()`, `c.isdecimal()`, `c.isdigit()`, or `c.isnumeric()`.

`str.isalpha()`

Return true if all characters in the string are alphabetic and there is at least one character, false otherwise. Alphabetic characters

are those characters defined in the Unicode character database as “Letter”, i.e., those with general category property being one of “Lm”, “Lt”, “Lu”, “Ll”, or “Lo”. Note that this is different from the “Alphabetic” property defined in the Unicode Standard.

`str.isdecimal()`

Return true if all characters in the string are decimal characters and there is at least one character, false otherwise. Decimal characters are those from general category “Nd”. This category includes digit characters, and all characters that that can be used to form decimal-radix numbers, e.g. U+0660, ARABIC-INDIC DIGIT ZERO.

`str.isdigit()`

Return true if all characters in the string are digits and there is at least one character, false otherwise. Digits include decimal characters and digits that need special handling, such as the compatibility superscript digits. Formally, a digit is a character that has the property value `Numeric_Type=Digit` or `Numeric_Type=Decimal`.

`str.isidentifier()`

Return true if the string is a valid identifier according to the language definition, section *Identifiers and keywords*.

`str.islower()`

Return true if all cased characters in the string are lowercase and there is at least one cased character, false otherwise. Cased characters are those with general category property being one of “Lu”, “Ll”, or “Lt” and lowercase characters are those with general category property “Ll”.

`str.isnumeric()`

Return true if all characters in the string are numeric characters, and there is at least one character, false otherwise. Numeric

characters include digit characters, and all characters that have the Unicode numeric value property, e.g. U+2155, VULGAR FRACTION ONE FIFTH. Formally, numeric characters are those with the property value `Numeric_Type=Digit`, `Numeric_Type=Decimal` or `Numeric_Type=Numeric`.

`str.isprintable()`

Return true if all characters in the string are printable or the string is empty, false otherwise. Nonprintable characters are those characters defined in the Unicode character database as “Other” or “Separator”, excepting the ASCII space (0x20) which is considered printable. (Note that printable characters in this context are those which should not be escaped when `repr()` is invoked on a string. It has no bearing on the handling of strings written to `sys.stdout` or `sys.stderr`.)

`str.isspace()`

Return true if there are only whitespace characters in the string and there is at least one character, false otherwise. Whitespace characters are those characters defined in the Unicode character database as “Other” or “Separator” and those with bidirectional property being one of “WS”, “B”, or “S”.

`str.istitle()`

Return true if the string is a titlecased string and there is at least one character, for example uppercase characters may only follow uncased characters and lowercase characters only cased ones. Return false otherwise.

`str.isupper()`

Return true if all cased characters in the string are uppercase and there is at least one cased character, false otherwise. Cased characters are those with general category property being one of “Lu”, “Ll”, or “Lt” and uppercase characters are those with general

category property “Lu”.

`str.join(iterable)`

Return a string which is the concatenation of the strings in the *iterable* *iterable*. A `TypeError` will be raised if there are any non-string values in *seq*, including `bytes` objects. The separator between elements is the string providing this method.

`str.ljust(width[, fillchar])`

Return the string left justified in a string of length *width*. Padding is done using the specified *fillchar* (default is a space). The original string is returned if *width* is less than `len(s)`.

`str.lower()`

Return a copy of the string converted to lowercase.

`str.lstrip([chars])`

Return a copy of the string with leading characters removed. The *chars* argument is a string specifying the set of characters to be removed. If omitted or `None`, the *chars* argument defaults to removing whitespace. The *chars* argument is not a prefix; rather, all combinations of its values are stripped:

```
>>> '  spacious  '.lstrip()
'spacious  '
>>> 'www.example.com'.lstrip('cmowz.')
'example.com'
```

static `str.maketrans(x[, y[, z]])`

This static method returns a translation table usable for `str.translate()`.

If there is only one argument, it must be a dictionary mapping Unicode ordinals (integers) or characters (strings of length 1) to

Unicode ordinals, strings (of arbitrary lengths) or None. Character keys will then be converted to ordinals.

If there are two arguments, they must be strings of equal length, and in the resulting dictionary, each character in *x* will be mapped to the character at the same position in *y*. If there is a third argument, it must be a string, whose characters will be mapped to None in the result.

`str.partition(sep)`

Split the string at the first occurrence of *sep*, and return a 3-tuple containing the part before the separator, the separator itself, and the part after the separator. If the separator is not found, return a 3-tuple containing the string itself, followed by two empty strings.

`str.replace(old, new[, count])`

Return a copy of the string with all occurrences of substring *old* replaced by *new*. If the optional argument *count* is given, only the first *count* occurrences are replaced.

`str.rfind(sub[, start[, end]])`

Return the highest index in the string where substring *sub* is found, such that *sub* is contained within `s[start:end]`. Optional arguments *start* and *end* are interpreted as in slice notation. Return `-1` on failure.

`str.rindex(sub[, start[, end]])`

Like `rfind()` but raises `ValueError` when the substring *sub* is not found.

`str.rjust(width[, fillchar])`

Return the string right justified in a string of length *width*. Padding is done using the specified *fillchar* (default is a space). The

original string is returned if *width* is less than `len(s)`.

`str.rpartition(sep)`

Split the string at the last occurrence of *sep*, and return a 3-tuple containing the part before the separator, the separator itself, and the part after the separator. If the separator is not found, return a 3-tuple containing two empty strings, followed by the string itself.

`str.rsplit([sep[, maxsplit]])`

Return a list of the words in the string, using *sep* as the delimiter string. If *maxsplit* is given, at most *maxsplit* splits are done, the *rightmost* ones. If *sep* is not specified or `None`, any whitespace string is a separator. Except for splitting from the right, `rsplit()` behaves like `split()` which is described in detail below.

`str.rstrip([chars])`

Return a copy of the string with trailing characters removed. The *chars* argument is a string specifying the set of characters to be removed. If omitted or `None`, the *chars* argument defaults to removing whitespace. The *chars* argument is not a suffix; rather, all combinations of its values are stripped:

```
>>> '  spacious  '.rstrip()
'  spacious'
>>> 'mississippi'.rstrip('ipz')
'mississ'
```

`str.split([sep[, maxsplit]])`

Return a list of the words in the string, using *sep* as the delimiter string. If *maxsplit* is given, at most *maxsplit* splits are done (thus, the list will have at most `maxsplit+1` elements). If *maxsplit* is not specified, then there is no limit on the number of splits (all possible splits are made).

If *sep* is given, consecutive delimiters are not grouped together and are deemed to delimit empty strings (for example, `'1,,2'.split(',')` returns `['1', '', '2']`). The *sep* argument may consist of multiple characters (for example, `'1<>2<>3'.split('<>')` returns `['1', '2', '3']`). Splitting an empty string with a specified separator returns `['']`.

If *sep* is not specified or is `None`, a different splitting algorithm is applied: runs of consecutive whitespace are regarded as a single separator, and the result will contain no empty strings at the start or end if the string has leading or trailing whitespace. Consequently, splitting an empty string or a string consisting of just whitespace with a `None` separator returns `[]`.

For example, `' 1 2 3 '.split()` returns `['1', '2', '3']`, and `' 1 2 3 '.split(None, 1)` returns `['1', '2 3 ']`.

`str.splitlines([keepends])`

Return a list of the lines in the string, breaking at line boundaries. Line breaks are not included in the resulting list unless *keepends* is given and true.

`str.startswith(prefix[, start[, end]])`

Return `True` if string starts with the *prefix*, otherwise return `False`. *prefix* can also be a tuple of prefixes to look for. With optional *start*, test string beginning at that position. With optional *end*, stop comparing string at that position.

`str.strip([chars])`

Return a copy of the string with the leading and trailing characters removed. The *chars* argument is a string specifying the set of characters to be removed. If omitted or `None`, the *chars* argument defaults to removing whitespace. The *chars* argument

is not a prefix or suffix; rather, all combinations of its values are stripped:

```
>>> '  spacious  '.strip()
'spacious'
>>> 'www.example.com'.strip('cmowz.')
'example'
```

`str.swapcase()`

Return a copy of the string with uppercase characters converted to lowercase and vice versa.

`str.title()`

Return a titlecased version of the string where words start with an uppercase character and the remaining characters are lowercase.

The algorithm uses a simple language-independent definition of a word as groups of consecutive letters. The definition works in many contexts but it means that apostrophes in contractions and possessives form word boundaries, which may not be the desired result:

```
>>> "they're bill's friends from the UK".title()
'They'Re Bill'S Friends From The Uk'
```

A workaround for apostrophes can be constructed using regular expressions:

```
>>> import re
>>> def titlecase(s):
    return re.sub(r"[A-Za-z]+('[A-Za-z]+)?",
                  lambda mo: mo.group(0)[0].upper() +
                              mo.group(0)[1:].lower(),
                  s)

>>> titlecase("they're bill's friends.")
'They're Bill's Friends.'
```

`str.translate(map)`

Return a copy of the *s* where all characters have been mapped through the *map* which must be a dictionary of Unicode ordinals (integers) to Unicode ordinals, strings or `None`. Unmapped characters are left untouched. Characters mapped to `None` are deleted.

You can use `str.maketrans()` to create a translation map from character-to-character mappings in different formats.

Note: An even more flexible approach is to create a custom character mapping codec using the `codecs` module (see `encodings.cp1251` for an example).

`str.upper()`

Return a copy of the string converted to uppercase.

`str.zfill(width)`

Return the numeric string left filled with zeros in a string of length *width*. A sign prefix is handled correctly. The original string is returned if *width* is less than `len(s)`.

4.6.2. Old String Formatting Operations

Note: The formatting operations described here are obsolete and may go away in future versions of Python. Use the new *String Formatting* in new code.

String objects have one unique built-in operation: the `%` operator (modulo). This is also known as the string *formatting* or *interpolation* operator. Given `format % values` (where *format* is a string), `%` conversion specifications in *format* are replaced with zero or more elements of *values*. The effect is similar to the using `sprintf()` in the

C language.

If *format* requires a single argument, *values* may be a single non-tuple object. [4] Otherwise, *values* must be a tuple with exactly the number of items specified by the format string, or a single mapping object (for example, a dictionary).

A conversion specifier contains two or more characters and has the following components, which must occur in this order:

1. The '%' character, which marks the start of the specifier.
2. Mapping key (optional), consisting of a parenthesised sequence of characters (for example, (somename)).
3. Conversion flags (optional), which affect the result of some conversion types.
4. Minimum field width (optional). If specified as an '*' (asterisk), the actual width is read from the next element of the tuple in *values*, and the object to convert comes after the minimum field width and optional precision.
5. Precision (optional), given as a '.' (dot) followed by the precision. If specified as '*' (an asterisk), the actual width is read from the next element of the tuple in *values*, and the value to convert comes after the precision.
6. Length modifier (optional).
7. Conversion type.

When the right argument is a dictionary (or other mapping type), then the formats in the string *must* include a parenthesised mapping key into that dictionary inserted immediately after the '%' character. The mapping key selects the value to be formatted from the mapping. For example:

```
>>> print('%(language)s has %(number)03d quote types.' %  
...       {'language': "Python", "number": 2})  
Python has 002 quote types.
```

In this case no * specifiers may occur in a format (since they require a sequential parameter list).

The conversion flag characters are:

Flag	Meaning
'#'	The value conversion will use the “alternate form” (where defined below).
'0'	The conversion will be zero padded for numeric values.
'_'	The converted value is left adjusted (overrides the '0' conversion if both are given).
' '	(a space) A blank should be left before a positive number (or empty string) produced by a signed conversion.
'+'	A sign character ('+' or '-') will precede the conversion (overrides a “space” flag).

A length modifier (h, l, or L) may be present, but is ignored as it is not necessary for Python – so e.g. %ld is identical to %d.

The conversion types are:

Conversion	Meaning	Notes
'd'	Signed integer decimal.	
'i'	Signed integer decimal.	
'o'	Signed octal value.	(1)
'u'	Obsolete type – it is identical to 'd'.	(7)
'x'	Signed hexadecimal (lowercase).	(2)
'X'	Signed hexadecimal (uppercase).	(2)
'e'	Floating point exponential format (lowercase).	(3)
'E'	Floating point exponential format (uppercase).	(3)
'f'	Floating point decimal format.	(3)
'F'	Floating point decimal format.	(3)
'g'	Floating point format. Uses lowercase exponential format if exponent is less than -4	

	or not less than precision, decimal format otherwise.	(4)
'G'	Floating point format. Uses uppercase exponential format if exponent is less than -4 or not less than precision, decimal format otherwise.	(4)
'c'	Single character (accepts integer or single character string).	
'r'	String (converts any Python object using <code>repr()</code>).	(5)
's'	String (converts any Python object using <code>str()</code>).	
'%'	No argument is converted, results in a '%' character in the result.	

Notes:

1. The alternate form causes a leading zero ('0') to be inserted between left-hand padding and the formatting of the number if the leading character of the result is not already a zero.
2. The alternate form causes a leading '0x' or '0X' (depending on whether the 'x' or 'X' format was used) to be inserted between left-hand padding and the formatting of the number if the leading character of the result is not already a zero.
3. The alternate form causes the result to always contain a decimal point, even if no digits follow it.

The precision determines the number of digits after the decimal point and defaults to 6.

4. The alternate form causes the result to always contain a decimal point, and trailing zeroes are not removed as they would otherwise be.

The precision determines the number of significant digits before and after the decimal point and defaults to 6.

5. The precision determines the maximal number of characters used.
7. See [PEP 237](#).

Since Python strings have an explicit length, `%s` conversions do not assume that `'\0'` is the end of the string.

Changed in version 3.1: `%f` conversions for numbers whose absolute value is over `1e50` are no longer replaced by `%g` conversions.

Additional string operations are defined in standard modules `string` and `re`.

4.6.3. Range Type

The `range` type is an immutable sequence which is commonly used for looping. The advantage of the `range` type is that an `range` object will always take the same amount of memory, no matter the size of the range it represents.

Range objects have relatively little behavior: they support indexing, contains, iteration, the `len()` function, and the following methods:

`range.count(x)`

Return the number of `i`'s for which `s[i] == x`.

New in version 3.2.

`range.index(x)`

Return the smallest `i` such that `s[i] == x`. Raises `ValueError` when `x` is not in the range.

New in version 3.2.

4.6.4. Mutable Sequence Types

List and bytearray objects support additional operations that allow in-place modification of the object. Other mutable sequence types (when added to the language) should also support these operations. Strings and tuples are immutable sequence types: such objects cannot be modified once created. The following operations are defined on mutable sequence types (where x is an arbitrary object).

Note that while lists allow their items to be of any type, bytearray object “items” are all integers in the range $0 \leq x < 256$.

Operation	Result	Notes
<code>s[i] = x</code>	item i of s is replaced by x	
<code>s[i:j] = t</code>	slice of s from i to j is replaced by the contents of the iterable t	
<code>del s[i:j]</code>	same as <code>s[i:j] = []</code>	
<code>s[i:j:k] = t</code>	the elements of <code>s[i:j:k]</code> are replaced by those of t	(1)
<code>del s[i:j:k]</code>	removes the elements of <code>s[i:j:k]</code> from the list	
<code>s.append(x)</code>	same as <code>s[len(s):len(s)] = [x]</code>	
<code>s.extend(x)</code>	same as <code>s[len(s):len(s)] = x</code>	(2)
<code>s.count(x)</code>	return number of i 's for which <code>s[i] == x</code>	
<code>s.index(x[, i[, j]])</code>	return smallest k such that <code>s[k] == x</code> and $i \leq k < j$	(3)
<code>s.insert(i, x)</code>	same as <code>s[i:i] = [x]</code>	(4)

<code>s.pop([i])</code>	same as <code>x = s[i]; del s[i]; return x</code>	(5)
<code>s.remove(x)</code>	same as <code>del s[s.index(x)]</code>	(3)
<code>s.reverse()</code>	reverses the items of <code>s</code> in place	(6)
<code>s.sort([key[, reverse]])</code>	sort the items of <code>s</code> in place	(6), (7), (8)

Notes:

1. `t` must have the same length as the slice it is replacing.
2. `x` can be any iterable object.
3. Raises **ValueError** when `x` is not found in `s`. When a negative index is passed as the second or third parameter to the `index()` method, the sequence length is added, as for slice indices. If it is still negative, it is truncated to zero, as for slice indices.
4. When a negative index is passed as the first parameter to the `insert()` method, the sequence length is added, as for slice indices. If it is still negative, it is truncated to zero, as for slice indices.
5. The optional argument `i` defaults to `-1`, so that by default the last item is removed and returned.
6. The `sort()` and `reverse()` methods modify the sequence in place for economy of space when sorting or reversing a large sequence. To remind you that they operate by side effect, they don't return the sorted or reversed sequence.
7. The `sort()` method takes optional arguments for controlling the comparisons. Each must be specified as a keyword argument.

key specifies a function of one argument that is used to extract a comparison key from each list element: `key=str.lower`. The default value is `None`. Use `functools.cmp_to_key()` to convert an old-style *cmp* function to a *key* function.

reverse is a boolean value. If set to `True`, then the list elements are sorted as if each comparison were reversed.

The `sort()` method is guaranteed to be stable. A sort is stable if it guarantees not to change the relative order of elements that compare equal — this is helpful for sorting in multiple passes (for example, sort by department, then by salary grade).

CPython implementation detail: While a list is being sorted, the effect of attempting to mutate, or even inspect, the list is undefined. The C implementation of Python makes the list appear empty for the duration, and raises `ValueError` if it can detect that the list has been mutated during a sort.

8. `sort()` is not supported by `bytearray` objects.

4.6.5. Bytes and Byte Array Methods

Bytes and `bytearray` objects, being “strings of bytes”, have all methods found on strings, with the exception of `encode()`, `format()` and `isidentifier()`, which do not make sense with these types. For converting the objects to strings, they have a `decode()` method.

Wherever one of these methods needs to interpret the bytes as characters (e.g. the `is...()` methods), the ASCII character set is assumed.

Note: The methods on bytes and bytearray objects don't accept strings as their arguments, just as the methods on strings don't accept bytes as their arguments. For example, you have to write

```
a = "abc"
b = a.replace("a", "f")
```

and

```
a = b"abc"
b = a.replace(b"a", b"f")
```

bytes. **decode**(*encoding*="utf-8", *errors*="strict")

bytearray. **decode**(*encoding*="utf-8", *errors*="strict")

Return a string decoded from the given bytes. Default encoding is 'utf-8'. *errors* may be given to set a different error handling scheme. The default for *errors* is 'strict', meaning that encoding errors raise a **UnicodeError**. Other possible values are 'ignore', 'replace' and any other name registered via **codecs.register_error()**, see section *Codec Base Classes*. For a list of possible encodings, see section *Standard Encodings*.

Changed in version 3.1: Added support for keyword arguments.

The bytes and bytearray types have an additional class method:

classmethod bytes. **fromhex**(*string*)

classmethod bytearray. **fromhex**(*string*)

This **bytes** class method returns a bytes or bytearray object, decoding the given string object. The string must contain two hexadecimal digits per byte, spaces are ignored.

```
>>> bytes.fromhex('f0 f1f2 ')
b'\xf0\xf1\xf2'
```

The `maketrans` and `translate` methods differ in semantics from the versions available on strings:

`bytes.translate(table[, delete])`

`bytearray.translate(table[, delete])`

Return a copy of the bytes or bytearray object where all bytes occurring in the optional argument *delete* are removed, and the remaining bytes have been mapped through the given translation table, which must be a bytes object of length 256.

You can use the `bytes.maketrans()` method to create a translation table.

Set the *table* argument to `None` for translations that only delete characters:

```
>>> b'read this short text'.translate(None, b'aeiou')
b'rd ths shrt txt'
```

static `bytes.maketrans(from, to)`

static `bytearray.maketrans(from, to)`

This static method returns a translation table usable for `bytes.translate()` that will map each character in *from* into the character at the same position in *to*; *from* and *to* must be bytes objects and have the same length.

New in version 3.1.

4.7. Set Types — `set`, `frozenset`

A *set* object is an unordered collection of distinct *hashable* objects. Common uses include membership testing, removing duplicates from a sequence, and computing mathematical operations such as intersection, union, difference, and symmetric difference. (For other containers see the built in `dict`, `list`, and `tuple` classes, and the `collections` module.)

Like other collections, sets support `x in set`, `len(set)`, and `for x in set`. Being an unordered collection, sets do not record element position or order of insertion. Accordingly, sets do not support indexing, slicing, or other sequence-like behavior.

There are currently two built-in set types, `set` and `frozenset`. The `set` type is mutable — the contents can be changed using methods like `add()` and `remove()`. Since it is mutable, it has no hash value and cannot be used as either a dictionary key or as an element of another set. The `frozenset` type is immutable and *hashable* — its contents cannot be altered after it is created; it can therefore be used as a dictionary key or as an element of another set.

Non-empty sets (not frozensets) can be created by placing a comma-separated list of elements within braces, for example: `{'jack', 'sjoerd'}`, in addition to the `set` constructor.

The constructors for both classes work the same:

```
class set([iterable])
```

```
class frozenset([iterable])
```

Return a new set or frozenset object whose elements are taken from *iterable*. The elements of a set must be hashable. To

represent sets of sets, the inner sets must be `frozenset` objects. If *iterable* is not specified, a new empty set is returned.

Instances of `set` and `frozenset` provide the following operations:

`len(s)`

Return the cardinality of set *s*.

`x in s`

Test *x* for membership in *s*.

`x not in s`

Test *x* for non-membership in *s*.

`isdisjoint(other)`

Return True if the set has no elements in common with *other*. Sets are disjoint if and only if their intersection is the empty set.

`issubset(other)`

`set <= other`

Test whether every element in the set is in *other*.

`set < other`

Test whether the set is a true subset of *other*, that is, `set <= other` and `set != other`.

`issuperset(other)`

`set >= other`

Test whether every element in *other* is in the set.

`set > other`

Test whether the set is a true superset of *other*, that is, `set >= other` and `set != other`.

`union(other, ...)`

set | other | ...

Return a new set with elements from the set and all others.

intersection(*other*, ...)

set & other & ...

Return a new set with elements common to the set and all others.

difference(*other*, ...)

set - other - ...

Return a new set with elements in the set that are not in the others.

symmetric_difference(*other*)

set ^ other

Return a new set with elements in either the set or *other* but not both.

copy()

Return a new set with a shallow copy of *s*.

Note, the non-operator versions of `union()`, `intersection()`, `difference()`, and `symmetric_difference()`, `issubset()`, and `issuperset()` methods will accept any iterable as an argument. In contrast, their operator based counterparts require their arguments to be sets. This precludes error-prone constructions like `set('abc') & 'cbs'` in favor of the more readable `set('abc').intersection('cbs')`.

Both `set` and `frozenset` support set to set comparisons. Two sets are equal if and only if every element of each set is contained in the other (each is a subset of the other). A set is less than another set if and only if the first set is a proper subset of the second set (is a subset, but is not equal). A set is greater than another set if and only if the first set is a proper superset of the

second set (is a superset, but is not equal).

Instances of `set` are compared to instances of `frozenset` based on their members. For example, `set('abc') == frozenset('abc')` returns `True` and so does `set('abc') in set([frozenset('abc')])`.

The subset and equality comparisons do not generalize to a complete ordering function. For example, any two disjoint sets are not equal and are not subsets of each other, so *all* of the following return `False`: `a < b`, `a == b`, Or `a > b`.

Since sets only define partial ordering (subset relationships), the output of the `list.sort()` method is undefined for lists of sets.

Set elements, like dictionary keys, must be *hashable*.

Binary operations that mix `set` instances with `frozenset` return the type of the first operand. For example: `frozenset('ab') | set('bc')` returns an instance of `frozenset`.

The following table lists operations available for `set` that do not apply to immutable instances of `frozenset`:

update(*other*, ...)

set |= **other** | ...

Update the set, adding elements from all others.

intersection_update(*other*, ...)

set &= **other** & ...

Update the set, keeping only elements found in it and all others.

difference_update(*other*, ...)

set -= **other** | ...

Update the set, removing elements found in others.

`symmetric_difference_update(other)`

`set ^= other`

Update the set, keeping only elements found in either set, but not in both.

`add(elem)`

Add element *elem* to the set.

`remove(elem)`

Remove element *elem* from the set. Raises `KeyError` if *elem* is not contained in the set.

`discard(elem)`

Remove element *elem* from the set if it is present.

`pop()`

Remove and return an arbitrary element from the set. Raises `KeyError` if the set is empty.

`clear()`

Remove all elements from the set.

Note, the non-operator versions of the `update()`, `intersection_update()`, `difference_update()`, and `symmetric_difference_update()` methods will accept any iterable as an argument.

Note, the *elem* argument to the `__contains__()`, `remove()`, and `discard()` methods may be a set. To support searching for an equivalent frozenset, the *elem* set is temporarily mutated during the search and then restored. During the search, the *elem* set should not be read or mutated since it does not have a

meaningful value.

4.8. Mapping Types — dict

A *mapping* object maps *hashable* values to arbitrary objects. Mappings are mutable objects. There is currently only one standard mapping type, the *dictionary*. (For other containers see the built in `list`, `set`, and `tuple` classes, and the `collections` module.)

A dictionary's keys are *almost* arbitrary values. Values that are not *hashable*, that is, values containing lists, dictionaries or other mutable types (that are compared by value rather than by object identity) may not be used as keys. Numeric types used for keys obey the normal rules for numeric comparison: if two numbers compare equal (such as `1` and `1.0`) then they can be used interchangeably to index the same dictionary entry. (Note however, that since computers store floating-point numbers as approximations it is usually unwise to use them as dictionary keys.)

Dictionaries can be created by placing a comma-separated list of `key: value` pairs within braces, for example: `{'jack': 4098, 'sjoerd': 4127}` or `{4098: 'jack', 4127: 'sjoerd'}`, or by the `dict` constructor.

class `dict`(*[arg]*)

Return a new dictionary initialized from an optional positional argument or from a set of keyword arguments. If no arguments are given, return a new empty dictionary. If the positional argument *arg* is a mapping object, return a dictionary mapping the same keys to the same values as does the mapping object. Otherwise the positional argument must be a sequence, a container that supports iteration, or an iterator object. The elements of the argument must each also be of one of those kinds, and each must in turn contain exactly two objects. The first is used as a key in the new dictionary, and the second as the

key's value. If a given key is seen more than once, the last value associated with it is retained in the new dictionary.

If keyword arguments are given, the keywords themselves with their associated values are added as items to the dictionary. If a key is specified both in the positional argument and as a keyword argument, the value associated with the keyword is retained in the dictionary. For example, these all return a dictionary equal to `{"one": 1, "two": 2}`:

- `dict(one=1, two=2)`
- `dict({'one': 1, 'two': 2})`
- `dict(zip(('one', 'two'), (1, 2)))`
- `dict(['two', 2], ['one', 1])`

The first example only works for keys that are valid Python identifiers; the others work with any valid keys.

These are the operations that dictionaries support (and therefore, custom mapping types should support too):

len(d)

Return the number of items in the dictionary *d*.

d[key]

Return the item of *d* with key *key*. Raises a `KeyError` if *key* is not in the map.

If a subclass of `dict` defines a method `__missing__()`, if the key *key* is not present, the `d[key]` operation calls that method with the key *key* as argument. The `d[key]` operation then returns or raises whatever is returned or raised by the `__missing__(key)` call if the key is not present. No other operations or methods invoke `__missing__()`. If `__missing__()` is not defined, `KeyError` is raised. `__missing__()` must be a

method; it cannot be an instance variable:

```
>>> class Counter(dict):
...     def __missing__(self, key):
...         return 0
>>> c = Counter()
>>> c['red']
0
>>> c['red'] += 1
>>> c['red']
1
```

See `collections.Counter` for a complete implementation including other methods helpful for accumulating and managing tallies.

d[key] = value

Set `d[key]` to *value*.

del d[key]

Remove `d[key]` from *d*. Raises a `KeyError` if *key* is not in the map.

key in d

Return `True` if *d* has a key *key*, else `False`.

key not in d

Equivalent to `not key in d`.

iter(d)

Return an iterator over the keys of the dictionary. This is a shortcut for `iter(d.keys())`.

clear()

Remove all items from the dictionary.

copy()

Return a shallow copy of the dictionary.

classmethod `fromkeys(seq[, value])`

Create a new dictionary with keys from *seq* and values set to *value*.

`fromkeys()` is a class method that returns a new dictionary. *value* defaults to **None**.

get(*key*[, *default*])

Return the value for *key* if *key* is in the dictionary, else *default*. If *default* is not given, it defaults to **None**, so that this method never raises a **KeyError**.

items()

Return a new view of the dictionary's items ((*key*, *value*) pairs). See below for documentation of view objects.

keys()

Return a new view of the dictionary's keys. See below for documentation of view objects.

pop(*key*[, *default*])

If *key* is in the dictionary, remove it and return its value, else return *default*. If *default* is not given and *key* is not in the dictionary, a **KeyError** is raised.

popitem()

Remove and return an arbitrary (*key*, *value*) pair from the dictionary.

`popitem()` is useful to destructively iterate over a dictionary, as often used in set algorithms. If the dictionary is empty, calling `popitem()` raises a **KeyError**.

setdefault(*key*[, *default*])

If *key* is in the dictionary, return its value. If not, insert *key* with a value of *default* and return *default*. *default* defaults to **None**.

update([*other*])

Update the dictionary with the key/value pairs from *other*, overwriting existing keys. Return **None**.

update() accepts either another dictionary object or an iterable of key/value pairs (as tuples or other iterables of length two). If keyword arguments are specified, the dictionary is then updated with those key/value pairs: `d.update(red=1, blue=2)`.

values()

Return a new view of the dictionary's values. See below for documentation of view objects.

4.8.1. Dictionary view objects

The objects returned by `dict.keys()`, `dict.values()` and `dict.items()` are *view objects*. They provide a dynamic view on the dictionary's entries, which means that when the dictionary changes, the view reflects these changes.

Dictionary views can be iterated over to yield their respective data, and support membership tests:

len(dictview)

Return the number of entries in the dictionary.

iter(dictview)

Return an iterator over the keys, values or items (represented as tuples of `(key, value)`) in the dictionary.

Keys and values are iterated over in an arbitrary order which is non-random, varies across Python implementations, and depends on the dictionary's history of insertions and deletions. If keys, values and items views are iterated over with no intervening modifications to the dictionary, the order of items will directly correspond. This allows the creation of `(value, key)` pairs using `zip()`: `pairs = zip(d.values(), d.keys())`. Another way to create the same list is `pairs = [(v, k) for (k, v) in d.items()]`.

Iterating views while adding or deleting entries in the dictionary may raise a `RuntimeError` or fail to iterate over all entries.

x in dictview

Return `True` if `x` is in the underlying dictionary's keys, values or items (in the latter case, `x` should be a `(key, value)` tuple).

Keys views are set-like since their entries are unique and hashable. If all values are hashable, so that `(key, value)` pairs are unique and hashable, then the items view is also set-like. (Values views are not treated as set-like since the entries are generally not unique.) For set-like views, all of the operations defined for the abstract base class `collections.Set` are available (for example, `==`, `<`, or `^`).

An example of dictionary view usage:

```
>>> dishes = {'eggs': 2, 'sausage': 1, 'bacon': 1, 'spam': 500}
>>> keys = dishes.keys()
>>> values = dishes.values()

>>> # iteration
>>> n = 0
>>> for val in values:
...     n += val
>>> print(n)
504
```

```
>>> # keys and values are iterated over in the same order
>>> list(keys)
['eggs', 'bacon', 'sausage', 'spam']
>>> list(values)
[2, 1, 1, 500]

>>> # view objects are dynamic and reflect dict changes
>>> del dishes['eggs']
>>> del dishes['sausage']
>>> list(keys)
['spam', 'bacon']

>>> # set operations
>>> keys & {'eggs', 'bacon', 'salad'}
{'bacon'}
>>> keys ^ {'sausage', 'juice'}
{'juice', 'eggs', 'bacon', 'spam'}
```

4.9. memoryview type

`memoryview` objects allow Python code to access the internal data of an object that supports the *buffer protocol* without copying. Memory is generally interpreted as simple bytes.

`class memoryview(obj)`

Create a `memoryview` that references `obj`. `obj` must support the buffer protocol. Builtin objects that support the buffer protocol include `bytes` and `bytearray`.

A `memoryview` has the notion of an *element*, which is the atomic memory unit handled by the originating object `obj`. For many simple types such as `bytes` and `bytearray`, an element is a single byte, but other types such as `array.array` may have bigger elements.

`len(view)` returns the total number of elements in the memoryview, `view`. The `itemsize` attribute will give you the number of bytes in a single element.

A `memoryview` supports slicing to expose its data. Taking a single index will return a single element as a `bytes` object. Full slicing will result in a subview:

```
>>> v = memoryview(b'abcefg')
>>> v[1]
b'b'
>>> v[-1]
b'g'
>>> v[1:4]
<memory at 0x77ab28>
>>> bytes(v[1:4])
b'bce'
```

If the object the memoryview is over supports changing its data, the memoryview supports slice assignment:

```
>>> data = bytearray(b'abcefg')
>>> v = memoryview(data)
>>> v.readonly
False
>>> v[0] = b'z'
>>> data
bytearray(b'zbcefg')
>>> v[1:4] = b'123'
>>> data
bytearray(b'a123fg')
>>> v[2] = b'spam'
Traceback (most recent call last):
File "<stdin>", line 1, in <module>
ValueError: cannot modify size of memoryview object
```

Notice how the size of the memoryview object cannot be changed.

`memoryview` has several methods:

tobytes()

Return the data in the buffer as a bytestring. This is equivalent to calling the `bytes` constructor on the memoryview.

```
>>> m = memoryview(b"abc")
>>> m.tobytes()
b'abc'
>>> bytes(m)
b'abc'
```

tolist()

Return the data in the buffer as a list of integers.

```
>>> memoryview(b'abc').tolist()
[97, 98, 99]
```

release()

Release the underlying buffer exposed by the memoryview object. Many objects take special actions when a view is held on them (for example, a `bytearray` would temporarily forbid resizing); therefore, calling `release()` is handy to remove these restrictions (and free any dangling resources) as soon as possible.

After this method has been called, any further operation on the view raises a `ValueError` (except `release()` itself which can be called multiple times):

```
>>> m = memoryview(b'abc')
>>> m.release()
>>> m[0]
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
ValueError: operation forbidden on released memoryview ob
```

The context management protocol can be used for a similar effect, using the `with` statement:

```
>>> with memoryview(b'abc') as m:
...     m[0]
...
b'a'
>>> m[0]
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
ValueError: operation forbidden on released memoryview ob
```

New in version 3.2.

There are also several readonly attributes available:

format

A string containing the format (in `struct` module style) for each element in the view. This defaults to `'B'`, a simple

bytestring.

itemsize

The size in bytes of each element of the memoryview:

```
>>> m = memoryview(array.array('H', [1,2,3]))
>>> m.itemsize
2
>>> m[0]
b'\x01\x00'
>>> len(m[0]) == m.itemsize
True
```

shape

A tuple of integers the length of **ndim** giving the shape of the memory as a N-dimensional array.

ndim

An integer indicating how many dimensions of a multi-dimensional array the memory represents.

strides

A tuple of integers the length of **ndim** giving the size in bytes to access each element for each dimension of the array.

readonly

A bool indicating whether the memory is read only.

4.10. Context Manager Types

Python's `with` statement supports the concept of a runtime context defined by a context manager. This is implemented using a pair of methods that allow user-defined classes to define a runtime context that is entered before the statement body is executed and exited when the statement ends:

`contextmanager.__enter__()`

Enter the runtime context and return either this object or another object related to the runtime context. The value returned by this method is bound to the identifier in the `as` clause of `with` statements using this context manager.

An example of a context manager that returns itself is a *file object*. File objects return themselves from `__enter__()` to allow `open()` to be used as the context expression in a `with` statement.

An example of a context manager that returns a related object is the one returned by `decimal.localcontext()`. These managers set the active decimal context to a copy of the original decimal context and then return the copy. This allows changes to be made to the current decimal context in the body of the `with` statement without affecting code outside the `with` statement.

`contextmanager.__exit__(exc_type, exc_val, exc_tb)`

Exit the runtime context and return a Boolean flag indicating if any exception that occurred should be suppressed. If an exception occurred while executing the body of the `with` statement, the arguments contain the exception type, value and traceback information. Otherwise, all three arguments are `None`.

Returning a true value from this method will cause the `with`

statement to suppress the exception and continue execution with the statement immediately following the `with` statement. Otherwise the exception continues propagating after this method has finished executing. Exceptions that occur during execution of this method will replace any exception that occurred in the body of the `with` statement.

The exception passed in should never be reraised explicitly - instead, this method should return a false value to indicate that the method completed successfully and does not want to suppress the raised exception. This allows context management code (such as `contextlib.nested`) to easily detect whether or not an `__exit__()` method has actually failed.

Python defines several context managers to support easy thread synchronisation, prompt closure of files or other objects, and simpler manipulation of the active decimal arithmetic context. The specific types are not treated specially beyond their implementation of the context management protocol. See the `contextlib` module for some examples.

Python's *generators* and the `contextlib.contextmanager` decorator provide a convenient way to implement these protocols. If a generator function is decorated with the `contextlib.contextmanager` decorator, it will return a context manager implementing the necessary `__enter__()` and `__exit__()` methods, rather than the iterator produced by an undecorated generator function.

Note that there is no specific slot for any of these methods in the type structure for Python objects in the Python/C API. Extension types wanting to define these methods must provide them as a normal Python accessible method. Compared to the overhead of setting up the runtime context, the overhead of a single class dictionary lookup is negligible.

4.11. Other Built-in Types

The interpreter supports several other kinds of objects. Most of these support only one or two operations.

4.11.1. Modules

The only special operation on a module is attribute access: `m.name`, where *m* is a module and *name* accesses a name defined in *m*'s symbol table. Module attributes can be assigned to. (Note that the `import` statement is not, strictly speaking, an operation on a module object; `import foo` does not require a module object named *foo* to exist, rather it requires an (external) *definition* for a module named *foo* somewhere.)

A special member of every module is `__dict__`. This is the dictionary containing the module's symbol table. Modifying this dictionary will actually change the module's symbol table, but direct assignment to the `__dict__` attribute is not possible (you can write `m.__dict__['a'] = 1`, which defines `m.a` to be `1`, but you can't write `m.__dict__ = {}`). Modifying `__dict__` directly is not recommended.

Modules built into the interpreter are written like this: `<module 'sys' (built-in)>`. If loaded from a file, they are written as `<module 'os' from '/usr/local/lib/pythonX.Y/os.pyc'>`.

4.11.2. Classes and Class Instances

See *Objects, values and types* and *Class definitions* for these.

4.11.3. Functions

Function objects are created by function definitions. The only operation on a function object is to call it: `func(argument-list)`.

There are really two flavors of function objects: built-in functions and user-defined functions. Both support the same operation (to call the function), but the implementation is different, hence the different object types.

See *Function definitions* for more information.

4.11.4. Methods

Methods are functions that are called using the attribute notation. There are two flavors: built-in methods (such as `append()` on lists) and class instance methods. Built-in methods are described with the types that support them.

If you access a method (a function defined in a class namespace) through an instance, you get a special object: a *bound method* (also called *instance method*) object. When called, it will add the `self` argument to the argument list. Bound methods have two special read-only attributes: `m.__self__` is the object on which the method operates, and `m.__func__` is the function implementing the method. Calling `m(arg-1, arg-2, ..., arg-n)` is completely equivalent to calling `m.__func__(m.__self__, arg-1, arg-2, ..., arg-n)`.

Like function objects, bound method objects support getting arbitrary attributes. However, since method attributes are actually stored on the underlying function object (`meth.__func__`), setting method attributes on bound methods is disallowed. Attempting to set a method attribute results in a `TypeError` being raised. In order to set a method attribute, you need to explicitly set it on the underlying function object:

```
class C:
    def method(self):
        pass

c = C()
c.method.__func__.whoami = 'my name is c'
```

See *The standard type hierarchy* for more information.

4.11.5. Code Objects

Code objects are used by the implementation to represent “pseudo-compiled” executable Python code such as a function body. They differ from function objects because they don’t contain a reference to their global execution environment. Code objects are returned by the built-in `compile()` function and can be extracted from function objects through their `__code__` attribute. See also the `code` module.

A code object can be executed or evaluated by passing it (instead of a source string) to the `exec()` or `eval()` built-in functions.

See *The standard type hierarchy* for more information.

4.11.6. Type Objects

Type objects represent the various object types. An object’s type is accessed by the built-in function `type()`. There are no special operations on types. The standard module `types` defines names for all standard built-in types.

Types are written like this: `<class 'int'>`.

4.11.7. The Null Object

This object is returned by functions that don’t explicitly return a

value. It supports no special operations. There is exactly one null object, named `None` (a built-in name).

It is written as `None`.

4.11.8. The Ellipsis Object

This object is commonly used by slicing (see *Slicings*). It supports no special operations. There is exactly one ellipsis object, named `Ellipsis` (a built-in name).

It is written as `Ellipsis` or `...`.

4.11.9. Boolean Values

Boolean values are the two constant objects `False` and `True`. They are used to represent truth values (although other values can also be considered false or true). In numeric contexts (for example when used as the argument to an arithmetic operator), they behave like the integers 0 and 1, respectively. The built-in function `bool()` can be used to cast any value to a Boolean, if the value can be interpreted as a truth value (see section Truth Value Testing above).

They are written as `False` and `True`, respectively.

4.11.10. Internal Objects

See *The standard type hierarchy* for this information. It describes stack frame objects, traceback objects, and slice objects.

4.12. Special Attributes

The implementation adds a few special read-only attributes to several object types, where they are relevant. Some of these are not reported by the `dir()` built-in function.

`object.__dict__`

A dictionary or other mapping object used to store an object's (writable) attributes.

`instance.__class__`

The class to which a class instance belongs.

`class.__bases__`

The tuple of base classes of a class object.

`class.__name__`

The name of the class or type.

The following attributes are only supported by *new-style classes*.

`class.__mro__`

This attribute is a tuple of classes that are considered when looking for base classes during method resolution.

`class.mro()`

This method can be overridden by a metaclass to customize the method resolution order for its instances. It is called at class instantiation, and its result is stored in `__mro__`.

`class.__subclasses__()`

Each new-style class keeps a list of weak references to its immediate subclasses. This method returns a list of all those references still alive. Example:

```
>>> int.__subclasses__()  
[<type 'bool'>]
```

Footnotes

- [1] Additional information on these special methods may be found in the Python Reference Manual (*Basic customization*).
- [2] As a consequence, the list `[1, 2]` is considered equal to `[1.0, 2.0]`, and similarly for tuples.
- [3] They must have since the parser can't tell the type of the operands.
- [4] To format only a tuple you should therefore provide a singleton tuple whose only element is the tuple to be formatted.

5. Built-in Exceptions

In Python, all exceptions must be instances of a class that derives from `BaseException`. In a `try` statement with an `except` clause that mentions a particular class, that clause also handles any exception classes derived from that class (but not exception classes from which *it* is derived). Two exception classes that are not related via subclassing are never equivalent, even if they have the same name.

The built-in exceptions listed below can be generated by the interpreter or built-in functions. Except where mentioned, they have an “associated value” indicating the detailed cause of the error. This may be a string or a tuple of several items of information (e.g., an error code and a string explaining the code). The associated value is usually passed as arguments to the exception class’s constructor.

User code can raise built-in exceptions. This can be used to test an exception handler or to report an error condition “just like” the situation in which the interpreter raises the same exception; but beware that there is nothing to prevent user code from raising an inappropriate error.

The built-in exception classes can be sub-classed to define new exceptions; programmers are encouraged to at least derive new exceptions from the `Exception` class and not `BaseException`. More information on defining exceptions is available in the Python Tutorial under *User-defined Exceptions*.

The following exceptions are used mostly as base classes for other exceptions.

exception `BaseException`

The base class for all built-in exceptions. It is not meant to be directly inherited by user-defined classes (for that, use

Exception). If `bytes()` or `str()` is called on an instance of this class, the representation of the argument(s) to the instance are returned, or the empty string when there were no arguments.

args

The tuple of arguments given to the exception constructor. Some built-in exceptions (like `IOError`) expect a certain number of arguments and assign a special meaning to the elements of this tuple, while others are usually called only with a single string giving an error message.

with_traceback(*tb*)

This method sets *tb* as the new traceback for the exception and returns the exception object. It is usually used in exception handling code like this:

```
try:
    ...
except SomeException:
    tb = sys.exc_info()[2]
    raise OtherException(...).with_traceback(tb)
```

exception Exception

All built-in, non-system-exiting exceptions are derived from this class. All user-defined exceptions should also be derived from this class.

exception ArithmeticError

The base class for those built-in exceptions that are raised for various arithmetic errors: `OverflowError`, `ZeroDivisionError`, `FloatingPointError`.

exception BufferError

Raised when a *buffer* related operation cannot be performed.

exception LookupError

The base class for the exceptions that are raised when a key or index used on a mapping or sequence is invalid: `IndexError`, `KeyError`. This can be raised directly by `codecs.lookup()`.

exception `EnvironmentError`

The base class for exceptions that can occur outside the Python system: `IOError`, `OSError`. When exceptions of this type are created with a 2-tuple, the first item is available on the instance's `errno` attribute (it is assumed to be an error number), and the second item is available on the `strerror` attribute (it is usually the associated error message). The tuple itself is also available on the `args` attribute.

When an `EnvironmentError` exception is instantiated with a 3-tuple, the first two items are available as above, while the third item is available on the `filename` attribute. However, for backwards compatibility, the `args` attribute contains only a 2-tuple of the first two constructor arguments.

The `filename` attribute is `None` when this exception is created with other than 3 arguments. The `errno` and `strerror` attributes are also `None` when the instance was created with other than 2 or 3 arguments. In this last case, `args` contains the verbatim constructor arguments as a tuple.

The following exceptions are the exceptions that are usually raised.

exception `AssertionError`

Raised when an `assert` statement fails.

exception `AttributeError`

Raised when an attribute reference (see [Attribute references](#)) or assignment fails. (When an object does not support attribute references or attribute assignments at all, `TypeError` is raised.)

exception **EOFError**

Raised when one of the built-in functions (`input()` or `raw_input()`) hits an end-of-file condition (EOF) without reading any data. (N.B.: the `file.read()` and `file.readline()` methods return an empty string when they hit EOF.)

exception **FloatingPointError**

Raised when a floating point operation fails. This exception is always defined, but can only be raised when Python is configured with the `--with-fpectl` option, or the `WANT_SIGFPE_HANDLER` symbol is defined in the `pyconfig.h` file.

exception **GeneratorExit**

Raise when a *generator's* `close()` method is called. It directly inherits from `BaseException` instead of `Exception` since it is technically not an error.

exception **IOError**

Raised when an I/O operation (such as the built-in `print()` or `open()` functions or a method of a *file object*) fails for an I/O-related reason, e.g., “file not found” or “disk full”.

This class is derived from `EnvironmentError`. See the discussion above for more information on exception instance attributes.

exception **ImportError**

Raised when an `import` statement fails to find the module definition or when a `from ... import` fails to find a name that is to be imported.

exception **IndexError**

Raised when a sequence subscript is out of range. (Slice indices are silently truncated to fall in the allowed range; if an index is not an integer, `TypeError` is raised.)

exception **KeyError**

Raised when a mapping (dictionary) key is not found in the set of existing keys.

exception **KeyboardInterrupt**

Raised when the user hits the interrupt key (normally `Control-C` or `Delete`). During execution, a check for interrupts is made regularly. The exception inherits from `BaseException` so as to not be accidentally caught by code that catches `Exception` and thus prevent the interpreter from exiting.

exception **MemoryError**

Raised when an operation runs out of memory but the situation may still be rescued (by deleting some objects). The associated value is a string indicating what kind of (internal) operation ran out of memory. Note that because of the underlying memory management architecture (C's `malloc()` function), the interpreter may not always be able to completely recover from this situation; it nevertheless raises an exception so that a stack traceback can be printed, in case a run-away program was the cause.

exception **NameError**

Raised when a local or global name is not found. This applies only to unqualified names. The associated value is an error message that includes the name that could not be found.

exception **NotImplementedError**

This exception is derived from `RuntimeError`. In user defined base classes, abstract methods should raise this exception when they require derived classes to override the method.

exception **OSError**

This exception is derived from `EnvironmentError`. It is raised when a function returns a system-related error (not for illegal

argument types or other incidental errors). The `errno` attribute is a numeric error code from `errno`, and the `strerror` attribute is the corresponding string, as would be printed by the C function `perror()`. See the module `errno`, which contains names for the error codes defined by the underlying operating system.

For exceptions that involve a file system path (such as `chdir()` or `unlink()`), the exception instance will contain a third attribute, `filename`, which is the file name passed to the function.

exception **OverflowError**

Raised when the result of an arithmetic operation is too large to be represented. This cannot occur for integers (which would rather raise `MemoryError` than give up). Because of the lack of standardization of floating point exception handling in C, most floating point operations also aren't checked.

exception **ReferenceError**

This exception is raised when a weak reference proxy, created by the `weakref.proxy()` function, is used to access an attribute of the referent after it has been garbage collected. For more information on weak references, see the `weakref` module.

exception **RuntimeError**

Raised when an error is detected that doesn't fall in any of the other categories. The associated value is a string indicating what precisely went wrong. (This exception is mostly a relic from a previous version of the interpreter; it is not used very much any more.)

exception **StopIteration**

Raised by built-in function `next()` and an *iterator's* `__next__()` method to signal that there are no further values.

exception **SyntaxError**

Raised when the parser encounters a syntax error. This may occur in an `import` statement, in a call to the built-in functions `exec()` or `eval()`, or when reading the initial script or standard input (also interactively).

Instances of this class have attributes `filename`, `lineno`, `offset` and `text` for easier access to the details. `str()` of the exception instance returns only the message.

exception **IndentationError**

Base class for syntax errors related to incorrect indentation. This is a subclass of `SyntaxError`.

exception **TabError**

Raised when indentation contains an inconsistent use of tabs and spaces. This is a subclass of `IndentationError`.

exception **SystemError**

Raised when the interpreter finds an internal error, but the situation does not look so serious to cause it to abandon all hope. The associated value is a string indicating what went wrong (in low-level terms).

You should report this to the author or maintainer of your Python interpreter. Be sure to report the version of the Python interpreter (`sys.version`; it is also printed at the start of an interactive Python session), the exact error message (the exception's associated value) and if possible the source of the program that triggered the error.

exception **SystemExit**

This exception is raised by the `sys.exit()` function. When it is not handled, the Python interpreter exits; no stack traceback is

printed. If the associated value is an integer, it specifies the system exit status (passed to C's `exit()` function); if it is `None`, the exit status is zero; if it has another type (such as a string), the object's value is printed and the exit status is one.

Instances have an attribute `code` which is set to the proposed exit status or error message (defaulting to `None`). Also, this exception derives directly from `BaseException` and not `Exception`, since it is not technically an error.

A call to `sys.exit()` is translated into an exception so that clean-up handlers (`finally` clauses of `try` statements) can be executed, and so that a debugger can execute a script without running the risk of losing control. The `os._exit()` function can be used if it is absolutely positively necessary to exit immediately (for example, in the child process after a call to `fork()`).

The exception inherits from `BaseException` instead of `Exception` so that it is not accidentally caught by code that catches `Exception`. This allows the exception to properly propagate up and cause the interpreter to exit.

exception **TypeError**

Raised when an operation or function is applied to an object of inappropriate type. The associated value is a string giving details about the type mismatch.

exception **UnboundLocalError**

Raised when a reference is made to a local variable in a function or method, but no value has been bound to that variable. This is a subclass of `NameError`.

exception **UnicodeError**

Raised when a Unicode-related encoding or decoding error

occurs. It is a subclass of `ValueError`.

exception **UnicodeEncodeError**

Raised when a Unicode-related error occurs during encoding. It is a subclass of `UnicodeError`.

exception **UnicodeDecodeError**

Raised when a Unicode-related error occurs during decoding. It is a subclass of `UnicodeError`.

exception **UnicodeTranslateError**

Raised when a Unicode-related error occurs during translating. It is a subclass of `UnicodeError`.

exception **ValueError**

Raised when a built-in operation or function receives an argument that has the right type but an inappropriate value, and the situation is not described by a more precise exception such as `IndexError`.

exception **VMSError**

Only available on VMS. Raised when a VMS-specific error occurs.

exception **WindowsError**

Raised when a Windows-specific error occurs or when the error number does not correspond to an `errno` value. The `winerror` and `strerror` values are created from the return values of the `GetLastError()` and `FormatMessage()` functions from the Windows Platform API. The `errno` value maps the `winerror` value to corresponding `errno.h` values. This is a subclass of `OSError`.

exception **ZeroDivisionError**

Raised when the second argument of a division or modulo

operation is zero. The associated value is a string indicating the type of the operands and the operation.

The following exceptions are used as warning categories; see the [warnings](#) module for more information.

exception **Warning**

Base class for warning categories.

exception **UserWarning**

Base class for warnings generated by user code.

exception **DeprecationWarning**

Base class for warnings about deprecated features.

exception **PendingDeprecationWarning**

Base class for warnings about features which will be deprecated in the future.

exception **SyntaxWarning**

Base class for warnings about dubious syntax

exception **RuntimeWarning**

Base class for warnings about dubious runtime behavior.

exception **FutureWarning**

Base class for warnings about constructs that will change semantically in the future.

exception **ImportWarning**

Base class for warnings about probable mistakes in module imports.

exception **UnicodeWarning**

Base class for warnings related to Unicode.

exception **BytesWarning**

Base class for warnings related to **bytes** and **buffer**.

exception **ResourceWarning**

Base class for warnings related to resource usage.

New in version 3.2.

5.1. Exception hierarchy

The class hierarchy for built-in exceptions is:

```
BaseException
+-- SystemExit
+-- KeyboardInterrupt
+-- GeneratorExit
+-- Exception
    +-- StopIteration
    +-- ArithmeticError
        |   +-- FloatingPointError
        |   +-- OverflowError
        |   +-- ZeroDivisionError
    +-- AssertionError
    +-- AttributeError
    +-- BufferError
    +-- EnvironmentError
        |   +-- IOError
        |   +-- OSError
        |       +-- WindowsError (Windows)
        |       +-- VMSError (VMS)
    +-- EOFError
    +-- ImportError
    +-- LookupError
        |   +-- IndexError
        |   +-- KeyError
    +-- MemoryError
    +-- NameError
        |   +-- UnboundLocalError
    +-- ReferenceError
    +-- RuntimeError
        |   +-- NotImplementedError
    +-- SyntaxError
        |   +-- IndentationError
        |   +-- TabError
    +-- SystemError
    +-- TypeError
    +-- ValueError
        |   +-- UnicodeError
        |       +-- UnicodeDecodeError
        |       +-- UnicodeEncodeError
        |       +-- UnicodeTranslateError

6. String Services

The modules described in this chapter provide a wide range of string manipulation operations.

In addition, Python's built-in string classes support the sequence type methods described in the *Sequence Types — str, bytes, bytearray, list, tuple, range* section, and also the string-specific methods described in the *String Methods* section. To output formatted strings, see the *String Formatting* section. Also, see the `re` module for string functions based on regular expressions.

6.1. `string` — Common string operations

See also: *Sequence Types* — *str*, *bytes*, *bytearray*, *list*, *tuple*, *range*

String Methods

Source code: `Lib/string.py`

6.1.1. String constants

The constants defined in this module are:

string.**ascii_letters**

The concatenation of the `ascii_lowercase` and `ascii_uppercase` constants described below. This value is not locale-dependent.

string.**ascii_lowercase**

The lowercase letters `'abcdefghijklmnopqrstuvwxyz'`. This value is not locale-dependent and will not change.

string.**ascii_uppercase**

The uppercase letters `'ABCDEFGHIJKLMNOPQRSTUVWXYZ'`. This value is not locale-dependent and will not change.

string.**digits**

The string `'0123456789'`.

string.**hexdigits**

The string `'0123456789abcdefABCDEF'`.

string.**octdigits**

The string `'01234567'`.

string.**punctuation**

String of ASCII characters which are considered punctuation characters in the `c` locale.

string.**printable**

String of ASCII characters which are considered printable. This is a combination of `digits`, `ascii_letters`, `punctuation`, and `whitespace`.

string.**whitespace**

A string containing all ASCII characters that are considered whitespace. This includes the characters space, tab, linefeed, return, formfeed, and vertical tab.

6.1.2. String Formatting

The built-in string class provides the ability to do complex variable substitutions and value formatting via the `format()` method described in [PEP 3101](#). The `Formatter` class in the `string` module allows you to create and customize your own string formatting behaviors using the same implementation as the built-in `format()` method.

`class string.Formatter`

The `Formatter` class has the following public methods:

`format(format_string, *args, **kwargs)`

`format()` is the primary API method. It takes a format template string, and an arbitrary set of positional and keyword argument. `format()` is just a wrapper that calls `vformat()`.

`vformat(format_string, args, kwargs)`

This function does the actual work of formatting. It is exposed as a separate function for cases where you want to pass in a predefined dictionary of arguments, rather than unpacking and repacking the dictionary as individual arguments using the `*args` and `**kwargs` syntax. `vformat()` does the work of breaking up the format template string into character data and replacement fields. It calls the various methods described below.

In addition, the `Formatter` defines a number of methods that are intended to be replaced by subclasses:

`parse(format_string)`

Loop over the `format_string` and return an iterable of tuples (`literal_text`, `field_name`, `format_spec`, `conversion`). This is

used by `vformat()` to break the string into either literal text, or replacement fields.

The values in the tuple conceptually represent a span of literal text followed by a single replacement field. If there is no literal text (which can happen if two replacement fields occur consecutively), then *literal_text* will be a zero-length string. If there is no replacement field, then the values of *field_name*, *format_spec* and *conversion* will be `None`.

`get_field(field_name, args, kwargs)`

Given *field_name* as returned by `parse()` (see above), convert it to an object to be formatted. Returns a tuple (obj, used_key). The default version takes strings of the form defined in [PEP 3101](#), such as “0[name]” or “label.title”. *args* and *kwargs* are as passed in to `vformat()`. The return value *used_key* has the same meaning as the *key* parameter to `get_value()`.

`get_value(key, args, kwargs)`

Retrieve a given field value. The *key* argument will be either an integer or a string. If it is an integer, it represents the index of the positional argument in *args*; if it is a string, then it represents a named argument in *kwargs*.

The *args* parameter is set to the list of positional arguments to `vformat()`, and the *kwargs* parameter is set to the dictionary of keyword arguments.

For compound field names, these functions are only called for the first component of the field name; Subsequent components are handled through normal attribute and indexing operations.

So for example, the field expression ‘0.name’ would cause

`get_value()` to be called with a *key* argument of 0. The `name` attribute will be looked up after `get_value()` returns by calling the built-in `getattr()` function.

If the index or keyword refers to an item that does not exist, then an `IndexError` or `KeyError` should be raised.

`check_unused_args(used_args, args, kwargs)`

Implement checking for unused arguments if desired. The arguments to this function is the set of all argument keys that were actually referred to in the format string (integers for positional arguments, and strings for named arguments), and a reference to the *args* and *kwargs* that was passed to `vformat`. The set of unused args can be calculated from these parameters. `check_unused_args()` is assumed to raise an exception if the check fails.

`format_field(value, format_spec)`

`format_field()` simply calls the global `format()` built-in. The method is provided so that subclasses can override it.

`convert_field(value, conversion)`

Converts the value (returned by `get_field()`) given a conversion type (as in the tuple returned by the `parse()` method). The default version understands 'r' (repr) and 's' (str) conversion types.

6.1.3. Format String Syntax

The `str.format()` method and the `Formatter` class share the same syntax for format strings (although in the case of `Formatter`, subclasses can define their own format string syntax).

Format strings contain “replacement fields” surrounded by curly braces `{}`. Anything that is not contained in braces is considered literal text, which is copied unchanged to the output. If you need to include a brace character in the literal text, it can be escaped by doubling: `{{` and `}}`.

The grammar for a replacement field is as follows:

```
replacement_field ::= "{" [field_name] ["!" conversion] [']
field_name        ::= arg_name ( "." attribute_name | "[" element_index
arg_name          ::= [identifier | integer]
attribute_name    ::= identifier
element_index     ::= integer | index_string
index_string      ::= <any source character except "]"> +
conversion       ::= "r" | "s" | "a"
format_spec      ::= <described in the next section>
```

In less formal terms, the replacement field can start with a *field_name* that specifies the object whose value is to be formatted and inserted into the output instead of the replacement field. The *field_name* is optionally followed by a *conversion* field, which is preceded by an exclamation point `!`, and a *format_spec*, which is preceded by a colon `:`. These specify a non-default format for the replacement value.

See also the [Format Specification Mini-Language](#) section.

The *field_name* itself begins with an *arg_name* that is either either a number or a keyword. If it's a number, it refers to a positional

argument, and if it's a keyword, it refers to a named keyword argument. If the numerical `arg_names` in a format string are 0, 1, 2, ... in sequence, they can all be omitted (not just some) and the numbers 0, 1, 2, ... will be automatically inserted in that order. The `arg_name` can be followed by any number of index or attribute expressions. An expression of the form `'.name'` selects the named attribute using `getattr()`, while an expression of the form `'[index]'` does an index lookup using `__getitem__()`.

Changed in version 3.1: The positional argument specifiers can be omitted, so `'{} {}'` is equivalent to `'{0} {1}'`.

Some simple format string examples:

```
"First, thou shalt count to {0}" # References first positional
"Bring me a {}"                # Implicitly references the fi
"From {} to {}"                # Same as "From {0} to {1}"
"My quest is {name}"           # References keyword argument
"Weight in tons {0.weight}"    # 'weight' attribute of first
"Units destroyed: {players[0]}" # First element of keyword arg
```

The `conversion` field causes a type coercion before formatting. Normally, the job of formatting a value is done by the `__format__()` method of the value itself. However, in some cases it is desirable to force a type to be formatted as a string, overriding its own definition of formatting. By converting the value to a string before calling `__format__()`, the normal formatting logic is bypassed.

Three conversion flags are currently supported: `'!s'` which calls `str()` on the value, `'!r'` which calls `repr()` and `'!a'` which calls `ascii()`.

Some examples:

```
"Harold's a clever {0!s}"      # Calls str() on the argument
"Bring out the holy {name!r}" # Calls repr() on the argument
```

```
"More {!a}" # Calls ascii() on the argumen
```

The *format_spec* field contains a specification of how the value should be presented, including such details as field width, alignment, padding, decimal precision and so on. Each value type can define its own “formatting mini-language” or interpretation of the *format_spec*.

Most built-in types support a common formatting mini-language, which is described in the next section.

A *format_spec* field can also include nested replacement fields within it. These nested replacement fields can contain only a field name; conversion flags and format specifications are not allowed. The replacement fields within the *format_spec* are substituted before the *format_spec* string is interpreted. This allows the formatting of a value to be dynamically specified.

See the *Format examples* section for some examples.

6.1.3.1. Format Specification Mini-Language

“Format specifications” are used within replacement fields contained within a format string to define how individual values are presented (see *Format String Syntax*). They can also be passed directly to the built-in `format()` function. Each formattable type may define how the format specification is to be interpreted.

Most built-in types implement the following options for format specifications, although some of the formatting options are only supported by the numeric types.

A general convention is that an empty format string (“”) produces the same result as if you had called `str()` on the value. A non-empty format string typically modifies the result.

The general form of a *standard format specifier* is:

```
format_spec ::= [[fill]align][sign][#][0][width][,][.precision]
fill        ::= <a character other than '{' or '}'>
align       ::= "<" | ">" | "=" | "^"
sign        ::= "+" | "-" | " "
width       ::= integer
precision   ::= integer
type        ::= "b" | "c" | "d" | "e" | "E" | "f" | "F" | "g"
```

The *fill* character can be any character other than '{' or '}'. The presence of a fill character is signaled by the character following it, which must be one of the alignment options. If the second character of *format_spec* is not a valid alignment option, then it is assumed that both the fill character and the alignment option are absent.

The meaning of the various alignment options is as follows:

Option	Meaning
'<'	Forces the field to be left-aligned within the available space (this is the default for most objects).
'>'	Forces the field to be right-aligned within the available space (this is the default for numbers).
'='	Forces the padding to be placed after the sign (if any) but before the digits. This is used for printing fields in the form '+000000120'. This alignment option is only valid for numeric types.
'^'	Forces the field to be centered within the available space.

Note that unless a minimum field width is defined, the field width will always be the same size as the data to fill it, so that the alignment option has no meaning in this case.

The *sign* option is only valid for number types, and can be one of the following:

Option	Meaning
'+'	indicates that a sign should be used for both positive as well as negative numbers.
'-'	indicates that a sign should be used only for negative numbers (this is the default behavior).
space	indicates that a leading space should be used on positive numbers, and a minus sign on negative numbers.

The '#' option causes the “alternate form” to be used for the conversion. The alternate form is defined differently for different types. This option is only valid for integer, float, complex and Decimal types. For integers, when binary, octal, or hexadecimal output is used, this option adds the prefix respective '0b', '0o', or '0x' to the output value. For floats, complex and Decimal the alternate form causes the result of the conversion to always contain a decimal-point character, even if no digits follow it. Normally, a decimal-point character appears in the result of these conversions only if a digit follows it. In addition, for 'g' and 'G' conversions, trailing zeros are not removed from the result.

The ',' option signals the use of a comma for a thousands separator. For a locale aware separator, use the 'n' integer presentation type instead.

Changed in version 3.1: Added the ',' option (see also [PEP 378](#)).

width is a decimal integer defining the minimum field width. If not specified, then the field width will be determined by the content.

If the *width* field is preceded by a zero ('0') character, this enables zero-padding. This is equivalent to an *alignment* type of '=' and a *fill* character of '0'.

The *precision* is a decimal number indicating how many digits should

be displayed after the decimal point for a floating point value formatted with 'f' and 'F', or before and after the decimal point for a floating point value formatted with 'g' or 'G'. For non-number types the field indicates the maximum field size - in other words, how many characters will be used from the field content. The *precision* is not allowed for integer values.

Finally, the *type* determines how the data should be presented.

The available string presentation types are:

Type	Meaning
's'	String format. This is the default type for strings and may be omitted.
None	The same as 's'.

The available integer presentation types are:

Type	Meaning
'b'	Binary format. Outputs the number in base 2.
'c'	Character. Converts the integer to the corresponding unicode character before printing.
'd'	Decimal Integer. Outputs the number in base 10.
'o'	Octal format. Outputs the number in base 8.
'x'	Hex format. Outputs the number in base 16, using lower- case letters for the digits above 9.
'X'	Hex format. Outputs the number in base 16, using upper- case letters for the digits above 9.
'n'	Number. This is the same as 'd', except that it uses the current locale setting to insert the appropriate number separator characters.
None	The same as 'd'.

In addition to the above presentation types, integers can be formatted with the floating point presentation types listed below

(except 'n' and None). When doing so, `float()` is used to convert the integer to a floating point number before formatting.

The available presentation types for floating point and decimal values are:

Type	Meaning
'e'	Exponent notation. Prints the number in scientific notation using the letter 'e' to indicate the exponent.
'E'	Exponent notation. Same as 'e' except it uses an upper case 'E' as the separator character.
'f'	Fixed point. Displays the number as a fixed-point number.
'F'	Fixed point. Same as 'f', but converts <code>nan</code> to <code>NAN</code> and <code>inf</code> to <code>INF</code> .
'g'	<p>General format. For a given precision <code>p >= 1</code>, this rounds the number to <code>p</code> significant digits and then formats the result in either fixed-point format or in scientific notation, depending on its magnitude.</p> <p>The precise rules are as follows: suppose that the result formatted with presentation type 'e' and precision <code>p-1</code> would have exponent <code>exp</code>. Then if <code>-4 <= exp < p</code>, the number is formatted with presentation type 'f' and precision <code>p-1-exp</code>. Otherwise, the number is formatted with presentation type 'e' and precision <code>p-1</code>. In both cases insignificant trailing zeros are removed from the significand, and the decimal point is also removed if there are no remaining digits following it.</p> <p>Positive and negative infinity, positive and negative zero, and nans, are formatted as <code>inf</code>, <code>-inf</code>, <code>0</code>, <code>-0</code> and <code>nan</code> respectively, regardless of the precision.</p>

	A precision of 0 is treated as equivalent to a precision of 1.
'G'	General format. Same as 'g' except switches to 'E' if the number gets too large. The representations of infinity and NaN are uppcased, too.
'n'	Number. This is the same as 'g', except that it uses the current locale setting to insert the appropriate number separator characters.
'%'	Percentage. Multiplies the number by 100 and displays in fixed ('f') format, followed by a percent sign.
None	Similar to 'g', except with at least one digit past the decimal point and a default precision of 12. This is intended to match <code>str()</code> , except you can add the other format modifiers.

6.1.3.2. Format examples

This section contains examples of the new format syntax and comparison with the old %-formatting.

In most of the cases the syntax is similar to the old %-formatting, with the addition of the `{}` and with `:` used instead of `%`. For example, `'%03.2f'` can be translated to `'{:03.2f}'`.

The new format syntax also supports new and different options, shown in the follow examples.

Accessing arguments by position:

```
>>> '{0}, {1}, {2}'.format('a', 'b', 'c')
'a, b, c'
>>> '{}, {}, {}'.format('a', 'b', 'c') # 3.1+ only
'a, b, c'
>>> '{2}, {1}, {0}'.format('a', 'b', 'c')
'c, b, a'
>>> '{2}, {1}, {0}'.format(*'abc') # unpacking argument se
```

```
'c, b, a'  
>>> '{0}{1}{0}'.format('abra', 'cad') # arguments' indices ca  
'abracadabra'
```

Accessing arguments by name:

```
>>> 'Coordinates: {latitude}, {longitude}'.format(latitude='37.  
'Coordinates: 37.24N, -115.81W'  
>>> coord = {'latitude': '37.24N', 'longitude': '-115.81W'}  
>>> 'Coordinates: {latitude}, {longitude}'.format(**coord)  
'Coordinates: 37.24N, -115.81W'
```

Accessing arguments' attributes:

```
>>> c = 3-5j  
>>> ('The complex number {0} is formed from the real part {0.re  
... 'and the imaginary part {0.imag}.'.format(c)  
'The complex number (3-5j) is formed from the real part 3.0 and  
>>> class Point:  
...     def __init__(self, x, y):  
...         self.x, self.y = x, y  
...     def __str__(self):  
...         return 'Point({self.x}, {self.y})'.format(self=self  
...  
>>> str(Point(4, 2))  
'Point(4, 2)'
```

Accessing arguments' items:

```
>>> coord = (3, 5)  
>>> 'X: {0[0]}; Y: {0[1]}'.format(coord)  
'X: 3; Y: 5'
```

Replacing %s and %r:

```
>>> "repr() shows quotes: {!r}; str() doesn't: {!s}".format('te  
"repr() shows quotes: 'test1'; str() doesn't: test2"
```

Aligning the text and specifying a width:

```
>>> '{:<30}'.format('left aligned')
'left aligned'
>>> '{:>30}'.format('right aligned')
'right aligned'
>>> '{:^30}'.format('centered')
'centered'
>>> '{:*^30}'.format('centered') # use '*' as a fill char
'*****centered*****'
```

Replacing %+f, %-f, and % f and specifying a sign:

```
>>> '{:+f}; {:+f}'.format(3.14, -3.14) # show it always
'+3.140000; -3.140000'
>>> '{: f}; {: f}'.format(3.14, -3.14) # show a space for posi
' 3.140000; -3.140000'
>>> '{:-f}; {:-f}'.format(3.14, -3.14) # show only the minus -
'3.140000; -3.140000'
```

Replacing %x and %o and converting the value to different bases:

```
>>> # format also supports binary numbers
>>> "int: {0:d}; hex: {0:x}; oct: {0:o}; bin: {0:b}".format(
'int: 42; hex: 2a; oct: 52; bin: 101010'
>>> # with 0x, 0o, or 0b as prefix:
>>> "int: {0:d}; hex: {0:#x}; oct: {0:#o}; bin: {0:#b}".form
'int: 42; hex: 0x2a; oct: 0o52; bin: 0b101010'
```

Using the comma as a thousands separator:

```
>>> '{:,}'.format(1234567890)
'1,234,567,890'
```

Expressing a percentage:

```
>>> points = 19
>>> total = 22
>>> 'Correct answers: {:.2%}'.format(points/total)
'Correct answers: 86.36%'
```

Using type-specific formatting:

```
>>> import datetime
>>> d = datetime.datetime(2010, 7, 4, 12, 15, 58)
>>> '{:%Y-%m-%d %H:%M:%S}'.format(d)
'2010-07-04 12:15:58'
```

Nesting arguments and more complex examples:

```
>>> for align, text in zip('<^>', ['left', 'center', 'right']):
...     '{0:{fill}{align}16}'.format(text, fill=align, align=al
...
'left<<<<<<<<<<<<<<<<<<'
'^^^^^center^^^^^'
'>>>>>>>>>>>>>>>right'
>>>
>>> octets = [192, 168, 0, 1]
>>> '{:02X}{:02X}{:02X}{:02X}'.format(*octets)
'C0A80001'
>>> int(_, 16)
323223521
>>>
>>> width = 5
>>> for num in range(5,12):
...     for base in 'dXob':
...         print('{0:{width}{base}}'.format(num, base=base, wi
...         print()
...
5      5      5      101
6      6      6      110
7      7      7      111
8      8      10     1000
9      9      11     1001
10     A      12     1010
11     B      13     1011
```

6.1.4. Template strings

Templates provide simpler string substitutions as described in [PEP 292](#). Instead of the normal %-based substitutions, Templates support \$-based substitutions, using the following rules:

- `$$` is an escape; it is replaced with a single `$`.
- `$identifier` names a substitution placeholder matching a mapping key of `"identifier"`. By default, `"identifier"` must spell a Python identifier. The first non-identifier character after the `$` character terminates this placeholder specification.
- `${identifier}` is equivalent to `$identifier`. It is required when valid identifier characters follow the placeholder but are not part of the placeholder, such as `"${noun}ification"`.

Any other appearance of `$` in the string will result in a `ValueError` being raised.

The `string` module provides a `Template` class that implements these rules. The methods of `Template` are:

`class string.Template(template)`

The constructor takes a single argument which is the template string.

`substitute(mapping, **kwds)`

Performs the template substitution, returning a new string. `mapping` is any dictionary-like object with keys that match the placeholders in the template. Alternatively, you can provide keyword arguments, where the keywords are the placeholders. When both `mapping` and `kwds` are given and there are duplicates, the placeholders from `kwds` take

precedence.

safe_substitute(mapping, **kwargs)

Like `substitute()`, except that if placeholders are missing from *mapping* and *kwargs*, instead of raising a `KeyError` exception, the original placeholder will appear in the resulting string intact. Also, unlike with `substitute()`, any other appearances of the `$` will simply return `$` instead of raising `ValueError`.

While other exceptions may still occur, this method is called “safe” because substitutions always tries to return a usable string instead of raising an exception. In another sense, `safe_substitute()` may be anything other than safe, since it will silently ignore malformed templates containing dangling delimiters, unmatched braces, or placeholders that are not valid Python identifiers.

`Template` instances also provide one public data attribute:

template

This is the object passed to the constructor’s *template* argument. In general, you shouldn’t change it, but read-only access is not enforced.

Here is an example of how to use a `Template`:

```
>>> from string import Template
>>> s = Template('$who likes $what')
>>> s.substitute(who='tim', what='kung pao')
'tim likes kung pao'
>>> d = dict(who='tim')
>>> Template('Give $who $100').substitute(d)
Traceback (most recent call last):
[...]
ValueError: Invalid placeholder in string: line 1, col 10
>>> Template('$who likes $what').substitute(d)
```

```
Traceback (most recent call last):
[...]
KeyError: 'what'
>>> Template('$who likes $what').safe_substitute(d)
'tim likes $what'
```

Advanced usage: you can derive subclasses of `Template` to customize the placeholder syntax, delimiter character, or the entire regular expression used to parse template strings. To do this, you can override these class attributes:

- *delimiter* – This is the literal string describing a placeholder introducing delimiter. The default value is `$`. Note that this should *not* be a regular expression, as the implementation will call `re.escape()` on this string as needed.
- *idpattern* – This is the regular expression describing the pattern for non-braced placeholders (the braces will be added automatically as appropriate). The default value is the regular expression `[_a-z][_a-z0-9]*`.
- *flags* – The regular expression flags that will be applied when compiling the regular expression used for recognizing substitutions. The default value is `re.IGNORECASE`. Note that `re.VERBOSE` will always be added to the flags, so custom *idpatterns* must follow conventions for verbose regular expressions.

New in version 3.2.

Alternatively, you can provide the entire regular expression pattern by overriding the class attribute *pattern*. If you do this, the value must be a regular expression object with four named capturing groups. The capturing groups correspond to the rules given above, along with the invalid placeholder rule:

- *escaped* – This group matches the escape sequence, e.g. `$$`, in the default pattern.
- *named* – This group matches the unbraced placeholder name; it should not include the delimiter in capturing group.
- *braced* – This group matches the brace enclosed placeholder name; it should not include either the delimiter or braces in the capturing group.
- *invalid* – This group matches any other delimiter pattern (usually a single delimiter), and it should appear last in the regular expression.

6.1.5. Helper functions

`string.capwords(s, sep=None)`

Split the argument into words using `str.split()`, capitalize each word using `str.capitalize()`, and join the capitalized words using `str.join()`. If the optional second argument `sep` is absent or `None`, runs of whitespace characters are replaced by a single space and leading and trailing whitespace are removed, otherwise `sep` is used to split and join the words.

6.2. re — Regular expression operations

This module provides regular expression matching operations similar to those found in Perl.

Both patterns and strings to be searched can be Unicode strings as well as 8-bit strings. However, Unicode strings and 8-bit strings cannot be mixed: that is, you cannot match an Unicode string with a byte pattern or vice-versa; similarly, when asking for a substitution, the replacement string must be of the same type as both the pattern and the search string.

Regular expressions use the backslash character (`'\'`) to indicate special forms or to allow special characters to be used without invoking their special meaning. This collides with Python's usage of the same character for the same purpose in string literals; for example, to match a literal backslash, one might have to write `'\\\\'` as the pattern string, because the regular expression must be `\\`, and each backslash must be expressed as `\\` inside a regular Python string literal.

The solution is to use Python's raw string notation for regular expression patterns; backslashes are not handled in any special way in a string literal prefixed with `'r'`. So `r"\n"` is a two-character string containing `'\'` and `'n'`, while `"\n"` is a one-character string containing a newline. Usually patterns will be expressed in Python code using this raw string notation.

It is important to note that most regular expression operations are available as module-level functions and methods on *compiled regular expressions*. The functions are shortcuts that don't require you to compile a regex object first, but miss some fine-tuning

parameters.

See also:

Mastering Regular Expressions

Book on regular expressions by Jeffrey Friedl, published by O'Reilly. The second edition of the book no longer covers Python at all, but the first edition covered writing good regular expression patterns in great detail.

6.2.1. Regular Expression Syntax

A regular expression (or RE) specifies a set of strings that matches it; the functions in this module let you check if a particular string matches a given regular expression (or if a given regular expression matches a particular string, which comes down to the same thing).

Regular expressions can be concatenated to form new regular expressions; if A and B are both regular expressions, then AB is also a regular expression. In general, if a string p matches A and another string q matches B , the string pq will match AB . This holds unless A or B contain low precedence operations; boundary conditions between A and B ; or have numbered group references. Thus, complex expressions can easily be constructed from simpler primitive expressions like the ones described here. For details of the theory and implementation of regular expressions, consult the Friedl book referenced above, or almost any textbook about compiler construction.

A brief explanation of the format of regular expressions follows. For further information and a gentler presentation, consult the [Regular Expression HOWTO](#).

Regular expressions can contain both special and ordinary characters. Most ordinary characters, like 'A', 'a', or '0', are the simplest regular expressions; they simply match themselves. You can concatenate ordinary characters, so `last` matches the string 'last'. (In the rest of this section, we'll write RE's in `this special style`, usually without quotes, and strings to be matched 'in single quotes'.)

Some characters, like '|' or '(', are special. Special characters either stand for classes of ordinary characters, or affect how the

regular expressions around them are interpreted. Regular expression pattern strings may not contain null bytes, but can specify the null byte using the `\number` notation, e.g., `'\x00'`.

The special characters are:

`'.'`

(Dot.) In the default mode, this matches any character except a newline. If the **DOTALL** flag has been specified, this matches any character including a newline.

`'^'`

(Caret.) Matches the start of the string, and in **MULTILINE** mode also matches immediately after each newline.

`'$'`

Matches the end of the string or just before the newline at the end of the string, and in **MULTILINE** mode also matches before a newline. `foo` matches both 'foo' and 'foobar', while the regular expression `foo$` matches only 'foo'. More interestingly, searching for `foo.$` in `'foo1\nfoo2\n'` matches 'foo2' normally, but 'foo1' in **MULTILINE** mode; searching for a single `$` in `'foo\n'` will find two (empty) matches: one just before the newline, and one at the end of the string.

`'*'`

Causes the resulting RE to match 0 or more repetitions of the preceding RE, as many repetitions as are possible. `ab*` will match 'a', 'ab', or 'a' followed by any number of 'b's.

`'+'`

Causes the resulting RE to match 1 or more repetitions of the preceding RE. `ab+` will match 'a' followed by any non-zero number of 'b's; it will not match just 'a'.

`'?'`

Causes the resulting RE to match 0 or 1 repetitions of the preceding RE. `ab?` will match either 'a' or 'ab'.

`*?`, `+?`, `??`

The `'*'`, `'+'`, and `'?'` qualifiers are all *greedy*; they match as much text as possible. Sometimes this behaviour isn't desired; if the RE `<.*>` is matched against `'<H1>title</H1>'`, it will match the entire string, and not just `'<H1>'`. Adding `'?'` after the qualifier makes it perform the match in *non-greedy* or *minimal* fashion; as few characters as possible will be matched. Using `.*?` in the previous expression will match only `'<H1>'`.

`{m}`

Specifies that exactly m copies of the previous RE should be matched; fewer matches cause the entire RE not to match. For example, `a{6}` will match exactly six `'a'` characters, but not five.

`{m, n}`

Causes the resulting RE to match from m to n repetitions of the preceding RE, attempting to match as many repetitions as possible. For example, `a{3,5}` will match from 3 to 5 `'a'` characters. Omitting m specifies a lower bound of zero, and omitting n specifies an infinite upper bound. As an example, `a{4,}b` will match `aaaab` or a thousand `'a'` characters followed by a `b`, but not `aaab`. The comma may not be omitted or the modifier would be confused with the previously described form.

`{m, n}?`

Causes the resulting RE to match from m to n repetitions of the preceding RE, attempting to match as few repetitions as possible. This is the non-greedy version of the previous qualifier. For example, on the 6-character string `'aaaaaa'`, `a{3,5}` will match 5 `'a'` characters, while `a{3,5}?` will only match 3 characters.

`'\'`

Either escapes special characters (permitting you to match characters like `'*'`, `'?'`, and so forth), or signals a special sequence; special sequences are discussed below.

If you're not using a raw string to express the pattern, remember that Python also uses the backslash as an escape sequence in string literals; if the escape sequence isn't recognized by Python's parser, the backslash and subsequent character are included in the resulting string. However, if Python would recognize the resulting sequence, the backslash should be repeated twice. This is complicated and hard to understand, so it's highly recommended that you use raw strings for all but the simplest expressions.

[]

Used to indicate a set of characters. Characters can be listed individually, or a range of characters can be indicated by giving two characters and separating them by a '-'. Special characters are not active inside sets. For example, [akm\$] will match any of the characters 'a', 'k', 'm', or '\$'; [a-z] will match any lowercase letter, and [a-zA-Z0-9] matches any letter or digit. Character classes such as \w or \s (defined below) are also acceptable inside a range, although the characters they match depends on whether **ASCII** or **LOCALE** mode is in force. If you want to include a ']' or a '-' inside a set, precede it with a backslash, or place it as the first character. The pattern [] will match ']', for example.

You can match the characters not within a range by *complementing* the set. This is indicated by including a '^' as the first character of the set; '^' elsewhere will simply match the '^' character. For example, [^5] will match any character except '5', and [^^] will match any character except '^'.

Note that inside [] the special forms and special characters lose their meanings and only the syntaxes described here are valid. For example, +, *, (,), and so on are treated as literals inside

`[]`, and backreferences cannot be used inside `[]`.

`|`

`A|B`, where `A` and `B` can be arbitrary REs, creates a regular expression that will match either `A` or `B`. An arbitrary number of REs can be separated by the `|` in this way. This can be used inside groups (see below) as well. As the target string is scanned, REs separated by `|` are tried from left to right. When one pattern completely matches, that branch is accepted. This means that once `A` matches, `B` will not be tested further, even if it would produce a longer overall match. In other words, the `|` operator is never greedy. To match a literal `|`, use `\|`, or enclose it inside a character class, as in `[|]`.

`(...)`

Matches whatever regular expression is inside the parentheses, and indicates the start and end of a group; the contents of a group can be retrieved after a match has been performed, and can be matched later in the string with the `\number` special sequence, described below. To match the literals `'(` or `)'`, use `\(` or `\)`, or enclose them inside a character class: `[([])]`.

`(?...)`

This is an extension notation (a `'?'` following a `'(` is not meaningful otherwise). The first character after the `'?'` determines what the meaning and further syntax of the construct is. Extensions usually do not create a new group; `(?P<name>...)` is the only exception to this rule. Following are the currently supported extensions.

`(?aiLmsux)`

(One or more letters from the set `'a'`, `'i'`, `'L'`, `'m'`, `'s'`, `'u'`, `'x'`.) The group matches the empty string; the letters set the corresponding flags: `re.A` (ASCII-only matching), `re.I` (ignore case), `re.L` (locale dependent), `re.M` (multi-line), `re.S` (dot

matches all), and `re.X` (verbose), for the entire regular expression. (The flags are described in [Module Contents](#).) This is useful if you wish to include the flags as part of the regular expression, instead of passing a *flag* argument to the `re.compile()` function.

Note that the `(?x)` flag changes how the expression is parsed. It should be used first in the expression string, or after one or more whitespace characters. If there are non-whitespace characters before the flag, the results are undefined.

`(?:...)`

A non-capturing version of regular parentheses. Matches whatever regular expression is inside the parentheses, but the substring matched by the group *cannot* be retrieved after performing a match or referenced later in the pattern.

`(?P<name>...)`

Similar to regular parentheses, but the substring matched by the group is accessible within the rest of the regular expression via the symbolic group name *name*. Group names must be valid Python identifiers, and each group name must be defined only once within a regular expression. A symbolic group is also a numbered group, just as if the group were not named. So the group named `id` in the example below can also be referenced as the numbered group `1`.

For example, if the pattern is `(?P<id>[a-zA-Z_]\w*)`, the group can be referenced by its name in arguments to methods of match objects, such as `m.group('id')` or `m.end('id')`, and also by name in the regular expression itself (using `(?P=id)`) and replacement text given to `.sub()` (using `\g<id>`).

`(?P=name)`

Matches whatever text was matched by the earlier group named

name.

`(?#...)`

A comment; the contents of the parentheses are simply ignored.

`(?=...)`

Matches if `...` matches next, but doesn't consume any of the string. This is called a lookahead assertion. For example, `Isaac (?=Asimov)` will match `'Isaac '` only if it's followed by `'Asimov'`.

`(?!...)`

Matches if `...` doesn't match next. This is a negative lookahead assertion. For example, `Isaac (?!Asimov)` will match `'Isaac '` only if it's *not* followed by `'Asimov'`.

`(?<=...)`

Matches if the current position in the string is preceded by a match for `...` that ends at the current position. This is called a *positive lookbehind assertion*. `(?<=abc)def` will find a match in `abcdef`, since the lookbehind will back up 3 characters and check if the contained pattern matches. The contained pattern must only match strings of some fixed length, meaning that `abc` or `a|b` are allowed, but `a*` and `a{3,4}` are not. Note that patterns which start with positive lookbehind assertions will never match at the beginning of the string being searched; you will most likely want to use the `search()` function rather than the `match()` function:

```
>>> import re
>>> m = re.search('(?<=abc)def', 'abcdef')
>>> m.group(0)
'def'
```

This example looks for a word following a hyphen:

```
>>> m = re.search('(?!<=-)\w+', 'spam-egg')
>>> m.group(0)
'egg'
```

`(?!...)`

Matches if the current position in the string is not preceded by a match for `...`. This is called a *negative lookbehind assertion*. Similar to positive lookbehind assertions, the contained pattern must only match strings of some fixed length. Patterns which start with negative lookbehind assertions may match at the beginning of the string being searched.

`(?(id/name)yes-pattern|no-pattern)`

Will try to match with `yes-pattern` if the group with given *id* or *name* exists, and with `no-pattern` if it doesn't. `no-pattern` is optional and can be omitted. For example, `(<)?(\w+@\w+(?:\.\w+)+)(?(1)>)` is a poor email matching pattern, which will match with `'<user@host.com>'` as well as `'user@host.com'`, but not with `'<user@host.com'`.

The special sequences consist of `'\'` and a character from the list below. If the ordinary character is not on the list, then the resulting RE will match the second character. For example, `\$` matches the character `'$'`.

`\number`

Matches the contents of the group of the same number. Groups are numbered starting from 1. For example, `(.+) \1` matches `'the the'` or `'55 55'`, but not `'the end'` (note the space after the group). This special sequence can only be used to match one of the first 99 groups. If the first digit of *number* is 0, or *number* is 3 octal digits long, it will not be interpreted as a group match, but as the character with octal value *number*. Inside the `'['` and `']'` of a character class, all numeric escapes are treated as characters.

`\A`

Matches only at the start of the string.

`\b`

Matches the empty string, but only at the beginning or end of a

word. A word is defined as a sequence of Unicode alphanumeric or underscore characters, so the end of a word is indicated by whitespace or a non-alphanumeric, non-underscore Unicode character. Note that formally, `\b` is defined as the boundary between a `\w` and a `\W` character (or vice versa). By default Unicode alphanumerics are the ones used, but this can be changed by using the **ASCII** flag. Inside a character range, `\b` represents the backspace character, for compatibility with Python's string literals.

`\B`

Matches the empty string, but only when it is *not* at the beginning or end of a word. This is just the opposite of `\b`, so word characters are Unicode alphanumerics or the underscore, although this can be changed by using the **ASCII** flag.

`\d`

For Unicode (str) patterns:

Matches any Unicode decimal digit (that is, any character in Unicode character category `[Nd]`). This includes `[0-9]`, and also many other digit characters. If the **ASCII** flag is used only `[0-9]` is matched (but the flag affects the entire regular expression, so in such cases using an explicit `[0-9]` may be a better choice).

For 8-bit (bytes) patterns:

Matches any decimal digit; this is equivalent to `[0-9]`.

`\D`

Matches any character which is not a Unicode decimal digit. This is the opposite of `\d`. If the **ASCII** flag is used this becomes the equivalent of `[^0-9]` (but the flag affects the entire regular expression, so in such cases using an explicit `[^0-9]` may be a better choice).

`\s`

For Unicode (str) patterns:

Matches Unicode whitespace characters (which includes `[\t\n\r\f\v]`, and also many other characters, for example the non-breaking spaces mandated by typography rules in many languages). If the **ASCII** flag is used, only `[\t\n\r\f\v]` is matched (but the flag affects the entire regular expression, so in such cases using an explicit `[\t\n\r\f\v]` may be a better choice).

For 8-bit (bytes) patterns:

Matches characters considered whitespace in the ASCII character set; this is equivalent to `[\t\n\r\f\v]`.

`\S`

Matches any character which is not a Unicode whitespace character. This is the opposite of `\s`. If the **ASCII** flag is used this becomes the equivalent of `[^\t\n\r\f\v]` (but the flag affects the entire regular expression, so in such cases using an explicit `[^\t\n\r\f\v]` may be a better choice).

`\w`

For Unicode (str) patterns:

Matches Unicode word characters; this includes most characters that can be part of a word in any language, as well as numbers and the underscore. If the **ASCII** flag is used, only `[a-zA-Z0-9_]` is matched (but the flag affects the entire regular expression, so in such cases using an explicit `[a-zA-Z0-9_]` may be a better choice).

For 8-bit (bytes) patterns:

Matches characters considered alphanumeric in the ASCII character set; this is equivalent to `[a-zA-Z0-9_]`.

`\W`

Matches any character which is not a Unicode word character.

This is the opposite of `\w`. If the **ASCII** flag is used this becomes the equivalent of `[\^a-zA-Z0-9_]` (but the flag affects the entire regular expression, so in such cases using an explicit `[\^a-zA-Z0-9_]` may be a better choice).

`\Z`

Matches only at the end of the string.

Most of the standard escapes supported by Python string literals are also accepted by the regular expression parser:

```
\a      \b      \f      \n
\r      \t      \v      \x
\\
```

Octal escapes are included in a limited form: If the first digit is a 0, or if there are three octal digits, it is considered an octal escape. Otherwise, it is a group reference. As for string literals, octal escapes are always at most three digits in length.

6.2.2. Matching vs Searching

Python offers two different primitive operations based on regular expressions: **match** checks for a match only at the beginning of the string, while **search** checks for a match anywhere in the string (this is what Perl does by default).

Note that `match` may differ from `search` even when using a regular expression beginning with `'^'`: `'^'` matches only at the start of the string, or in **MULTILINE** mode also immediately following a newline. The “match” operation succeeds only if the pattern matches at the start of the string regardless of mode, or at the starting position given by the optional `pos` argument regardless of whether a newline precedes it.

```
>>> re.match("c", "abcdef") # No match
>>> re.search("c", "abcdef") # Match
<_sre.SRE_Match object at ...>
```

6.2.3. Module Contents

The module defines several functions, constants, and an exception. Some of the functions are simplified versions of the full featured methods for compiled regular expressions. Most non-trivial applications always use the compiled form.

`re.compile(pattern, flags=0)`

Compile a regular expression pattern into a regular expression object, which can be used for matching using its `match()` and `search()` methods, described below.

The expression's behaviour can be modified by specifying a *flags* value. Values can be any of the following variables, combined using bitwise OR (the `|` operator).

The sequence

```
prog = re.compile(pattern)
result = prog.match(string)
```

is equivalent to

```
result = re.match(pattern, string)
```

but using `re.compile()` and saving the resulting regular expression object for reuse is more efficient when the expression will be used several times in a single program.

Note: The compiled versions of the most recent patterns passed to `re.match()`, `re.search()` or `re.compile()` are cached, so programs that use only a few regular expressions at a time needn't worry about compiling regular expressions.

re. **A**

re. **ASCII**

Make `\w`, `\W`, `\b`, `\B`, `\d`, `\D`, `\s` and `\S` perform ASCII-only matching instead of full Unicode matching. This is only meaningful for Unicode patterns, and is ignored for byte patterns.

Note that for backward compatibility, the `re.U` flag still exists (as well as its synonym `re.UNICODE` and its embedded counterpart (`?u`)), but these are redundant in Python 3 since matches are Unicode by default for strings (and Unicode matching isn't allowed for bytes).

re. **I**

re. **IGNORECASE**

Perform case-insensitive matching; expressions like `[A-Z]` will match lowercase letters, too. This is not affected by the current locale and works for Unicode characters as expected.

re. **L**

re. **LOCALE**

Make `\w`, `\W`, `\b`, `\B`, `\s` and `\S` dependent on the current locale. The use of this flag is discouraged as the locale mechanism is very unreliable, and it only handles one “culture” at a time anyway; you should use Unicode matching instead, which is the default in Python 3 for Unicode (str) patterns.

re. **M**

re. **MULTILINE**

When specified, the pattern character `^` matches at the beginning of the string and at the beginning of each line (immediately following each newline); and the pattern character `$` matches at the end of the string and at the end of each line (immediately preceding each newline). By default, `^` matches only at the beginning of the string, and `$` only at the end of the string and immediately before the newline (if any) at the end of

the string.

re. **S**

re. **DOTALL**

Make the `'.'` special character match any character at all, including a newline; without this flag, `'.'` will match anything *except* a newline.

re. **X**

re. **VERBOSE**

This flag allows you to write regular expressions that look nicer. Whitespace within the pattern is ignored, except when in a character class or preceded by an unescaped backslash, and, when a line contains a `'#'` neither in a character class or preceded by an unescaped backslash, all characters from the leftmost such `'#'` through the end of the line are ignored.

That means that the two following regular expression objects that match a decimal number are functionally equal:

```
a = re.compile(r"""\d + # the integral part
                \.   # the decimal point
                \d * # some fractional digits""", re.X)
b = re.compile(r"\d+\.\d*")
```

re. **search(pattern, string, flags=0)**

Scan through *string* looking for a location where the regular expression *pattern* produces a match, and return a corresponding *match object*. Return **None** if no position in the string matches the pattern; note that this is different from finding a zero-length match at some point in the string.

re. **match(pattern, string, flags=0)**

If zero or more characters at the beginning of *string* match the regular expression *pattern*, return a corresponding *match object*. Return **None** if the string does not match the pattern; note that this

is different from a zero-length match.

Note: If you want to locate a match anywhere in *string*, use `search()` instead.

re. **split**(*pattern*, *string*, *maxsplit*=0, *flags*=0)

Split *string* by the occurrences of *pattern*. If capturing parentheses are used in *pattern*, then the text of all groups in the pattern are also returned as part of the resulting list. If *maxsplit* is nonzero, at most *maxsplit* splits occur, and the remainder of the string is returned as the final element of the list.

```
>>> re.split('\W+', 'Words, words, words.')
['Words', 'words', 'words', '']
>>> re.split('(\W+)', 'Words, words, words.')
['Words', ',', ' ', 'words', ',', ' ', 'words', '.', ' ', '']
>>> re.split('\W+', 'Words, words, words.', 1)
['Words', 'words, words.']
>>> re.split('[a-f]+', '0a3B9', flags=re.IGNORECASE)
['0', '3', '9']
```

If there are capturing groups in the separator and it matches at the start of the string, the result will start with an empty string. The same holds for the end of the string:

```
>>> re.split('(\W+)', '...words, words...')
['', '...', 'words', ',', ' ', 'words', '...', '']
```

That way, separator components are always found at the same relative indices within the result list (e.g., if there's one capturing group in the separator, the 0th, the 2nd and so forth).

Note that *split* will never split a string on an empty pattern match. For example:

```
>>> re.split('x*', 'foo')
['foo']
>>> re.split("(?m)^\$", "foo\n\nbar\n")
```

```
['foo\n\nbar\n']
```

Changed in version 3.1: Added the optional flags argument.

re. **findall**(*pattern*, *string*, *flags=0*)

Return all non-overlapping matches of *pattern* in *string*, as a list of strings. The *string* is scanned left-to-right, and matches are returned in the order found. If one or more groups are present in the pattern, return a list of groups; this will be a list of tuples if the pattern has more than one group. Empty matches are included in the result unless they touch the beginning of another match.

re. **finditer**(*pattern*, *string*, *flags=0*)

Return an *iterator* yielding *match objects* over all non-overlapping matches for the RE *pattern* in *string*. The *string* is scanned left-to-right, and matches are returned in the order found. Empty matches are included in the result unless they touch the beginning of another match.

re. **sub**(*pattern*, *repl*, *string*, *count=0*, *flags=0*)

Return the string obtained by replacing the leftmost non-overlapping occurrences of *pattern* in *string* by the replacement *repl*. If the pattern isn't found, *string* is returned unchanged. *repl* can be a string or a function; if it is a string, any backslash escapes in it are processed. That is, `\n` is converted to a single newline character, `\r` is converted to a linefeed, and so forth. Unknown escapes such as `\j` are left alone. Backreferences, such as `\6`, are replaced with the substring matched by group 6 in the pattern. For example:

```
>>> re.sub(r'def\s+([a-zA-Z_][a-zA-Z_0-9]*)\s*\s*:',  
...       r'static PyObject*\npy_\1(void)\n{',  
...       'def myfunc():')  
'static PyObject*\npy_myfunc(void)\n{'
```

If *repl* is a function, it is called for every non-overlapping

occurrence of *pattern*. The function takes a single match object argument, and returns the replacement string. For example:

```
>>> def dashrepl(matchobj):
...     if matchobj.group(0) == '-': return ' '
...     else: return '-'
>>> re.sub('-{1,2}', dashrepl, 'pro----gram-files')
'pro--gram files'
>>> re.sub(r'\sAND\s', ' & ', 'Baked Beans And Spam', flags=
'Baked Beans & Spam'
```

The pattern may be a string or an RE object.

The optional argument *count* is the maximum number of pattern occurrences to be replaced; *count* must be a non-negative integer. If omitted or zero, all occurrences will be replaced. Empty matches for the pattern are replaced only when not adjacent to a previous match, so `sub('x*', '-', 'abc')` returns `'-a-b-c-'`.

In addition to character escapes and backreferences as described above, `\g<name>` will use the substring matched by the group named *name*, as defined by the `(?P<name>...)` syntax. `\g<number>` uses the corresponding group number; `\g<2>` is therefore equivalent to `\2`, but isn't ambiguous in a replacement such as `\g<2>0`. `\20` would be interpreted as a reference to group 20, not a reference to group 2 followed by the literal character `'0'`. The backreference `\g<0>` substitutes in the entire substring matched by the RE.

Changed in version 3.1: Added the optional flags argument.

re. **subn**(*pattern*, *repl*, *string*, *count=0*, *flags=0*)

Perform the same operation as `sub()`, but return a tuple `(new_string, number_of_subs_made)`.

Changed in version 3.1: Added the optional flags argument.

re. **escape**(*string*)

Return *string* with all non-alphanumerics backslashed; this is useful if you want to match an arbitrary literal string that may have regular expression metacharacters in it.

re. **purge**()

Clear the regular expression cache.

exception re. **error**

Exception raised when a string passed to one of the functions here is not a valid regular expression (for example, it might contain unmatched parentheses) or when some other error occurs during compilation or matching. It is never an error if a string contains no match for a pattern.

6.2.4. Regular Expression Objects

Compiled regular expression objects support the following methods and attributes.

`regex.search(string[, pos[, endpos]])`

Scan through *string* looking for a location where this regular expression produces a match, and return a corresponding *match object*. Return `None` if no position in the string matches the pattern; note that this is different from finding a zero-length match at some point in the string.

The optional second parameter *pos* gives an index in the string where the search is to start; it defaults to `0`. This is not completely equivalent to slicing the string; the `'^'` pattern character matches at the real beginning of the string and at positions just after a newline, but not necessarily at the index where the search is to start.

The optional parameter *endpos* limits how far the string will be searched; it will be as if the string is *endpos* characters long, so only the characters from *pos* to `endpos - 1` will be searched for a match. If *endpos* is less than *pos*, no match will be found, otherwise, if *rx* is a compiled regular expression object, `rx.search(string, 0, 50)` is equivalent to `rx.search(string[:50], 0)`.

```
>>> pattern = re.compile("d")
>>> pattern.search("dog")      # Match at index 0
<_sre.SRE_Match object at ...>
>>> pattern.search("dog", 1)  # No match; search doesn't inc
```

`regex.match(string[, pos[, endpos]])`

If zero or more characters at the *beginning* of *string* match this regular expression, return a corresponding *match object*. Return `None` if the string does not match the pattern; note that this is different from a zero-length match.

The optional *pos* and *endpos* parameters have the same meaning as for the `search()` method.

Note: If you want to locate a match anywhere in *string*, use `search()` instead.

```
>>> pattern = re.compile("o")
>>> pattern.match("dog")      # No match as "o" is not at th
>>> pattern.match("dog", 1)   # Match as "o" is the 2nd char
<_sre.SRE_Match object at ...>
```

`regex.split(string, maxsplit=0)`

Identical to the `split()` function, using the compiled pattern.

`regex.findall(string[, pos[, endpos]])`

Similar to the `findall()` function, using the compiled pattern, but also accepts optional *pos* and *endpos* parameters that limit the search region like for `match()`.

`regex.finditer(string[, pos[, endpos]])`

Similar to the `finditer()` function, using the compiled pattern, but also accepts optional *pos* and *endpos* parameters that limit the search region like for `match()`.

`regex.sub(repl, string, count=0)`

Identical to the `sub()` function, using the compiled pattern.

`regex.subn(repl, string, count=0)`

Identical to the `subn()` function, using the compiled pattern.

`regex.flags`

The flags argument used when the RE object was compiled, or `0` if no flags were provided.

`regex.groups`

The number of capturing groups in the pattern.

`regex.groupindex`

A dictionary mapping any symbolic group names defined by `(?P<id>)` to group numbers. The dictionary is empty if no symbolic groups were used in the pattern.

`regex.pattern`

The pattern string from which the RE object was compiled.

6.2.5. Match Objects

Match objects always have a boolean value of `True`, so that you can test whether e.g. `match()` resulted in a match with a simple if statement. They support the following methods and attributes:

`match.expand(template)`

Return the string obtained by doing backslash substitution on the template string *template*, as done by the `sub()` method. Escapes such as `\n` are converted to the appropriate characters, and numeric backreferences (`\1`, `\2`) and named backreferences (`\g<1>`, `\g<name>`) are replaced by the contents of the corresponding group.

`match.group([group1, ...])`

Returns one or more subgroups of the match. If there is a single argument, the result is a single string; if there are multiple arguments, the result is a tuple with one item per argument. Without arguments, *group1* defaults to zero (the whole match is returned). If a *groupN* argument is zero, the corresponding return value is the entire matching string; if it is in the inclusive range `[1..99]`, it is the string matching the corresponding parenthesized group. If a group number is negative or larger than the number of groups defined in the pattern, an `IndexError` exception is raised. If a group is contained in a part of the pattern that did not match, the corresponding result is `None`. If a group is contained in a part of the pattern that matched multiple times, the last match is returned.

```
>>> m = re.match(r"(\w+) (\w+)", "Isaac Newton, physicist")
>>> m.group(0)          # The entire match
'Isaac Newton'
>>> m.group(1)          # The first parenthesized subgroup.
```

```
'Isaac'  
>>> m.group(2)          # The second parenthesized subgroup.  
'Newton'  
>>> m.group(1, 2)      # Multiple arguments give us a tuple.  
('Isaac', 'Newton')
```

If the regular expression uses the `(?P<name>...)` syntax, the `groupN` arguments may also be strings identifying groups by their group name. If a string argument is not used as a group name in the pattern, an `IndexError` exception is raised.

A moderately complicated example:

```
>>> m = re.match(r"(?P<first_name>\w+) (?P<last_name>\w+)",  
>>> m.group('first_name')  
'Malcolm'  
>>> m.group('last_name')  
'Reynolds'
```

Named groups can also be referred to by their index:

```
>>> m.group(1)  
'Malcolm'  
>>> m.group(2)  
'Reynolds'
```

If a group matches multiple times, only the last match is accessible:

```
>>> m = re.match(r"(..)+", "a1b2c3") # Matches 3 times.  
>>> m.group(1)                       # Returns only the las  
'c3'
```

`match.groups(default=None)`

Return a tuple containing all the subgroups of the match, from 1 up to however many groups are in the pattern. The `default` argument is used for groups that did not participate in the match; it defaults to `None`.

For example:

```
>>> m = re.match(r"(\d+)\.(\d+)", "24.1632")
>>> m.groups()
('24', '1632')
```

If we make the decimal place and everything after it optional, not all groups might participate in the match. These groups will default to `None` unless the *default* argument is given:

```
>>> m = re.match(r"(\d+)\.?(?!\d+)?", "24")
>>> m.groups()          # Second group defaults to None.
('24', None)
>>> m.groups('0')     # Now, the second group defaults to '0'.
('24', '0')
```

`match.groupdict(default=None)`

Return a dictionary containing all the *named* subgroups of the match, keyed by the subgroup name. The *default* argument is used for groups that did not participate in the match; it defaults to `None`. For example:

```
>>> m = re.match(r"(?P<first_name>\w+) (?P<last_name>\w+)",
>>> m.groupdict()
{'first_name': 'Malcolm', 'last_name': 'Reynolds'}
```

`match.start([group])`

`match.end([group])`

Return the indices of the start and end of the substring matched by *group*; *group* defaults to zero (meaning the whole matched substring). Return `-1` if *group* exists but did not contribute to the match. For a match object *m*, and a group *g* that did contribute to the match, the substring matched by group *g* (equivalent to `m.group(g)`) is

```
m.string[m.start(g):m.end(g)]
```

Note that `m.start(group)` will equal `m.end(group)` if `group` matched a null string. For example, after `m = re.search('b(c?)', 'cba')`, `m.start(0)` is 1, `m.end(0)` is 2, `m.start(1)` and `m.end(1)` are both 2, and `m.start(2)` raises an `IndexError` exception.

An example that will remove `remove_this` from email addresses:

```
>>> email = "tony@tiremove_thisger.net"
>>> m = re.search("remove_this", email)
>>> email[:m.start()] + email[m.end():]
'tony@tiger.net'
```

`match.span([group])`

For a match `m`, return the 2-tuple `(m.start(group), m.end(group))`. Note that if `group` did not contribute to the match, this is `(-1, -1)`. `group` defaults to zero, the entire match.

`match.pos`

The value of `pos` which was passed to the `search()` or `match()` method of a *match object*. This is the index into the string at which the RE engine started looking for a match.

`match.endpos`

The value of `endpos` which was passed to the `search()` or `match()` method of a *match object*. This is the index into the string beyond which the RE engine will not go.

`match.lastindex`

The integer index of the last matched capturing group, or `None` if no group was matched at all. For example, the expressions `(a)b`, `((a)(b))`, and `((ab))` will have `lastindex == 1` if applied to the string `'ab'`, while the expression `(a)(b)` will have `lastindex ==`

2, if applied to the same string.

`match.lastgroup`

The name of the last matched capturing group, or `None` if the group didn't have a name, or if no group was matched at all.

`match.re`

The regular expression object whose `match()` or `search()` method produced this match instance.

`match.string`

The string passed to `match()` or `search()`.

6.2.6. Regular Expression Examples

6.2.6.1. Checking For a Pair

In this example, we'll use the following helper function to display match objects a little more gracefully:

```
def displaymatch(match):  
    if match is None:  
        return None  
    return '<Match: %r, groups=%r>' % (match.group(), match.gro
```

Suppose you are writing a poker program where a player's hand is represented as a 5-character string with each character representing a card, "a" for ace, "k" for king, "q" for queen, j for jack, "0" for 10, and "1" through "9" representing the card with that value.

To see if a given string is a valid hand, one could do the following:

```
>>> valid = re.compile(r"[0-9akqj]{5}$")  
>>> displaymatch(valid.match("ak05q")) # Valid.  
<Match: 'ak05q', groups=()>  
>>> displaymatch(valid.match("ak05e")) # Invalid.  
>>> displaymatch(valid.match("ak0")) # Invalid.  
>>> displaymatch(valid.match("727ak")) # Valid.  
<Match: '727ak', groups=()>
```

That last hand, "727ak", contained a pair, or two of the same valued cards. To match this with a regular expression, one could use backreferences as such:

```
>>> pair = re.compile(r".*(.)*\1")  
>>> displaymatch(pair.match("717ak")) # Pair of 7s.  
<Match: '717', groups=('7',)>  
>>> displaymatch(pair.match("718ak")) # No pairs.  
>>> displaymatch(pair.match("354aa")) # Pair of aces.  
<Match: '354aa', groups=('a',)>
```

To find out what card the pair consists of, one could use the `group()` method of the match object in the following manner:

```
>>> pair.match("717ak").group(1)
'7'

# Error because re.match() returns None, which doesn't have a g
>>> pair.match("718ak").group(1)
Traceback (most recent call last):
  File "<pyshell#23>", line 1, in <module>
    re.match(r".*(.)*\1", "718ak").group(1)
AttributeError: 'NoneType' object has no attribute 'group'

>>> pair.match("354aa").group(1)
'a'
```

6.2.6.2. Simulating scanf()

Python does not currently have an equivalent to `scanf()`. Regular expressions are generally more powerful, though also more verbose, than `scanf()` format strings. The table below offers some more-or-less equivalent mappings between `scanf()` format tokens and regular expressions.

scanf() Token	Regular Expression
%c	.
%5c	.{5}
%d	[-+]? \d+
%e, %E, %f, %g	[-+]? (\d+(\.\d*)? \.\d+)([eE][-+]? \d+)?
%i	[-+]? (0[xX][\dA-Fa-f]+ 0[0-7]* \d+)
%o	0[0-7]*
%s	\S+
%u	\d+
%x, %X	0[xX][\dA-Fa-f]+

To extract the filename and numbers from a string like

```
/usr/sbin/sendmail - 0 errors, 4 warnings
```

you would use a `scanf()` format like

```
%s - %d errors, %d warnings
```

The equivalent regular expression would be

```
(\S+) - (\d+) errors, (\d+) warnings
```

6.2.6.3. Avoiding recursion

If you create regular expressions that require the engine to perform a lot of recursion, you may encounter a `RuntimeError` exception with the message `maximum recursion limit exceeded`. For example,

```
>>> s = 'Begin ' + 1000*'a very long string ' + 'end'
>>> re.match('Begin (\w| )*? end', s).end()
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
  File "/usr/local/lib/python3.2/re.py", line 132, in match
    return _compile(pattern, flags).match(string)
RuntimeError: maximum recursion limit exceeded
```

You can often restructure your regular expression to avoid recursion.

Simple uses of the `*?` pattern are special-cased to avoid recursion. Thus, the above regular expression can avoid recursion by being recast as `Begin [a-zA-Z0-9_]*?end`. As a further benefit, such regular expressions will run faster than their recursive equivalents.

6.2.6.4. `search()` vs. `match()`

In a nutshell, `match()` only attempts to match a pattern at the beginning of a string where `search()` will match a pattern anywhere in a string. For example:

```
>>> re.match("o", "dog") # No match as "o" is not the first le
>>> re.search("o", "dog") # Match as search() looks everywhere
<_sre.SRE_Match object at ...>
```

Note: The following applies only to regular expression objects like those created with `re.compile("pattern")`, not the primitives `re.match(pattern, string)` or `re.search(pattern, string)`.

`match()` has an optional second parameter that gives an index in the string where the search is to start:

```
>>> pattern = re.compile("o")
>>> pattern.match("dog") # No match as "o" is not at the s

# Equivalent to the above expression as 0 is the default starti
>>> pattern.match("dog", 0)

# Match as "o" is the 2nd character of "dog" (index 0 is the fi
>>> pattern.match("dog", 1)
<_sre.SRE_Match object at ...>
>>> pattern.match("dog", 2) # No match as "o" is not the 3rd
```

6.2.6.5. Making a Phonebook

`split()` splits a string into a list delimited by the passed pattern. The method is invaluable for converting textual data into data structures that can be easily read and modified by Python as demonstrated in the following example that creates a phonebook.

First, here is the input. Normally it may come from a file, here we are using triple-quoted string syntax:

```
>>> input = """Ross McFluff: 834.345.1254 155 Elm Street
...
... Ronald Heathmore: 892.345.3428 436 Finley Avenue
... Frank Burger: 925.541.7625 662 South Dogwood Way
...
```

```
...  
... Heather Albrecht: 548.326.4584 919 Park Place"""
```

The entries are separated by one or more newlines. Now we convert the string into a list with each nonempty line having its own entry:

```
>>> entries = re.split("\n+", input)  
>>> entries  
['Ross McFluff: 834.345.1254 155 Elm Street',  
'Ronald Heathmore: 892.345.3428 436 Finley Avenue',  
'Frank Burger: 925.541.7625 662 South Dogwood Way',  
'Heather Albrecht: 548.326.4584 919 Park Place']
```

Finally, split each entry into a list with first name, last name, telephone number, and address. We use the `maxsplit` parameter of `split()` because the address has spaces, our splitting pattern, in it:

```
>>> [re.split("?:? ", entry, 3) for entry in entries]  
[['Ross', 'McFluff', '834.345.1254', '155 Elm Street'],  
 ['Ronald', 'Heathmore', '892.345.3428', '436 Finley Avenue'],  
 ['Frank', 'Burger', '925.541.7625', '662 South Dogwood Way'],  
 ['Heather', 'Albrecht', '548.326.4584', '919 Park Place']]
```

The `?:?` pattern matches the colon after the last name, so that it does not occur in the result list. With a `maxsplit` of 4, we could separate the house number from the street name:

```
>>> [re.split("?:? ", entry, 4) for entry in entries]  
[['Ross', 'McFluff', '834.345.1254', '155', 'Elm Street'],  
 ['Ronald', 'Heathmore', '892.345.3428', '436', 'Finley Avenue'],  
 ['Frank', 'Burger', '925.541.7625', '662', 'South Dogwood Way'],  
 ['Heather', 'Albrecht', '548.326.4584', '919', 'Park Place']]
```

6.2.6.6. Text Munging

`sub()` replaces every occurrence of a pattern with a string or the result of a function. This example demonstrates using `sub()` with a

function to “munge” text, or randomize the order of all the characters in each word of a sentence except for the first and last characters:

```
>>> def repl(m):
...     inner_word = list(m.group(2))
...     random.shuffle(inner_word)
...     return m.group(1) + "".join(inner_word) + m.group(3)
>>> text = "Professor Abdolmalek, please report your absences p
>>> re.sub(r"(\w)(\w+)(\w)", repl, text)
'Poefsrosr Aealmlobdk, pslae reorpt your abnseces plmrptoy.'
>>> re.sub(r"(\w)(\w+)(\w)", repl, text)
'Pofsroser Aodlambelk, plasee reorpt yuor asnebc es potlmpy.'
```

6.2.6.7. Finding all Adverbs

`findall()` matches *all* occurrences of a pattern, not just the first one as `search()` does. For example, if one was a writer and wanted to find all of the adverbs in some text, he or she might use `findall()` in the following manner:

```
>>> text = "He was carefully disguised but captured quickly by
>>> re.findall(r"\w+ly", text)
['carefully', 'quickly']
```

6.2.6.8. Finding all Adverbs and their Positions

If one wants more information about all matches of a pattern than the matched text, `finditer()` is useful as it provides *match objects* instead of strings. Continuing with the previous example, if one was a writer who wanted to find all of the adverbs *and their positions* in some text, he or she would use `finditer()` in the following manner:

```
>>> text = "He was carefully disguised but captured quickly by
>>> for m in re.finditer(r"\w+ly", text):
...     print('%02d-%02d: %s' % (m.start(), m.end(), m.group(0)))
07-16: carefully
```

```
40-47: quickly
```

6.2.6.9. Raw String Notation

Raw string notation (`r"text"`) keeps regular expressions sane. Without it, every backslash (`'\'`) in a regular expression would have to be prefixed with another one to escape it. For example, the two following lines of code are functionally identical:

```
>>> re.match(r"\W(.)\1\W", " ff ")
<_sre.SRE_Match object at ...>
>>> re.match("\\W(.)\\1\\W", " ff ")
<_sre.SRE_Match object at ...>
```

When one wants to match a literal backslash, it must be escaped in the regular expression. With raw string notation, this means `r"\"`. Without raw string notation, one must use `"\\\"`, making the following lines of code functionally identical:

```
>>> re.match(r"\"", r"\"")
<_sre.SRE_Match object at ...>
>>> re.match("\\\"", r"\"")
<_sre.SRE_Match object at ...>
```

6.2.6.10. Writing a Tokenizer

A [tokenizer](#) or [scanner](#) analyzes a string to categorize groups of characters. This is a useful first step in writing a compiler or interpreter.

The text categories are specified with regular expressions. The technique is to combine those into a single master regular expression and to loop over successive matches:

```
Token = collections.namedtuple('Token', 'typ value line column')
```

```

def tokenize(s):
    keywords = {'IF', 'THEN', 'FOR', 'NEXT', 'GOSUB', 'RETURN'}
    tok_spec = [
        ('NUMBER', r'\d+(\.\d*)?'), # Integer or decimal number
        ('ASSIGN', r':='),          # Assignment operator
        ('END', ';'),               # Statement terminator
        ('ID', r'[A-Za-z]+'),       # Identifiers
        ('OP', r'[+*\./\^-]'),      # Arithmetic operators
        ('NEWLINE', r'\n'),         # Line endings
        ('SKIP', r'[ \t]'),         # Skip over spaces and tabs
    ]
    tok_re = '|'.join('(P<%s>%s)' % pair for pair in tok_spec)
    gettok = re.compile(tok_re).match
    line = 1
    pos = line_start = 0
    mo = gettok(s)
    while mo is not None:
        typ = mo.lastgroup
        if typ == 'NEWLINE':
            line_start = pos
            line += 1
        elif typ != 'SKIP':
            if typ == 'ID' and val in keywords:
                typ = val
            yield Token(typ, mo.group(typ), line, mo.start()-li
            pos = mo.end()
            mo = gettok(s, pos)
    if pos != len(s):
        raise RuntimeError('Unexpected character %r on line %d'

>>> statements = '''\
total := total + price * quantity;
tax := price * 0.05;
...
>>> for token in tokenize(statements):
...     print(token)
...
Token(typ='ID', value='total', line=1, column=8)
Token(typ='ASSIGN', value=':=', line=1, column=14)
Token(typ='ID', value='total', line=1, column=17)
Token(typ='OP', value='+', line=1, column=23)
Token(typ='ID', value='price', line=1, column=25)
Token(typ='OP', value='*', line=1, column=31)
Token(typ='ID', value='quantity', line=1, column=33)
Token(typ='END', value=';', line=1, column=41)
Token(typ='ID', value='tax', line=2, column=9)
Token(typ='ASSIGN', value=':=', line=2, column=13)

```

```
Token(typ='ID', value='price', line=2, column=16)
Token(typ='OP', value='*', line=2, column=22)
Token(typ='NUMBER', value='0.05', line=2, column=24)
Token(typ='END', value=';', line=2, column=28)
```

 [Python v3.2 documentation](#) » [The Python Standard Library](#) [previous](#) | [next](#) | [modules](#) | [index](#)

» [6. String Services](#) »

6.3. struct — Interpret bytes as packed binary data

This module performs conversions between Python values and C structs represented as Python `bytes` objects. This can be used in handling binary data stored in files or from network connections, among other sources. It uses *Format Strings* as compact descriptions of the layout of the C structs and the intended conversion to/from Python values.

Note: By default, the result of packing a given C struct includes pad bytes in order to maintain proper alignment for the C types involved; similarly, alignment is taken into account when unpacking. This behavior is chosen so that the bytes of a packed struct correspond exactly to the layout in memory of the corresponding C struct. To handle platform-independent data formats or omit implicit pad bytes, use `standard` size and alignment instead of `native` size and alignment: see *Byte Order, Size, and Alignment* for details.

6.3.1. Functions and Exceptions

The module defines the following exception and functions:

exception `struct.error`

Exception raised on various occasions; argument is a string describing what is wrong.

`struct.pack(fmt, v1, v2, ...)`

Return a bytes object containing the values *v1*, *v2*, ... packed according to the format string *fmt*. The arguments must match the values required by the format exactly.

`struct.pack_into(fmt, buffer, offset, v1, v2, ...)`

Pack the values *v1*, *v2*, ... according to the format string *fmt* and write the packed bytes into the writable buffer *buffer* starting at position *offset*. Note that *offset* is a required argument.

`struct.unpack(fmt, buffer)`

Unpack from the buffer *buffer* (presumably packed by `pack(fmt, ...)`) according to the format string *fmt*. The result is a tuple even if it contains exactly one item. The buffer must contain exactly the amount of data required by the format (`len(bytes)` must equal `calcsize(fmt)`).

`struct.unpack_from(fmt, buffer, offset=0)`

Unpack from *buffer* starting at position *offset*, according to the format string *fmt*. The result is a tuple even if it contains exactly one item. *buffer* must contain at least the amount of data required by the format (`len(buffer[offset:])` must be at least `calcsize(fmt)`).

`struct.calcsize(fmt)`

Return the size of the struct (and hence of the bytes object produced by `pack(fmt, ...)`) corresponding to the format string *fmt*.

6.3.2. Format Strings

Format strings are the mechanism used to specify the expected layout when packing and unpacking data. They are built up from *Format Characters*, which specify the type of data being packed/unpacked. In addition, there are special characters for controlling the *Byte Order, Size, and Alignment*.

6.3.2.1. Byte Order, Size, and Alignment

By default, C types are represented in the machine's native format and byte order, and properly aligned by skipping pad bytes if necessary (according to the rules used by the C compiler).

Alternatively, the first character of the format string can be used to indicate the byte order, size and alignment of the packed data, according to the following table:

Character	Byte order	Size	Alignment
@	native	native	native
=	native	standard	none
<	little-endian	standard	none
>	big-endian	standard	none
!	network (= big-endian)	standard	none

If the first character is not one of these, '@' is assumed.

Native byte order is big-endian or little-endian, depending on the host system. For example, Intel x86 and AMD64 (x86-64) are little-endian; Motorola 68000 and PowerPC G5 are big-endian; ARM and Intel Itanium feature switchable endianness (bi-endian). Use `sys.byteorder` to check the endianness of your system.

Native size and alignment are determined using the C compiler's `sizeof` expression. This is always combined with native byte order.

Standard size depends only on the format character; see the table in the *Format Characters* section.

Note the difference between '@' and '=': both use native byte order, but the size and alignment of the latter is standardized.

The form '!' is available for those poor souls who claim they can't remember whether network byte order is big-endian or little-endian.

There is no way to indicate non-native byte order (force byte-swapping); use the appropriate choice of '<' or '>'.

Notes:

1. Padding is only automatically added between successive structure members. No padding is added at the beginning or the end of the encoded struct.
2. No padding is added when using non-native size and alignment, e.g. with '<', '>', '=', and '!'.
3. To align the end of a structure to the alignment requirement of a particular type, end the format with the code for that type with a repeat count of zero. See *Examples*.

6.3.2.2. Format Characters

Format characters have the following meaning; the conversion between C and Python values should be obvious given their types. The 'Standard size' column refers to the size of the packed value in bytes when using standard size; that is, when the format string starts with one of '<', '>', '!' or '='. When using native size, the size of the packed value is platform-dependent.

Format	C Type	Python type	Standard size	Notes
x	pad byte	no value		
c	char	bytes of length 1	1	
b	signed char	integer	1	(1),(3)
B	unsigned char	integer	1	(3)
?	_Bool	bool	1	(1)
h	short	integer	2	(3)
H	unsigned short	integer	2	(3)
i	int	integer	4	(3)
I	unsigned int	integer	4	(3)
l	long	integer	4	(3)
L	unsigned long	integer	4	(3)
q	long long	integer	8	(2), (3)
Q	unsigned long long	integer	8	(2), (3)
f	float	float	4	(4)
d	double	float	8	(4)
s	char[]	bytes		
p	char[]	bytes		
P	void *	integer		(5)

Notes:

1. The '?' conversion code corresponds to the `_Bool` type defined by C99. If this type is not available, it is simulated using a `char`. In standard mode, it is always represented by one byte.
2. The 'q' and 'Q' conversion codes are available in native mode only if the platform C compiler supports C `long long`, or, on Windows, `__int64`. They are always available in standard modes.

3. When attempting to pack a non-integer using any of the integer conversion codes, if the non-integer has a `__index__()` method then that method is called to convert the argument to an integer before packing.

Changed in version 3.2: Use of the `__index__()` method for non-integers is new in 3.2.

4. For the `'f'` and `'d'` conversion codes, the packed representation uses the IEEE 754 binary32 (for `'f'`) or binary64 (for `'d'`) format, regardless of the floating-point format used by the platform.
5. The `'P'` format character is only available for the native byte ordering (selected as the default or with the `'@'` byte order character). The byte order character `'='` chooses to use little- or big-endian ordering based on the host system. The `struct` module does not interpret this as native ordering, so the `'P'` format is not available.

A format character may be preceded by an integral repeat count. For example, the format string `'4h'` means exactly the same as `'hhhh'`.

Whitespace characters between formats are ignored; a count and its format must not contain whitespace though.

For the `'s'` format character, the count is interpreted as the length of the bytes, not a repeat count like for the other format characters; for example, `'10s'` means a single 10-byte string, while `'10c'` means 10 characters. For packing, the string is truncated or padded with null bytes as appropriate to make it fit. For unpacking, the resulting bytes object always has exactly the specified number of bytes. As a special case, `'0s'` means a single, empty string (while `'0c'` means 0 characters).

When packing a value `x` using one of the integer formats (`'b'`, `'B'`, `'h'`, `'H'`, `'i'`, `'I'`, `'l'`, `'L'`, `'q'`, `'Q'`), if `x` is outside the valid range for that format then `struct.error` is raised.

Changed in version 3.1: In 3.0, some of the integer formats wrapped out-of-range values and raised `DeprecationWarning` instead of `struct.error`.

The `'p'` format character encodes a “Pascal string”, meaning a short variable-length string stored in a *fixed number of bytes*, given by the count. The first byte stored is the length of the string, or 255, whichever is smaller. The bytes of the string follow. If the string passed in to `pack()` is too long (longer than the count minus 1), only the leading `count-1` bytes of the string are stored. If the string is shorter than `count-1`, it is padded with null bytes so that exactly count bytes in all are used. Note that for `unpack()`, the `'p'` format character consumes `count` bytes, but that the string returned can never contain more than 255 bytes.

For the `'?'` format character, the return value is either `True` or `False`. When packing, the truth value of the argument object is used. Either 0 or 1 in the native or standard bool representation will be packed, and any non-zero value will be True when unpacking.

6.3.2.3. Examples

Note: All examples assume a native byte order, size, and alignment with a big-endian machine.

A basic example of packing/unpacking three integers:

```
>>> from struct import *
>>> pack('hhl', 1, 2, 3)
b'\x00\x01\x00\x02\x00\x00\x00\x03'
```

```
>>> unpack('hh1', b'\x00\x01\x00\x02\x00\x00\x00\x03')
(1, 2, 3)
>>> calcsize('hh1')
8
```

Unpacked fields can be named by assigning them to variables or by wrapping the result in a named tuple:

```
>>> record = b'raymond \x32\x12\x08\x01\x08'
>>> name, serialnum, school, gradelevel = unpack('<10sHHb', record)

>>> from collections import namedtuple
>>> Student = namedtuple('Student', 'name serialnum school gradelevel')
>>> Student._make(unpack('<10sHHb', record))
Student(name=b'raymond ', serialnum=4658, school=264, gradelevel=8)
```

The ordering of format characters may have an impact on size since the padding needed to satisfy alignment requirements is different:

```
>>> pack('ci', b'*', 0x12131415)
b'*\x00\x00\x00\x12\x13\x14\x15'
>>> pack('ic', 0x12131415, b'*')
b'\x12\x13\x14\x15*'
>>> calcsize('ci')
8
>>> calcsize('ic')
5
```

The following format `'llh01'` specifies two pad bytes at the end, assuming longs are aligned on 4-byte boundaries:

```
>>> pack('llh01', 1, 2, 3)
b'\x00\x00\x00\x01\x00\x00\x00\x02\x00\x03\x00\x00'
```

This only works when native size and alignment are in effect; standard size and alignment does not enforce any alignment.

See also:

Module `array`

Packed binary storage of homogeneous data.

Module `xdrlib`

Packing and unpacking of XDR data.

6.3.3. Classes

The `struct` module also defines the following type:

`class struct.Struct(format)`

Return a new Struct object which writes and reads binary data according to the format string *format*. Creating a Struct object once and calling its methods is more efficient than calling the `struct` functions with the same format since the format string only needs to be compiled once.

Compiled Struct objects support the following methods and attributes:

`pack(v1, v2, ...)`

Identical to the `pack()` function, using the compiled format. (`len(result)` will equal `self.size`.)

`pack_into(buffer, offset, v1, v2, ...)`

Identical to the `pack_into()` function, using the compiled format.

`unpack(buffer)`

Identical to the `unpack()` function, using the compiled format. (`len(buffer)` must equal `self.size`.)

`unpack_from(buffer, offset=0)`

Identical to the `unpack_from()` function, using the compiled format. (`len(buffer[offset:])` must be at least `self.size`.)

`format`

The format string used to construct this Struct object.

size

The calculated size of the struct (and hence of the bytes object produced by the `pack()` method) corresponding to `format`.

6.4. `difflib` — Helpers for computing deltas

This module provides classes and functions for comparing sequences. It can be used for example, for comparing files, and can produce difference information in various formats, including HTML and context and unified diffs. For comparing directories and files, see also, the `filecmp` module.

`class difflib.SequenceMatcher`

This is a flexible class for comparing pairs of sequences of any type, so long as the sequence elements are *hashable*. The basic algorithm predates, and is a little fancier than, an algorithm published in the late 1980's by Ratcliff and Obershelp under the hyperbolic name “gestalt pattern matching.” The idea is to find the longest contiguous matching subsequence that contains no “junk” elements (the Ratcliff and Obershelp algorithm doesn't address junk). The same idea is then applied recursively to the pieces of the sequences to the left and to the right of the matching subsequence. This does not yield minimal edit sequences, but does tend to yield matches that “look right” to people.

Timing: The basic Ratcliff-Obershelp algorithm is cubic time in the worst case and quadratic time in the expected case. `SequenceMatcher` is quadratic time for the worst case and has expected-case behavior dependent in a complicated way on how many elements the sequences have in common; best case time is linear.

Automatic junk heuristic: `SequenceMatcher` supports a heuristic that automatically treats certain sequence items as junk. The heuristic counts how many times each individual item appears in

the sequence. If an item's duplicates (after the first one) account for more than 1% of the sequence and the sequence is at least 200 items long, this item is marked as "popular" and is treated as junk for the purpose of sequence matching. This heuristic can be turned off by setting the `autojunk` argument to `False` when creating the `SequenceMatcher`.

New in version 3.2: The `autojunk` parameter.

`class difflib.Differ`

This is a class for comparing sequences of lines of text, and producing human-readable differences or deltas. Differ uses `SequenceMatcher` both to compare sequences of lines, and to compare sequences of characters within similar (near-matching) lines.

Each line of a `Differ` delta begins with a two-letter code:

Code	Meaning
'- '	line unique to sequence 1
'+ '	line unique to sequence 2
' ' '	line common to both sequences
'? '	line not present in either input sequence

Lines beginning with '?' attempt to guide the eye to intraline differences, and were not present in either input sequence. These lines can be confusing if the sequences contain tab characters.

`class difflib.HtmlDiff`

This class can be used to create an HTML table (or a complete HTML file containing the table) showing a side by side, line by line comparison of text with inter-line and intra-line change highlights. The table can be generated in either full or contextual

difference mode.

The constructor for this class is:

```
__init__(tabsize=8, wrapcolumn=None, linejunk=None, charjunk=IS_CHARACTER_JUNK)
```

Initializes instance of `HtmlDiff`.

tabsize is an optional keyword argument to specify tab stop spacing and defaults to `8`.

wrapcolumn is an optional keyword to specify column number where lines are broken and wrapped, defaults to `None` where lines are not wrapped.

linejunk and *charjunk* are optional keyword arguments passed into `ndiff()` (used by `HtmlDiff` to generate the side by side HTML differences). See `ndiff()` documentation for argument default values and descriptions.

The following methods are public:

```
make_file(fromlines, tolines, fromdesc="", todesc="", context=False, numlines=5)
```

Compares *fromlines* and *tolines* (lists of strings) and returns a string which is a complete HTML file containing a table showing line by line differences with inter-line and intra-line changes highlighted.

fromdesc and *todesc* are optional keyword arguments to specify from/to file column header strings (both default to an empty string).

context and *numlines* are both optional keyword arguments. Set *context* to `True` when contextual differences are to be

shown, else the default is `False` to show the full files. `numlines` defaults to `5`. When `context` is `True` `numlines` controls the number of context lines which surround the difference highlights. When `context` is `False` `numlines` controls the number of lines which are shown before a difference highlight when using the “next” hyperlinks (setting to zero would cause the “next” hyperlinks to place the next difference highlight at the top of the browser without any leading context).

```
make_table(fromlines, tolines, fromdesc="", todesc="",  
context=False, numlines=5)
```

Compares *fromlines* and *tolines* (lists of strings) and returns a string which is a complete HTML table showing line by line differences with inter-line and intra-line changes highlighted.

The arguments for this method are the same as those for the `make_file()` method.

`Tools/scripts/diff.py` is a command-line front-end to this class and contains a good example of its use.

```
difflib.context_diff(a, b, fromfile="", tofile="", fromfiledate="",  
tofiledate="", n=3, lineterm='\n')
```

Compare *a* and *b* (lists of strings); return a delta (a *generator* generating the delta lines) in context diff format.

Context diffs are a compact way of showing just the lines that have changed plus a few lines of context. The changes are shown in a before/after style. The number of context lines is set by *n* which defaults to three.

By default, the diff control lines (those with `***` or `---`) are created with a trailing newline. This is helpful so that inputs

created from `file.readlines()` result in diffs that are suitable for use with `file.writelines()` since both the inputs and outputs have trailing newlines.

For inputs that do not have trailing newlines, set the `lineterm` argument to `""` so that the output will be uniformly newline free.

The context diff format normally has a header for filenames and modification times. Any or all of these may be specified using strings for `fromfile`, `tofile`, `fromfiledate`, and `tofiledate`. The modification times are normally expressed in the ISO 8601 format. If not specified, the strings default to blanks.

```
>>> s1 = ['bacon\n', 'eggs\n', 'ham\n', 'guido\n']
>>> s2 = ['python\n', 'eggy\n', 'hamster\n', 'guido\n']
>>> for line in context_diff(s1, s2, fromfile='before.py', tofile='after.py'):
...     sys.stdout.write(line)
*** before.py
--- after.py
*****
*** 1,4 ****
! bacon
! eggs
! ham
  guido
--- 1,4 ----
! python
! eggy
! hamster
  guido
```

See [A command-line interface to difflib](#) for a more detailed example.

`difflib.get_close_matches(word, possibilities, n=3, cutoff=0.6)`

Return a list of the best “good enough” matches. `word` is a sequence for which close matches are desired (typically a string), and `possibilities` is a list of sequences against which to match

word (typically a list of strings).

Optional argument *n* (default 3) is the maximum number of close matches to return; *n* must be greater than 0.

Optional argument *cutoff* (default 0.6) is a float in the range [0, 1]. Possibilities that don't score at least that similar to *word* are ignored.

The best (no more than *n*) matches among the possibilities are returned in a list, sorted by similarity score, most similar first.

```
>>> get_close_matches('appel', ['ape', 'apple', 'peach', 'pu
['apple', 'ape']
>>> import keyword
>>> get_close_matches('wheel', keyword.kwlist)
['while']
>>> get_close_matches('apple', keyword.kwlist)
[]
>>> get_close_matches('accept', keyword.kwlist)
['except']
```

`difflib.ndiff(a, b, linejunk=None, charjunk=IS_CHARACTER_JUNK)`

Compare *a* and *b* (lists of strings); return a **Differ**-style delta (a *generator* generating the delta lines).

Optional keyword parameters *linejunk* and *charjunk* are for filter functions (or **None**):

linejunk: A function that accepts a single string argument, and returns true if the string is junk, or false if not. The default is **None**. There is also a module-level function `IS_LINE_JUNK()`, which filters out lines without visible characters, except for at most one pound character ('#') – however the underlying **SequenceMatcher** class does a dynamic analysis of which lines are so frequent as

to constitute noise, and this usually works better than using this function.

charjunk: A function that accepts a character (a string of length 1), and returns if the character is junk, or false if not. The default is module-level function `IS_CHARACTER_JUNK()`, which filters out whitespace characters (a blank or tab; note: bad idea to include newline in this!).

`Tools/scripts/ndiff.py` is a command-line front-end to this function.

```
>>> diff = ndiff('one\ntwo\nthree\n'.splitlines(1),
...              'ore\ntree\nemu\n'.splitlines(1))
>>> print(''.join(diff), end="")
- one
?  ^
+ ore
?  ^
- two
- three
?  -
+ tree
+ emu
```

`difflib.restore(sequence, which)`

Return one of the two sequences that generated a delta.

Given a *sequence* produced by `Differ.compare()` or `ndiff()`, extract lines originating from file 1 or 2 (parameter *which*), stripping off line prefixes.

Example:

```
>>> diff = ndiff('one\ntwo\nthree\n'.splitlines(1),
...              'ore\ntree\nemu\n'.splitlines(1))
>>> diff = list(diff) # materialize the generated delta into
>>> print(''.join(restore(diff, 1)), end="")
one
```

```
two
three
>>> print(''.join(restore(diff, 2)), end="")
ore
tree
emu
```

`difflib.unified_diff(a, b, fromfile="", tofile="", fromfiledate="", tofiledate="", n=3, lineterm='\n')`

Compare *a* and *b* (lists of strings); return a delta (a *generator* generating the delta lines) in unified diff format.

Unified diffs are a compact way of showing just the lines that have changed plus a few lines of context. The changes are shown in a inline style (instead of separate before/after blocks). The number of context lines is set by *n* which defaults to three.

By default, the diff control lines (those with `---`, `+++`, or `@@`) are created with a trailing newline. This is helpful so that inputs created from `file.readlines()` result in diffs that are suitable for use with `file.writelines()` since both the inputs and outputs have trailing newlines.

For inputs that do not have trailing newlines, set the *lineterm* argument to `""` so that the output will be uniformly newline free.

The context diff format normally has a header for filenames and modification times. Any or all of these may be specified using strings for *fromfile*, *tofile*, *fromfiledate*, and *tofiledate*. The modification times are normally expressed in the ISO 8601 format. If not specified, the strings default to blanks.

```
>>> s1 = ['bacon\n', 'eggs\n', 'ham\n', 'guido\n']
>>> s2 = ['python\n', 'eggy\n', 'hamster\n', 'guido\n']
>>> for line in unified_diff(s1, s2, fromfile='before.py', t
...     sys.stdout.write(line)
--- before.py
```

```
+++ after.py
@@ -1,4 +1,4 @@
-bacon
-eggs
-ham
+python
+eggy
+hamster
  guido
```

See [A command-line interface to `diff`](#) for a more detailed example.

`diff`lib. **IS_LINE_JUNK**(*line*)

Return true for ignorable lines. The line *line* is ignorable if *line* is blank or contains a single '#', otherwise it is not ignorable. Used as a default for parameter *linejunk* in `ndiff()` in older versions.

`diff`lib. **IS_CHARACTER_JUNK**(*ch*)

Return true for ignorable characters. The character *ch* is ignorable if *ch* is a space or tab, otherwise it is not ignorable. Used as a default for parameter *charjunk* in `ndiff()`.

Pattern Matching: The Gestalt Approach

Discussion of a similar algorithm by John W. Ratcliff and D. E. Metzener. This was published in [Dr. Dobb's Journal](#) in July, 1988.

6.4.1. SequenceMatcher Objects

The `SequenceMatcher` class has this constructor:

```
class difflib.SequenceMatcher(isjunk=None, a="", b="",
                               autojunk=True)
```

Optional argument *isjunk* must be `None` (the default) or a one-argument function that takes a sequence element and returns true if and only if the element is “junk” and should be ignored. Passing `None` for *isjunk* is equivalent to passing `lambda x: 0`; in other words, no elements are ignored. For example, pass:

```
lambda x: x in " \t"
```

if you’re comparing lines as sequences of characters, and don’t want to synch up on blanks or hard tabs.

The optional arguments *a* and *b* are sequences to be compared; both default to empty strings. The elements of both sequences must be *hashable*.

The optional argument *autojunk* can be used to disable the automatic junk heuristic.

New in version 3.2: The *autojunk* parameter.

`SequenceMatcher` objects get three data attributes: *bjunk* is the set of elements of *b* for which *isjunk* is `True`; *bpopular* is the set of non-junk elements considered popular by the heuristic (if it is not disabled); *b2j* is a dict mapping the remaining elements of *b* to a list of positions where they occur. All three are reset whenever *b* is reset with `set_seqs()` or `set_seq2()`.

New in version 3.2: The *bjunk* and *bpopular* attributes.

`SequenceMatcher` objects have the following methods:

`set_seqs(a, b)`

Set the two sequences to be compared.

`SequenceMatcher` computes and caches detailed information about the second sequence, so if you want to compare one sequence against many sequences, use `set_seq2()` to set the commonly used sequence once and call `set_seq1()` repeatedly, once for each of the other sequences.

`set_seq1(a)`

Set the first sequence to be compared. The second sequence to be compared is not changed.

`set_seq2(b)`

Set the second sequence to be compared. The first sequence to be compared is not changed.

`find_longest_match(a1o, a1i, b1o, b1i)`

Find longest matching block in `a[a1o:a1i]` and `b[b1o:b1i]`.

If *isjunk* was omitted or `None`, `find_longest_match()` returns `(i, j, k)` such that `a[i:i+k]` is equal to `b[j:j+k]`, where `a1o <= i <= i+k <= a1i` and `b1o <= j <= j+k <= b1i`. For all `(i', j', k')` meeting those conditions, the additional conditions `k >= k'`, `i <= i'`, and if `i == i'`, `j <= j'` are also met. In other words, of all maximal matching blocks, return one that starts earliest in *a*, and of all those maximal matching blocks that start earliest in *a*, return the one that starts earliest in *b*.

```
>>> s = SequenceMatcher(None, "abcd", "abcd abcd")
>>> s.find_longest_match(0, 5, 0, 9)
Match(a=0, b=4, size=5)
```

If *isjunk* was provided, first the longest matching block is determined as above, but with the additional restriction that no junk element appears in the block. Then that block is extended as far as possible by matching (only) junk elements on both sides. So the resulting block never matches on junk except as identical junk happens to be adjacent to an interesting match.

Here's the same example as before, but considering blanks to be junk. That prevents ' abcd' from matching the ' abcd' at the tail end of the second sequence directly. Instead only the 'abcd' can match, and matches the leftmost 'abcd' in the second sequence:

```
>>> s = SequenceMatcher(lambda x: x==" ", " abcd", "abcd")
>>> s.find_longest_match(0, 5, 0, 9)
Match(a=1, b=0, size=4)
```

If no blocks match, this returns (a1o, b1o, 0).

This method returns a *named tuple* Match(a, b, size).

get_matching_blocks()

Return list of triples describing matching subsequences. Each triple is of the form (i, j, n), and means that a[i:i+n] == b[j:j+n]. The triples are monotonically increasing in i and j.

The last triple is a dummy, and has the value (len(a), len(b), 0). It is the only triple with n == 0. If (i, j, n) and (i', j', n') are adjacent triples in the list, and the second is not the last triple in the list, then i+n != i' or j+n != j'; in other words, adjacent triples always describe non-adjacent equal blocks.

```
>>> s = SequenceMatcher(None, "abxcd", "abcd")
>>> s.get_matching_blocks()
[Match(a=0, b=0, size=2), Match(a=3, b=2, size=2), Match(
```

get_opcodes()

Return list of 5-tuples describing how to turn *a* into *b*. Each tuple is of the form (tag, *i1*, *i2*, *j1*, *j2*). The first tuple has *i1* == *j1* == 0, and remaining tuples have *i1* equal to the *i2* from the preceding tuple, and, likewise, *j1* equal to the previous *j2*.

The *tag* values are strings, with these meanings:

Value	Meaning
'replace'	a[<i>i1</i> : <i>i2</i>] should be replaced by b[<i>j1</i> : <i>j2</i>].
'delete'	a[<i>i1</i> : <i>i2</i>] should be deleted. Note that <i>j1</i> == <i>j2</i> in this case.
'insert'	b[<i>j1</i> : <i>j2</i>] should be inserted at a[<i>i1</i> : <i>i1</i>]. Note that <i>i1</i> == <i>i2</i> in this case.
'equal'	a[<i>i1</i> : <i>i2</i>] == b[<i>j1</i> : <i>j2</i>] (the sub-sequences are equal).

For example:

```
>>> a = "qabxcd"
>>> b = "abycdf"
>>> s = SequenceMatcher(None, a, b)
>>> for tag, i1, i2, j1, j2 in s.get_opcodes():
...     print("%7s a[%d:%d] (%s) b[%d:%d] (%s)" %
...           (tag, i1, i2, a[i1:i2], j1, j2, b[j1:j2]))
delete a[0:1] (q) b[0:0] ()
equal a[1:3] (ab) b[0:2] (ab)
replace a[3:4] (x) b[2:3] (y)
equal a[4:6] (cd) b[3:5] (cd)
insert a[6:6] () b[5:6] (f)
```

get_grouped_opcodes(*n*=3)

Return a *generator* of groups with up to n lines of context.

Starting with the groups returned by `get_opcodes()`, this method splits out smaller change clusters and eliminates intervening ranges which have no changes.

The groups are returned in the same format as `get_opcodes()`.

`ratio()`

Return a measure of the sequences' similarity as a float in the range $[0, 1]$.

Where T is the total number of elements in both sequences, and M is the number of matches, this is $2.0 * M / T$. Note that this is `1.0` if the sequences are identical, and `0.0` if they have nothing in common.

This is expensive to compute if `get_matching_blocks()` or `get_opcodes()` hasn't already been called, in which case you may want to try `quick_ratio()` or `real_quick_ratio()` first to get an upper bound.

`quick_ratio()`

Return an upper bound on `ratio()` relatively quickly.

`real_quick_ratio()`

Return an upper bound on `ratio()` very quickly.

The three methods that return the ratio of matching to total characters can give different results due to differing levels of approximation, although `quick_ratio()` and `real_quick_ratio()` are always at least as large as `ratio()`:

```
>>> s = SequenceMatcher(None, "abcd", "bcde")
```

```
>>> s.ratio()
0.75
>>> s.quick_ratio()
0.75
>>> s.real_quick_ratio()
1.0
```

6.4.2. SequenceMatcher Examples

This example compares two strings, considering blanks to be “junk”:

```
>>> s = SequenceMatcher(lambda x: x == " ",  
...                       "private Thread currentThread;",  
...                       "private volatile Thread currentThread;
```

`ratio()` returns a float in `[0, 1]`, measuring the similarity of the sequences. As a rule of thumb, a `ratio()` value over 0.6 means the sequences are close matches:

```
>>> print(round(s.ratio(), 3))  
0.866
```

If you're only interested in where the sequences match, `get_matching_blocks()` is handy:

```
>>> for block in s.get_matching_blocks():  
...     print("a[%d] and b[%d] match for %d elements" % block)  
a[0] and b[0] match for 8 elements  
a[8] and b[17] match for 21 elements  
a[29] and b[38] match for 0 elements
```

Note that the last tuple returned by `get_matching_blocks()` is always a dummy, `(len(a), len(b), 0)`, and this is the only case in which the last tuple element (number of elements matched) is `0`.

If you want to know how to change the first sequence into the second, use `get_opcodes()`:

```
>>> for opcode in s.get_opcodes():  
...     print("%6s a[%d:%d] b[%d:%d]" % opcode)  
equal a[0:8] b[0:8]  
insert a[8:8] b[8:17]  
equal a[8:29] b[17:38]
```

See also:

- The `get_close_matches()` function in this module which shows how simple code building on `SequenceMatcher` can be used to do useful work.
- [Simple version control recipe](#) for a small application built with `SequenceMatcher`.

6.4.3. Differ Objects

Note that `Differ`-generated deltas make no claim to be **minimal** diffs. To the contrary, minimal diffs are often counter-intuitive, because they synch up anywhere possible, sometimes accidental matches 100 pages apart. Restricting synch points to contiguous matches preserves some notion of locality, at the occasional cost of producing a longer diff.

The `Differ` class has this constructor:

```
class difflib.Differ(linejunk=None, charjunk=None)
```

Optional keyword parameters *linejunk* and *charjunk* are for filter functions (or `None`):

linejunk: A function that accepts a single string argument, and returns true if the string is junk. The default is `None`, meaning that no line is considered junk.

charjunk: A function that accepts a single character argument (a string of length 1), and returns true if the character is junk. The default is `None`, meaning that no character is considered junk.

`Differ` objects are used (deltas generated) via a single method:

```
compare(a, b)
```

Compare two sequences of lines, and generate the delta (a sequence of lines).

Each sequence must contain individual single-line strings ending with newlines. Such sequences can be obtained from the `readlines()` method of file-like objects. The delta generated also consists of newline-terminated strings, ready

to be printed as-is via the `writelines()` method of a file-like object.

6.4.4. Differ Example

This example compares two texts. First we set up the texts, sequences of individual single-line strings ending with newlines (such sequences can also be obtained from the `readlines()` method of file-like objects):

```
>>> text1 = ''' 1. Beautiful is better than ugly.
... 2. Explicit is better than implicit.
... 3. Simple is better than complex.
... 4. Complex is better than complicated.
... '''.splitlines(1)
>>> len(text1)
4
>>> text1[0][-1]
'\n'
>>> text2 = ''' 1. Beautiful is better than ugly.
... 3. Simple is better than complex.
... 4. Complicated is better than complex.
... 5. Flat is better than nested.
... '''.splitlines(1)
```

Next we instantiate a `Differ` object:

```
>>> d = Differ()
```

Note that when instantiating a `Differ` object we may pass functions to filter out line and character “junk.” See the `Differ()` constructor for details.

Finally, we compare the two:

```
>>> result = list(d.compare(text1, text2))
```

`result` is a list of strings, so let's pretty-print it:

```
>>> from pprint import pprint
```

```

>>> pprint(result)
[' 1. Beautiful is better than ugly.\n',
'- 2. Explicit is better than implicit.\n',
'- 3. Simple is better than complex.\n',
'+ 3.   Simple is better than complex.\n',
'?   ++\n',
'- 4. Complex is better than complicated.\n',
'?       ^               ---- ^\n',
'+ 4. Complicated is better than complex.\n',
'?       +++++ ^               ^\n',
'+ 5. Flat is better than nested.\n']

```

As a single multi-line string it looks like this:

```

>>> import sys
>>> sys.stdout.writelines(result)
1. Beautiful is better than ugly.
- 2. Explicit is better than implicit.
- 3. Simple is better than complex.
+ 3.   Simple is better than complex.
?   ++
- 4. Complex is better than complicated.
?       ^               ---- ^
+ 4. Complicated is better than complex.
?       +++++ ^               ^
+ 5. Flat is better than nested.

```

6.4.5. A command-line interface to difflib

This example shows how to use difflib to create a `diff`-like utility. It is also contained in the Python source distribution, as `Tools/scripts/diff.py`.

```
""" Command line interface to difflib.py providing diffs in four
* ndiff: lists every line and highlights interline changes.
* context: highlights clusters of changes in a before/after format.
* unified: highlights clusters of changes in an inline format.
* html: generates side by side comparison with change highlights.
"""

import sys, os, time, difflib, optparse

def main():
    # Configure the option parser
    usage = "usage: %prog [options] fromfile tofile"
    parser = optparse.OptionParser(usage)
    parser.add_option("-c", action="store_true", default=False,
                    help='Produce a context format diff (default)')
    parser.add_option("-u", action="store_true", default=False,
                    help='Produce a unified format diff')
    hlp = 'Produce HTML side by side diff (can use -c and -l in conjunction)'
    parser.add_option("-m", action="store_true", default=False,
                    help=hlp)
    parser.add_option("-n", action="store_true", default=False,
                    help='Produce a ndiff format diff')
    parser.add_option("-l", "--lines", type="int", default=3,
                    help='Set number of context lines (default is 3)')
    (options, args) = parser.parse_args()

    if len(args) == 0:
        parser.print_help()
        sys.exit(1)
    if len(args) != 2:
        parser.error("need to specify both a fromfile and tofile")

    n = options.lines
    fromfile, tofile = args # as specified in the usage string

    # we're passing these as arguments to the diff function
```

```
fromdate = time.ctime(os.stat(fromfile).st_mtime)
todate = time.ctime(os.stat(tofile).st_mtime)
fromlines = open(fromfile, 'U').readlines()
tolines = open(tofile, 'U').readlines()

if options.u:
    diff = difflib.unified_diff(fromlines, tolines, fromfile,
                                tofile, fromdate, todate, n=n)

elif options.n:
    diff = difflib.ndiff(fromlines, tolines)
elif options.m:
    diff = difflib.HtmlDiff().make_file(fromlines, tolines,
                                         tofile, context=opt
                                         numlines=n)

else:
    diff = difflib.context_diff(fromlines, tolines, fromfile,
                                tofile, fromdate, todate, n=n)

# we're using writelines because diff is a generator
sys.stdout.writelines(diff)

if __name__ == '__main__':
    main()
```

6.5. textwrap — Text wrapping and filling

Source code: [Lib/textwrap.py](#)

The `textwrap` module provides two convenience functions, `wrap()` and `fill()`, as well as `TextWrapper`, the class that does all the work, and a utility function `dedent()`. If you're just wrapping or filling one or two text strings, the convenience functions should be good enough; otherwise, you should use an instance of `TextWrapper` for efficiency.

`textwrap.wrap(text, width=70, **kwargs)`

Wraps the single paragraph in `text` (a string) so every line is at most `width` characters long. Returns a list of output lines, without final newlines.

Optional keyword arguments correspond to the instance attributes of `TextWrapper`, documented below. `width` defaults to 70.

`textwrap.fill(text, width=70, **kwargs)`

Wraps the single paragraph in `text`, and returns a single string containing the wrapped paragraph. `fill()` is shorthand for

```
"\n".join(wrap(text, ...))
```

In particular, `fill()` accepts exactly the same keyword arguments as `wrap()`.

Both `wrap()` and `fill()` work by creating a `TextWrapper` instance and calling a single method on it. That instance is not reused, so for applications that wrap/fill many text strings, it will be more efficient

for you to create your own `TextWrapper` object.

Text is preferably wrapped on whitespaces and right after the hyphens in hyphenated words; only then will long words be broken if necessary, unless `TextWrapper.break_long_words` is set to false.

An additional utility function, `dedent()`, is provided to remove indentation from strings that have unwanted whitespace to the left of the text.

`textwrap.dedent(text)`

Remove any common leading whitespace from every line in *text*.

This can be used to make triple-quoted strings line up with the left edge of the display, while still presenting them in the source code in indented form.

Note that tabs and spaces are both treated as whitespace, but they are not equal: the lines `" hello"` and `"\thello"` are considered to have no common leading whitespace.

For example:

```
def test():
    # end first line with \ to avoid the empty line!
    s = '''\
    hello
        world
    '''
    print(repr(s))          # prints '    hello\n        world'
    print(repr(dedent(s))) # prints 'hello\n world'
```

`class textwrap.TextWrapper(**kwargs)`

The `TextWrapper` constructor accepts a number of optional keyword arguments. Each keyword argument corresponds to an instance attribute, so for example

```
wrapper = TextWrapper(initial_indent="* ")
```

is the same as

```
wrapper = TextWrapper()  
wrapper.initial_indent = "* "
```

You can re-use the same `TextWrapper` object many times, and you can change any of its options through direct assignment to instance attributes between uses.

The `TextWrapper` instance attributes (and keyword arguments to the constructor) are as follows:

width

(default: `70`) The maximum length of wrapped lines. As long as there are no individual words in the input text longer than `width`, `TextWrapper` guarantees that no output line will be longer than `width` characters.

expand_tabs

(default: `True`) If true, then all tab characters in *text* will be expanded to spaces using the `expandtabs()` method of *text*.

replace_whitespace

(default: `True`) If true, each whitespace character (as defined by `string.whitespace`) remaining after tab expansion will be replaced by a single space.

Note: If `expand_tabs` is false and `replace_whitespace` is true, each tab character will be replaced by a single space, which is *not* the same as tab expansion.

Note: If `replace_whitespace` is false, newlines may appear in the middle of a line and cause strange output. For this

reason, text should be split into paragraphs (using `str.splitlines()` or similar) which are wrapped separately.

drop_whitespace

(default: `True`) If true, whitespace that, after wrapping, happens to end up at the beginning or end of a line is dropped (leading whitespace in the first line is always preserved, though).

initial_indent

(default: `' '`) String that will be prepended to the first line of wrapped output. Counts towards the length of the first line.

subsequent_indent

(default: `' '`) String that will be prepended to all lines of wrapped output except the first. Counts towards the length of each line except the first.

fix_sentence_endings

(default: `False`) If true, `TextWrapper` attempts to detect sentence endings and ensure that sentences are always separated by exactly two spaces. This is generally desired for text in a monospaced font. However, the sentence detection algorithm is imperfect: it assumes that a sentence ending consists of a lowercase letter followed by one of `'.'`, `'!'`, or `'?'`, possibly followed by one of `'\"'` or `\"'`, followed by a space. One problem with this algorithm is that it is unable to detect the difference between “Dr.” in

```
[...] Dr. Frankenstein's monster [...]
```

and “Spot.” in

```
[...] See Spot. See Spot run [...]
```

`fix_sentence_endings` is false by default.

Since the sentence detection algorithm relies on `string.lowercase` for the definition of “lowercase letter,” and a convention of using two spaces after a period to separate sentences on the same line, it is specific to English-language texts.

break_long_words

(default: `True`) If true, then words longer than `width` will be broken in order to ensure that no lines are longer than `width`. If it is false, long words will not be broken, and some lines may be longer than `width`. (Long words will be put on a line by themselves, in order to minimize the amount by which `width` is exceeded.)

break_on_hyphens

(default: `True`) If true, wrapping will occur preferably on whitespaces and right after hyphens in compound words, as it is customary in English. If false, only whitespaces will be considered as potentially good places for line breaks, but you need to set `break_long_words` to false if you want truly insecable words. Default behaviour in previous versions was to always allow breaking hyphenated words.

`TextWrapper` also provides two public methods, analogous to the module-level convenience functions:

wrap(*text*)

Wraps the single paragraph in *text* (a string) so every line is at most `width` characters long. All wrapping options are taken from instance attributes of the `TextWrapper` instance. Returns a list of output lines, without final newlines.

fill(*text*)

Wraps the single paragraph in *text*, and returns a single string containing the wrapped paragraph.

6.6. codecs — Codec registry and base classes

This module defines base classes for standard Python codecs (encoders and decoders) and provides access to the internal Python codec registry which manages the codec and error handling lookup process.

It defines the following functions:

`codecs.register(search_function)`

Register a codec search function. Search functions are expected to take one argument, the encoding name in all lower case letters, and return a `CodecInfo` object having the following attributes:

- `name` The name of the encoding;
- `encode` The stateless encoding function;
- `decode` The stateless decoding function;
- `incrementalencoder` An incremental encoder class or factory function;
- `incrementaldecoder` An incremental decoder class or factory function;
- `streamwriter` A stream writer class or factory function;
- `streamreader` A stream reader class or factory function.

The various functions or classes take the following arguments:

encode and *decode*: These must be functions or methods which have the same interface as the `encode()/decode()` methods of Codec instances (see Codec Interface). The functions/methods are expected to work in a stateless mode.

incrementalencoder and *incrementaldecoder*: These have to be factory functions providing the following interface:

```
factory(errors='strict')
```

The factory functions must return objects providing the interfaces defined by the base classes `IncrementalEncoder` and `IncrementalDecoder`, respectively. Incremental codecs can maintain state.

streamreader and *streamwriter*: These have to be factory functions providing the following interface:

```
factory(stream, errors='strict')
```

The factory functions must return objects providing the interfaces defined by the base classes `StreamWriter` and `StreamReader`, respectively. Stream codecs can maintain state.

Possible values for errors are

- `'strict'`: raise an exception in case of an encoding error
- `'replace'`: replace malformed data with a suitable replacement marker, such as `'?'` or `'\ufffd'`
- `'ignore'`: ignore malformed data and continue without further notice
- `'xmlcharrefreplace'`: replace with the appropriate XML character reference (for encoding only)
- `'backslashreplace'`: replace with backslashed escape sequences (for encoding only)
- `'surrogateescape'`: replace with surrogate U+DCxx, see **PEP 383**

as well as any other error handling name defined via `register_error()`.

In case a search function cannot find a given encoding, it should return **None**.

`codecs.lookup(encoding)`

Looks up the codec info in the Python codec registry and returns a **CodecInfo** object as defined above.

Encodings are first looked up in the registry's cache. If not found, the list of registered search functions is scanned. If no **CodecInfo** object is found, a **LookupError** is raised. Otherwise, the **CodecInfo** object is stored in the cache and returned to the caller.

To simplify access to the various codecs, the module provides these additional functions which use **lookup()** for the codec lookup:

`codecs.getencoder(encoding)`

Look up the codec for the given encoding and return its encoder function.

Raises a **LookupError** in case the encoding cannot be found.

`codecs.getdecoder(encoding)`

Look up the codec for the given encoding and return its decoder function.

Raises a **LookupError** in case the encoding cannot be found.

`codecs.getincrementalencoder(encoding)`

Look up the codec for the given encoding and return its incremental encoder class or factory function.

Raises a **LookupError** in case the encoding cannot be found or the codec doesn't support an incremental encoder.

`codecs.getincrementaldecoder(encoding)`

Look up the codec for the given encoding and return its incremental decoder class or factory function.

Raises a **LookupError** in case the encoding cannot be found or the codec doesn't support an incremental decoder.

`codecs.getreader(encoding)`

Look up the codec for the given encoding and return its `StreamReader` class or factory function.

Raises a **LookupError** in case the encoding cannot be found.

`codecs.getwriter(encoding)`

Look up the codec for the given encoding and return its `StreamWriter` class or factory function.

Raises a **LookupError** in case the encoding cannot be found.

`codecs.register_error(name, error_handler)`

Register the error handling function *error_handler* under the name *name*. *error_handler* will be called during encoding and decoding in case of an error, when *name* is specified as the errors parameter.

For encoding *error_handler* will be called with a **UnicodeEncodeError** instance, which contains information about the location of the error. The error handler must either raise this or a different exception or return a tuple with a replacement for the unencodable part of the input and a position where encoding should continue. The encoder will encode the replacement and continue encoding the original input at the specified position. Negative position values will be treated as being relative to the end of the input string. If the resulting position is out of bound an **IndexError** will be raised.

Decoding and translating works similar, except `UnicodeDecodeError` or `UnicodeTranslateError` will be passed to the handler and that the replacement from the error handler will be put into the output directly.

`codecs.lookup_error(name)`

Return the error handler previously registered under the name *name*.

Raises a `LookupError` in case the handler cannot be found.

`codecs.strict_errors(exception)`

Implements the `strict` error handling: each encoding or decoding error raises a `UnicodeError`.

`codecs.replace_errors(exception)`

Implements the `replace` error handling: malformed data is replaced with a suitable replacement character such as `'?'` in bytestrings and `'\ufffd'` in Unicode strings.

`codecs.ignore_errors(exception)`

Implements the `ignore` error handling: malformed data is ignored and encoding or decoding is continued without further notice.

`codecs.xmlcharrefreplace_errors(exception)`

Implements the `xmlcharrefreplace` error handling (for encoding only): the unencodable character is replaced by an appropriate XML character reference.

`codecs.backslashreplace_errors(exception)`

Implements the `backslashreplace` error handling (for encoding only): the unencodable character is replaced by a backslashed escape sequence.

To simplify working with encoded files or stream, the module also defines these utility functions:

```
codecs.open(filename, mode[, encoding[, errors[, buffering]]])
```

Open an encoded file using the given *mode* and return a wrapped version providing transparent encoding/decoding. The default file mode is `'r'` meaning to open the file in read mode.

Note: The wrapped version's methods will accept and return strings only. Bytes arguments will be rejected.

Note: Files are always opened in binary mode, even if no binary mode was specified. This is done to avoid data loss due to encodings using 8-bit values. This means that no automatic conversion of `b'\n'` is done on reading and writing.

encoding specifies the encoding which is to be used for the file.

errors may be given to define the error handling. It defaults to `'strict'` which causes a `ValueError` to be raised in case an encoding error occurs.

buffering has the same meaning as for the built-in `open()` function. It defaults to line buffered.

```
codecs.EncodedFile(file, data_encoding, file_encoding=None, errors='strict')
```

Return a wrapped version of file which provides transparent encoding translation.

Bytes written to the wrapped file are interpreted according to the given *data_encoding* and then written to the original file as bytes using the *file_encoding*.

If *file_encoding* is not given, it defaults to *data_encoding*.

errors may be given to define the error handling. It defaults to `'strict'`, which causes `ValueError` to be raised in case an encoding error occurs.

`codecs.iterencode(iterator, encoding, errors='strict', **kwargs)`

Uses an incremental encoder to iteratively encode the input provided by *iterator*. This function is a *generator*. *errors* (as well as any other keyword argument) is passed through to the incremental encoder.

`codecs.iterdecode(iterator, encoding, errors='strict', **kwargs)`

Uses an incremental decoder to iteratively decode the input provided by *iterator*. This function is a *generator*. *errors* (as well as any other keyword argument) is passed through to the incremental decoder.

The module also provides the following constants which are useful for reading and writing to platform dependent files:

`codecs.BOM`
`codecs.BOM_BE`
`codecs.BOM_LE`
`codecs.BOM_UTF8`
`codecs.BOM_UTF16`
`codecs.BOM_UTF16_BE`
`codecs.BOM_UTF16_LE`
`codecs.BOM_UTF32`
`codecs.BOM_UTF32_BE`
`codecs.BOM_UTF32_LE`

These constants define various encodings of the Unicode byte order mark (BOM) used in UTF-16 and UTF-32 data streams to indicate the byte order used in the stream or file and in UTF-8 as a Unicode signature. `BOM_UTF16` is either `BOM_UTF16_BE` or `BOM_UTF16_LE` depending on the platform's native byte order, `BOM` is an alias for `BOM_UTF16`, `BOM_LE` for `BOM_UTF16_LE` and `BOM_BE` for `BOM_UTF16_BE`. The others represent the BOM in UTF-8 and UTF-

32 encodings.

6.6.1. Codec Base Classes

The `codecs` module defines a set of base classes which define the interface and can also be used to easily write your own codecs for use in Python.

Each codec has to define four interfaces to make it usable as codec in Python: stateless encoder, stateless decoder, stream reader and stream writer. The stream reader and writers typically reuse the stateless encoder/decoder to implement the file protocols.

The `Codec` class defines the interface for stateless encoders/decoders.

To simplify and standardize error handling, the `encode()` and `decode()` methods may implement different error handling schemes by providing the *errors* string argument. The following string values are defined and implemented by all standard Python codecs:

Value	Meaning
'strict'	Raise <code>UnicodeError</code> (or a subclass); this is the default.
'ignore'	Ignore the character and continue with the next.
'replace'	Replace with a suitable replacement character; Python will use the official U+FFFD REPLACEMENT CHARACTER for the built-in Unicode codecs on decoding and '?' on encoding.
'xmlcharrefreplace'	Replace with the appropriate XML character reference (only for encoding).
'backslashreplace'	Replace with backslashed escape sequences (only for encoding).
'surrogateescape'	Replace byte with surrogate U+DCxx, as

defined in [PEP 383](#).

In addition, the following error handlers are specific to a single codec:

Value	Codec	Meaning
'surrogatepass'	utf-8	Allow encoding and decoding of surrogate codes in UTF-8.

New in version 3.1: The 'surrogateescape' and 'surrogatepass' error handlers.

The set of allowed values can be extended via `register_error()`.

6.6.1.1. Codec Objects

The `codec` class defines these methods which also define the function interfaces of the stateless encoder and decoder:

`Codec.encode(input[, errors])`

Encodes the object *input* and returns a tuple (output object, length consumed). Encoding converts a string object to a bytes object using a particular character set encoding (e.g., `cp1252` or `iso-8859-1`).

errors defines the error handling to apply. It defaults to 'strict' handling.

The method may not store state in the `codec` instance. Use `StreamCodec` for codecs which have to keep state in order to make encoding/decoding efficient.

The encoder must be able to handle zero length input and return an empty object of the output object type in this situation.

`Codec.decode(input[, errors])`

Decodes the object *input* and returns a tuple (output object, length consumed). Decoding converts a bytes object encoded using a particular character set encoding to a string object.

input must be a bytes object or one which provides the read-only character buffer interface – for example, buffer objects and memory mapped files.

errors defines the error handling to apply. It defaults to `'strict'` handling.

The method may not store state in the `Codec` instance. Use `StreamCodec` for codecs which have to keep state in order to make encoding/decoding efficient.

The decoder must be able to handle zero length input and return an empty object of the output object type in this situation.

The `IncrementalEncoder` and `IncrementalDecoder` classes provide the basic interface for incremental encoding and decoding. Encoding/decoding the input isn't done with one call to the stateless encoder/decoder function, but with multiple calls to the `encode()/decode()` method of the incremental encoder/decoder. The incremental encoder/decoder keeps track of the encoding/decoding process during method calls.

The joined output of calls to the `encode()/decode()` method is the same as if all the single inputs were joined into one, and this input was encoded/decoded with the stateless encoder/decoder.

6.6.1.2. IncrementalEncoder Objects

The `IncrementalEncoder` class is used for encoding an input in

multiple steps. It defines the following methods which every incremental encoder must define in order to be compatible with the Python codec registry.

```
class codecs.IncrementalEncoder([errors])
```

Constructor for an **IncrementalEncoder** instance.

All incremental encoders must provide this constructor interface. They are free to add additional keyword arguments, but only the ones defined here are used by the Python codec registry.

The **IncrementalEncoder** may implement different error handling schemes by providing the *errors* keyword argument. These parameters are predefined:

- `'strict'` Raise **ValueError** (or a subclass); this is the default.
- `'ignore'` Ignore the character and continue with the next.
- `'replace'` Replace with a suitable replacement character
- `'xmlcharrefreplace'` Replace with the appropriate XML character reference
- `'backslashreplace'` Replace with backslashed escape sequences.

The *errors* argument will be assigned to an attribute of the same name. Assigning to this attribute makes it possible to switch between different error handling strategies during the lifetime of the **IncrementalEncoder** object.

The set of allowed values for the *errors* argument can be extended with **register_error()**.

```
encode(object[, final])
```

Encodes *object* (taking the current state of the encoder into

account) and returns the resulting encoded object. If this is the last call to `encode()` *final* must be true (the default is false).

`reset()`

Reset the encoder to the initial state.

`IncrementalEncoder.getstate()`

Return the current state of the encoder which must be an integer. The implementation should make sure that `0` is the most common state. (States that are more complicated than integers can be converted into an integer by marshaling/pickling the state and encoding the bytes of the resulting string into an integer).

`IncrementalEncoder.setstate(state)`

Set the state of the encoder to *state*. *state* must be an encoder state returned by `getstate()`.

6.6.1.3. IncrementalDecoder Objects

The `IncrementalDecoder` class is used for decoding an input in multiple steps. It defines the following methods which every incremental decoder must define in order to be compatible with the Python codec registry.

`class codecs.IncrementalDecoder([errors])`

Constructor for an `IncrementalDecoder` instance.

All incremental decoders must provide this constructor interface. They are free to add additional keyword arguments, but only the ones defined here are used by the Python codec registry.

The `IncrementalDecoder` may implement different error handling schemes by providing the *errors* keyword argument. These

parameters are predefined:

- `'strict'` Raise `ValueError` (or a subclass); this is the default.
- `'ignore'` Ignore the character and continue with the next.
- `'replace'` Replace with a suitable replacement character.

The `errors` argument will be assigned to an attribute of the same name. Assigning to this attribute makes it possible to switch between different error handling strategies during the lifetime of the `IncrementalDecoder` object.

The set of allowed values for the `errors` argument can be extended with `register_error()`.

`decode(object[, final])`

Decodes `object` (taking the current state of the decoder into account) and returns the resulting decoded object. If this is the last call to `decode()` `final` must be true (the default is false). If `final` is true the decoder must decode the input completely and must flush all buffers. If this isn't possible (e.g. because of incomplete byte sequences at the end of the input) it must initiate error handling just like in the stateless case (which might raise an exception).

`reset()`

Reset the decoder to the initial state.

`getstate()`

Return the current state of the decoder. This must be a tuple with two items, the first must be the buffer containing the still undecoded input. The second must be an integer and can be additional state info. (The implementation should make sure that `0` is the most common additional state info.) If this

additional state info is `0` it must be possible to set the decoder to the state which has no input buffered and `0` as the additional state info, so that feeding the previously buffered input to the decoder returns it to the previous state without producing any output. (Additional state info that is more complicated than integers can be converted into an integer by marshaling/pickling the info and encoding the bytes of the resulting string into an integer.)

setstate(*state*)

Set the state of the encoder to *state*. *state* must be a decoder state returned by `getstate()`.

The `StreamWriter` and `StreamReader` classes provide generic working interfaces which can be used to implement new encoding submodules very easily. See `encodings.utf_8` for an example of how this is done.

6.6.1.4. StreamWriter Objects

The `StreamWriter` class is a subclass of `codec` and defines the following methods which every stream writer must define in order to be compatible with the Python codec registry.

`class codecs. StreamWriter(stream[, errors])`

Constructor for a `StreamWriter` instance.

All stream writers must provide this constructor interface. They are free to add additional keyword arguments, but only the ones defined here are used by the Python codec registry.

stream must be a file-like object open for writing binary data.

The `StreamWriter` may implement different error handling

schemes by providing the *errors* keyword argument. These parameters are predefined:

- `'strict'` Raise `ValueError` (or a subclass); this is the default.
- `'ignore'` Ignore the character and continue with the next.
- `'replace'` Replace with a suitable replacement character
- `'xmlcharrefreplace'` Replace with the appropriate XML character reference
- `'backslashreplace'` Replace with backslashed escape sequences.

The *errors* argument will be assigned to an attribute of the same name. Assigning to this attribute makes it possible to switch between different error handling strategies during the lifetime of the `StreamWriter` object.

The set of allowed values for the *errors* argument can be extended with `register_error()`.

`write(object)`

Writes the object's contents encoded to the stream.

`writelines(list)`

Writes the concatenated list of strings to the stream (possibly by reusing the `write()` method).

`reset()`

Flushes and resets the codec buffers used for keeping state.

Calling this method should ensure that the data on the output is put into a clean state that allows appending of new fresh data without having to rescan the whole stream to recover state.

In addition to the above methods, the `StreamWriter` must also inherit all other methods and attributes from the underlying stream.

6.6.1.5. StreamReader Objects

The `StreamReader` class is a subclass of `codec` and defines the following methods which every stream reader must define in order to be compatible with the Python codec registry.

```
class codecs.StreamReader(stream[, errors])
```

Constructor for a `StreamReader` instance.

All stream readers must provide this constructor interface. They are free to add additional keyword arguments, but only the ones defined here are used by the Python codec registry.

stream must be a file-like object open for reading (binary) data.

The `StreamReader` may implement different error handling schemes by providing the *errors* keyword argument. These parameters are defined:

- `'strict'` Raise `ValueError` (or a subclass); this is the default.
- `'ignore'` Ignore the character and continue with the next.
- `'replace'` Replace with a suitable replacement character.

The *errors* argument will be assigned to an attribute of the same name. Assigning to this attribute makes it possible to switch between different error handling strategies during the lifetime of the `StreamReader` object.

The set of allowed values for the *errors* argument can be extended with `register_error()`.

`read([size[, chars[, firstline]])`

Decodes data from the stream and returns the resulting object.

chars indicates the number of characters to read from the stream. `read()` will never return more than *chars* characters, but it might return less, if there are not enough characters available.

size indicates the approximate maximum number of bytes to read from the stream for decoding purposes. The decoder can modify this setting as appropriate. The default value `-1` indicates to read and decode as much as possible. *size* is intended to prevent having to decode huge files in one step.

firstline indicates that it would be sufficient to only return the first line, if there are decoding errors on later lines.

The method should use a greedy read strategy meaning that it should read as much data as is allowed within the definition of the encoding and the given size, e.g. if optional encoding endings or state markers are available on the stream, these should be read too.

`readline([size[, keepends]])`

Read one line from the input stream and return the decoded data.

size, if given, is passed as size argument to the stream's `readline()` method.

If *keepends* is false line-endings will be stripped from the lines returned.

`readlines([sizehint[, keepends]])`

Read all lines available on the input stream and return them as a list of lines.

Line-endings are implemented using the codec's decoder method and are included in the list entries if *keepends* is true.

sizehint, if given, is passed as the *size* argument to the stream's `read()` method.

`reset()`

Resets the codec buffers used for keeping state.

Note that no stream repositioning should take place. This method is primarily intended to be able to recover from decoding errors.

In addition to the above methods, the `StreamReader` must also inherit all other methods and attributes from the underlying stream.

The next two base classes are included for convenience. They are not needed by the codec registry, but may provide useful in practice.

6.6.1.6. StreamReaderWriter Objects

The `StreamReaderWriter` allows wrapping streams which work in both read and write modes.

The design is such that one can use the factory functions returned by the `lookup()` function to construct the instance.

`class codecs. StreamReaderWriter(stream, Reader, Writer, errors)`

Creates a `StreamReaderWriter` instance. *stream* must be a file-like object. *Reader* and *Writer* must be factory functions or classes providing the `StreamReader` and `StreamWriter` interface resp. Error handling is done in the same way as defined for the stream

readers and writers.

`StreamReaderWriter` instances define the combined interfaces of `StreamReader` and `StreamWriter` classes. They inherit all other methods and attributes from the underlying stream.

6.6.1.7. StreamRecorder Objects

The `StreamRecorder` provide a frontend - backend view of encoding data which is sometimes useful when dealing with different encoding environments.

The design is such that one can use the factory functions returned by the `lookup()` function to construct the instance.

```
class codecs. StreamRecorder(stream, encode, decode, Reader,  
Writer, errors)
```

Creates a `StreamRecorder` instance which implements a two-way conversion: *encode* and *decode* work on the frontend (the input to `read()` and output of `write()`) while *Reader* and *Writer* work on the backend (reading and writing to the stream).

You can use these objects to do transparent direct recordings from e.g. Latin-1 to UTF-8 and back.

stream must be a file-like object.

encode, *decode* must adhere to the `codec` interface. *Reader*, *Writer* must be factory functions or classes providing objects of the `StreamReader` and `StreamWriter` interface respectively.

encode and *decode* are needed for the frontend translation, *Reader* and *Writer* for the backend translation.

Error handling is done in the same way as defined for the stream

readers and writers.

`StreamRecorder` instances define the combined interfaces of `StreamReader` and `StreamWriter` classes. They inherit all other methods and attributes from the underlying stream.

6.6.2. Encodings and Unicode

Strings are stored internally as sequences of codepoints (to be precise as `Py_UNICODE` arrays). Depending on the way Python is compiled (either via `--without-wide-unicode` or `--with-wide-unicode`, with the former being the default) `Py_UNICODE` is either a 16-bit or 32-bit data type. Once a string object is used outside of CPU and memory, CPU endianness and how these arrays are stored as bytes become an issue. Transforming a string object into a sequence of bytes is called encoding and recreating the string object from the sequence of bytes is known as decoding. There are many different methods for how this transformation can be done (these methods are also called encodings). The simplest method is to map the codepoints 0-255 to the bytes `0x0-0xff`. This means that a string object that contains codepoints above `U+00FF` can't be encoded with this method (which is called `'latin-1'` or `'iso-8859-1'`). `str.encode()` will raise a `UnicodeEncodeError` that looks like this: `UnicodeEncodeError: 'latin-1' codec can't encode character '\u1234' in position 3: ordinal not in range(256)`.

There's another group of encodings (the so called charmap encodings) that choose a different subset of all Unicode code points and how these codepoints are mapped to the bytes `0x0-0xff`. To see how this is done simply open e.g. `encodings/cp1252.py` (which is an encoding that is used primarily on Windows). There's a string constant with 256 characters that shows you which character is mapped to which byte value.

All of these encodings can only encode 256 of the 65536 (or 1114111) codepoints defined in Unicode. A simple and straightforward way that can store each Unicode code point, is to store each codepoint as two consecutive bytes. There are two

possibilities: Store the bytes in big endian or in little endian order. These two encodings are called UTF-16-BE and UTF-16-LE respectively. Their disadvantage is that if e.g. you use UTF-16-BE on a little endian machine you will always have to swap bytes on encoding and decoding. UTF-16 avoids this problem: Bytes will always be in natural endianness. When these bytes are read by a CPU with a different endianness, then bytes have to be swapped though. To be able to detect the endianness of a UTF-16 byte sequence, there's the so called BOM (the "Byte Order Mark"). This is the Unicode character `U+FEFF`. This character will be prepended to every UTF-16 byte sequence. The byte swapped version of this character (`0xFFFE`) is an illegal character that may not appear in a Unicode text. So when the first character in an UTF-16 byte sequence appears to be a `U+FFFE` the bytes have to be swapped on decoding. Unfortunately upto Unicode 4.0 the character `U+FEFF` had a second purpose as a `ZERO WIDTH NO-BREAK SPACE`: A character that has no width and doesn't allow a word to be split. It can e.g. be used to give hints to a ligature algorithm. With Unicode 4.0 using `U+FEFF` as a `ZERO WIDTH NO-BREAK SPACE` has been deprecated (with `U+2060` (`WORD JOINER`) assuming this role). Nevertheless Unicode software still must be able to handle `U+FEFF` in both roles: As a BOM it's a device to determine the storage layout of the encoded bytes, and vanishes once the byte sequence has been decoded into a string; as a `ZERO WIDTH NO-BREAK SPACE` it's a normal character that will be decoded like any other.

There's another encoding that is able to encoding the full range of Unicode characters: UTF-8. UTF-8 is an 8-bit encoding, which means there are no issues with byte order in UTF-8. Each byte in a UTF-8 byte sequence consists of two parts: Marker bits (the most significant bits) and payload bits. The marker bits are a sequence of zero to six 1 bits followed by a 0 bit. Unicode characters are encoded like this (with x being payload bits, which when concatenated give

the Unicode character):

Range	Encoding
U-00000000 ... U-0000007F	0xxxxxxx
U-00000080 ... U-000007FF	110xxxxx 10xxxxxx
U-00000800 ... U-0000FFFF	1110xxxx 10xxxxxx 10xxxxxx
U-00010000 ... U-001FFFFF	11110xxx 10xxxxxx 10xxxxxx 10xxxxxx
U-00200000 ... U-03FFFFFF	111110xx 10xxxxxx 10xxxxxx 10xxxxxx 10xxxxxx
U-04000000 ... U-7FFFFFFF	1111110x 10xxxxxx 10xxxxxx 10xxxxxx 10xxxxxx 10xxxxxx

The least significant bit of the Unicode character is the rightmost x bit.

As UTF-8 is an 8-bit encoding no BOM is required and any `U+FEFF` character in the decoded string (even if it's the first character) is treated as a `ZERO WIDTH NO-BREAK SPACE`.

Without external information it's impossible to reliably determine which encoding was used for encoding a string. Each charmap encoding can decode any random byte sequence. However that's not possible with UTF-8, as UTF-8 byte sequences have a structure that doesn't allow arbitrary byte sequences. To increase the reliability with which a UTF-8 encoding can be detected, Microsoft invented a variant of UTF-8 (that Python 2.5 calls "`utf-8-sig`") for its Notepad program: Before any of the Unicode characters is written to the file, a UTF-8 encoded BOM (which looks like this as a byte sequence: `0xef`, `0xbb`, `0xbf`) is written. As it's rather improbable that any charmap encoded file starts with these byte values (which would e.g. map to

LATIN SMALL LETTER I WITH DIAERESIS
RIGHT-POINTING DOUBLE ANGLE QUOTATION MARK

INVERTED QUESTION MARK

in iso-8859-1), this increases the probability that a utf-8-sig encoding can be correctly guessed from the byte sequence. So here the BOM is not used to be able to determine the byte order used for generating the byte sequence, but as a signature that helps in guessing the encoding. On encoding the utf-8-sig codec will write `0xef`, `0xbb`, `0xbf` as the first three bytes to the file. On decoding utf-8-sig will skip those three bytes if they appear as the first three bytes in the file.

6.6.3. Standard Encodings

Python comes with a number of codecs built-in, either implemented as C functions or with dictionaries as mapping tables. The following table lists the codecs by name, together with a few common aliases, and the languages for which the encoding is likely used. Neither the list of aliases nor the list of languages is meant to be exhaustive. Notice that spelling alternatives that only differ in case or use a hyphen instead of an underscore are also valid aliases; therefore, e.g. `'utf-8'` is a valid alias for the `'utf_8'` codec.

Many of the character sets support the same languages. They vary in individual characters (e.g. whether the EURO SIGN is supported or not), and in the assignment of characters to code positions. For the European languages in particular, the following variants typically exist:

- an ISO 8859 codeset
- a Microsoft Windows code page, which is typically derived from a 8859 codeset, but replaces control characters with additional graphic characters
- an IBM EBCDIC code page
- an IBM PC code page, which is ASCII compatible

Codec	Aliases	Languages
ascii	646, us-ascii	English
big5	big5-tw, csbig5	Traditional Chinese
big5hkscs	big5-hkscs, hkscs	Traditional Chinese
cp037	IBM037, IBM039	English
cp424	EBCDIC-CP-HE, IBM424	Hebrew
cp437	437, IBM437	English
	EBCDIC-CP-BE,	

cp500	EBCDIC-CP-CH, IBM500	Western Europe
cp720		Arabic
cp737		Greek
cp775	IBM775	Baltic languages
cp850	850, IBM850	Western Europe
cp852	852, IBM852	Central and Eastern Europe
cp855	855, IBM855	Bulgarian, Byelorussian, Macedonian, Russian, Serbian
cp856		Hebrew
cp857	857, IBM857	Turkish
cp858	858, IBM858	Western Europe
cp860	860, IBM860	Portuguese
cp861	861, CP-IS, IBM861	Icelandic
cp862	862, IBM862	Hebrew
cp863	863, IBM863	Canadian
cp864	IBM864	Arabic
cp865	865, IBM865	Danish, Norwegian
cp866	866, IBM866	Russian
cp869	869, CP-GR, IBM869	Greek
cp874		Thai
cp875		Greek
cp932	932, ms932, mskanji, ms-kanji	Japanese
cp949	949, ms949, uhc	Korean
cp950	950, ms950	Traditional Chinese
cp1006		Urdu
cp1026	ibm1026	Turkish
cp1140	ibm1140	Western Europe
cp1250	windows-1250	Central and Eastern

		Europe
cp1251	windows-1251	Bulgarian, Byelorussian, Macedonian, Russian, Serbian
cp1252	windows-1252	Western Europe
cp1253	windows-1253	Greek
cp1254	windows-1254	Turkish
cp1255	windows-1255	Hebrew
cp1256	windows-1256	Arabic
cp1257	windows-1257	Baltic languages
cp1258	windows-1258	Vietnamese
euc_jp	eucjp, ujis, u-jis	Japanese
euc_jis_2004	jisx0213, eucjis2004	Japanese
euc_jisx0213	eucjisx0213	Japanese
euc_kr	euckr, korean, ksc5601, ks_c-5601, ks_c-5601- 1987, ksx1001, ks_x- 1001	Korean
gb2312	chinese, csiso58gb231280, euc- cn, euccn, eucgb2312- cn, gb2312-1980, gb2312-80, iso- ir-58	Simplified Chinese

shift_jis_2004	shiftjis2004, sjis_2004, sjis2004	Japanese
shift_jisx0213	shiftjisx0213, sjisx0213, s_jisx0213	Japanese
utf_32	U32, utf32	all languages
utf_32_be	UTF-32BE	all languages
utf_32_le	UTF-32LE	all languages
utf_16	U16, utf16	all languages
utf_16_be	UTF-16BE	all languages
utf_16_le	UTF-16LE	all languages
utf_7	U7, unicode-1-1-utf-7	all languages
utf_8	U8, UTF, utf8	all languages
utf_8_sig		all languages

Codec	Aliases	Purpose
idna		Implements RFC 3490 , see also encodings.idna
mbcs	dbcs	Windows only: Encode operand according to the ANSI codepage (CP_ACP)
palmos		Encoding of PalmOS 3.5
punycode		Implements RFC 3492

raw_unicode_escape		Produce a string that is suitable as raw Unicode literal in Python source code
undefined		Raise an exception for all conversions. Can be used as the system encoding if no automatic coercion between byte and Unicode strings is desired.
unicode_escape		Produce a string that is suitable as Unicode literal in Python source code
unicode_internal		Return the internal representation of the operand

The following codecs provide bytes-to-bytes mappings.

Codec	Aliases	Purpose
base64_codec	base64, base-64	Convert operand to MIME base64
bz2_codec	bz2	Compress the operand using bz2
hex_codec	hex	Convert operand to hexadecimal representation, with two digits per byte
quopri_codec	quopri, quoted-printable, quotedprintable	Convert operand to MIME quoted printable
uu_codec	uu	Convert the operand using uuencode
zlib_codec	zip, zlib	Compress the operand using gzip

The following codecs provide string-to-string mappings.

--	--	--

Codec	Aliases	Purpose
rot_13	rot13	Returns the Caesar-cypher encryption of the operand

New in version 3.2: bytes-to-bytes and string-to-string codecs.

6.6.4. `encodings.idna` — Internationalized Domain Names in Applications

This module implements [RFC 3490](#) (Internationalized Domain Names in Applications) and [RFC 3492](#) (Nameprep: A Stringprep Profile for Internationalized Domain Names (IDN)). It builds upon the `punycode` encoding and `stringprep`.

These RFCs together define a protocol to support non-ASCII characters in domain names. A domain name containing non-ASCII characters (such as `www.Alliancefrançaise.nu`) is converted into an ASCII-compatible encoding (ACE, such as `www.xn--alliancefranaise-npb.nu`). The ACE form of the domain name is then used in all places where arbitrary characters are not allowed by the protocol, such as DNS queries, HTTP *Host* fields, and so on. This conversion is carried out in the application; if possible invisible to the user: The application should transparently convert Unicode domain labels to IDNA on the wire, and convert back ACE labels to Unicode before presenting them to the user.

Python supports this conversion in several ways: The `idna` codec allows to convert between Unicode and the ACE. Furthermore, the `socket` module transparently converts Unicode host names to ACE, so that applications need not be concerned about converting host names themselves when they pass them to the socket module. On top of that, modules that have host names as function parameters, such as `http.client` and `ftplib`, accept Unicode host names (`http.client` then also transparently sends an IDNA hostname in the *Host* field if it sends that field at all).

When receiving host names from the wire (such as in reverse name lookup), no automatic conversion to Unicode is performed:

Applications wishing to present such host names to the user should decode them to Unicode.

The module `encodings.idna` also implements the nameprep procedure, which performs certain normalizations on host names, to achieve case-insensitivity of international domain names, and to unify similar characters. The nameprep functions can be used directly if desired.

`encodings.idna.nameprep(label)`

Return the nameprepped version of *label*. The implementation currently assumes query strings, so `AllowUnassigned` is true.

`encodings.idna.ToASCII(label)`

Convert a label to ASCII, as specified in [RFC 3490](#). `UseSTD3ASCIIRules` is assumed to be false.

`encodings.idna.ToUnicode(label)`

Convert a label to Unicode, as specified in [RFC 3490](#).

6.6.5. `encodings.mbc`s — Windows ANSI codepage

Encode operand according to the ANSI codepage (CP_ACP). This codec only supports `'strict'` and `'replace'` error handlers to encode, and `'strict'` and `'ignore'` error handlers to decode.

Availability: Windows only.

Changed in version 3.2: Before 3.2, the `errors` argument was ignored; `'replace'` was always used to encode, and `'ignore'` to decode.

6.6.6. `encodings.utf_8_sig` — UTF-8 codec with BOM signature

This module implements a variant of the UTF-8 codec: On encoding a UTF-8 encoded BOM will be prepended to the UTF-8 encoded bytes. For the stateful encoder this is only done once (on the first write to the byte stream). For decoding an optional UTF-8 encoded BOM at the start of the data will be skipped.

6.7. unicodedata — Unicode Database

This module provides access to the Unicode Character Database (UCD) which defines character properties for all Unicode characters. The data contained in this database is compiled from the [UCD version 6.0.0](#).

The module uses the same names and symbols as defined by Unicode Standard Annex #44, “[Unicode Character Database](#)”. It defines the following functions:

`unicodedata.lookup(name)`

Look up character by name. If a character with the given name is found, return the corresponding character. If not found, `KeyError` is raised.

`unicodedata.name(chr[, default])`

Returns the name assigned to the character `chr` as a string. If no name is defined, `default` is returned, or, if not given, `ValueError` is raised.

`unicodedata.decimal(chr[, default])`

Returns the decimal value assigned to the character `chr` as integer. If no such value is defined, `default` is returned, or, if not given, `ValueError` is raised.

`unicodedata.digit(chr[, default])`

Returns the digit value assigned to the character `chr` as integer. If no such value is defined, `default` is returned, or, if not given, `ValueError` is raised.

`unicodedata.numeric(chr[, default])`

Returns the numeric value assigned to the character *chr* as float. If no such value is defined, *default* is returned, or, if not given, `ValueError` is raised.

`unicodedata.category(chr)`

Returns the general category assigned to the character *chr* as string.

`unicodedata.bidirectional(chr)`

Returns the bidirectional category assigned to the character *chr* as string. If no such value is defined, an empty string is returned.

`unicodedata.combining(chr)`

Returns the canonical combining class assigned to the character *chr* as integer. Returns `0` if no combining class is defined.

`unicodedata.east_asian_width(chr)`

Returns the east asian width assigned to the character *chr* as string.

`unicodedata.mirrored(chr)`

Returns the mirrored property assigned to the character *chr* as integer. Returns `1` if the character has been identified as a “mirrored” character in bidirectional text, `0` otherwise.

`unicodedata.decomposition(chr)`

Returns the character decomposition mapping assigned to the character *chr* as string. An empty string is returned in case no such mapping is defined.

`unicodedata.normalize(form, unistr)`

Return the normal form *form* for the Unicode string *unistr*. Valid values for *form* are ‘NFC’, ‘NFKC’, ‘NFD’, and ‘NFKD’.

The Unicode standard defines various normalization forms of a Unicode string, based on the definition of canonical equivalence and compatibility equivalence. In Unicode, several characters can be expressed in various way. For example, the character U+00C7 (LATIN CAPITAL LETTER C WITH CEDILLA) can also be expressed as the sequence U+0327 (COMBINING CEDILLA) U+0043 (LATIN CAPITAL LETTER C).

For each character, there are two normal forms: normal form C and normal form D. Normal form D (NFD) is also known as canonical decomposition, and translates each character into its decomposed form. Normal form C (NFC) first applies a canonical decomposition, then composes pre-combined characters again.

In addition to these two forms, there are two additional normal forms based on compatibility equivalence. In Unicode, certain characters are supported which normally would be unified with other characters. For example, U+2160 (ROMAN NUMERAL ONE) is really the same thing as U+0049 (LATIN CAPITAL LETTER I). However, it is supported in Unicode for compatibility with existing character sets (e.g. gb2312).

The normal form KD (NFKD) will apply the compatibility decomposition, i.e. replace all compatibility characters with their equivalents. The normal form KC (NFKC) first applies the compatibility decomposition, followed by the canonical composition.

Even if two unicode strings are normalized and look the same to a human reader, if one has combining characters and the other doesn't, they may not compare equal.

In addition, the module exposes the following constant:

`unicodedata.unidata_version`

The version of the Unicode database used in this module.

`unicodedata.ucd_3_2_0`

This is an object that has the same methods as the entire module, but uses the Unicode database version 3.2 instead, for applications that require this specific version of the Unicode database (such as IDNA).

Examples:

```
>>> import unicodedata
>>> unicodedata.lookup('LEFT CURLY BRACKET')
'{'
>>> unicodedata.name('/')
'SOLIDUS'
>>> unicodedata.decimal('9')
9
>>> unicodedata.decimal('a')
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
ValueError: not a decimal
>>> unicodedata.category('A') # 'L'etter, 'u'ppercase
'Lu'
>>> unicodedata.bidirectional('\u0660') # 'A'rabic, 'N'umber
'AN'
```

6.8. `stringprep` — Internet String Preparation

When identifying things (such as host names) in the internet, it is often necessary to compare such identifications for “equality”. Exactly how this comparison is executed may depend on the application domain, e.g. whether it should be case-insensitive or not. It may be also necessary to restrict the possible identifications, to allow only identifications consisting of “printable” characters.

RFC 3454 defines a procedure for “preparing” Unicode strings in internet protocols. Before passing strings onto the wire, they are processed with the preparation procedure, after which they have a certain normalized form. The RFC defines a set of tables, which can be combined into profiles. Each profile must define which tables it uses, and what other optional parts of the `stringprep` procedure are part of the profile. One example of a `stringprep` profile is `nameprep`, which is used for internationalized domain names.

The module `stringprep` only exposes the tables from RFC 3454. As these tables would be very large to represent them as dictionaries or lists, the module uses the Unicode character database internally. The module source code itself was generated using the `mkstringprep.py` utility.

As a result, these tables are exposed as functions, not as data structures. There are two kinds of tables in the RFC: sets and mappings. For a set, `stringprep` provides the “characteristic function”, i.e. a function that returns true if the parameter is part of the set. For mappings, it provides the mapping function: given the key, it returns the associated value. Below is a list of all functions available in the module.

stringprep.**in_table_a1**(*code*)

Determine whether *code* is in tableA.1 (Unassigned code points in Unicode 3.2).

stringprep.**in_table_b1**(*code*)

Determine whether *code* is in tableB.1 (Commonly mapped to nothing).

stringprep.**map_table_b2**(*code*)

Return the mapped value for *code* according to tableB.2 (Mapping for case-folding used with NFKC).

stringprep.**map_table_b3**(*code*)

Return the mapped value for *code* according to tableB.3 (Mapping for case-folding used with no normalization).

stringprep.**in_table_c11**(*code*)

Determine whether *code* is in tableC.1.1 (ASCII space characters).

stringprep.**in_table_c12**(*code*)

Determine whether *code* is in tableC.1.2 (Non-ASCII space characters).

stringprep.**in_table_c11_c12**(*code*)

Determine whether *code* is in tableC.1 (Space characters, union of C.1.1 and C.1.2).

stringprep.**in_table_c21**(*code*)

Determine whether *code* is in tableC.2.1 (ASCII control characters).

stringprep.**in_table_c22**(*code*)

Determine whether *code* is in tableC.2.2 (Non-ASCII control characters).

stringprep.**in_table_c21_c22**(*code*)

Determine whether *code* is in tableC.2 (Control characters, union of C.2.1 and C.2.2).

stringprep.**in_table_c3**(*code*)

Determine whether *code* is in tableC.3 (Private use).

stringprep.**in_table_c4**(*code*)

Determine whether *code* is in tableC.4 (Non-character code points).

stringprep.**in_table_c5**(*code*)

Determine whether *code* is in tableC.5 (Surrogate codes).

stringprep.**in_table_c6**(*code*)

Determine whether *code* is in tableC.6 (Inappropriate for plain text).

stringprep.**in_table_c7**(*code*)

Determine whether *code* is in tableC.7 (Inappropriate for canonical representation).

stringprep.**in_table_c8**(*code*)

Determine whether *code* is in tableC.8 (Change display properties or are deprecated).

stringprep.**in_table_c9**(*code*)

Determine whether *code* is in tableC.9 (Tagging characters).

stringprep.**in_table_d1**(*code*)

Determine whether *code* is in tableD.1 (Characters with bidirectional property “R” or “AL”).

stringprep.**in_table_d2**(*code*)

Determine whether *code* is in tableD.2 (Characters with

bidirectional property “L”).

7. Data Types

The modules described in this chapter provide a variety of specialized data types such as dates and times, fixed-type arrays, heap queues, synchronized queues, and sets.

Python also provides some built-in data types, in particular, `dict`, `list`, `set` and `frozenset`, and `tuple`. The `str` class is used to hold Unicode strings, and the `bytes` class is used to hold binary data.

The following modules are documented in this chapter:

- 7.1. `datetime` — Basic date and time types
 - 7.1.1. Available Types
 - 7.1.2. `timedelta` Objects
 - 7.1.3. `date` Objects
 - 7.1.4. `datetime` Objects
 - 7.1.5. `time` Objects
 - 7.1.6. `tzinfo` Objects
 - 7.1.7. `timezone` Objects
 - 7.1.8. `strftime()` and `strptime()` Behavior
- 7.2. `calendar` — General calendar-related functions
- 7.3. `collections` — Container datatypes
 - 7.3.1. `Counter` objects
 - 7.3.2. `deque` objects
 - 7.3.2.1. `deque` Recipes
 - 7.3.3. `defaultdict` objects
 - 7.3.3.1. `defaultdict` Examples
 - 7.3.4. `namedtuple()` Factory Function for Tuples with Named Fields
 - 7.3.5. `OrderedDict` objects
 - 7.3.6. `UserDict` objects

- 7.3.7. `UserList` objects
- 7.3.8. `UserString` objects
- 7.3.9. ABCs - abstract base classes
- 7.4. `heapq` — Heap queue algorithm
 - 7.4.1. Basic Examples
 - 7.4.2. Priority Queue Implementation Notes
 - 7.4.3. Theory
- 7.5. `bisect` — Array bisection algorithm
 - 7.5.1. Searching Sorted Lists
 - 7.5.2. Other Examples
- 7.6. `array` — Efficient arrays of numeric values
- 7.7. `sched` — Event scheduler
 - 7.7.1. Scheduler Objects
- 7.8. `queue` — A synchronized queue class
 - 7.8.1. Queue Objects
- 7.9. `weakref` — Weak references
 - 7.9.1. Weak Reference Objects
 - 7.9.2. Example
- 7.10. `types` — Names for built-in types
- 7.11. `copy` — Shallow and deep copy operations
- 7.12. `pprint` — Data pretty printer
 - 7.12.1. PrettyPrinter Objects
 - 7.12.2. pprint Example
- 7.13. `reprlib` — Alternate `repr()` implementation
 - 7.13.1. Repr Objects
 - 7.13.2. Subclassing Repr Objects

7.1. `datetime` — Basic date and time types

The `datetime` module supplies classes for manipulating dates and times in both simple and complex ways. While date and time arithmetic is supported, the focus of the implementation is on efficient member extraction for output formatting and manipulation. For related functionality, see also the `time` and `calendar` modules.

There are two kinds of date and time objects: “naive” and “aware”. This distinction refers to whether the object has any notion of time zone, daylight saving time, or other kind of algorithmic or political time adjustment. Whether a naive `datetime` object represents Coordinated Universal Time (UTC), local time, or time in some other timezone is purely up to the program, just like it’s up to the program whether a particular number represents metres, miles, or mass. Naive `datetime` objects are easy to understand and to work with, at the cost of ignoring some aspects of reality.

For applications requiring more, `datetime` and `time` objects have an optional time zone information member, `tzinfo`, that can contain an instance of a subclass of the abstract `tzinfo` class. These `tzinfo` objects capture information about the offset from UTC time, the time zone name, and whether Daylight Saving Time is in effect. Note that only one concrete `tzinfo` class, the `timezone` class, is supplied by the `datetime` module. The `timezone` class can represent simple timezones with fixed offset from UTC such as UTC itself or North American EST and EDT timezones. Supporting timezones at whatever level of detail is required is up to the application. The rules for time adjustment across the world are more political than rational, change frequently, and there is no standard suitable for every application aside from UTC.

The `datetime` module exports the following constants:

`datetime.MINYEAR`

The smallest year number allowed in a `date` or `datetime` object.

`MINYEAR` is `1`.

`datetime.MAXYEAR`

The largest year number allowed in a `date` or `datetime` object.

`MAXYEAR` is `9999`.

See also:

Module `calendar`

General calendar related functions.

Module `time`

Time access and conversions.

7.1.1. Available Types

class `datetime.date`

An idealized naive date, assuming the current Gregorian calendar always was, and always will be, in effect. Attributes: `year`, `month`, and `day`.

class `datetime.time`

An idealized time, independent of any particular day, assuming that every day has exactly $24 \times 60 \times 60$ seconds (there is no notion of “leap seconds” here). Attributes: `hour`, `minute`, `second`, `microsecond`, and `tzinfo`.

class `datetime.datetime`

A combination of a date and a time. Attributes: `year`, `month`, `day`, `hour`, `minute`, `second`, `microsecond`, and `tzinfo`.

class `datetime.timedelta`

A duration expressing the difference between two `date`, `time`, or `datetime` instances to microsecond resolution.

class `datetime.tzinfo`

An abstract base class for time zone information objects. These are used by the `datetime` and `time` classes to provide a customizable notion of time adjustment (for example, to account for time zone and/or daylight saving time).

class `datetime.timezone`

A class that implements the `tzinfo` abstract base class as a fixed offset from the UTC.

New in version 3.2.

Objects of these types are immutable.

Objects of the `date` type are always naive.

An object *d* of type `time` or `datetime` may be naive or aware. *d* is aware if `d.tzinfo` is not `None` and `d.tzinfo.utcoffset(d)` does not return `None`. If `d.tzinfo` is `None`, or if `d.tzinfo` is not `None` but `d.tzinfo.utcoffset(d)` returns `None`, *d* is naive.

The distinction between naive and aware doesn't apply to `timedelta` objects.

Subclass relationships:

```
object
  timedelta
  tzinfo
    timezone
  time
  date
    datetime
```

7.1.2. `timedelta` Objects

A `timedelta` object represents a duration, the difference between two dates or times.

```
class datetime.timedelta(days=0, seconds=0, microseconds=0,  
milliseconds=0, minutes=0, hours=0, weeks=0)
```

All arguments are optional and default to `0`. Arguments may be integers or floats, and may be positive or negative.

Only `days`, `seconds` and `microseconds` are stored internally. Arguments are converted to those units:

- A millisecond is converted to 1000 microseconds.
- A minute is converted to 60 seconds.
- An hour is converted to 3600 seconds.
- A week is converted to 7 days.

and `days`, `seconds` and `microseconds` are then normalized so that the representation is unique, with

- `0 <= microseconds < 1000000`
- `0 <= seconds < 3600*24` (the number of seconds in one day)
- `-999999999 <= days <= 999999999`

If any argument is a float and there are fractional microseconds, the fractional microseconds left over from all arguments are combined and their sum is rounded to the nearest microsecond. If no argument is a float, the conversion and normalization processes are exact (no information is lost).

If the normalized value of `days` lies outside the indicated range, `OverflowError` is raised.

Note that normalization of negative values may be surprising at

first. For example,

```
>>> from datetime import timedelta
>>> d = timedelta(microseconds=-1)
>>> (d.days, d.seconds, d.microseconds)
(-1, 86399, 999999)
```

Class attributes are:

`timedelta.min`

The most negative `timedelta` object, `timedelta(-999999999)`.

`timedelta.max`

The most positive `timedelta` object, `timedelta(days=999999999, hours=23, minutes=59, seconds=59, microseconds=999999)`.

`timedelta.resolution`

The smallest possible difference between non-equal `timedelta` objects, `timedelta(microseconds=1)`.

Note that, because of normalization, `timedelta.max > -timedelta.min`. `-timedelta.max` is not representable as a `timedelta` object.

Instance attributes (read-only):

Attribute	Value
days	Between -999999999 and 999999999 inclusive
seconds	Between 0 and 86399 inclusive
microseconds	Between 0 and 999999 inclusive

Supported operations:

Operation	Result
$t1 = t2 + t3$	Sum of $t2$ and $t3$. Afterwards $t1-t2 ==$

	$t3$ and $t1-t3 == t2$ are true. (1)
$t1 = t2 - t3$	Difference of $t2$ and $t3$. Afterwards $t1 == t2 - t3$ and $t2 == t1 + t3$ are true. (1)
$t1 = t2 * i$ or $t1 = i * t2$	Delta multiplied by an integer. Afterwards $t1 // i == t2$ is true, provided $i != 0$.
	In general, $t1 * i == t1 * (i-1) + t1$ is true. (1)
$t1 = t2 * f$ or $t1 = f * t2$	Delta multiplied by a float. The result is rounded to the nearest multiple of <code>timedelta.resolution</code> using round-half-to-even.
$f = t2 / t3$	Division (3) of $t2$ by $t3$. Returns a float object.
$t1 = t2 / f$ or $t1 = t2 / i$	Delta divided by a float or an int. The result is rounded to the nearest multiple of <code>timedelta.resolution</code> using round-half-to-even.
$t1 = t2 // i$ or $t1 = t2 // t3$	The floor is computed and the remainder (if any) is thrown away. In the second case, an integer is returned. (3)
$t1 = t2 \% t3$	The remainder is computed as a timedelta object. (3)
$q, r = \text{divmod}(t1, t2)$	Computes the quotient and the remainder: $q = t1 // t2$ (3) and $r = t1 \% t2$. q is an integer and r is a timedelta object.
$+t1$	Returns a timedelta object with the same value. (2)
$-t1$	equivalent to <code>timedelta(-t1.days, -t1.seconds, -t1.microseconds)</code> , and to $t1 * -1$. (1)(4)
$\text{abs}(t)$	equivalent to $+t$ when $t.days \geq 0$, and to $-t$ when $t.days < 0$. (2)
	Returns a string in the form <code>[D day[s],</code>

<code>str(t)</code>	<code>][H]H:MM:SS[.UUUUUU]</code> , where D is negative for negative <code>t</code> . (5)
<code>repr(t)</code>	Returns a string in the form <code>datetime.timedelta(D[, S[, U]])</code> , where D is negative for negative <code>t</code> . (5)

Notes:

1. This is exact, but may overflow.
2. This is exact, and cannot overflow.
3. Division by 0 raises `ZeroDivisionError`.
4. `-timedelta.max` is not representable as a `timedelta` object.
5. String representations of `timedelta` objects are normalized similarly to their internal representation. This leads to somewhat unusual results for negative timedeltas. For example:

```
>>> timedelta(hours=-5)
datetime.timedelta(-1, 68400)
>>> print(_)
-1 day, 19:00:00
```

In addition to the operations listed above `timedelta` objects support certain additions and subtractions with `date` and `datetime` objects (see below).

Changed in version 3.2: Floor division and true division of a `timedelta` object by another `timedelta` object are now supported, as are remainder operations and the `divmod()` function. True division and multiplication of a `timedelta` object by a `float` object are now supported.

Comparisons of `timedelta` objects are supported with the `timedelta`

object representing the smaller duration considered to be the smaller `timedelta`. In order to stop mixed-type comparisons from falling back to the default comparison by object address, when a `timedelta` object is compared to an object of a different type, `TypeError` is raised unless the comparison is `==` or `!=`. The latter cases return `False` or `True`, respectively.

`timedelta` objects are *hashable* (usable as dictionary keys), support efficient pickling, and in Boolean contexts, a `timedelta` object is considered to be true if and only if it isn't equal to `timedelta(0)`.

Instance methods:

`timedelta.total_seconds()`

Return the total number of seconds contained in the duration. Equivalent to `td / timedelta(seconds=1)`.

Note that for very large time intervals (greater than 270 years on most platforms) this method will lose microsecond accuracy.

New in version 3.2.

Example usage:

```
>>> from datetime import timedelta
>>> year = timedelta(days=365)
>>> another_year = timedelta(weeks=40, days=84, hours=23,
...                          minutes=50, seconds=600) # adds up
>>> year.total_seconds()
31536000.0
>>> year == another_year
True
>>> ten_years = 10 * year
>>> ten_years, ten_years.days // 365
(datetime.timedelta(3650), 10)
>>> nine_years = ten_years - year
>>> nine_years, nine_years.days // 365
(datetime.timedelta(3285), 9)
```

```
>>> three_years = nine_years // 3;
>>> three_years, three_years.days // 365
(datetime.timedelta(1095), 3)
>>> abs(three_years - ten_years) == 2 * three_years + year
True
```

7.1.3. `date` Objects

A `date` object represents a date (year, month and day) in an idealized calendar, the current Gregorian calendar indefinitely extended in both directions. January 1 of year 1 is called day number 1, January 2 of year 1 is called day number 2, and so on. This matches the definition of the “proleptic Gregorian” calendar in Dershowitz and Reingold’s book *Calendrical Calculations*, where it’s the base calendar for all computations. See the book for algorithms for converting between proleptic Gregorian ordinals and many other calendar systems.

class `datetime.date`(*year*, *month*, *day*)

All arguments are required. Arguments may be integers, in the following ranges:

- `MINYEAR <= year <= MAXYEAR`
- `1 <= month <= 12`
- `1 <= day <= number of days in the given month and year`

If an argument outside those ranges is given, `ValueError` is raised.

Other constructors, all class methods:

classmethod `date.today`()

Return the current local date. This is equivalent to `date.fromtimestamp(time.time())`.

classmethod `date.fromtimestamp`(*timestamp*)

Return the local date corresponding to the POSIX timestamp, such as is returned by `time.time()`. This may raise `ValueError`, if the timestamp is out of the range of values supported by the

platform C `localtime()` function. It's common for this to be restricted to years from 1970 through 2038. Note that on non-POSIX systems that include leap seconds in their notion of a timestamp, leap seconds are ignored by `fromtimestamp()`.

classmethod `date.fromordinal(ordinal)`

Return the date corresponding to the proleptic Gregorian ordinal, where January 1 of year 1 has ordinal 1. `ValueError` is raised unless `1 <= ordinal <= date.max.toordinal()`. For any date `d`, `date.fromordinal(d.toordinal()) == d`.

Class attributes:

`date.min`

The earliest representable date, `date(MINYEAR, 1, 1)`.

`date.max`

The latest representable date, `date(MAXYEAR, 12, 31)`.

`date.resolution`

The smallest possible difference between non-equal date objects, `timedelta(days=1)`.

Instance attributes (read-only):

`date.year`

Between `MINYEAR` and `MAXYEAR` inclusive.

`date.month`

Between 1 and 12 inclusive.

`date.day`

Between 1 and the number of days in the given month of the given year.

Supported operations:

Operation	Result
<code>date2 = date1 + timedelta</code>	<i>date2</i> is <code>timedelta.days</code> days removed from <i>date1</i> . (1)
<code>date2 = date1 - timedelta</code>	Computes <i>date2</i> such that <code>date2 + timedelta == date1</code> . (2)
<code>timedelta = date1 - date2</code>	(3)
<code>date1 < date2</code>	<i>date1</i> is considered less than <i>date2</i> when <i>date1</i> precedes <i>date2</i> in time. (4)

Notes:

1. *date2* is moved forward in time if `timedelta.days > 0`, or backward if `timedelta.days < 0`. Afterward `date2 - date1 == timedelta.days`. `timedelta.seconds` and `timedelta.microseconds` are ignored. `OverflowError` is raised if `date2.year` would be smaller than `MINYEAR` or larger than `MAXYEAR`.
2. This isn't quite equivalent to `date1 + (-timedelta)`, because `-timedelta` in isolation can overflow in cases where `date1 - timedelta` does not. `timedelta.seconds` and `timedelta.microseconds` are ignored.
3. This is exact, and cannot overflow. `timedelta.seconds` and `timedelta.microseconds` are 0, and `date2 + timedelta == date1` after.
4. In other words, `date1 < date2` if and only if `date1.toordinal() < date2.toordinal()`. In order to stop comparison from falling back to the default scheme of comparing object addresses, date comparison normally raises `TypeError` if the other comparand isn't also a `date` object. However, `NotImplemented` is returned instead if the other comparand has a `timetuple()` attribute. This hook gives other kinds of date objects a chance at implementing mixed-type comparison. If not, when a `date` object is compared to an object of a different type, `TypeError` is raised unless the

comparison is `==` or `!=`. The latter cases return `False` or `True`, respectively.

Dates can be used as dictionary keys. In Boolean contexts, all `date` objects are considered to be true.

Instance methods:

`date.replace(year, month, day)`

Return a date with the same value, except for those members given new values by whichever keyword arguments are specified. For example, if `d == date(2002, 12, 31)`, then `d.replace(day=26) == date(2002, 12, 26)`.

`date.timetuple()`

Return a `time.struct_time` such as returned by `time.localtime()`. The hours, minutes and seconds are 0, and the DST flag is -1. `d.timetuple()` is equivalent to `time.struct_time((d.year, d.month, d.day, 0, 0, 0, d.weekday(), yday, -1))`, where `yday = d.toordinal() - date(d.year, 1, 1).toordinal() + 1` is the day number within the current year starting with 1 for January 1st.

`date.toordinal()`

Return the proleptic Gregorian ordinal of the date, where January 1 of year 1 has ordinal 1. For any `date` object `d`, `date.fromordinal(d.toordinal()) == d`.

`date.weekday()`

Return the day of the week as an integer, where Monday is 0 and Sunday is 6. For example, `date(2002, 12, 4).weekday() == 2`, a Wednesday. See also `isoweekday()`.

`date.isoweekday()`

Return the day of the week as an integer, where Monday is 1 and Sunday is 7. For example, `date(2002, 12, 4).isoweekday() == 3`, a Wednesday. See also `weekday()`, `isocalendar()`.

`date.isocalendar()`

Return a 3-tuple, (ISO year, ISO week number, ISO weekday).

The ISO calendar is a widely used variant of the Gregorian calendar. See <http://www.phys.uu.nl/~vgent/calendar/isocalendar.htm> for a good explanation.

The ISO year consists of 52 or 53 full weeks, and where a week starts on a Monday and ends on a Sunday. The first week of an ISO year is the first (Gregorian) calendar week of a year containing a Thursday. This is called week number 1, and the ISO year of that Thursday is the same as its Gregorian year.

For example, 2004 begins on a Thursday, so the first week of ISO year 2004 begins on Monday, 29 Dec 2003 and ends on Sunday, 4 Jan 2004, so that `date(2003, 12, 29).isocalendar() == (2004, 1, 1)` and `date(2004, 1, 4).isocalendar() == (2004, 1, 7)`.

`date.isoformat()`

Return a string representing the date in ISO 8601 format, 'YYYY-MM-DD'. For example, `date(2002, 12, 4).isoformat() == '2002-12-04'`.

`date.__str__()`

For a date `d`, `str(d)` is equivalent to `d.isoformat()`.

`date.ctime()`

Return a string representing the date, for example `date(2002, 12, 4).ctime() == 'Wed Dec 4 00:00:00 2002'`. `d.ctime()` is equivalent to `time.ctime(time.mktime(d.timetuple()))` on platforms where the native C `ctime()` function (which `time.ctime()` invokes, but which `date.ctime()` does not invoke) conforms to the C standard.

`date.strftime(format)`

Return a string representing the date, controlled by an explicit format string. Format codes referring to hours, minutes or seconds will see 0 values. See section *strftime() and strptime() Behavior*.

Example of counting days to an event:

```
>>> import time
>>> from datetime import date
>>> today = date.today()
>>> today
datetime.date(2007, 12, 5)
>>> today == date.fromtimestamp(time.time())
True
>>> my_birthday = date(today.year, 6, 24)
>>> if my_birthday < today:
...     my_birthday = my_birthday.replace(year=today.year + 1)
>>> my_birthday
datetime.date(2008, 6, 24)
>>> time_to_birthday = abs(my_birthday - today)
>>> time_to_birthday.days
202
```

Example of working with `date`:

```
>>> from datetime import date
>>> d = date.fromordinal(730920) # 730920th day after 1. 1. 000
>>> d
datetime.date(2002, 3, 11)
>>> t = d.timetuple()
>>> for i in t:
...     print(i)
```

```
2002          # year
3             # month
11           # day
0
0
0
0            # weekday (0 = Monday)
70           # 70th day in the year
-1
>>> ic = d.isocalendar()
>>> for i in ic:
...     print(i)
2002          # ISO year
11           # ISO week number
1            # ISO day number ( 1 = Monday )
>>> d.isoformat()
'2002-03-11'
>>> d.strftime("%d/%m/%y")
'11/03/02'
>>> d.strftime("%A %d. %B %Y")
'Monday 11. March 2002'
```

7.1.4. `datetime` Objects

A `datetime` object is a single object containing all the information from a `date` object and a `time` object. Like a `date` object, `datetime` assumes the current Gregorian calendar extended in both directions; like a `time` object, `datetime` assumes there are exactly 3600×24 seconds in every day.

Constructor:

```
class datetime.datetime(year, month, day, hour=0, minute=0,
second=0, microsecond=0, tzinfo=None)
```

The year, month and day arguments are required. `tzinfo` may be `None`, or an instance of a `tzinfo` subclass. The remaining arguments may be integers, in the following ranges:

- `MINYEAR <= year <= MAXYEAR`
- `1 <= month <= 12`
- `1 <= day <= number of days in the given month and year`
- `0 <= hour < 24`
- `0 <= minute < 60`
- `0 <= second < 60`
- `0 <= microsecond < 1000000`

If an argument outside those ranges is given, `ValueError` is raised.

Other constructors, all class methods:

```
classmethod datetime.today()
```

Return the current local datetime, with `tzinfo` `None`. This is equivalent to `datetime.fromtimestamp(time.time())`. See also `now()`, `fromtimestamp()`.

classmethod `datetime.now(tz=None)`

Return the current local date and time. If optional argument `tz` is `None` or not specified, this is like `today()`, but, if possible, supplies more precision than can be gotten from going through a `time.time()` timestamp (for example, this may be possible on platforms supplying the C `gettimeofday()` function).

Else `tz` must be an instance of a class `tzinfo` subclass, and the current date and time are converted to `tz`'s time zone. In this case the result is equivalent to `tz.fromutc(datetime.utcnow().replace(tzinfo=tz))`. See also `today()`, `utcnow()`.

classmethod `datetime.utcnow()`

Return the current UTC date and time, with `tzinfo None`. This is like `now()`, but returns the current UTC date and time, as a naive `datetime` object. An aware current UTC datetime can be obtained by calling `datetime.now(timezone.utc)`. See also `now()`.

classmethod `datetime.fromtimestamp(timestamp, tz=None)`

Return the local date and time corresponding to the POSIX timestamp, such as is returned by `time.time()`. If optional argument `tz` is `None` or not specified, the timestamp is converted to the platform's local date and time, and the returned `datetime` object is naive.

Else `tz` must be an instance of a class `tzinfo` subclass, and the timestamp is converted to `tz`'s time zone. In this case the result is equivalent to `tz.fromutc(datetime.fromtimestamp(timestamp).replace(tzinfo=`

`fromtimestamp())` may raise `ValueError`, if the timestamp is out of

the range of values supported by the platform C `localtime()` or `gmtime()` functions. It's common for this to be restricted to years in 1970 through 2038. Note that on non-POSIX systems that include leap seconds in their notion of a timestamp, leap seconds are ignored by `fromtimestamp()`, and then it's possible to have two timestamps differing by a second that yield identical `datetime` objects. See also `utcfromtimestamp()`.

classmethod `datetime.utcfromtimestamp(timestamp)`

Return the UTC `datetime` corresponding to the POSIX timestamp, with `tzinfo` `None`. This may raise `ValueError`, if the timestamp is out of the range of values supported by the platform C `gmtime()` function. It's common for this to be restricted to years in 1970 through 2038. See also `fromtimestamp()`.

classmethod `datetime.fromordinal(ordinal)`

Return the `datetime` corresponding to the proleptic Gregorian ordinal, where January 1 of year 1 has ordinal 1. `ValueError` is raised unless `1 <= ordinal <= datetime.max.toordinal()`. The hour, minute, second and microsecond of the result are all 0, and `tzinfo` is `None`.

classmethod `datetime.combine(date, time)`

Return a new `datetime` object whose date members are equal to the given `date` object's, and whose time and `tzinfo` members are equal to the given `time` object's. For any `datetime` object `d`, `d == datetime.combine(d.date(), d.timetz())`. If `date` is a `datetime` object, its time and `tzinfo` members are ignored.

classmethod `datetime.strptime(date_string, format)`

Return a `datetime` corresponding to `date_string`, parsed according to `format`. This is equivalent to `datetime(*`

`(time.strptime(date_string, format)[0:6]))`. **ValueError** is raised if the `date_string` and `format` can't be parsed by `time.strptime()` or if it returns a value which isn't a time tuple. See section *strptime() and strftime() Behavior*.

Class attributes:

`datetime.min`

The earliest representable **datetime**, `datetime(MINYEAR, 1, 1, tzinfo=None)`.

`datetime.max`

The latest representable **datetime**, `datetime(MAXYEAR, 12, 31, 23, 59, 59, 999999, tzinfo=None)`.

`datetime.resolution`

The smallest possible difference between non-equal **datetime** objects, `timedelta(microseconds=1)`.

Instance attributes (read-only):

`datetime.year`

Between **MINYEAR** and **MAXYEAR** inclusive.

`datetime.month`

Between 1 and 12 inclusive.

`datetime.day`

Between 1 and the number of days in the given month of the given year.

`datetime.hour`

In `range(24)`.

`datetime.minute`

In `range(60)`.

`datetime.second`

In `range(60)`.

`datetime.microsecond`

In `range(1000000)`.

`datetime.tzinfo`

The object passed as the `tzinfo` argument to the `datetime` constructor, or `None` if none was passed.

Supported operations:

Operation	Result
<code>datetime2 = datetime1 + timedelta</code>	(1)
<code>datetime2 = datetime1 - timedelta</code>	(2)
<code>timedelta = datetime1 - datetime2</code>	(3)
<code>datetime1 < datetime2</code>	Compares <code>datetime</code> to <code>datetime</code> . (4)

1. `datetime2` is a duration of `timedelta` removed from `datetime1`, moving forward in time if `timedelta.days > 0`, or backward if `timedelta.days < 0`. The result has the same `tzinfo` member as the input `datetime`, and `datetime2 - datetime1 == timedelta` after. `OverflowError` is raised if `datetime2.year` would be smaller than `MINYEAR` or larger than `MAXYEAR`. Note that no time zone adjustments are done even if the input is an aware object.
2. Computes the `datetime2` such that `datetime2 + timedelta == datetime1`. As for addition, the result has the same `tzinfo` member as the input `datetime`, and no time zone adjustments are done even if the input is aware. This isn't quite equivalent to `datetime1 + (-timedelta)`, because `-timedelta` in isolation can overflow in cases where `datetime1 - timedelta` does not.
3. Subtraction of a `datetime` from a `datetime` is defined only if both

operands are naive, or if both are aware. If one is aware and the other is naive, `TypeError` is raised.

If both are naive, or both are aware and have the same `tzinfo` member, the `tzinfo` members are ignored, and the result is a `timedelta` object `t` such that `datetime2 + t == datetime1`. No time zone adjustments are done in this case.

If both are aware and have different `tzinfo` members, `a-b` acts as if `a` and `b` were first converted to naive UTC datetimes first. The result is `(a.replace(tzinfo=None) - a.utcoffset()) - (b.replace(tzinfo=None) - b.utcoffset())` except that the implementation never overflows.

4. `datetime1` is considered less than `datetime2` when `datetime1` precedes `datetime2` in time.

If one comparand is naive and the other is aware, `TypeError` is raised. If both comparands are aware, and have the same `tzinfo` member, the common `tzinfo` member is ignored and the base datetimes are compared. If both comparands are aware and have different `tzinfo` members, the comparands are first adjusted by subtracting their UTC offsets (obtained from `self.utcoffset()`).

Note: In order to stop comparison from falling back to the default scheme of comparing object addresses, `datetime` comparison normally raises `TypeError` if the other comparand isn't also a `datetime` object. However, `NotImplemented` is returned instead if the other comparand has a `timetuple()` attribute. This hook gives other kinds of date objects a chance at implementing mixed-type comparison. If not, when a `datetime` object is compared to an object of a different type,

`TypeError` is raised unless the comparison is `==` or `!=`. The latter cases return `False` or `True`, respectively.

`datetime` objects can be used as dictionary keys. In Boolean contexts, all `datetime` objects are considered to be true.

Instance methods:

`datetime.date()`

Return `date` object with same year, month and day.

`datetime.time()`

Return `time` object with same hour, minute, second and microsecond. `tzinfo` is `None`. See also method `timetz()`.

`datetime.timetz()`

Return `time` object with same hour, minute, second, microsecond, and `tzinfo` members. See also method `time()`.

`datetime.replace([year[, month[, day[, hour[, minute[, second[, microsecond[, tzinfo]]]]]]])`

Return a `datetime` with the same members, except for those members given new values by whichever keyword arguments are specified. Note that `tzinfo=None` can be specified to create a naive `datetime` from an aware `datetime` with no conversion of date and time members.

`datetime.astimezone(tz)`

Return a `datetime` object with new `tzinfo` member `tz`, adjusting the date and time members so the result is the same UTC time as `self`, but in `tz`'s local time.

`tz` must be an instance of a `tzinfo` subclass, and its `utcoffset()`

and `dst()` methods must not return `None`. `self` must be aware (`self.tzinfo` must not be `None`, and `self.utcoffset()` must not return `None`).

If `self.tzinfo` is `tz`, `self.astimezone(tz)` is equal to `self`: no adjustment of date or time members is performed. Else the result is local time in time zone `tz`, representing the same UTC time as `self`: after `astz = dt.astimezone(tz)`, `astz - astz.utcoffset()` will usually have the same date and time members as `dt - dt.utcoffset()`. The discussion of class `tzinfo` explains the cases at Daylight Saving Time transition boundaries where this cannot be achieved (an issue only if `tz` models both standard and daylight time).

If you merely want to attach a time zone object `tz` to a datetime `dt` without adjustment of date and time members, use `dt.replace(tzinfo=tz)`. If you merely want to remove the time zone object from an aware datetime `dt` without conversion of date and time members, use `dt.replace(tzinfo=None)`.

Note that the default `tzinfo.fromutc()` method can be overridden in a `tzinfo` subclass to affect the result returned by `astimezone()`. Ignoring error cases, `astimezone()` acts like:

```
def astimezone(self, tz):
    if self.tzinfo is tz:
        return self
    # Convert self to UTC, and attach the new time zone object
    utc = (self - self.utcoffset()).replace(tzinfo=tz)
    # Convert from UTC to tz's local time.
    return tz.fromutc(utc)
```

`datetime.utcoffset()`

If `tzinfo` is `None`, returns `None`, else returns

`self.tzinfo.utcoffset(self)`, and raises an exception if the latter doesn't return `None`, or a `timedelta` object representing a whole number of minutes with magnitude less than one day.

`datetime.dst()`

If `tzinfo` is `None`, returns `None`, else returns `self.tzinfo.dst(self)`, and raises an exception if the latter doesn't return `None`, or a `timedelta` object representing a whole number of minutes with magnitude less than one day.

`datetime.tzname()`

If `tzinfo` is `None`, returns `None`, else returns `self.tzinfo.tzname(self)`, raises an exception if the latter doesn't return `None` or a string object,

`datetime.timetuple()`

Return a `time.struct_time` such as returned by `time.localtime()`. `d.timetuple()` is equivalent to `time.struct_time((d.year, d.month, d.day, d.hour, d.minute, d.second, d.weekday(), yday, dst))`, where `yday = d.toordinal() - date(d.year, 1, 1).toordinal() + 1` is the day number within the current year starting with `1` for January 1st. The `tm_isdst` flag of the result is set according to the `dst()` method: `tzinfo` is `None` or `dst()` returns `None`, `tm_isdst` is set to `-1`; else if `dst()` returns a non-zero value, `tm_isdst` is set to `1`; else `tm_isdst` is set to `0`.

`datetime.utctimetuple()`

If `datetime` instance `d` is naive, this is the same as `d.timetuple()` except that `tm_isdst` is forced to `0` regardless of what `d.dst()` returns. DST is never in effect for a UTC time.

If *d* is aware, *d* is normalized to UTC time, by subtracting `d.utcoffset()`, and a `time.struct_time` for the normalized time is returned. `tm_isdst` is forced to 0. Note that an `OverflowError` may be raised if *d.year* was `MINYEAR` or `MAXYEAR` and UTC adjustment spills over a year boundary.

`datetime.toordinal()`

Return the proleptic Gregorian ordinal of the date. The same as `self.date().toordinal()`.

`datetime.weekday()`

Return the day of the week as an integer, where Monday is 0 and Sunday is 6. The same as `self.date().weekday()`. See also `isoweekday()`.

`datetime.isoweekday()`

Return the day of the week as an integer, where Monday is 1 and Sunday is 7. The same as `self.date().isoweekday()`. See also `weekday()`, `isocalendar()`.

`datetime.isocalendar()`

Return a 3-tuple, (ISO year, ISO week number, ISO weekday). The same as `self.date().isocalendar()`.

`datetime.isoformat(sep='T')`

Return a string representing the date and time in ISO 8601 format, YYYY-MM-DDTHH:MM:SS.mmmmmm or, if `microsecond` is 0, YYYY-MM-DDTHH:MM:SS

If `utcoffset()` does not return `None`, a 6-character string is appended, giving the UTC offset in (signed) hours and minutes: YYYY-MM-DDTHH:MM:SS.mmmmmm+HH:MM or, if `microsecond` is 0 YYYY-MM-DDTHH:MM:SS+HH:MM

The optional argument `sep` (default `'T'`) is a one-character separator, placed between the date and time portions of the result. For example,

```
>>> from datetime import tzinfo, timedelta, datetime
>>> class TZ(tzinfo):
...     def utcoffset(self, dt): return timedelta(minutes=-3)
...
>>> datetime(2002, 12, 25, tzinfo=TZ()).isoformat(' ')
'2002-12-25 00:00:00-06:39'
```

`datetime.__str__()`

For a `datetime` instance `d`, `str(d)` is equivalent to `d.isoformat('')`.

`datetime.ctime()`

Return a string representing the date and time, for example `datetime(2002, 12, 4, 20, 30, 40).ctime() == 'Wed Dec 4 20:30:40 2002'`. `d.ctime()` is equivalent to `time.ctime(time.mktime(d.timetuple()))` on platforms where the native C `ctime()` function (which `time.ctime()` invokes, but which `datetime.ctime()` does not invoke) conforms to the C standard.

`datetime.strftime(format)`

Return a string representing the date and time, controlled by an explicit format string. See section [strftime\(\) and strptime\(\) Behavior](#).

Examples of working with datetime objects:

```
>>> from datetime import datetime, date, time
>>> # Using datetime.combine()
>>> d = date(2005, 7, 14)
>>> t = time(12, 30)
>>> datetime.combine(d, t)
datetime.datetime(2005, 7, 14, 12, 30)
```

```

>>> # Using datetime.now() or datetime.utcnow()
>>> datetime.now()
datetime.datetime(2007, 12, 6, 16, 29, 43, 79043) # GMT +1
>>> datetime.utcnow()
datetime.datetime(2007, 12, 6, 15, 29, 43, 79060)
>>> # Using datetime.strptime()
>>> dt = datetime.strptime("21/11/06 16:30", "%d/%m/%y %H:%M")
>>> dt
datetime.datetime(2006, 11, 21, 16, 30)
>>> # Using datetime.timetuple() to get tuple of all attributes
>>> tt = dt.timetuple()
>>> for it in tt:
...     print(it)
...
2006 # year
11 # month
21 # day
16 # hour
30 # minute
0 # second
1 # weekday (0 = Monday)
325 # number of days since 1st January
-1 # dst - method tzinfo.dst() returned None
>>> # Date in ISO format
>>> ic = dt.isocalendar()
>>> for it in ic:
...     print(it)
...
2006 # ISO year
47 # ISO week
2 # ISO weekday
>>> # Formatting datetime
>>> dt.strftime("%A, %d. %B %Y %I:%M%p")
'Tuesday, 21. November 2006 04:30PM'

```

Using datetime with tzinfo:

```

>>> from datetime import timedelta, datetime, tzinfo
>>> class GMT1(tzinfo):
...     def __init__(self): # DST starts last Sunday in
...         d = datetime(dt.year, 4, 1) # ends last Sunday in
...         self.dston = d - timedelta(days=d.weekday() + 1)
...         d = datetime(dt.year, 11, 1)
...         self.dstoff = d - timedelta(days=d.weekday() + 1)
...     def utcoffset(self, dt):

```

```

...     return timedelta(hours=1) + self.dst(dt)
...     def dst(self, dt):
...         if self.dston <= dt.replace(tzinfo=None) < self.ds
...             return timedelta(hours=1)
...         else:
...             return timedelta(0)
...     def tzname(self, dt):
...         return "GMT +1"
...
>>> class GMT2(tzinfo):
...     def __init__(self):
...         d = datetime(dt.year, 4, 1)
...         self.dston = d - timedelta(days=d.weekday() + 1)
...         d = datetime(dt.year, 11, 1)
...         self.dstoff = d - timedelta(days=d.weekday() + 1)
...     def utcoffset(self, dt):
...         return timedelta(hours=1) + self.dst(dt)
...     def dst(self, dt):
...         if self.dston <= dt.replace(tzinfo=None) < self.ds
...             return timedelta(hours=2)
...         else:
...             return timedelta(0)
...     def tzname(self, dt):
...         return "GMT +2"
...
>>> gmt1 = GMT1()
>>> # Daylight Saving Time
>>> dt1 = datetime(2006, 11, 21, 16, 30, tzinfo=gmt1)
>>> dt1.dst()
datetime.timedelta(0)
>>> dt1.utcoffset()
datetime.timedelta(0, 3600)
>>> dt2 = datetime(2006, 6, 14, 13, 0, tzinfo=gmt1)
>>> dt2.dst()
datetime.timedelta(0, 3600)
>>> dt2.utcoffset()
datetime.timedelta(0, 7200)
>>> # Convert datetime to another time zone
>>> dt3 = dt2.astimezone(GMT2())
>>> dt3
datetime.datetime(2006, 6, 14, 14, 0, tzinfo=<GMT2 object at 0x
>>> dt2
datetime.datetime(2006, 6, 14, 13, 0, tzinfo=<GMT1 object at 0x
>>> dt2.utctimetuple() == dt3.utctimetuple()
True

```

7.1.5. `time` Objects

A time object represents a (local) time of day, independent of any particular day, and subject to adjustment via a `tzinfo` object.

```
class datetime.time(hour=0, minute=0, second=0, microsecond=0, tzinfo=None)
```

All arguments are optional. `tzinfo` may be `None`, or an instance of a `tzinfo` subclass. The remaining arguments may be integers, in the following ranges:

- `0 <= hour < 24`
- `0 <= minute < 60`
- `0 <= second < 60`
- `0 <= microsecond < 1000000`.

If an argument outside those ranges is given, `ValueError` is raised. All default to `0` except `tzinfo`, which defaults to `None`.

Class attributes:

`time.min`

The earliest representable `time`, `time(0, 0, 0, 0)`.

`time.max`

The latest representable `time`, `time(23, 59, 59, 999999)`.

`time.resolution`

The smallest possible difference between non-equal `time` objects, `timedelta(microseconds=1)`, although note that arithmetic on `time` objects is not supported.

Instance attributes (read-only):

`time.hour`

In `range(24)`.

`time.minute`

In `range(60)`.

`time.second`

In `range(60)`.

`time.microsecond`

In `range(1000000)`.

`time.tzinfo`

The object passed as the `tzinfo` argument to the `time` constructor, or `None` if none was passed.

Supported operations:

- comparison of `time` to `time`, where *a* is considered less than *b* when *a* precedes *b* in time. If one comparand is naive and the other is aware, `TypeError` is raised. If both comparands are aware, and have the same `tzinfo` member, the common `tzinfo` member is ignored and the base times are compared. If both comparands are aware and have different `tzinfo` members, the comparands are first adjusted by subtracting their UTC offsets (obtained from `self.utcoffset()`). In order to stop mixed-type comparisons from falling back to the default comparison by object address, when a `time` object is compared to an object of a different type, `TypeError` is raised unless the comparison is `==` or `!=`. The latter cases return `False` or `True`, respectively.
- hash, use as dict key
- efficient pickling
- in Boolean contexts, a `time` object is considered to be true if and only if, after converting it to minutes and subtracting `utcoffset()`

(or `0` if that's `None`), the result is non-zero.

Instance methods:

`time.replace([hour[, minute[, second[, microsecond[, tzinfo]]]])`

Return a `time` with the same value, except for those members given new values by whichever keyword arguments are specified. Note that `tzinfo=None` can be specified to create a naive `time` from an aware `time`, without conversion of the time members.

`time.isoformat()`

Return a string representing the time in ISO 8601 format, HH:MM:SS.mmmmmm or, if `self.microsecond` is 0, HH:MM:SS If `utcoffset()` does not return `None`, a 6-character string is appended, giving the UTC offset in (signed) hours and minutes: HH:MM:SS.mmmmmm+HH:MM or, if `self.microsecond` is 0, HH:MM:SS+HH:MM

`time.__str__()`

For a time `t`, `str(t)` is equivalent to `t.isoformat()`.

`time.strftime(format)`

Return a string representing the time, controlled by an explicit format string. See section *strftime() and strptime() Behavior*.

`time.utcoffset()`

If `tzinfo` is `None`, returns `None`, else returns `self.tzinfo.utcoffset(None)`, and raises an exception if the latter doesn't return `None` or a `timedelta` object representing a whole number of minutes with magnitude less than one day.

`time.dst()`

If `tzinfo` is `None`, returns `None`, else returns

`self.tzinfo.dst(None)`, and raises an exception if the latter doesn't return `None`, or a `timedelta` object representing a whole number of minutes with magnitude less than one day.

`time.tzname()`

If `tzinfo` is `None`, returns `None`, else returns `self.tzinfo.tzname(None)`, or raises an exception if the latter doesn't return `None` or a string object.

Example:

```
>>> from datetime import time, tzinfo
>>> class GMT1(tzinfo):
...     def utcoffset(self, dt):
...         return timedelta(hours=1)
...     def dst(self, dt):
...         return timedelta(0)
...     def tzname(self, dt):
...         return "Europe/Prague"
...
>>> t = time(12, 10, 30, tzinfo=GMT1())
>>> t
datetime.time(12, 10, 30, tzinfo=<GMT1 object at 0x...>)
>>> gmt = GMT1()
>>> t.isoformat()
'12:10:30+01:00'
>>> t.dst()
datetime.timedelta(0)
>>> t.tzname()
'Europe/Prague'
>>> t.strftime("%H:%M:%S %Z")
'12:10:30 Europe/Prague'
```

7.1.6. `tzinfo` Objects

`tzinfo` is an abstract base class, meaning that this class should not be instantiated directly. You need to derive a concrete subclass, and (at least) supply implementations of the standard `tzinfo` methods needed by the `datetime` methods you use. The `datetime` module supplies a simple concrete subclass of `tzinfo` `timezone` which can represent timezones with fixed offset from UTC such as UTC itself or North American EST and EDT.

An instance of (a concrete subclass of) `tzinfo` can be passed to the constructors for `datetime` and `time` objects. The latter objects view their members as being in local time, and the `tzinfo` object supports methods revealing offset of local time from UTC, the name of the time zone, and DST offset, all relative to a date or time object passed to them.

Special requirement for pickling: A `tzinfo` subclass must have an `__init__()` method that can be called with no arguments, else it can be pickled but possibly not unpickled again. This is a technical requirement that may be relaxed in the future.

A concrete subclass of `tzinfo` may need to implement the following methods. Exactly which methods are needed depends on the uses made of aware `datetime` objects. If in doubt, simply implement all of them.

`tzinfo.utcoffset(dt)`

Return offset of local time from UTC, in minutes east of UTC. If local time is west of UTC, this should be negative. Note that this is intended to be the total offset from UTC; for example, if a `tzinfo` object represents both time zone and DST adjustments,

`utcoffset()` should return their sum. If the UTC offset isn't known, return `None`. Else the value returned must be a `timedelta` object specifying a whole number of minutes in the range -1439 to 1439 inclusive (1440 = 24*60; the magnitude of the offset must be less than one day). Most implementations of `utcoffset()` will probably look like one of these two:

```
return CONSTANT # fixed-offset class
return CONSTANT + self.dst(dt) # daylight-aware class
```

If `utcoffset()` does not return `None`, `dst()` should not return `None` either.

The default implementation of `utcoffset()` raises `NotImplementedError`.

`tzinfo.dst(dt)`

Return the daylight saving time (DST) adjustment, in minutes east of UTC, or `None` if DST information isn't known. Return `timedelta(0)` if DST is not in effect. If DST is in effect, return the offset as a `timedelta` object (see `utcoffset()` for details). Note that DST offset, if applicable, has already been added to the UTC offset returned by `utcoffset()`, so there's no need to consult `dst()` unless you're interested in obtaining DST info separately. For example, `datetime.timetuple()` calls its `tzinfo` member's `dst()` method to determine how the `tm_isdst` flag should be set, and `tzinfo.fromutc()` calls `dst()` to account for DST changes when crossing time zones.

An instance `tz` of a `tzinfo` subclass that models both standard and daylight times must be consistent in this sense:

```
tz.utcoffset(dt) - tz.dst(dt)
```

must return the same result for every `datetime dt` with `dt.tzinfo == tz`. For sane `tzinfo` subclasses, this expression yields the time zone's "standard offset", which should not depend on the date or the time, but only on geographic location. The implementation of `datetime.astimezone()` relies on this, but cannot detect violations; it's the programmer's responsibility to ensure it. If a `tzinfo` subclass cannot guarantee this, it may be able to override the default implementation of `tzinfo.fromutc()` to work correctly with `astimezone()` regardless.

Most implementations of `dst()` will probably look like one of these two:

```
def dst(self):  
    # a fixed-offset class: doesn't account for DST  
    return timedelta(0)
```

or

```
def dst(self):  
    # Code to set dston and dstoff to the time zone's DST  
    # transition times based on the input dt.year, and express  
    # in standard local time. Then  
  
    if dston <= dt.replace(tzinfo=None) < dstoff:  
        return timedelta(hours=1)  
    else:  
        return timedelta(0)
```

The default implementation of `dst()` raises `NotImplementedError`.

`tzinfo.tzname(dt)`

Return the time zone name corresponding to the `datetime` object `dt`, as a string. Nothing about string names is defined by the `datetime` module, and there's no requirement that it mean anything in particular. For example, "GMT", "UTC", "-500", "-5:00",

“EDT”, “US/Eastern”, “America/New York” are all valid replies. Return `None` if a string name isn’t known. Note that this is a method rather than a fixed string primarily because some `tzinfo` subclasses will wish to return different names depending on the specific value of `dt` passed, especially if the `tzinfo` class is accounting for daylight time.

The default implementation of `tzname()` raises `NotImplementedError`.

These methods are called by a `datetime` or `time` object, in response to their methods of the same names. A `datetime` object passes itself as the argument, and a `time` object passes `None` as the argument. A `tzinfo` subclass’s methods should therefore be prepared to accept a `dt` argument of `None`, or of class `datetime`.

When `None` is passed, it’s up to the class designer to decide the best response. For example, returning `None` is appropriate if the class wishes to say that time objects don’t participate in the `tzinfo` protocols. It may be more useful for `utcoffset(None)` to return the standard UTC offset, as there is no other convention for discovering the standard offset.

When a `datetime` object is passed in response to a `datetime` method, `dt.tzinfo` is the same object as `self`. `tzinfo` methods can rely on this, unless user code calls `tzinfo` methods directly. The intent is that the `tzinfo` methods interpret `dt` as being in local time, and not need worry about objects in other timezones.

There is one more `tzinfo` method that a subclass may wish to override:

```
tzinfo.fromutc(dt)
```

This is called from the default `datetime.astimezone()` implementation. When called from that, `dt.tzinfo` is *self*, and *dt*'s date and time members are to be viewed as expressing a UTC time. The purpose of `fromutc()` is to adjust the date and time members, returning an equivalent datetime in *self*'s local time.

Most `tzinfo` subclasses should be able to inherit the default `fromutc()` implementation without problems. It's strong enough to handle fixed-offset time zones, and time zones accounting for both standard and daylight time, and the latter even if the DST transition times differ in different years. An example of a time zone the default `fromutc()` implementation may not handle correctly in all cases is one where the standard offset (from UTC) depends on the specific date and time passed, which can happen for political reasons. The default implementations of `astimezone()` and `fromutc()` may not produce the result you want if the result is one of the hours straddling the moment the standard offset changes.

Skipping code for error cases, the default `fromutc()` implementation acts like:

```
def fromutc(self, dt):
    # raise ValueError error if dt.tzinfo is not self
    dtoff = dt.utcoffset()
    dtdst = dt.dst()
    # raise ValueError if dtoff is None or dtdst is None
    delta = dtoff - dtdst # this is self's standard offset
    if delta:
        dt += delta # convert to standard local time
        dtdst = dt.dst()
        # raise ValueError if dtdst is None
    if dtdst:
        return dt + dtdst
    else:
        return dt
```

Example `tzinfo` classes:

```
from datetime import tzinfo, timedelta, datetime

ZERO = timedelta(0)
HOUR = timedelta(hours=1)

# A UTC class.

class UTC(tzinfo):
    """UTC"""

    def utcoffset(self, dt):
        return ZERO

    def tzname(self, dt):
        return "UTC"

    def dst(self, dt):
        return ZERO

utc = UTC()

# A class building tzinfo objects for fixed-offset time zones.
# Note that FixedOffset(0, "UTC") is a different way to build a
# UTC tzinfo object.

class FixedOffset(tzinfo):
    """Fixed offset in minutes east from UTC."""

    def __init__(self, offset, name):
        self.__offset = timedelta(minutes = offset)
        self.__name = name

    def utcoffset(self, dt):
        return self.__offset

    def tzname(self, dt):
        return self.__name

    def dst(self, dt):
        return ZERO

# A class capturing the platform's idea of local time.

import time as _time
```

```

STD OFFSET = timedelta(seconds = -_time.timezone)
if _time.daylight:
    DST OFFSET = timedelta(seconds = -_time.altzone)
else:
    DST OFFSET = STD OFFSET

DST DIFF = DST OFFSET - STD OFFSET

class LocalTimezone(tzinfo):

    def utcoffset(self, dt):
        if self._isdst(dt):
            return DST OFFSET
        else:
            return STD OFFSET

    def dst(self, dt):
        if self._isdst(dt):
            return DST DIFF
        else:
            return ZERO

    def tzname(self, dt):
        return _time.tzname[self._isdst(dt)]

    def _isdst(self, dt):
        tt = (dt.year, dt.month, dt.day,
              dt.hour, dt.minute, dt.second,
              dt.weekday(), 0, 0)
        stamp = _time.mktime(tt)
        tt = _time.localtime(stamp)
        return tt.tm_isdst > 0

Local = LocalTimezone()

# A complete implementation of current DST rules for major US t

def first_sunday_on_or_after(dt):
    days_to_go = 6 - dt.weekday()
    if days_to_go:
        dt += timedelta(days_to_go)
    return dt

# US DST Rules

        return self.stdoffset + self.dst(dt)

```

```

    def dst(self, dt):
        if dt is None or dt.tzinfo is None:
            # An exception may be sensible here, in one or both

```

```

        # It depends on how you want to treat them. The de
        # fromutc() implementation (called by the default a
        # implementation) passes a datetime with dt.tzinfo
        return ZERO
    assert dt.tzinfo is self

    # Find start and end times for US DST. For years before
    # ZERO for no DST.
    if 2006 < dt.year:
        dststart, dstend = DSTSTART_2007, DSTEND_2007
    elif 1986 < dt.year < 2007:
        dststart, dstend = DSTSTART_1987_2006, DSTEND_1987_
    elif 1966 < dt.year < 1987:
        dststart, dstend = DSTSTART_1967_1986, DSTEND_1967_
    else:
        return ZERO

    start = first_sunday_on_or_after(dststart.replace(year=
    end = first_sunday_on_or_after(dstend.replace(year=dt.y

    # Can't compare naive to aware objects, so strip the ti
    # dt first.
    if start <= dt.replace(tzinfo=None) < end:
        return HOUR
    else:
        return ZERO

Eastern = USTimeZone(-5, "Eastern", "EST", "EDT")
Central = USTimeZone(-6, "Central", "CST", "CDT")
Mountain = USTimeZone(-7, "Mountain", "MST", "MDT")
Pacific = USTimeZone(-8, "Pacific", "PST", "PDT")

```

Note that there are unavoidable subtleties twice per year in a `tzinfo` subclass accounting for both standard and daylight time, at the DST transition points. For concreteness, consider US Eastern (UTC -0500), where EDT begins the minute after 1:59 (EST) on the second Sunday in March, and ends the minute after 1:59 (EDT) on the first Sunday in November:

UTC	3:MM	4:MM	5:MM	6:MM	7:MM	8:MM
EST	22:MM	23:MM	0:MM	1:MM	2:MM	3:MM
EDT	23:MM	0:MM	1:MM	2:MM	3:MM	4:MM

```
start 22:MM 23:MM 0:MM 1:MM 3:MM 4:MM
end   23:MM 0:MM 1:MM 1:MM 2:MM 3:MM
```

When DST starts (the “start” line), the local wall clock leaps from 1:59 to 3:00. A wall time of the form 2:MM doesn’t really make sense on that day, so `astimezone(Eastern)` won’t deliver a result with `hour == 2` on the day DST begins. In order for `astimezone()` to make this guarantee, the `tzinfo.dst()` method must consider times in the “missing hour” (2:MM for Eastern) to be in daylight time.

When DST ends (the “end” line), there’s a potentially worse problem: there’s an hour that can’t be spelled unambiguously in local wall time: the last hour of daylight time. In Eastern, that’s times of the form 5:MM UTC on the day daylight time ends. The local wall clock leaps from 1:59 (daylight time) back to 1:00 (standard time) again. Local times of the form 1:MM are ambiguous. `astimezone()` mimics the local clock’s behavior by mapping two adjacent UTC hours into the same local hour then. In the Eastern example, UTC times of the form 5:MM and 6:MM both map to 1:MM when converted to Eastern. In order for `astimezone()` to make this guarantee, the `tzinfo.dst()` method must consider times in the “repeated hour” to be in standard time. This is easily arranged, as in the example, by expressing DST switch times in the time zone’s standard local time.

Applications that can’t bear such ambiguities should avoid using hybrid `tzinfo` subclasses; there are no ambiguities when using `timezone`, or any other fixed-offset `tzinfo` subclass (such as a class representing only EST (fixed offset -5 hours), or only EDT (fixed offset -4 hours)).

7.1.7. `timezone` Objects

A `timezone` object represents a timezone that is defined by a fixed offset from UTC. Note that objects of this class cannot be used to represent timezone information in the locations where different offsets are used in different days of the year or where historical changes have been made to civil time.

`class datetime.timezone(offset[, name])`

The *offset* argument must be specified as a `timedelta` object representing the difference between the local time and UTC. It must be strictly between `-timedelta(hours=24)` and `timedelta(hours=24)` and represent a whole number of minutes, otherwise `ValueError` is raised.

The *name* argument is optional. If specified it must be a string that is used as the value returned by the `tzname(dt)` method. Otherwise, `tzname(dt)` returns a string 'UTCsHH:MM', where *s* is the sign of *offset*, HH and MM are two digits of `offset.hours` and `offset.minutes` respectively.

`timezone.utcoffset(dt)`

Return the fixed value specified when the `timezone` instance is constructed. The *dt* argument is ignored. The return value is a `timedelta` instance equal to the difference between the local time and UTC.

`timezone.tzname(dt)`

Return the fixed value specified when the `timezone` instance is constructed or a string 'UTCsHH:MM', where *s* is the sign of *offset*, HH and MM are two digits of `offset.hours` and

`offset.minutes` respectively.

`timezone.dst(dt)`

Always returns `None`.

`timezone.fromutc(dt)`

Return `dt + offset`. The `dt` argument must be an aware `datetime` instance, with `tzinfo` set to `self`.

Class attributes:

`timezone.utc`

The UTC timezone, `timezone(timedelta(0))`.

7.1.8. `strftime()` and `strptime()` Behavior

`date`, `datetime`, and `time` objects all support a `strftime(format)` method, to create a string representing the time under the control of an explicit format string. Broadly speaking, `d.strftime(fmt)` acts like the `time` module's `time.strftime(fmt, d.timetuple())` although not all objects support a `timetuple()` method.

Conversely, the `datetime.strptime()` class method creates a `datetime` object from a string representing a date and time and a corresponding format string. `datetime.strptime(date_string, format)` is equivalent to `datetime(*(time.strptime(date_string, format)[0:6]))`.

For `time` objects, the format codes for year, month, and day should not be used, as time objects have no such values. If they're used anyway, `1900` is substituted for the year, and `1` for the month and day.

For `date` objects, the format codes for hours, minutes, seconds, and microseconds should not be used, as `date` objects have no such values. If they're used anyway, `0` is substituted for them.

For a naive object, the `%z` and `%Z` format codes are replaced by empty strings.

For an aware object:

`%z`

`utcoffset()` is transformed into a 5-character string of the form `+HHMM` or `-HHMM`, where `HH` is a 2-digit string giving the number of UTC offset hours, and `MM` is a 2-digit string giving the

number of UTC offset minutes. For example, if `utcoffset()` returns `timedelta(hours=-3, minutes=-30)`, `%z` is replaced with the string `'-0330'`.

`%Z`

If `tzname()` returns `None`, `%Z` is replaced by an empty string. Otherwise `%Z` is replaced by the returned value, which must be a string.

The full set of format codes supported varies across platforms, because Python calls the platform C library's `strftime()` function, and platform variations are common.

The following is a list of all the format codes that the C standard (1989 version) requires, and these work on all platforms with a standard C implementation. Note that the 1999 version of the C standard added additional format codes.

Directive	Meaning	Notes
<code>%a</code>	Locale's abbreviated weekday name.	
<code>%A</code>	Locale's full weekday name.	
<code>%b</code>	Locale's abbreviated month name.	
<code>%B</code>	Locale's full month name.	
<code>%c</code>	Locale's appropriate date and time representation.	
<code>%d</code>	Day of the month as a decimal number [01,31].	
<code>%f</code>	Microsecond as a decimal number [0,999999], zero-padded on the left	(1)
<code>%H</code>	Hour (24-hour clock) as a decimal number [00,23].	
<code>%I</code>	Hour (12-hour clock) as a decimal number [01,12].	
<code>%j</code>	Day of the year as a decimal number [001,366].	

%m	Month as a decimal number [01,12].	
%M	Minute as a decimal number [00,59].	
%p	Locale's equivalent of either AM or PM.	(2)
%S	Second as a decimal number [00,59].	(3)
%U	Week number of the year (Sunday as the first day of the week) as a decimal number [00,53]. All days in a new year preceding the first Sunday are considered to be in week 0.	(4)
%w	Weekday as a decimal number [0(Sunday),6].	
%W	Week number of the year (Monday as the first day of the week) as a decimal number [00,53]. All days in a new year preceding the first Monday are considered to be in week 0.	(4)
%x	Locale's appropriate date representation.	
%X	Locale's appropriate time representation.	
%y	Year without century as a decimal number [00,99].	
%Y	Year with century as a decimal number [0001,9999] (strptime), [1000,9999] (strftime).	(5)
%z	UTC offset in the form +HHMM or -HHMM (empty string if the the object is naive).	(6)
%Z	Time zone name (empty string if the object is naive).	
%%	A literal '%' character.	

Notes:

1. When used with the `strptime()` method, the `%f` directive accepts from one to six digits and zero pads on the right. `%f` is an extension to the set of format characters in the C standard (but implemented separately in datetime objects, and therefore

always available).

2. When used with the `strptime()` method, the `%p` directive only affects the output hour field if the `%I` directive is used to parse the hour.
3. Unlike `time` module, `datetime` module does not support leap seconds.
4. When used with the `strptime()` method, `%U` and `%W` are only used in calculations when the day of the week and the year are specified.
5. For technical reasons, `strptime()` method does not support dates before year 1000: `t.strptime(format)` will raise a `ValueError` when `t.year < 1000` even if `format` does not contain `%Y` directive. The `strptime()` method can parse years in the full `[1, 9999]` range, but years `< 1000` must be zero-filled to 4-digit width.

Changed in version 3.2: In previous versions, `strptime()` method was restricted to years `>= 1900`.

6. For example, if `utcoffset()` returns `timedelta(hours=-3, minutes=-30)`, `%z` is replaced with the string `'-0330'`.

Changed in version 3.2: When the `%z` directive is provided to the `strptime()` method, an aware `datetime` object will be produced. The `tzinfo` of the result will be set to a `timezone` instance.

7.2. calendar — General calendar-related functions

Source code: [Lib/calendar.py](#)

This module allows you to output calendars like the Unix `cal` program, and provides additional useful functions related to the calendar. By default, these calendars have Monday as the first day of the week, and Sunday as the last (the European convention). Use `setfirstweekday()` to set the first day of the week to Sunday (6) or to any other weekday. Parameters that specify dates are given as integers. For related functionality, see also the `datetime` and `time` modules.

Most of these functions and classes rely on the `datetime` module which uses an idealized calendar, the current Gregorian calendar extended in both directions. This matches the definition of the “proleptic Gregorian” calendar in Dershowitz and Reingold’s book “Calendrical Calculations”, where it’s the base calendar for all computations.

`class calendar.Calendar(firstweekday=0)`

Creates a `Calendar` object. `firstweekday` is an integer specifying the first day of the week. 0 is Monday (the default), 6 is Sunday.

A `Calendar` object provides several methods that can be used for preparing the calendar data for formatting. This class doesn’t do any formatting itself. This is the job of subclasses.

`Calendar` instances have the following methods:

`iterweekdays()`

Return an iterator for the week day numbers that will be used for one week. The first value from the iterator will be the same as the value of the `firstweekday` property.

`itermonthdates(year, month)`

Return an iterator for the month *month* (1-12) in the year *year*. This iterator will return all days (as `datetime.date` objects) for the month and all days before the start of the month or after the end of the month that are required to get a complete week.

`itermonthdays2(year, month)`

Return an iterator for the month *month* in the year *year* similar to `itermonthdates()`. Days returned will be tuples consisting of a day number and a week day number.

`itermonthdays(year, month)`

Return an iterator for the month *month* in the year *year* similar to `itermonthdates()`. Days returned will simply be day numbers.

`monthdatescalendar(year, month)`

Return a list of the weeks in the month *month* of the year as full weeks. Weeks are lists of seven `datetime.date` objects.

`monthdays2calendar(year, month)`

Return a list of the weeks in the month *month* of the year as full weeks. Weeks are lists of seven tuples of day numbers and weekday numbers.

`monthdayscalendar(year, month)`

Return a list of the weeks in the month *month* of the year as full weeks. Weeks are lists of seven day numbers.

yeardatescalendar(*year*, *width*=3)

Return the data for the specified year ready for formatting. The return value is a list of month rows. Each month row contains up to *width* months (defaulting to 3). Each month contains between 4 and 6 weeks and each week contains 1–7 days. Days are `datetime.date` objects.

yeardays2calendar(*year*, *width*=3)

Return the data for the specified year ready for formatting (similar to `yeardatescalendar()`). Entries in the week lists are tuples of day numbers and weekday numbers. Day numbers outside this month are zero.

yeardayscalendar(*year*, *width*=3)

Return the data for the specified year ready for formatting (similar to `yeardatescalendar()`). Entries in the week lists are day numbers. Day numbers outside this month are zero.

`class calendar.TextCalendar`(*firstweekday*=0)

This class can be used to generate plain text calendars.

`TextCalendar` instances have the following methods:

formatmonth(*theyear*, *themonth*, *w*=0, *l*=0)

Return a month's calendar in a multi-line string. If *w* is provided, it specifies the width of the date columns, which are centered. If *l* is given, it specifies the number of lines that each week will use. Depends on the first weekday as specified in the constructor or set by the `setfirstweekday()` method.

prmonth(*theyear*, *themonth*, *w*=0, *l*=0)

Print a month's calendar as returned by `formatmonth()`.

formatyear(*theyear*, *w=2*, *l=1*, *c=6*, *m=3*)

Return a *m*-column calendar for an entire year as a multi-line string. Optional parameters *w*, *l*, and *c* are for date column width, lines per week, and number of spaces between month columns, respectively. Depends on the first weekday as specified in the constructor or set by the `setfirstweekday()` method. The earliest year for which a calendar can be generated is platform-dependent.

pryear(*theyear*, *w=2*, *l=1*, *c=6*, *m=3*)

Print the calendar for an entire year as returned by `formatyear()`.

class calendar.**HTMLCalendar**(*firstweekday=0*)

This class can be used to generate HTML calendars.

HTMLCalendar instances have the following methods:

formatmonth(*theyear*, *themoth*, *withyear=True*)

Return a month's calendar as an HTML table. If *withyear* is true the year will be included in the header, otherwise just the month name will be used.

formatyear(*theyear*, *width=3*)

Return a year's calendar as an HTML table. *width* (defaulting to 3) specifies the number of months per row.

formatyearpage(*theyear*, *width=3*, *css='calendar.css'*, *encoding=None*)

Return a year's calendar as a complete HTML page. *width* (defaulting to 3) specifies the number of months per row. *css* is the name for the cascading style sheet to be used. `None` can be passed if no style sheet should be used. *encoding* specifies the encoding to be used for the output (defaulting to

the system default encoding).

```
class calendar.LocaleTextCalendar(firstweekday=0, locale=None)
```

This subclass of `TextCalendar` can be passed a locale name in the constructor and will return month and weekday names in the specified locale. If this locale includes an encoding all strings containing month and weekday names will be returned as unicode.

```
class calendar.LocaleHTMLCalendar(firstweekday=0, locale=None)
```

This subclass of `HTMLCalendar` can be passed a locale name in the constructor and will return month and weekday names in the specified locale. If this locale includes an encoding all strings containing month and weekday names will be returned as unicode.

Note: The `formatweekday()` and `formatmonthname()` methods of these two classes temporarily change the current locale to the given *locale*. Because the current locale is a process-wide setting, they are not thread-safe.

For simple text calendars this module provides the following functions.

```
calendar.setfirstweekday(weekday)
```

Sets the weekday (0 is Monday, 6 is Sunday) to start each week. The values `MONDAY`, `TUESDAY`, `WEDNESDAY`, `THURSDAY`, `FRIDAY`, `SATURDAY`, and `SUNDAY` are provided for convenience. For example, to set the first weekday to Sunday:

```
import calendar
calendar.setfirstweekday(calendar.SUNDAY)
```

```
calendar.firstweekday()
```

Returns the current setting for the weekday to start each week.

`calendar.isleap(year)`

Returns **True** if *year* is a leap year, otherwise **False**.

`calendar.leapdays(y1, y2)`

Returns the number of leap years in the range from *y1* to *y2* (exclusive), where *y1* and *y2* are years.

This function works for ranges spanning a century change.

`calendar.weekday(year, month, day)`

Returns the day of the week (0 is Monday) for *year* (1970–...), *month* (1–12), *day* (1–31).

`calendar.weekheader(n)`

Return a header containing abbreviated weekday names. *n* specifies the width in characters for one weekday.

`calendar.monthrange(year, month)`

Returns weekday of first day of the month and number of days in month, for the specified *year* and *month*.

`calendar.monthcalendar(year, month)`

Returns a matrix representing a month's calendar. Each row represents a week; days outside of the month are represented by zeros. Each week begins with Monday unless set by `setfirstweekday()`.

`calendar.pmonth(theyear, themonth, w=0, l=0)`

Prints a month's calendar as returned by `month()`.

`calendar.month(theyear, themonth, w=0, l=0)`

Returns a month's calendar in a multi-line string using the

`formatmonth()` of the `TextCalendar` class.

`calendar.prcal(year, w=0, l=0, c=6, m=3)`

Prints the calendar for an entire year as returned by `calendar()`.

`calendar.calendar(year, w=2, l=1, c=6, m=3)`

Returns a 3-column calendar for an entire year as a multi-line string using the `formatyear()` of the `TextCalendar` class.

`calendar.timegm(tuple)`

An unrelated but handy function that takes a time tuple such as returned by the `gmtime()` function in the `time` module, and returns the corresponding Unix timestamp value, assuming an epoch of 1970, and the POSIX encoding. In fact, `time.gmtime()` and `timegm()` are each others' inverse.

The `calendar` module exports the following data attributes:

`calendar.day_name`

An array that represents the days of the week in the current locale.

`calendar.day_abbr`

An array that represents the abbreviated days of the week in the current locale.

`calendar.month_name`

An array that represents the months of the year in the current locale. This follows normal convention of January being month number 1, so it has a length of 13 and `month_name[0]` is the empty string.

`calendar.month_abbr`

An array that represents the abbreviated months of the year in the current locale. This follows normal convention of January

being month number 1, so it has a length of 13 and `month_abbr[0]` is the empty string.

Module `datetime`

Object-oriented interface to dates and times with similar functionality to the `time` module.

Module `time`

Low-level time related functions.

7.3. collections — Container datatypes

Source code: [Lib/collections.py](#) and [Lib/_abcoll.py](#)

This module implements specialized container datatypes providing alternatives to Python's general purpose built-in containers, `dict`, `list`, `set`, and `tuple`.

<code>namedtuple()</code>	factory function for creating tuple subclasses with named fields
<code>deque</code>	list-like container with fast appends and pops on either end
<code>Counter</code>	dict subclass for counting hashable objects
<code>OrderedDict</code>	dict subclass that remembers the order entries were added
<code>defaultdict</code>	dict subclass that calls a factory function to supply missing values
<code>UserDict</code>	wrapper around dictionary objects for easier dict subclassing
<code>UserList</code>	wrapper around list objects for easier list subclassing
<code>UserString</code>	wrapper around string objects for easier string subclassing

In addition to the concrete container classes, the collections module provides *ABCs* - *abstract base classes* that can be used to test whether a class provides a particular interface, for example, whether it is hashable or a mapping.

7.3.1. counter objects

A counter tool is provided to support convenient and rapid tallies. For example:

```
>>> # Tally occurrences of words in a list
>>> cnt = Counter()
>>> for word in ['red', 'blue', 'red', 'green', 'blue', 'blue']
...     cnt[word] += 1
>>> cnt
Counter({'blue': 3, 'red': 2, 'green': 1})

>>> # Find the ten most common words in Hamlet
>>> import re
>>> words = re.findall('\w+', open('hamlet.txt').read().lower())
>>> Counter(words).most_common(10)
[('the', 1143), ('and', 966), ('to', 762), ('of', 669), ('i', 6
('you', 554), ('a', 546), ('my', 514), ('hamlet', 471), ('in'
```

`class collections.Counter([iterable-or-mapping])`

A **Counter** is a **dict** subclass for counting hashable objects. It is an unordered collection where elements are stored as dictionary keys and their counts are stored as dictionary values. Counts are allowed to be any integer value including zero or negative counts. The **Counter** class is similar to bags or multisets in other languages.

Elements are counted from an *iterable* or initialized from another *mapping* (or counter):

```
>>> c = Counter() # a new, empty counter
>>> c = Counter('gallahad') # a new counter
>>> c = Counter({'red': 4, 'blue': 2}) # a new counter
>>> c = Counter(cats=4, dogs=8) # a new counter
```

Counter objects have a dictionary interface except that they

return a zero count for missing items instead of raising a `KeyError`:

```
>>> c = Counter(['eggs', 'ham'])
>>> c['bacon'] # count of a missing item
0
```

Setting a count to zero does not remove an element from a counter. Use `del` to remove it entirely:

```
>>> c['sausage'] = 0 # counter entry
>>> del c['sausage'] # del actually removes the entry
```

New in version 3.1.

Counter objects support three methods beyond those available for all dictionaries:

`elements()`

Return an iterator over elements repeating each as many times as its count. Elements are returned in arbitrary order. If an element's count is less than one, `elements()` will ignore it.

```
>>> c = Counter(a=4, b=2, c=0, d=-2)
>>> list(c.elements())
['a', 'a', 'a', 'a', 'b', 'b']
```

`most_common([n])`

Return a list of the n most common elements and their counts from the most common to the least. If n is not specified, `most_common()` returns *all* elements in the counter. Elements with equal counts are ordered arbitrarily:

```
>>> Counter('abracadabra').most_common(3)
[('a', 5), ('r', 2), ('b', 2)]
```

subtract([*iterable-or-mapping*])

Elements are subtracted from an *iterable* or from another *mapping* (or counter). Like `dict.update()` but subtracts counts instead of replacing them. Both inputs and outputs may be zero or negative.

```
>>> c = Counter(a=4, b=2, c=0, d=-2)
>>> d = Counter(a=1, b=2, c=3, d=4)
>>> c.subtract(d)
Counter({'a': 3, 'b': 0, 'c': -3, 'd': -6})
```

New in version 3.2.

The usual dictionary methods are available for **Counter** objects except for two which work differently for counters.

fromkeys(*iterable*)

This class method is not implemented for **Counter** objects.

update([*iterable-or-mapping*])

Elements are counted from an *iterable* or added-in from another *mapping* (or counter). Like `dict.update()` but adds counts instead of replacing them. Also, the *iterable* is expected to be a sequence of elements, not a sequence of (key, value) pairs.

Common patterns for working with **Counter** objects:

```
sum(c.values())           # total of all counts
c.clear()                 # reset all counts
list(c)                   # list unique elements
set(c)                    # convert to a set
dict(c)                   # convert to a regular dictionary
c.items()                 # convert to a list of (elem, c)
Counter(dict(list_of_pairs)) # convert from a list of (elem, c)
c.most_common()[:n]      # n least common elements
c += Counter()           # remove zero and negative counts
```

Several mathematical operations are provided for combining `Counter` objects to produce multisets (counters that have counts greater than zero). Addition and subtraction combine counters by adding or subtracting the counts of corresponding elements. Intersection and union return the minimum and maximum of corresponding counts. Each operation can accept inputs with signed counts, but the output will exclude results with counts of zero or less.

```
>>> c = Counter(a=3, b=1)
>>> d = Counter(a=1, b=2)
>>> c + d                                # add two counters together:  c
Counter({'a': 4, 'b': 3})
>>> c - d                                # subtract (keeping only positive)
Counter({'a': 2})
>>> c & d                                 # intersection:  min(c[x], d[x])
Counter({'a': 1, 'b': 1})
>>> c | d                                 # union:  max(c[x], d[x])
Counter({'a': 3, 'b': 2})
```

Note: Counters were primarily designed to work with positive integers to represent running counts; however, care was taken to not unnecessarily preclude use cases needing other types or negative values. To help with those use cases, this section documents the minimum range and type restrictions.

- The `Counter` class itself is a dictionary subclass with no restrictions on its keys and values. The values are intended to be numbers representing counts, but you *could* store anything in the value field.
- The `most_common()` method requires only that the values be orderable.
- For in-place operations such as `c[key] += 1`, the value type need only support addition and subtraction. So fractions, floats, and decimals would work and negative values are supported. The same is also true for `update()` and `subtract()`

which allow negative and zero values for both inputs and outputs.

- The multiset methods are designed only for use cases with positive values. The inputs may be negative or zero, but only outputs with positive values are created. There are no type restrictions, but the value type needs to support addition, subtraction, and comparison.
- The `elements()` method requires integer counts. It ignores zero and negative counts.

```
map(Counter, combinations_with_replacement('ABC', 2))  
-> AA AB AC BB BC CC
```

7.3.2. deque objects

```
class collections.deque([iterable[, maxlen]])
```

Returns a new deque object initialized left-to-right (using `append()`) with data from *iterable*. If *iterable* is not specified, the new deque is empty.

Deques are a generalization of stacks and queues (the name is pronounced “deck” and is short for “double-ended queue”). Deques support thread-safe, memory efficient appends and pops from either side of the deque with approximately the same $O(1)$ performance in either direction.

Though `list` objects support similar operations, they are optimized for fast fixed-length operations and incur $O(n)$ memory movement costs for `pop(0)` and `insert(0, v)` operations which change both the size and position of the underlying data representation.

If *maxlen* is not specified or is *None*, deques may grow to an arbitrary length. Otherwise, the deque is bounded to the specified maximum length. Once a bounded length deque is full, when new items are added, a corresponding number of items are discarded from the opposite end. Bounded length deques provide functionality similar to the `tail` filter in Unix. They are also useful for tracking transactions and other pools of data where only the most recent activity is of interest.

Deque objects support the following methods:

append(x)

Add x to the right side of the deque.

appendleft(x)

Add *x* to the left side of the deque.

clear()

Remove all elements from the deque leaving it with length 0.

count(x)

Count the number of deque elements equal to *x*.

New in version 3.2.

extend(iterable)

Extend the right side of the deque by appending elements from the iterable argument.

extendleft(iterable)

Extend the left side of the deque by appending elements from *iterable*. Note, the series of left appends results in reversing the order of elements in the iterable argument.

pop()

Remove and return an element from the right side of the deque. If no elements are present, raises an **IndexError**.

popleft()

Remove and return an element from the left side of the deque. If no elements are present, raises an **IndexError**.

remove(value)

Removed the first occurrence of *value*. If not found, raises a **ValueError**.

reverse()

Reverse the elements of the deque in-place and then return

None.

New in version 3.2.

rotate(*n*)

Rotate the deque *n* steps to the right. If *n* is negative, rotate to the left. Rotating one step to the right is equivalent to: `d.appendleft(d.pop())`.

Deque objects also provide one read-only attribute:

maxlen

Maximum size of a deque or *None* if unbounded.

New in version 3.1.

In addition to the above, deques support iteration, pickling, `len(d)`, `reversed(d)`, `copy.copy(d)`, `copy.deepcopy(d)`, membership testing with the `in` operator, and subscript references such as `d[-1]`. Indexed access is $O(1)$ at both ends but slows to $O(n)$ in the middle. For fast random access, use lists instead.

Example:

```
>>> from collections import deque
>>> d = deque('ghi')           # make a new deque with three items
>>> for elem in d:           # iterate over the deque's elements
...     print(elem.upper())
G
H
I

>>> d.append('j')           # add a new entry to the right side
>>> d.appendleft('f')       # add a new entry to the left side
>>> d                       # show the representation
deque(['f', 'g', 'h', 'i', 'j'])

>>> d.pop()                 # return and remove the rightmost element
'j'
```

```

>>> d.popleft()           # return and remove the le
'f'
>>> list(d)              # list the contents of the
['g', 'h', 'i']
>>> d[0]                 # peek at leftmost item
'g'
>>> d[-1]                # peek at rightmost item
'i'

>>> list(reversed(d))    # list the contents of a d
['i', 'h', 'g']
>>> 'h' in d             # search the deque
True
>>> d.extend('jkl')      # add multiple elements at
>>> d
deque(['g', 'h', 'i', 'j', 'k', 'l'])
>>> d.rotate(1)          # right rotation
>>> d
deque(['l', 'g', 'h', 'i', 'j', 'k'])
>>> d.rotate(-1)         # left rotation
>>> d
deque(['g', 'h', 'i', 'j', 'k', 'l'])

>>> deque(reversed(d))   # make a new deque in reve
deque(['l', 'k', 'j', 'i', 'h', 'g'])
>>> d.clear()            # empty the deque
>>> d.pop()              # cannot pop from an empty
Traceback (most recent call last):
  File "<pyshell#6>", line 1, in -toplevel-
    d.pop()
IndexError: pop from an empty deque

>>> d.extendleft('abc')  # extendleft() reverses th
>>> d
deque(['c', 'b', 'a'])

```

7.3.2.1. deque Recipes

This section shows various approaches to working with deques.

Bounded length deques provide functionality similar to the `tail` filter in Unix:

```
def tail(filename, n=10):
    'Return the last n lines of a file'
    return deque(open(filename), n)
```

Another approach to using deques is to maintain a sequence of recently added elements by appending to the right and popping to the left:

```
def moving_average(iterable, n=3):
    # moving_average([40, 30, 50, 46, 39, 44]) --> 40.0 42.0 45
    # http://en.wikipedia.org/wiki/Moving_average
    it = iter(iterable)
    d = deque(itertools.islice(it, n-1))
    d.appendleft(0)
    s = sum(d)
    for elem in it:
        s += elem - d.popleft()
        d.append(elem)
    yield s / n
```

The `rotate()` method provides a way to implement `deque` slicing and deletion. For example, a pure Python implementation of `del d[n]` relies on the `rotate()` method to position elements to be popped:

```
def delete_nth(d, n):
    d.rotate(-n)
    d.popleft()
    d.rotate(n)
```

To implement `deque` slicing, use a similar approach applying `rotate()` to bring a target element to the left side of the deque. Remove old entries with `popleft()`, add new entries with `extend()`, and then reverse the rotation. With minor variations on that approach, it is easy to implement Forth style stack manipulations such as `dup`, `drop`, `swap`, `over`, `pick`, `rot`, and `roll`.

7.3.3. defaultdict objects

class collections.**defaultdict**([*default_factory*[, ...]])

Returns a new dictionary-like object. **defaultdict** is a subclass of the built-in **dict** class. It overrides one method and adds one writable instance variable. The remaining functionality is the same as for the **dict** class and is not documented here.

The first argument provides the initial value for the **default_factory** attribute; it defaults to **None**. All remaining arguments are treated the same as if they were passed to the **dict** constructor, including keyword arguments.

defaultdict objects support the following method in addition to the standard **dict** operations:

__missing__(*key*)

If the **default_factory** attribute is **None**, this raises a **KeyError** exception with the *key* as argument.

If **default_factory** is not **None**, it is called without arguments to provide a default value for the given *key*, this value is inserted in the dictionary for the *key*, and returned.

If calling **default_factory** raises an exception this exception is propagated unchanged.

This method is called by the **__getitem__**() method of the **dict** class when the requested key is not found; whatever it returns or raises is then returned or raised by **__getitem__**() .

defaultdict objects support the following instance variable:

default_factory

This attribute is used by the `__missing__()` method; it is initialized from the first argument to the constructor, if present, or to `None`, if absent.

7.3.3.1. defaultdict Examples

Using `list` as the `default_factory`, it is easy to group a sequence of key-value pairs into a dictionary of lists:

```
>>> s = [('yellow', 1), ('blue', 2), ('yellow', 3), ('blue', 4)]
>>> d = defaultdict(list)
>>> for k, v in s:
...     d[k].append(v)
...
>>> list(d.items())
[('blue', [2, 4]), ('red', [1]), ('yellow', [1, 3])]
```

When each key is encountered for the first time, it is not already in the mapping; so an entry is automatically created using the `default_factory` function which returns an empty `list`. The `list.append()` operation then attaches the value to the new list. When keys are encountered again, the look-up proceeds normally (returning the list for that key) and the `list.append()` operation adds another value to the list. This technique is simpler and faster than an equivalent technique using `dict.setdefault()`:

```
>>> d = {}
>>> for k, v in s:
...     d.setdefault(k, []).append(v)
...
>>> list(d.items())
[('blue', [2, 4]), ('red', [1]), ('yellow', [1, 3])]
```

Setting the `default_factory` to `int` makes the `defaultdict` useful for counting (like a bag or multiset in other languages):

```

>>> s = 'mississippi'
>>> d = defaultdict(int)
>>> for k in s:
...     d[k] += 1
...
>>> list(d.items())
[('i', 4), ('p', 2), ('s', 4), ('m', 1)]

```

When a letter is first encountered, it is missing from the mapping, so the `default_factory` function calls `int()` to supply a default count of zero. The increment operation then builds up the count for each letter.

The function `int()` which always returns zero is just a special case of constant functions. A faster and more flexible way to create constant functions is to use a lambda function which can supply any constant value (not just zero):

```

>>> def constant_factory(value):
...     return lambda: value
>>> d = defaultdict(constant_factory('<missing>'))
>>> d.update(name='John', action='ran')
>>> '%(name)s %(action)s to %(object)s' % d
'John ran to <missing>'

```

Setting the `default_factory` to `set` makes the `defaultdict` useful for building a dictionary of sets:

```

>>> s = [('red', 1), ('blue', 2), ('red', 3), ('blue', 4), ('re
>>> d = defaultdict(set)
>>> for k, v in s:
...     d[k].add(v)
...
>>> list(d.items())
[('blue', set([2, 4])), ('red', set([1, 3]))]

```

7.3.4. `namedtuple()` Factory Function for Tuples with Named Fields

Named tuples assign meaning to each position in a tuple and allow for more readable, self-documenting code. They can be used wherever regular tuples are used, and they add the ability to access fields by name instead of position index.

```
collections.namedtuple(typename, field_names, verbose=False,  
rename=False)
```

Returns a new tuple subclass named *typename*. The new subclass is used to create tuple-like objects that have fields accessible by attribute lookup as well as being indexable and iterable. Instances of the subclass also have a helpful docstring (with *typename* and *field_names*) and a helpful `__repr__()` method which lists the tuple contents in a `name=value` format.

The *field_names* are a single string with each fieldname separated by whitespace and/or commas, for example `'x y'` or `'x, y'`. Alternatively, *field_names* can be a sequence of strings such as `['x', 'y']`.

Any valid Python identifier may be used for a fieldname except for names starting with an underscore. Valid identifiers consist of letters, digits, and underscores but do not start with a digit or underscore and cannot be a **keyword** such as *class*, *for*, *return*, *global*, *pass*, or *raise*.

If *rename* is true, invalid fieldnames are automatically replaced with positional names. For example, `['abc', 'def', 'ghi', 'abc']` is converted to `['abc', '_1', 'ghi', '_3']`, eliminating the keyword `def` and the duplicate fieldname `abc`.

If *verbose* is true, the class definition is printed just before being built.

Named tuple instances do not have per-instance dictionaries, so they are lightweight and require no more memory than regular tuples.

Changed in version 3.1: Added support for rename.

```
>>> # Basic example
>>> Point = namedtuple('Point', 'x y')
>>> p = Point(x=10, y=11)

>>> # Example using the verbose option to print the class definition
>>> Point = namedtuple('Point', 'x y', verbose=True)
class Point(tuple):
    'Point(x, y)'

    __slots__ = ()

    _fields = ('x', 'y')

    def __new__(_cls, x, y):
        'Create a new instance of Point(x, y)'
        return _tuple.__new__(_cls, (x, y))

    @classmethod
    def _make(cls, iterable, new=tuple.__new__, len=len):
        'Make a new Point object from a sequence or iterable'
        result = new(cls, iterable)
        if len(result) != 2:
            raise TypeError('Expected 2 arguments, got %d' % len(result))
        return result

    def __repr__(self):
        'Return a nicely formatted representation string'
        return self.__class__.__name__ + '(x=%r, y=%r)' % self._asdict()

    def _asdict(self):
        'Return a new OrderedDict which maps field names to values'
        return OrderedDict(zip(self._fields, self))

    def _replace(_self, **kws):
        'Return a new Point object replacing specified fields with new values'
        new = self.__class__.__new__(self.__class__, self._tuple)
```

```

        result = _self._make(map(kwds.pop, ('x', 'y'), _sel
        if kwds:
            raise ValueError('Got unexpected field names: %
        return result

    def __getnewargs__(self):
        'Return self as a plain tuple.  Used by copy and p
        return tuple(self)

    x = _property(_itemgetter(0), doc='Alias for field numb
    y = _property(_itemgetter(1), doc='Alias for field numb

>>> p = Point(11, y=22)      # instantiate with positional or ke
>>> p[0] + p[1]              # indexable like the plain tuple (1
33
>>> x, y = p                 # unpack like a regular tuple
>>> x, y
(11, 22)
>>> p.x + p.y                # fields also accessible by name
33
>>> p                        # readable __repr__ with a name=val
Point(x=11, y=22)

```

Named tuples are especially useful for assigning field names to result tuples returned by the `csv` or `sqlite3` modules:

```

EmployeeRecord = namedtuple('EmployeeRecord', 'name, age, title

import csv
for emp in map(EmployeeRecord._make, csv.reader(open("employees
    print(emp.name, emp.title)

import sqlite3
conn = sqlite3.connect('/companydata')
cursor = conn.cursor()
cursor.execute('SELECT name, age, title, department, paygrade F
for emp in map(EmployeeRecord._make, cursor.fetchall()):
    print(emp.name, emp.title)

```

In addition to the methods inherited from tuples, named tuples support three additional methods and one attribute. To prevent conflicts with field names, the method and attribute names start with

an underscore.

classmethod somenamedtuple._make(*iterable*)

Class method that makes a new instance from an existing sequence or iterable.

```
>>> t = [11, 22]
>>> Point._make(t)
Point(x=11, y=22)
```

somenamedtuple._asdict()

Return a new **OrderedDict** which maps field names to their corresponding values:

```
>>> p._asdict()
OrderedDict([('x', 11), ('y', 22)])
```

Changed in version 3.1: Returns an **OrderedDict** instead of a regular **dict**.

somenamedtuple._replace(*kwargs*)

Return a new instance of the named tuple replacing specified fields with new values:

```
>>> p = Point(x=11, y=22)
>>> p._replace(x=33)
Point(x=33, y=22)

>>> for partnum, record in inventory.items():
...     inventory[partnum] = record._replace(price=newprices[pa
```

somenamedtuple._fields

Tuple of strings listing the field names. Useful for introspection and for creating new named tuple types from existing named tuples.

```
>>> p._fields           # view the field names
```

```

('x', 'y')
>>> Color = namedtuple('Color', 'red green blue')
>>> Pixel = namedtuple('Pixel', Point._fields + Color._fields)
>>> Pixel(11, 22, 128, 255, 0)
Pixel(x=11, y=22, red=128, green=255, blue=0)

```

To retrieve a field whose name is stored in a string, use the `getattr()` function:

```

>>> getattr(p, 'x')
11

```

To convert a dictionary to a named tuple, use the double-star-operator (as described in *Unpacking Argument Lists*):

```

>>> d = {'x': 11, 'y': 22}
>>> Point(**d)
Point(x=11, y=22)

```

Since a named tuple is a regular Python class, it is easy to add or change functionality with a subclass. Here is how to add a calculated field and a fixed-width print format:

```

>>> class Point(namedtuple('Point', 'x y')):
...     __slots__ = ()
...     @property
...     def hypot(self):
...         return (self.x ** 2 + self.y ** 2) ** 0.5
...     def __str__(self):
...         return 'Point: x=%6.3f y=%6.3f hypot=%6.3f' % (se

```

```

>>> for p in Point(3, 4), Point(14, 5/7):
...     print(p)
Point: x= 3.000 y= 4.000 hypot= 5.000
Point: x=14.000 y= 0.714 hypot=14.018

```

The subclass shown above sets `__slots__` to an empty tuple. This helps keep memory requirements low by preventing the creation of

instance dictionaries.

Subclassing is not useful for adding new, stored fields. Instead, simply create a new named tuple type from the `_fields` attribute:

```
>>> Point3D = namedtuple('Point3D', Point._fields + ('z',))
```

Default values can be implemented by using `_replace()` to customize a prototype instance:

```
>>> Account = namedtuple('Account', 'owner balance transaction_')
>>> default_account = Account('<owner name>', 0.0, 0)
>>> johns_account = default_account._replace(owner='John')
```

Enumerated constants can be implemented with named tuples, but it is simpler and more efficient to use a simple class declaration:

```
>>> Status = namedtuple('Status', 'open pending closed')._make(
>>> Status.open, Status.pending, Status.closed
(0, 1, 2)
>>> class Status:
...     open, pending, closed = range(3)
```

See also: [Named tuple recipe adapted for Python 2.4.](#)

7.3.5. `OrderedDict` objects

Ordered dictionaries are just like regular dictionaries but they remember the order that items were inserted. When iterating over an ordered dictionary, the items are returned in the order their keys were first added.

`class collections.OrderedDict([items])`

Return an instance of a dict subclass, supporting the usual `dict` methods. An `OrderedDict` is a dict that remembers the order that keys were first inserted. If a new entry overwrites an existing entry, the original insertion position is left unchanged. Deleting an entry and reinserting it will move it to the end.

New in version 3.1.

`popitem(last=True)`

The `popitem()` method for ordered dictionaries returns and removes a (key, value) pair. The pairs are returned in LIFO order if `last` is true or FIFO order if false.

`move_to_end(key, last=True)`

Move an existing `key` to either end of an ordered dictionary. The item is moved to the right end if `last` is true (the default) or to the beginning if `last` is false. Raises `KeyError` if the `key` does not exist:

```
>>> d = OrderedDict.fromkeys('abcde')
>>> d.move_to_end('b')
>>> ''.join(d.keys)
'acdeb'
>>> d.move_to_end('b', last=False)
>>> ''.join(d.keys)
'bacde'
```

New in version 3.2.

In addition to the usual mapping methods, ordered dictionaries also support reverse iteration using `reversed()`.

Equality tests between `OrderedDict` objects are order-sensitive and are implemented as `list(od1.items())==list(od2.items())`. Equality tests between `OrderedDict` objects and other `Mapping` objects are order-insensitive like regular dictionaries. This allows `OrderedDict` objects to be substituted anywhere a regular dictionary is used.

The `OrderedDict` constructor and `update()` method both accept keyword arguments, but their order is lost because Python's function call semantics pass-in keyword arguments using a regular unordered dictionary.

See also: [Equivalent OrderedDict recipe](#) that runs on Python 2.4 or later.

Since an ordered dictionary remembers its insertion order, it can be used in conjunction with sorting to make a sorted dictionary:

```
>>> # regular unsorted dictionary
>>> d = {'banana': 3, 'apple':4, 'pear': 1, 'orange': 2}

>>> # dictionary sorted by key
>>> OrderedDict(sorted(d.items(), key=lambda t: t[0]))
OrderedDict([('apple', 4), ('banana', 3), ('orange', 2), ('pear', 1)])

>>> # dictionary sorted by value
>>> OrderedDict(sorted(d.items(), key=lambda t: t[1]))
OrderedDict([('pear', 1), ('orange', 2), ('banana', 3), ('apple', 4)])

>>> # dictionary sorted by length of the key string
>>> OrderedDict(sorted(d.items(), key=lambda t: len(t[0])))
OrderedDict([('pear', 1), ('apple', 4), ('orange', 2), ('banana', 3)])
```

The new sorted dictionaries maintain their sort order when entries are deleted. But when new keys are added, the keys are appended to the end and the sort is not maintained.

It is also straight-forward to create an ordered dictionary variant that remembers the order the keys were *last* inserted. If a new entry overwrites an existing entry, the original insertion position is changed and moved to the end:

```
class LastUpdatedOrderedDict(OrderedDict):
    'Store items in the order the keys were last added'
    def __setitem__(self, key, value):
        if key in self:
            del self[key]
        OrderedDict.__setitem__(self, key, value)
```

7.3.6. `UserDict` objects

The class, `UserDict` acts as a wrapper around dictionary objects. The need for this class has been partially supplanted by the ability to subclass directly from `dict`; however, this class can be easier to work with because the underlying dictionary is accessible as an attribute.

`class collections.UserDict([initialdata])`

Class that simulates a dictionary. The instance's contents are kept in a regular dictionary, which is accessible via the `data` attribute of `UserDict` instances. If *initialdata* is provided, `data` is initialized with its contents; note that a reference to *initialdata* will not be kept, allowing it be used for other purposes.

In addition to supporting the methods and operations of mappings, `UserDict` instances provide the following attribute:

data

A real dictionary used to store the contents of the `UserDict` class.

7.3.7. `UserList` objects

This class acts as a wrapper around list objects. It is a useful base class for your own list-like classes which can inherit from them and override existing methods or add new ones. In this way, one can add new behaviors to lists.

The need for this class has been partially supplanted by the ability to subclass directly from `list`; however, this class can be easier to work with because the underlying list is accessible as an attribute.

`class collections.UserList([list])`

Class that simulates a list. The instance's contents are kept in a regular list, which is accessible via the `data` attribute of `UserList` instances. The instance's contents are initially set to a copy of *list*, defaulting to the empty list `[]`. *list* can be any iterable, for example a real Python list or a `UserList` object.

In addition to supporting the methods and operations of mutable sequences, `UserList` instances provide the following attribute:

data

A real `list` object used to store the contents of the `UserList` class.

Subclassing requirements: Subclasses of `UserList` are expected to offer a constructor which can be called with either no arguments or one argument. List operations which return a new sequence attempt to create an instance of the actual implementation class. To do so, it assumes that the constructor can be called with a single parameter, which is a sequence object used as a data source.

If a derived class does not wish to comply with this requirement, all

of the special methods supported by this class will need to be overridden; please consult the sources for information about the methods which need to be provided in that case.

7.3.8. `UserString` objects

The class, `UserString` acts as a wrapper around string objects. The need for this class has been partially supplanted by the ability to subclass directly from `str`; however, this class can be easier to work with because the underlying string is accessible as an attribute.

`class collections.UserString([sequence])`

Class that simulates a string or a Unicode string object. The instance's content is kept in a regular string object, which is accessible via the `data` attribute of `UserString` instances. The instance's contents are initially set to a copy of `sequence`. The `sequence` can be an instance of `bytes`, `str`, `UserString` (or a subclass) or an arbitrary sequence which can be converted into a string using the built-in `str()` function.

7.3.9. ABCs - abstract base classes

The collections module offers the following ABCs:

ABC	Inherits	Abstract Methods	Mixin Methods
Container		<code>__contains__</code>	
Hashable		<code>__hash__</code>	
Iterable		<code>__iter__</code>	
Iterator	Iterable	<code>__next__</code>	<code>__iter__</code>
Sized		<code>__len__</code>	
Callable		<code>__call__</code>	
Sequence	Sized, Iterable, Container	<code>__getitem__</code>	<code>__contains__</code> , <code>__iter__</code> , <code>__reversed__</code> , <code>index</code> , and <code>count</code>
MutableSequence	Sequence	<code>__setitem__</code> , <code>__delitem__</code> , and <code>insert</code>	Inherited Sequence methods and <code>append</code> , <code>reverse</code> , <code>extend</code> , <code>pop</code> , <code>remove</code> , and <code>__iadd__</code>
Set	Sized, Iterable, Container		<code>__le__</code> , <code>__lt__</code> , <code>__eq__</code> , <code>__ne__</code> , <code>__gt__</code> , <code>__ge__</code> , <code>__and__</code> , <code>__or__</code> , <code>__sub__</code> , <code>__xor__</code> , and <code>isdisjoint</code>
MutableSet	Set	<code>add</code> and <code>discard</code>	Inherited Set methods and <code>clear</code> , <code>pop</code> , <code>remove</code> , <code>__ior__</code> , <code>__iand__</code> , <code>__ixor__</code> , and <code>__isub__</code>
Mapping	Sized, Iterable, Container	<code>__getitem__</code>	<code>__contains__</code> , <code>keys</code> , <code>items</code> , <code>values</code> , <code>get</code> , <code>__eq__</code> , and <code>__ne__</code>

MutableMapping	Mapping	<code>__setitem__</code> and <code>__delitem__</code>	Inherited Mapping methods and <code>pop</code> , <code>popitem</code> , <code>clear</code> , <code>update</code> , and <code>setdefault</code>
MappingView	Sized		<code>__len__</code>
KeysView	MappingView, Set		<code>__contains__</code> , <code>__iter__</code>
ItemsView	MappingView, Set		<code>__contains__</code> , <code>__iter__</code>
ValuesView	MappingView		<code>__contains__</code> , <code>__iter__</code>

These ABCs allow us to ask classes or instances if they provide particular functionality, for example:

```
size = None
if isinstance(myvar, collections.Sized):
    size = len(myvar)
```

Several of the ABCs are also useful as mixins that make it easier to develop classes supporting container APIs. For example, to write a class supporting the full `set` API, it is only necessary to supply the three underlying abstract methods: `__contains__()`, `__iter__()`, and `__len__()`. The ABC supplies the remaining methods such as `__and__()` and `isdisjoint()`

```
class ListBasedSet(collections.Set):
    ''' Alternate set implementation favoring space over speed
        and not requiring the set elements to be hashable. '''
    def __init__(self, iterable):
        self.elements = lst = []
        for value in iterable:
            if value not in lst:
                lst.append(value)
    def __iter__(self):
        return iter(self.elements)
    def __contains__(self, value):
        return value in self.elements
```

```
def __len__(self):
    return len(self.elements)

s1 = ListBasedSet('abcdef')
s2 = ListBasedSet('defghi')
overlap = s1 & s2           # The __and__() method is supported
```

Notes on using `Set` and `MutableSet` as a mixin:

1. Since some set operations create new sets, the default mixin methods need a way to create new instances from an iterable. The class constructor is assumed to have a signature in the form `ClassName(iterable)`. That assumption is factored-out to an internal classmethod called `_from_iterable()` which calls `cls(iterable)` to produce a new set. If the `Set` mixin is being used in a class with a different constructor signature, you will need to override `from_iterable()` with a classmethod that can construct new instances from an iterable argument.
2. To override the comparisons (presumably for speed, as the semantics are fixed), redefine `__le__()` and then the other operations will automatically follow suit.
3. The `Set` mixin provides a `_hash()` method to compute a hash value for the set; however, `__hash__()` is not defined because not all sets are hashable or immutable. To add set hashability using mixins, inherit from both `Set()` and `Hashable()`, then define `__hash__ = Set._hash`.

7.4. `heapq` — Heap queue algorithm

Source code: [Lib/heapq.py](#)

This module provides an implementation of the heap queue algorithm, also known as the priority queue algorithm.

Heaps are binary trees for which every parent node has a value less than or equal to any of its children. This implementation uses arrays for which `heap[k] <= heap[2*k+1]` and `heap[k] <= heap[2*k+2]` for all k , counting elements from zero. For the sake of comparison, non-existing elements are considered to be infinite. The interesting property of a heap is that its smallest element is always the root, `heap[0]`.

The API below differs from textbook heap algorithms in two aspects: (a) We use zero-based indexing. This makes the relationship between the index for a node and the indexes for its children slightly less obvious, but is more suitable since Python uses zero-based indexing. (b) Our pop method returns the smallest item, not the largest (called a “min heap” in textbooks; a “max heap” is more common in texts because of its suitability for in-place sorting).

These two make it possible to view the heap as a regular Python list without surprises: `heap[0]` is the smallest item, and `heap.sort()` maintains the heap invariant!

To create a heap, use a list initialized to `[]`, or you can transform a populated list into a heap via function `heapify()`.

The following functions are provided:

`heapq.heappush(heap, item)`

Push the value *item* onto the *heap*, maintaining the heap invariant.

`heapq.heappop(heap)`

Pop and return the smallest item from the *heap*, maintaining the heap invariant. If the heap is empty, `IndexError` is raised.

`heapq.heappushpop(heap, item)`

Push *item* on the heap, then pop and return the smallest item from the *heap*. The combined action runs more efficiently than `heappush()` followed by a separate call to `heappop()`.

`heapq.heapify(x)`

Transform list *x* into a heap, in-place, in linear time.

`heapq.heapreplace(heap, item)`

Pop and return the smallest item from the *heap*, and also push the new *item*. The heap size doesn't change. If the heap is empty, `IndexError` is raised.

This one step operation is more efficient than a `heappop()` followed by `heappush()` and can be more appropriate when using a fixed-size heap. The pop/push combination always returns an element from the heap and replaces it with *item*.

The value returned may be larger than the *item* added. If that isn't desired, consider using `heappushpop()` instead. Its push/pop combination returns the smaller of the two values, leaving the larger value on the heap.

The module also offers three general purpose functions based on heaps.

`heapq.merge(*iterables)`

Merge multiple sorted inputs into a single sorted output (for

example, merge timestamped entries from multiple log files). Returns an *iterator* over the sorted values.

Similar to `sorted(itertools.chain(*iterables))` but returns an iterable, does not pull the data into memory all at once, and assumes that each of the input streams is already sorted (smallest to largest).

`heapq.nlargest(n, iterable, key=None)`

Return a list with the n largest elements from the dataset defined by *iterable*. *key*, if provided, specifies a function of one argument that is used to extract a comparison key from each element in the iterable: `key=str.lower` Equivalent to: `sorted(iterable, key=key, reverse=True)[:n]`

`heapq.nsmallest(n, iterable, key=None)`

Return a list with the n smallest elements from the dataset defined by *iterable*. *key*, if provided, specifies a function of one argument that is used to extract a comparison key from each element in the iterable: `key=str.lower` Equivalent to: `sorted(iterable, key=key)[:n]`

The latter two functions perform best for smaller values of n . For larger values, it is more efficient to use the `sorted()` function. Also, when `n==1`, it is more efficient to use the built-in `min()` and `max()` functions.

7.4.1. Basic Examples

A `heapsort` can be implemented by pushing all values onto a heap and then popping off the smallest values one at a time:

```
>>> def heapsort(iterable):
...     'Equivalent to sorted(iterable)'
...     h = []
...     for value in iterable:
...         heappush(h, value)
...     return [heappop(h) for i in range(len(h))]
...
>>> heapsort([1, 3, 5, 7, 9, 2, 4, 6, 8, 0])
[0, 1, 2, 3, 4, 5, 6, 7, 8, 9]
```

Heap elements can be tuples. This is useful for assigning comparison values (such as task priorities) alongside the main record being tracked:

```
>>> h = []
>>> heappush(h, (5, 'write code'))
>>> heappush(h, (7, 'release product'))
>>> heappush(h, (1, 'write spec'))
>>> heappush(h, (3, 'create tests'))
>>> heappop(h)
(1, 'write spec')
```

7.4.2. Priority Queue Implementation Notes

A [priority queue](#) is common use for a heap, and it presents several implementation challenges:

- Sort stability: how do you get two tasks with equal priorities to be returned in the order they were originally added?
- Tuple comparison breaks for (priority, task) pairs if the priorities are equal and the tasks do not have a default comparison order.
- If the priority of a task changes, how do you move it to a new position in the heap?
- Or if a pending task needs to be deleted, how do you find it and remove it from the queue?

A solution to the first two challenges is to store entries as 3-element list including the priority, an entry count, and the task. The entry count serves as a tie-breaker so that two tasks with the same priority are returned in the order they were added. And since no two entry counts are the same, the tuple comparison will never attempt to directly compare two tasks.

The remaining challenges revolve around finding a pending task and making changes to its priority or removing it entirely. Finding a task can be done with a dictionary pointing to an entry in the queue.

Removing the entry or changing its priority is more difficult because it would break the heap structure invariants. So, a possible solution is to mark an entry as invalid and optionally add a new entry with the revised priority:

```
pq = [] # the priority queue list
counter = itertools.count(1) # unique sequence count
task_finder = {} # mapping of tasks to entries
INVALID = 0 # mark an entry as deleted
```

```
def add_task(priority, task, count=None):
    if count is None:
        count = next(counter)
    entry = [priority, count, task]
    task_finder[task] = entry
    heappush(pq, entry)

def get_top_priority():
    while True:
        priority, count, task = heappop(pq)
        del task_finder[task]
        if count is not INVALID:
            return task

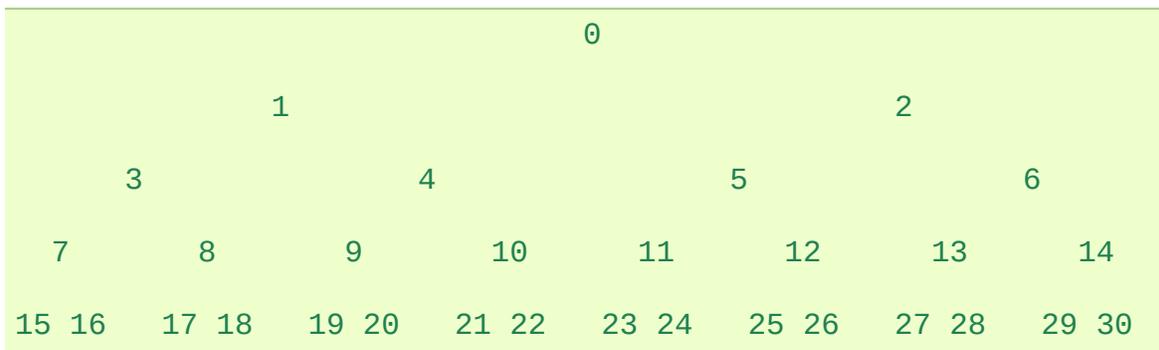

def delete_task(task):
    entry = task_finder[task]
    entry[1] = INVALID

def reprioritize(priority, task):
    entry = task_finder[task]
    add_task(priority, task, entry[1])
    entry[1] = INVALID
```

7.4.3. Theory

Heaps are arrays for which $a[k] \leq a[2k+1]$ and $a[k] \leq a[2k+2]$ for all k , counting elements from 0. For the sake of comparison, non-existing elements are considered to be infinite. The interesting property of a heap is that $a[0]$ is always its smallest element.

The strange invariant above is meant to be an efficient memory representation for a tournament. The numbers below are k , not $a[k]$:

In the tree above, each cell k is topping $2k+1$ and $2k+2$. In an usual binary tournament we see in sports, each cell is the winner over the two cells it tops, and we can trace the winner down the tree to see all opponents s/he had. However, in many computer applications of such tournaments, we do not need to trace the history of a winner. To be more memory efficient, when a winner is promoted, we try to replace it by something else at a lower level, and the rule becomes that a cell and the two cells it tops contain three different items, but the top cell “wins” over the two topped cells.

If this heap invariant is protected at all time, index 0 is clearly the overall winner. The simplest algorithmic way to remove it and find the “next” winner is to move some loser (let’s say cell 30 in the diagram above) into the 0 position, and then percolate this new 0 down the tree, exchanging values, until the invariant is re-established. This is

clearly logarithmic on the total number of items in the tree. By iterating over all items, you get an $O(n \log n)$ sort.

A nice feature of this sort is that you can efficiently insert new items while the sort is going on, provided that the inserted items are not “better” than the last O 'th element you extracted. This is especially useful in simulation contexts, where the tree holds all incoming events, and the “win” condition means the smallest scheduled time. When an event schedule other events for execution, they are scheduled into the future, so they can easily go into the heap. So, a heap is a good structure for implementing schedulers (this is what I used for my MIDI sequencer :-).

Various structures for implementing schedulers have been extensively studied, and heaps are good for this, as they are reasonably speedy, the speed is almost constant, and the worst case is not much different than the average case. However, there are other representations which are more efficient overall, yet the worst cases might be terrible.

Heaps are also very useful in big disk sorts. You most probably all know that a big sort implies producing “runs” (which are pre-sorted sequences, which size is usually related to the amount of CPU memory), followed by a merging passes for these runs, which merging is often very cleverly organised [1]. It is very important that the initial sort produces the longest runs possible. Tournaments are a good way to that. If, using all the memory available to hold a tournament, you replace and percolate items that happen to fit the current run, you'll produce runs which are twice the size of the memory for random input, and much better for input fuzzily ordered.

Moreover, if you output the O 'th item on disk and get an input which may not fit in the current tournament (because the value “wins” over the last output value), it cannot fit in the heap, so the size of the heap decreases. The freed memory could be cleverly reused immediately

for progressively building a second heap, which grows at exactly the same rate the first heap is melting. When the first heap completely vanishes, you switch heaps and start a new run. Clever and quite effective!

In a word, heaps are useful memory structures to know. I use them in a few applications, and I think it is good to keep a 'heap' module around. :-)

Footnotes

The disk balancing algorithms which are current, nowadays, are more annoying than clever, and this is a consequence of the seeking capabilities of the disks. On devices which cannot seek, like big tape drives, the story was quite different, and one had to be very clever to ensure (far in advance) that each tape [1] movement will be the most effective possible (that is, will best participate at "progressing" the merge). Some tapes were even able to read backwards, and this was also used to avoid the rewinding time. Believe me, real good tape sorts were quite spectacular to watch! From all times, sorting has always been a Great Art! :-)

7.5. `bisect` — Array bisection algorithm

Source code: [Lib/bisect.py](#)

This module provides support for maintaining a list in sorted order without having to sort the list after each insertion. For long lists of items with expensive comparison operations, this can be an improvement over the more common approach. The module is called `bisect` because it uses a basic bisection algorithm to do its work. The source code may be most useful as a working example of the algorithm (the boundary conditions are already right!).

The following functions are provided:

`bisect.bisect_left(a, x, lo=0, hi=len(a))`

Locate the insertion point for `x` in `a` to maintain sorted order. The parameters `lo` and `hi` may be used to specify a subset of the list which should be considered; by default the entire list is used. If `x` is already present in `a`, the insertion point will be before (to the left of) any existing entries. The return value is suitable for use as the first parameter to `list.insert()` assuming that `a` is already sorted.

The returned insertion point `i` partitions the array `a` into two halves so that `all(val < x for val in a[lo:i])` for the left side and `all(val >= x for val in a[i:hi])` for the right side.

`bisect.bisect_right(a, x, lo=0, hi=len(a))`

`bisect.bisect(a, x, lo=0, hi=len(a))`

Similar to `bisect_left()`, but returns an insertion point which comes after (to the right of) any existing entries of `x` in `a`.

The returned insertion point i partitions the array a into two halves so that `all(val <= x for val in a[lo:i])` for the left side and `all(val > x for val in a[i:hi])` for the right side.

`bisect.insort_left(a, x, lo=0, hi=len(a))`

Insert x in a in sorted order. This is equivalent to `a.insert(bisect.bisect_left(a, x, lo, hi), x)` assuming that a is already sorted. Keep in mind that the $O(\log n)$ search is dominated by the slow $O(n)$ insertion step.

`bisect.insort_right(a, x, lo=0, hi=len(a))`

`bisect.insort(a, x, lo=0, hi=len(a))`

Similar to `insort_left()`, but inserting x in a after any existing entries of x .

See also: [SortedCollection recipe](#) that uses `bisect` to build a full-featured collection class with straight-forward search methods and support for a key-function. The keys are precomputed to save unnecessary calls to the key function during searches.

7.5.1. Searching Sorted Lists

The above `bisect()` functions are useful for finding insertion points but can be tricky or awkward to use for common searching tasks. The following five functions show how to transform them into the standard lookups for sorted lists:

```
def index(a, x):
    'Locate the leftmost value exactly equal to x'
    i = bisect_left(a, x)
    if i != len(a) and a[i] == x:
        return i
    raise ValueError

def find_lt(a, x):
    'Find rightmost value less than x'
    i = bisect_left(a, x)
    if i:
        return a[i-1]
    raise ValueError

def find_le(a, x):
    'Find rightmost value less than or equal to x'
    i = bisect_right(a, x)
    if i:
        return a[i-1]
    raise ValueError

def find_gt(a, x):
    'Find leftmost value greater than x'
    i = bisect_right(a, x)
    if i != len(a):
        return a[i]
    raise ValueError

def find_ge(a, x):
    'Find leftmost item greater than or equal to x'
    i = bisect_left(a, x)
    if i != len(a):
        return a[i]
    raise ValueError
```

7.5.2. Other Examples

The `bisect()` function can be useful for numeric table lookups. This example uses `bisect()` to look up a letter grade for an exam score (say) based on a set of ordered numeric breakpoints: 90 and up is an 'A', 80 to 89 is a 'B', and so on:

```
>>> def grade(score, breakpoints=[60, 70, 80, 90], grades='FDCB')
...     i = bisect(breakpoints, score)
...     return grades[i]
...
>>> [grade(score) for score in [33, 99, 77, 70, 89, 90, 100]]
['F', 'A', 'C', 'C', 'B', 'A', 'A']
```

Unlike the `sorted()` function, it does not make sense for the `bisect()` functions to have *key* or *reversed* arguments because that would lead to an inefficient design (successive calls to `bisect` functions would not “remember” all of the previous key lookups).

Instead, it is better to search a list of precomputed keys to find the index of the record in question:

```
>>> data = [('red', 5), ('blue', 1), ('yellow', 8), ('black', 0)]
>>> data.sort(key=lambda r: r[1])
>>> keys = [r[1] for r in data]           # precomputed list of keys
>>> data[bisect_left(keys, 0)]
('black', 0)
>>> data[bisect_left(keys, 1)]
('blue', 1)
>>> data[bisect_left(keys, 5)]
('red', 5)
>>> data[bisect_left(keys, 8)]
('yellow', 8)
```

7.6. array — Efficient arrays of numeric values

This module defines an object type which can compactly represent an array of basic values: characters, integers, floating point numbers. Arrays are sequence types and behave very much like lists, except that the type of objects stored in them is constrained. The type is specified at object creation time by using a *type code*, which is a single character. The following type codes are defined:

Type code	C Type	Python Type	Minimum size in bytes
'b'	signed char	int	1
'B'	unsigned char	int	1
'u'	Py_UNICODE	Unicode character	2 (see note)
'h'	signed short	int	2
'H'	unsigned short	int	2
'i'	signed int	int	2
'I'	unsigned int	int	2
'l'	signed long	int	4
'L'	unsigned long	int	4
'f'	float	float	4
'd'	double	float	8

Note: The 'u' typecode corresponds to Python's unicode character. On narrow Unicode builds this is 2-bytes, on wide builds this is 4-bytes.

The actual representation of values is determined by the machine architecture (strictly speaking, by the C implementation). The actual

size can be accessed through the `itemsize` attribute.

The module defines the following type:

```
class array.array(typecode[, initializer])
```

A new array whose items are restricted by *typecode*, and initialized from the optional *initializer* value, which must be a list, object supporting the buffer interface, or iterable over elements of the appropriate type.

If given a list or string, the initializer is passed to the new array's `fromlist()`, `frombytes()`, or `fromunicode()` method (see below) to add initial items to the array. Otherwise, the iterable initializer is passed to the `extend()` method.

array.**typecodes**

A string with all available type codes.

Array objects support the ordinary sequence operations of indexing, slicing, concatenation, and multiplication. When using slice assignment, the assigned value must be an array object with the same type code; in all other cases, `TypeError` is raised. Array objects also implement the buffer interface, and may be used wherever buffer objects are supported.

The following data items and methods are also supported:

array.**typecode**

The typecode character used to create the array.

array.**itemsize**

The length in bytes of one array item in the internal representation.

array.**append**(*x*)

Append a new item with value *x* to the end of the array.

`array.buffer_info()`

Return a tuple `(address, length)` giving the current memory address and the length in elements of the buffer used to hold array's contents. The size of the memory buffer in bytes can be computed as `array.buffer_info()[1] * array.itemsize`. This is occasionally useful when working with low-level (and inherently unsafe) I/O interfaces that require memory addresses, such as certain `ioctl()` operations. The returned numbers are valid as long as the array exists and no length-changing operations are applied to it.

Note: When using array objects from code written in C or C++ (the only way to effectively make use of this information), it makes more sense to use the buffer interface supported by array objects. This method is maintained for backward compatibility and should be avoided in new code. The buffer interface is documented in [Buffer Protocol](#).

`array.byteswap()`

“Byteswap” all items of the array. This is only supported for values which are 1, 2, 4, or 8 bytes in size; for other types of values, `RuntimeError` is raised. It is useful when reading data from a file written on a machine with a different byte order.

`array.count(x)`

Return the number of occurrences of *x* in the array.

`array.extend(iterable)`

Append items from *iterable* to the end of the array. If *iterable* is another array, it must have *exactly* the same type code; if not, `TypeError` will be raised. If *iterable* is not an array, it must be

iterable and its elements must be the right type to be appended to the array.

`array.frombytes(s)`

Appends items from the string, interpreting the string as an array of machine values (as if it had been read from a file using the `fromfile()` method).

New in version 3.2: `fromstring()` is renamed to `frombytes()` for clarity.

`array.fromfile(f, n)`

Read n items (as machine values) from the *file object* f and append them to the end of the array. If less than n items are available, `EOFError` is raised, but the items that were available are still inserted into the array. f must be a real built-in file object; something else with a `read()` method won't do.

`array.fromlist(list)`

Append items from the list. This is equivalent to `for x in list: a.append(x)` except that if there is a type error, the array is unchanged.

`array.fromstring()`

Deprecated alias for `frombytes()`.

`array.fromunicode(s)`

Extends this array with data from the given unicode string. The array must be a type `'u'` array; otherwise a `ValueError` is raised. Use `array.frombytes(unicodestring.encode(enc))` to append Unicode data to an array of some other type.

`array.index(x)`

Return the smallest i such that i is the index of the first

occurrence of *x* in the array.

array.**insert**(*i*, *x*)

Insert a new item with value *x* in the array before position *i*. Negative values are treated as being relative to the end of the array.

array.**pop**([*i*])

Removes the item with the index *i* from the array and returns it. The optional argument defaults to `-1`, so that by default the last item is removed and returned.

array.**remove**(*x*)

Remove the first occurrence of *x* from the array.

array.**reverse**()

Reverse the order of the items in the array.

array.**tobytes**()

Convert the array to an array of machine values and return the bytes representation (the same sequence of bytes that would be written to a file by the `tofile()` method.)

New in version 3.2: `tostring()` is renamed to `tobytes()` for clarity.

array.**tofile**(*f*)

Write all items (as machine values) to the *file object* *f*.

array.**tolist**()

Convert the array to an ordinary list with the same items.

array.**tostring**()

Deprecated alias for `tobytes()`.

`array.tounicode()`

Convert the array to a unicode string. The array must be a type `'u'` array; otherwise a `ValueError` is raised. Use `array.tobytes().decode(enc)` to obtain a unicode string from an array of some other type.

When an array object is printed or converted to a string, it is represented as `array(typecode, initializer)`. The *initializer* is omitted if the array is empty, otherwise it is a string if the *typecode* is `'u'`, otherwise it is a list of numbers. The string is guaranteed to be able to be converted back to an array with the same type and value using `eval()`, so long as the `array()` function has been imported using `from array import array`. Examples:

```
array('l')
array('u', 'hello \u2641')
array('l', [1, 2, 3, 4, 5])
array('d', [1.0, 2.0, 3.14])
```

See also:

Module `struct`

Packing and unpacking of heterogeneous binary data.

Module `xdrlib`

Packing and unpacking of External Data Representation (XDR) data as used in some remote procedure call systems.

The Numerical Python Manual

The Numeric Python extension (NumPy) defines another array type; see <http://numpy.sourceforge.net/> for further information about Numerical Python. (A PDF version of the NumPy manual is available at <http://numpy.sourceforge.net/numdoc/numdoc.pdf>).

7.7. sched — Event scheduler

Source code: [Lib/sched.py](#)

The `sched` module defines a class which implements a general purpose event scheduler:

```
class sched.scheduler(timefunc, delayfunc)
```

The `scheduler` class defines a generic interface to scheduling events. It needs two functions to actually deal with the “outside world” — `timefunc` should be callable without arguments, and return a number (the “time”, in any units whatsoever). The `delayfunc` function should be callable with one argument, compatible with the output of `timefunc`, and should delay that many time units. `delayfunc` will also be called with the argument `@` after each event is run to allow other threads an opportunity to run in multi-threaded applications.

Example:

```
>>> import sched, time
>>> s = sched.scheduler(time.time, time.sleep)
>>> def print_time(): print("From print_time", time.time())
...
>>> def print_some_times():
...     print(time.time())
...     s.enter(5, 1, print_time, ())
...     s.enter(10, 1, print_time, ())
...     s.run()
...     print(time.time())
...
>>> print_some_times()
930343690.257
From print_time 930343695.274
From print_time 930343700.273
930343700.276
```

In multi-threaded environments, the `scheduler` class has limitations with respect to thread-safety, inability to insert a new task before the one currently pending in a running scheduler, and holding up the main thread until the event queue is empty. Instead, the preferred approach is to use the `threading.Timer` class instead.

Example:

```
>>> import time
>>> from threading import Timer
>>> def print_time():
...     print("From print_time", time.time())
...
>>> def print_some_times():
...     print(time.time())
...     Timer(5, print_time, ()).start()
...     Timer(10, print_time, ()).start()
...     time.sleep(11) # sleep while time-delay events execute
...     print(time.time())
...
>>> print_some_times()
930343690.257
From print_time 930343695.274
From print_time 930343700.273
930343701.301
```

7.7.1. Scheduler Objects

`scheduler` instances have the following methods and attributes:

`scheduler.enterabs(time, priority, action, argument)`

Schedule a new event. The *time* argument should be a numeric type compatible with the return value of the *timefunc* function passed to the constructor. Events scheduled for the same *time* will be executed in the order of their *priority*.

Executing the event means executing `action(*argument)`. *argument* must be a sequence holding the parameters for *action*.

Return value is an event which may be used for later cancellation of the event (see `cancel()`).

`scheduler.enter(delay, priority, action, argument)`

Schedule an event for *delay* more time units. Other than the relative time, the other arguments, the effect and the return value are the same as those for `enterabs()`.

`scheduler.cancel(event)`

Remove the event from the queue. If *event* is not an event currently in the queue, this method will raise a `ValueError`.

`scheduler.empty()`

Return true if the event queue is empty.

`scheduler.run()`

Run all scheduled events. This function will wait (using the `delayfunc()` function passed to the constructor) for the next event, then execute it and so on until there are no more scheduled events.

Either *action* or *delayfunc* can raise an exception. In either case, the scheduler will maintain a consistent state and propagate the exception. If an exception is raised by *action*, the event will not be attempted in future calls to `run()`.

If a sequence of events takes longer to run than the time available before the next event, the scheduler will simply fall behind. No events will be dropped; the calling code is responsible for canceling events which are no longer pertinent.

`scheduler.queue`

Read-only attribute returning a list of upcoming events in the order they will be run. Each event is shown as a *named tuple* with the following fields: time, priority, action, argument.

7.8. `queue` — A synchronized queue class

Source code: [Lib/queue.py](#)

The `queue` module implements multi-producer, multi-consumer queues. It is especially useful in threaded programming when information must be exchanged safely between multiple threads. The `Queue` class in this module implements all the required locking semantics. It depends on the availability of thread support in Python; see the `threading` module.

Implements three types of queue whose only difference is the order that the entries are retrieved. In a FIFO queue, the first tasks added are the first retrieved. In a LIFO queue, the most recently added entry is the first retrieved (operating like a stack). With a priority queue, the entries are kept sorted (using the `heapq` module) and the lowest valued entry is retrieved first.

The `queue` module defines the following classes and exceptions:

`class queue.Queue(maxsize=0)`

Constructor for a FIFO queue. *maxsize* is an integer that sets the upperbound limit on the number of items that can be placed in the queue. Insertion will block once this size has been reached, until queue items are consumed. If *maxsize* is less than or equal to zero, the queue size is infinite.

`class queue.LifoQueue(maxsize=0)`

Constructor for a LIFO queue. *maxsize* is an integer that sets the upperbound limit on the number of items that can be placed in the queue. Insertion will block once this size has been reached,

until queue items are consumed. If *maxsize* is less than or equal to zero, the queue size is infinite.

class `queue.PriorityQueue(maxsize=0)`

Constructor for a priority queue. *maxsize* is an integer that sets the upperbound limit on the number of items that can be placed in the queue. Insertion will block once this size has been reached, until queue items are consumed. If *maxsize* is less than or equal to zero, the queue size is infinite.

The lowest valued entries are retrieved first (the lowest valued entry is the one returned by `sorted(list(entries))[0]`). A typical pattern for entries is a tuple in the form: `(priority_number, data)`.

exception `queue.Empty`

Exception raised when non-blocking `get()` (or `get_nowait()`) is called on a `Queue` object which is empty.

exception `queue.Full`

Exception raised when non-blocking `put()` (or `put_nowait()`) is called on a `Queue` object which is full.

7.8.1. Queue Objects

Queue objects (`Queue`, `LifoQueue`, or `PriorityQueue`) provide the public methods described below.

`Queue.qsize()`

Return the approximate size of the queue. Note, `qsize() > 0` doesn't guarantee that a subsequent `get()` will not block, nor will `qsize() < maxsize` guarantee that `put()` will not block.

`Queue.empty()`

Return `True` if the queue is empty, `False` otherwise. If `empty()` returns `True` it doesn't guarantee that a subsequent call to `put()` will not block. Similarly, if `empty()` returns `False` it doesn't guarantee that a subsequent call to `get()` will not block.

`Queue.full()`

Return `True` if the queue is full, `False` otherwise. If `full()` returns `True` it doesn't guarantee that a subsequent call to `get()` will not block. Similarly, if `full()` returns `False` it doesn't guarantee that a subsequent call to `put()` will not block.

`Queue.put(item, block=True, timeout=None)`

Put *item* into the queue. If optional args *block* is true and *timeout* is `None` (the default), block if necessary until a free slot is available. If *timeout* is a positive number, it blocks at most *timeout* seconds and raises the `Full` exception if no free slot was available within that time. Otherwise (*block* is false), put an item on the queue if a free slot is immediately available, else raise the `Full` exception (*timeout* is ignored in that case).

`Queue.put_nowait(item)`

Equivalent to `put(item, False)`.

`Queue.get(block=True, timeout=None)`

Remove and return an item from the queue. If optional args *block* is true and *timeout* is None (the default), block if necessary until an item is available. If *timeout* is a positive number, it blocks at most *timeout* seconds and raises the `Empty` exception if no item was available within that time. Otherwise (*block* is false), return an item if one is immediately available, else raise the `Empty` exception (*timeout* is ignored in that case).

`Queue.get_nowait()`

Equivalent to `get(False)`.

Two methods are offered to support tracking whether enqueued tasks have been fully processed by daemon consumer threads.

`Queue.task_done()`

Indicate that a formerly enqueued task is complete. Used by queue consumer threads. For each `get()` used to fetch a task, a subsequent call to `task_done()` tells the queue that the processing on the task is complete.

If a `join()` is currently blocking, it will resume when all items have been processed (meaning that a `task_done()` call was received for every item that had been `put()` into the queue).

Raises a `ValueError` if called more times than there were items placed in the queue.

`Queue.join()`

Blocks until all items in the queue have been gotten and processed.

The count of unfinished tasks goes up whenever an item is added to the queue. The count goes down whenever a consumer thread calls `task_done()` to indicate that the item was retrieved and all work on it is complete. When the count of unfinished tasks drops to zero, `join()` unblocks.

Example of how to wait for enqueued tasks to be completed:

```
def worker():
    while True:
        item = q.get()
        do_work(item)
        q.task_done()

q = Queue()
for i in range(num_worker_threads):
    t = Thread(target=worker)
    t.daemon = True
    t.start()

for item in source():
    q.put(item)

q.join()      # block until all tasks are done
```

See also:

Class `multiprocessing.Queue`

A queue class for use in a multi-processing (rather than multi-threading) context.

`collections.deque` is an alternative implementation of unbounded queues with fast atomic `append()` and `popleft()` operations that do not require locking.

7.9. weakref — Weak references

Source code: [Lib/weakref.py](#)

The `weakref` module allows the Python programmer to create *weak references* to objects.

In the following, the term *referent* means the object which is referred to by a weak reference.

A weak reference to an object is not enough to keep the object alive: when the only remaining references to a referent are weak references, *garbage collection* is free to destroy the referent and reuse its memory for something else. A primary use for weak references is to implement caches or mappings holding large objects, where it's desired that a large object not be kept alive solely because it appears in a cache or mapping.

For example, if you have a number of large binary image objects, you may wish to associate a name with each. If you used a Python dictionary to map names to images, or images to names, the image objects would remain alive just because they appeared as values or keys in the dictionaries. The `WeakKeyDictionary` and `WeakValueDictionary` classes supplied by the `weakref` module are an alternative, using weak references to construct mappings that don't keep objects alive solely because they appear in the mapping objects. If, for example, an image object is a value in a `WeakValueDictionary`, then when the last remaining references to that image object are the weak references held by weak mappings, garbage collection can reclaim the object, and its corresponding entries in weak mappings are simply deleted.

`WeakKeyDictionary` and `WeakValueDictionary` use weak references in

their implementation, setting up callback functions on the weak references that notify the weak dictionaries when a key or value has been reclaimed by garbage collection. `WeakSet` implements the `set` interface, but keeps weak references to its elements, just like a `WeakKeyDictionary` does.

Most programs should find that using one of these weak container types is all they need – it's not usually necessary to create your own weak references directly. The low-level machinery used by the weak dictionary implementations is exposed by the `weakref` module for the benefit of advanced uses.

Note: Weak references to an object are cleared before the object's `__del__()` is called, to ensure that the weak reference callback (if any) finds the object still alive.

Not all objects can be weakly referenced; those objects which can include class instances, functions written in Python (but not in C), instance methods, sets, frozensets, some *file objects*, *generators*, type objects, sockets, arrays, deques, regular expression pattern objects, and code objects.

Changed in version 3.2: Added support for `thread.lock`, `threading.Lock`, and code objects.

Several built-in types such as `list` and `dict` do not directly support weak references but can add support through subclassing:

```
class Dict(dict):
    pass

obj = Dict(red=1, green=2, blue=3) # this object is weak refe
```

Other built-in types such as `tuple` and `int` do not support weak

references even when subclassed (This is an implementation detail and may be different across various Python implementations.).

Extension types can easily be made to support weak references; see [Weak Reference Support](#).

```
class weakref.ref(object[, callback])
```

Return a weak reference to *object*. The original object can be retrieved by calling the reference object if the referent is still alive; if the referent is no longer alive, calling the reference object will cause `None` to be returned. If *callback* is provided and not `None`, and the returned weakref object is still alive, the callback will be called when the object is about to be finalized; the weak reference object will be passed as the only parameter to the callback; the referent will no longer be available.

It is allowable for many weak references to be constructed for the same object. Callbacks registered for each weak reference will be called from the most recently registered callback to the oldest registered callback.

Exceptions raised by the callback will be noted on the standard error output, but cannot be propagated; they are handled in exactly the same way as exceptions raised from an object's `__del__()` method.

Weak references are *hashable* if the *object* is hashable. They will maintain their hash value even after the *object* was deleted. If `hash()` is called the first time only after the *object* was deleted, the call will raise `TypeError`.

Weak references support tests for equality, but not ordering. If the referents are still alive, two references have the same equality relationship as their referents (regardless of the *callback*). If either referent has been deleted, the references are equal only if

the reference objects are the same object.

This is a subclassable type rather than a factory function.

`weakref.proxy(object[, callback])`

Return a proxy to *object* which uses a weak reference. This supports use of the proxy in most contexts instead of requiring the explicit dereferencing used with weak reference objects. The returned object will have a type of either `ProxyType` or `CallableProxyType`, depending on whether *object* is callable. Proxy objects are not *hashable* regardless of the referent; this avoids a number of problems related to their fundamentally mutable nature, and prevent their use as dictionary keys. *callback* is the same as the parameter of the same name to the `ref()` function.

`weakref.getweakrefcount(object)`

Return the number of weak references and proxies which refer to *object*.

`weakref.getweakrefs(object)`

Return a list of all weak reference and proxy objects which refer to *object*.

`class weakref.WeakKeyDictionary([dict])`

Mapping class that references keys weakly. Entries in the dictionary will be discarded when there is no longer a strong reference to the key. This can be used to associate additional data with an object owned by other parts of an application without adding attributes to those objects. This can be especially useful with objects that override attribute accesses.

Note: Caution: Because a `WeakKeyDictionary` is built on top of a Python dictionary, it must not change size when iterating over

it. This can be difficult to ensure for a `WeakKeyDictionary` because actions performed by the program during iteration may cause items in the dictionary to vanish “by magic” (as a side effect of garbage collection).

`WeakKeyDictionary` objects have the following additional methods. These expose the internal references directly. The references are not guaranteed to be “live” at the time they are used, so the result of calling the references needs to be checked before being used. This can be used to avoid creating references that will cause the garbage collector to keep the keys around longer than needed.

`WeakKeyDictionary.keyrefs()`

Return an iterable of the weak references to the keys.

`class weakref.WeakValueDictionary([dict])`

Mapping class that references values weakly. Entries in the dictionary will be discarded when no strong reference to the value exists any more.

Note: Caution: Because a `WeakValueDictionary` is built on top of a Python dictionary, it must not change size when iterating over it. This can be difficult to ensure for a `WeakValueDictionary` because actions performed by the program during iteration may cause items in the dictionary to vanish “by magic” (as a side effect of garbage collection).

`WeakValueDictionary` objects have the following additional methods. These method have the same issues as the and `keyrefs()` method of `WeakKeyDictionary` objects.

`WeakValueDictionary.valuerefs()`

Return an iterable of the weak references to the values.

class weakref.**WeakSet**(*[elements]*)

Set class that keeps weak references to its elements. An element will be discarded when no strong reference to it exists any more.

weakref.**ReferenceType**

The type object for weak references objects.

weakref.**ProxyType**

The type object for proxies of objects which are not callable.

weakref.**CallableProxyType**

The type object for proxies of callable objects.

weakref.**ProxyTypes**

Sequence containing all the type objects for proxies. This can make it simpler to test if an object is a proxy without being dependent on naming both proxy types.

exception weakref.**ReferenceError**

Exception raised when a proxy object is used but the underlying object has been collected. This is the same as the standard [ReferenceError](#) exception.

See also:

PEP 0205 - Weak References

The proposal and rationale for this feature, including links to earlier implementations and information about similar features in other languages.

7.9.1. Weak Reference Objects

Weak reference objects have no attributes or methods, but do allow the referent to be obtained, if it still exists, by calling it:

```
>>> import weakref
>>> class Object:
...     pass
...
>>> o = Object()
>>> r = weakref.ref(o)
>>> o2 = r()
>>> o is o2
True
```

If the referent no longer exists, calling the reference object returns **None**:

```
>>> del o, o2
>>> print(r())
None
```

Testing that a weak reference object is still live should be done using the expression `ref() is not None`. Normally, application code that needs to use a reference object should follow this pattern:

```
# r is a weak reference object
o = r()
if o is None:
    # referent has been garbage collected
    print("Object has been deallocated; can't frobnicate.")
else:
    print("Object is still live!")
    o.do_something_useful()
```

Using a separate test for “liveness” creates race conditions in threaded applications; another thread can cause a weak reference to become invalidated before the weak reference is called; the idiom

shown above is safe in threaded applications as well as single-threaded applications.

Specialized versions of `ref` objects can be created through subclassing. This is used in the implementation of the `WeakValueDictionary` to reduce the memory overhead for each entry in the mapping. This may be most useful to associate additional information with a reference, but could also be used to insert additional processing on calls to retrieve the referent.

This example shows how a subclass of `ref` can be used to store additional information about an object and affect the value that's returned when the referent is accessed:

```
import weakref

class ExtendedRef(weakref.ref):
    def __init__(self, ob, callback=None, **annotations):
        super(ExtendedRef, self).__init__(ob, callback)
        self.__counter = 0
        for k, v in annotations.items():
            setattr(self, k, v)

    def __call__(self):
        """Return a pair containing the referent and the number
        times the reference has been called.
        """
        ob = super(ExtendedRef, self).__call__()
        if ob is not None:
            self.__counter += 1
            ob = (ob, self.__counter)
        return ob
```

7.9.2. Example

This simple example shows how an application can use objects IDs to retrieve objects that it has seen before. The IDs of the objects can then be used in other data structures without forcing the objects to remain alive, but the objects can still be retrieved by ID if they do.

```
import weakref

_id2obj_dict = weakref.WeakValueDictionary()

def remember(obj):
    oid = id(obj)
    _id2obj_dict[oid] = obj
    return oid

def id2obj(oid):
    return _id2obj_dict[oid]
```

7.10. `types` — Names for built-in types

Source code: [Lib/types.py](#)

This module defines names for some object types that are used by the standard Python interpreter, but not exposed as builtins like `int` or `str` are. Also, it does not include some of the types that arise transparently during processing such as the `listiterator` type.

Typical use is for `isinstance()` or `issubclass()` checks.

The module defines the following names:

`types.FunctionType`

`types.LambdaType`

The type of user-defined functions and functions created by `lambda` expressions.

`types.GeneratorType`

The type of *generator*-iterator objects, produced by calling a generator function.

`types.CodeType`

The type for code objects such as returned by `compile()`.

`types.MethodType`

The type of methods of user-defined class instances.

`types.BuiltinFunctionType`

`types.BuiltinMethodType`

The type of built-in functions like `len()` or `sys.exit()`, and methods of built-in classes. (Here, the term “built-in” means

“written in C”.)

`types.ModuleType`

The type of modules.

`types.TracebackType`

The type of traceback objects such as found in `sys.exc_info()` [2].

`types.FrameType`

The type of frame objects such as found in `tb.tb_frame` if `tb` is a traceback object.

`types.GetSetDescriptorType`

The type of objects defined in extension modules with `PyGetSetDef`, such as `FrameType.f_locals` or `array.array.typecode`. This type is used as descriptor for object attributes; it has the same purpose as the `property` type, but for classes defined in extension modules.

`types.MemberDescriptorType`

The type of objects defined in extension modules with `PyMemberDef`, such as `datetime.timedelta.days`. This type is used as descriptor for simple C data members which use standard conversion functions; it has the same purpose as the `property` type, but for classes defined in extension modules.

CPython implementation detail: In other implementations of Python, this type may be identical to `GetSetDescriptorType`.

7.11. `copy` — Shallow and deep copy operations

This module provides generic (shallow and deep) copying operations.

Interface summary:

`copy.copy(x)`

Return a shallow copy of *x*.

`copy.deepcopy(x)`

Return a deep copy of *x*.

exception `copy.error`

Raised for module specific errors.

The difference between shallow and deep copying is only relevant for compound objects (objects that contain other objects, like lists or class instances):

- A *shallow copy* constructs a new compound object and then (to the extent possible) inserts *references* into it to the objects found in the original.
- A *deep copy* constructs a new compound object and then, recursively, inserts *copies* into it of the objects found in the original.

Two problems often exist with deep copy operations that don't exist with shallow copy operations:

- Recursive objects (compound objects that, directly or indirectly, contain a reference to themselves) may cause a recursive loop.
- Because deep copy copies *everything* it may copy too much,

e.g., administrative data structures that should be shared even between copies.

The `deepcopy()` function avoids these problems by:

- keeping a “memo” dictionary of objects already copied during the current copying pass; and
- letting user-defined classes override the copying operation or the set of components copied.

This module does not copy types like module, method, stack trace, stack frame, file, socket, window, array, or any similar types. It does “copy” functions and classes (shallow and deeply), by returning the original object unchanged; this is compatible with the way these are treated by the `pickle` module.

Shallow copies of dictionaries can be made using `dict.copy()`, and of lists by assigning a slice of the entire list, for example, `copied_list = original_list[:]`.

Classes can use the same interfaces to control copying that they use to control pickling. See the description of module `pickle` for information on these methods. The `copy` module does not use the `copyreg` registration module.

In order for a class to define its own copy implementation, it can define special methods `__copy__()` and `__deepcopy__()`. The former is called to implement the shallow copy operation; no additional arguments are passed. The latter is called to implement the deep copy operation; it is passed one argument, the memo dictionary. If the `__deepcopy__()` implementation needs to make a deep copy of a component, it should call the `deepcopy()` function with the component as first argument and the memo dictionary as second argument.

See also:

Module `pickle`

Discussion of the special methods used to support object state retrieval and restoration.

7.12. pprint — Data pretty printer

Source code: [Lib/pprint.py](#)

The `pprint` module provides a capability to “pretty-print” arbitrary Python data structures in a form which can be used as input to the interpreter. If the formatted structures include objects which are not fundamental Python types, the representation may not be loadable. This may be the case if objects such as files, sockets, classes, or instances are included, as well as many other built-in objects which are not representable as Python constants.

The formatted representation keeps objects on a single line if it can, and breaks them onto multiple lines if they don't fit within the allowed width. Construct `PrettyPrinter` objects explicitly if you need to adjust the width constraint.

Dictionaries are sorted by key before the display is computed.

The `pprint` module defines one class:

```
class pprint.PrettyPrinter(indent=1, width=80, depth=None,
stream=None)
```

Construct a `PrettyPrinter` instance. This constructor understands several keyword parameters. An output stream may be set using the `stream` keyword; the only method used on the stream object is the file protocol's `write()` method. If not specified, the `PrettyPrinter` adopts `sys.stdout`. Three additional parameters may be used to control the formatted representation. The keywords are `indent`, `depth`, and `width`. The amount of indentation added for each recursive level is specified by `indent`; the default is one. Other values can cause output to look a little odd, but can make nesting easier to spot. The number of levels

which may be printed is controlled by *depth*; if the data structure being printed is too deep, the next contained level is replaced by `...`. By default, there is no constraint on the depth of the objects being formatted. The desired output width is constrained using the *width* parameter; the default is 80 characters. If a structure cannot be formatted within the constrained width, a best effort will be made.

```
>>> import pprint
>>> stuff = ['spam', 'eggs', 'lumberjack', 'knights', 'ni']
>>> stuff.insert(0, stuff[:])
>>> pp = pprint.PrettyPrinter(indent=4)
>>> pp.pprint(stuff)
[ ['spam', 'eggs', 'lumberjack', 'knights', 'ni'],
  'spam',
  'eggs',
  'lumberjack',
  'knights',
  'ni']
>>> tup = ('spam', ('eggs', ('lumberjack', ('knights', ('ni'
... ('parrot', ('fresh fruit',)))))))
>>> pp = pprint.PrettyPrinter(depth=6)
>>> pp.pprint(tup)
('spam', ('eggs', ('lumberjack', ('knights', ('ni', ('dead',
```

The `PrettyPrinter` class supports several derivative functions:

`pprint.pformat(object, indent=1, width=80, depth=None)`

Return the formatted representation of *object* as a string. *indent*, *width* and *depth* will be passed to the `PrettyPrinter` constructor as formatting parameters.

`pprint.pprint(object, stream=None, indent=1, width=80, depth=None)`

Prints the formatted representation of *object* on *stream*, followed by a newline. If *stream* is `None`, `sys.stdout` is used. This may be used in the interactive interpreter instead of the `print()` function

for inspecting values (you can even reassign `print = pprint.pprint` for use within a scope). `indent`, `width` and `depth` will be passed to the `PrettyPrinter` constructor as formatting parameters.

```
>>> import pprint
>>> stuff = ['spam', 'eggs', 'lumberjack', 'knights', 'ni']
>>> stuff.insert(0, stuff)
>>> pprint.pprint(stuff)
[<Recursion on list with id=...>,
 'spam',
 'eggs',
 'lumberjack',
 'knights',
 'ni']
```

`pprint.isreadable(object)`

Determine if the formatted representation of *object* is “readable,” or can be used to reconstruct the value using `eval()`. This always returns `False` for recursive objects.

```
>>> pprint.isreadable(stuff)
False
```

`pprint.isrecursive(object)`

Determine if *object* requires a recursive representation.

One more support function is also defined:

`pprint.saferepr(object)`

Return a string representation of *object*, protected against recursive data structures. If the representation of *object* exposes a recursive entry, the recursive reference will be represented as `<Recursion on typename with id=number>`. The representation is not otherwise formatted.

```
>>> pprint.saferepr(stuff)
```

```
"[<Recursion on list with id=...>, 'spam', 'eggs', 'lumberja
```

7.12.1. PrettyPrinter Objects

PrettyPrinter instances have the following methods:

`PrettyPrinter.pformat(object)`

Return the formatted representation of *object*. This takes into account the options passed to the **PrettyPrinter** constructor.

`PrettyPrinter.pprint(object)`

Print the formatted representation of *object* on the configured stream, followed by a newline.

The following methods provide the implementations for the corresponding functions of the same names. Using these methods on an instance is slightly more efficient since new **PrettyPrinter** objects don't need to be created.

`PrettyPrinter.isreadable(object)`

Determine if the formatted representation of the object is "readable," or can be used to reconstruct the value using `eval()`. Note that this returns `False` for recursive objects. If the *depth* parameter of the **PrettyPrinter** is set and the object is deeper than allowed, this returns `False`.

`PrettyPrinter.isrecursive(object)`

Determine if the object requires a recursive representation.

This method is provided as a hook to allow subclasses to modify the way objects are converted to strings. The default implementation uses the internals of the `saferepr()` implementation.

`PrettyPrinter.format(object, context, maxlevels, level)`

Returns three values: the formatted version of *object* as a string,

a flag indicating whether the result is readable, and a flag indicating whether recursion was detected. The first argument is the object to be presented. The second is a dictionary which contains the `id()` of objects that are part of the current presentation context (direct and indirect containers for *object* that are affecting the presentation) as the keys; if an object needs to be presented which is already represented in *context*, the third return value should be `True`. Recursive calls to the `format()` method should add additional entries for containers to this dictionary. The third argument, *maxlevels*, gives the requested limit to recursion; this will be `0` if there is no requested limit. This argument should be passed unmodified to recursive calls. The fourth argument, *level*, gives the current level; recursive calls should be passed a value less than that of the current call.

7.12.2. pprint Example

This example demonstrates several uses of the `pprint()` function and its parameters.

```
>>> import pprint
>>> tup = ('spam', ('eggs', ('lumberjack', ('knights', ('ni', (
... ('parrot', ('fresh fruit',)))))))
>>> stuff = ['a' * 10, tup, ['a' * 30, 'b' * 30], ['c' * 20, 'd' * 20]]
>>> pprint.pprint(stuff)
['aaaaaaaaaa',
 ('spam',
 ('eggs',
 ('lumberjack',
 ('knights', ('ni', ('dead', ('parrot', ('fresh fruit',)))))))]
['aaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaa', 'bbbbbbbbbbbbbbbbbbbbbbbbbbbbbb']
['cccccccccccccccccccc', 'dddddddddddddddddddd']]
>>> pprint.pprint(stuff, depth=3)
['aaaaaaaaaa',
 ('spam', ('eggs', (...))),
 ['aaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaa', 'bbbbbbbbbbbbbbbbbbbbbbbbbbbbbb']
 ['cccccccccccccccccccc', 'dddddddddddddddddddd']]
>>> pprint.pprint(stuff, width=60)
['aaaaaaaaaa',
 ('spam',
 ('eggs',
 ('lumberjack',
 ('knights',
 ('ni', ('dead', ('parrot', ('fresh fruit',))))))),
 ['aaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaa',
 'bbbbbbbbbbbbbbbbbbbbbbbbbbbbbb'],
 ['cccccccccccccccccccc', 'dddddddddddddddddddd']]
```

7.13. reprlib — Alternate repr() implementation

Source code: [Lib/reprlib.py](#)

The `reprlib` module provides a means for producing object representations with limits on the size of the resulting strings. This is used in the Python debugger and may be useful in other contexts as well.

This module provides a class, an instance, and a function:

`class reprlib.Repr`

Class which provides formatting services useful in implementing functions similar to the built-in `repr()`; size limits for different object types are added to avoid the generation of representations which are excessively long.

`reprlib.aRepr`

This is an instance of `Repr` which is used to provide the `repr()` function described below. Changing the attributes of this object will affect the size limits used by `repr()` and the Python debugger.

`reprlib.repr(obj)`

This is the `repr()` method of `aRepr`. It returns a string similar to that returned by the built-in function of the same name, but with limits on most sizes.

In addition to size-limiting tools, the module also provides a decorator for detecting recursive calls to `__repr__()` and substituting a placeholder string instead.

`@reprlib.recursive_repr(fillvalue="...")`

Decorator for `__repr__()` methods to detect recursive calls within the same thread. If a recursive call is made, the *fillvalue* is returned, otherwise, the usual `__repr__()` call is made. For example:

```
>>> class MyList(list):
...     @recursive_repr()
...     def __repr__(self):
...         return '<' + '|'.join(map(repr, self)) + '>'
...
>>> m = MyList('abc')
>>> m.append(m)
>>> m.append('x')
>>> print(m)
<'a'|'b'|'c'|...|'x'>
```

New in version 3.2.

7.13.1. Repr Objects

Repr instances provide several members which can be used to provide size limits for the representations of different object types, and methods which format specific object types.

Repr.maxlevel

Depth limit on the creation of recursive representations. The default is `6`.

Repr.maxdict

Repr.maxlist

Repr.maxtuple

Repr.maxset

Repr.maxfrozenset

Repr.maxdeque

Repr.maxarray

Limits on the number of entries represented for the named object type. The default is `4` for **maxdict**, `5` for **maxarray**, and `6` for the others.

Repr.maxlong

Maximum number of characters in the representation for an integer. Digits are dropped from the middle. The default is `40`.

Repr.maxstring

Limit on the number of characters in the representation of the string. Note that the “normal” representation of the string is used as the character source: if escape sequences are needed in the representation, these may be mangled when the representation is shortened. The default is `30`.

Repr.maxother

This limit is used to control the size of object types for which no specific formatting method is available on the **Repr** object. It is

applied in a similar manner as `maxstring`. The default is `20`.

`Repr.repr(obj)`

The equivalent to the built-in `repr()` that uses the formatting imposed by the instance.

`Repr.repr1(obj, level)`

Recursive implementation used by `repr()`. This uses the type of `obj` to determine which formatting method to call, passing it `obj` and `level`. The type-specific methods should call `repr1()` to perform recursive formatting, with `level - 1` for the value of `level` in the recursive call.

`Repr.repr_TYPE(obj, level)`

Formatting methods for specific types are implemented as methods with a name based on the type name. In the method name, **TYPE** is replaced by `string.join(string.split(type(obj).__name__, '_'))`. Dispatch to these methods is handled by `repr1()`. Type-specific methods which need to recursively format a value should call `self.repr1(subobj, level - 1)`.

7.13.2. Subclassing Repr Objects

The use of dynamic dispatching by `Repr.repr1()` allows subclasses of `Repr` to add support for additional built-in object types or to modify the handling of types already supported. This example shows how special support for file objects could be added:

```
import reprlib
import sys

class MyRepr(reprlib.Repr):
    def repr_file(self, obj, level):
        if obj.name in ['<stdin>', '<stdout>', '<stderr>']:
            return obj.name
        else:
            return repr(obj)

aRepr = MyRepr()
print(aRepr.repr(sys.stdin))           # prints '<stdin>'
```

8. Numeric and Mathematical Modules

The modules described in this chapter provide numeric and math-related functions and data types. The `numbers` module defines an abstract hierarchy of numeric types. The `math` and `cmath` modules contain various mathematical functions for floating-point and complex numbers. For users more interested in decimal accuracy than in speed, the `decimal` module supports exact representations of decimal numbers.

The following modules are documented in this chapter:

- 8.1. `numbers` — Numeric abstract base classes
 - 8.1.1. The numeric tower
 - 8.1.2. Notes for type implementors
 - 8.1.2.1. Adding More Numeric ABCs
 - 8.1.2.2. Implementing the arithmetic operations
- 8.2. `math` — Mathematical functions
 - 8.2.1. Number-theoretic and representation functions
 - 8.2.2. Power and logarithmic functions
 - 8.2.3. Trigonometric functions
 - 8.2.4. Angular conversion
 - 8.2.5. Hyperbolic functions
 - 8.2.6. Special functions
 - 8.2.7. Constants
- 8.3. `cmath` — Mathematical functions for complex numbers
 - 8.3.1. Conversions to and from polar coordinates
 - 8.3.2. Power and logarithmic functions
 - 8.3.3. Trigonometric functions
 - 8.3.4. Hyperbolic functions
 - 8.3.5. Classification functions

- 8.3.6. Constants
- 8.4. `decimal` — Decimal fixed point and floating point arithmetic
 - 8.4.1. Quick-start Tutorial
 - 8.4.2. Decimal objects
 - 8.4.2.1. Logical operands
 - 8.4.3. Context objects
 - 8.4.4. Signals
 - 8.4.5. Floating Point Notes
 - 8.4.5.1. Mitigating round-off error with increased precision
 - 8.4.5.2. Special values
 - 8.4.6. Working with threads
 - 8.4.7. Recipes
 - 8.4.8. Decimal FAQ
- 8.5. `fractions` — Rational numbers
- 8.6. `random` — Generate pseudo-random numbers
 - 8.6.1. Notes on Reproducibility
 - 8.6.2. Examples and Recipes

8.1. `numbers` — Numeric abstract base classes

The `numbers` module ([PEP 3141](#)) defines a hierarchy of numeric abstract base classes which progressively define more operations. None of the types defined in this module can be instantiated.

class `numbers.Number`

The root of the numeric hierarchy. If you just want to check if an argument `x` is a number, without caring what kind, use `isinstance(x, Number)`.

8.1.1. The numeric tower

class `numbers.Complex`

Subclasses of this type describe complex numbers and include the operations that work on the built-in `complex` type. These are: conversions to `complex` and `bool`, `real`, `imag`, `+`, `-`, `*`, `/`, `abs()`, `conjugate()`, `==`, and `!=`. All except `-` and `!=` are abstract.

real

Abstract. Retrieves the real component of this number.

imag

Abstract. Retrieves the imaginary component of this number.

conjugate()

Abstract. Returns the complex conjugate. For example, `(1+3j).conjugate() == (1-3j)`.

class `numbers.Real`

To `Complex`, `Real` adds the operations that work on real numbers.

In short, those are: a conversion to `float`, `trunc()`, `round()`, `math.floor()`, `math.ceil()`, `divmod()`, `//`, `%`, `<`, `<=`, `>`, and `>=`.

`Real` also provides defaults for `complex()`, `real`, `imag`, and `conjugate()`.

class `numbers.Rational`

Subtypes `Real` and adds `numerator` and `denominator` properties, which should be in lowest terms. With these, it provides a default for `float()`.

numerator

Abstract.

denominator

Abstract.

class numbers.**Integral**

Subtypes **Rational** and adds a conversion to **int**. Provides defaults for **float()**, **numerator**, and **denominator**, and bit-string operations: `<<`, `>>`, `&`, `^`, `|`, `~`.

8.1.2. Notes for type implementors

Implementors should be careful to make equal numbers equal and hash them to the same values. This may be subtle if there are two different extensions of the real numbers. For example, `fractions.Fraction` implements `hash()` as follows:

```
def __hash__(self):
    if self.denominator == 1:
        # Get integers right.
        return hash(self.numerator)
    # Expensive check, but definitely correct.
    if self == float(self):
        return hash(float(self))
    else:
        # Use tuple's hash to avoid a high collision rate on
        # simple fractions.
        return hash((self.numerator, self.denominator))
```

8.1.2.1. Adding More Numeric ABCs

There are, of course, more possible ABCs for numbers, and this would be a poor hierarchy if it precluded the possibility of adding those. You can add `MyFoo` between `Complex` and `Real` with:

```
class MyFoo(Complex): ...
MyFoo.register(Real)
```

8.1.2.2. Implementing the arithmetic operations

We want to implement the arithmetic operations so that mixed-mode operations either call an implementation whose author knew about the types of both arguments, or convert both to the nearest built in type and do the operation there. For subtypes of `Integral`, this means that `__add__()` and `__radd__()` should be defined as:

```

class MyIntegral(Integral):

    def __add__(self, other):
        if isinstance(other, MyIntegral):
            return do_my_adding_stuff(self, other)
        elif isinstance(other, OtherTypeIKnowAbout):
            return do_my_other_adding_stuff(self, other)
        else:
            return NotImplemented

    def __radd__(self, other):
        if isinstance(other, MyIntegral):
            return do_my_adding_stuff(other, self)
        elif isinstance(other, OtherTypeIKnowAbout):
            return do_my_other_adding_stuff(other, self)
        elif isinstance(other, Integral):
            return int(other) + int(self)
        elif isinstance(other, Real):
            return float(other) + float(self)
        elif isinstance(other, Complex):
            return complex(other) + complex(self)
        else:
            return NotImplemented

```

There are 5 different cases for a mixed-type operation on subclasses of `Complex`. I'll refer to all of the above code that doesn't refer to `MyIntegral` and `OtherTypeIKnowAbout` as "boilerplate". `a` will be an instance of `A`, which is a subtype of `Complex` (`a : A <: Complex`), and `b : B <: Complex`. I'll consider `a + b`:

1. If `A` defines an `__add__()` which accepts `b`, all is well.
2. If `A` falls back to the boilerplate code, and it were to return a value from `__add__()`, we'd miss the possibility that `B` defines a more intelligent `__radd__()`, so the boilerplate should return `NotImplemented` from `__add__()`. (Or `A` may not implement `__add__()` at all.)
3. Then `B`'s `__radd__()` gets a chance. If it accepts `a`, all is well.
4. If it falls back to the boilerplate, there are no more possible

methods to try, so this is where the default implementation should live.

5. If `B <: A`, Python tries `B.__radd__` before `A.__add__`. This is ok, because it was implemented with knowledge of `A`, so it can handle those instances before delegating to `Complex`.

If `A <: Complex` and `B <: Real` without sharing any other knowledge, then the appropriate shared operation is the one involving the built in `complex`, and both `__radd__()` s land there, so `a+b == b+a`.

Because most of the operations on any given type will be very similar, it can be useful to define a helper function which generates the forward and reverse instances of any given operator. For example, `fractions.Fraction` uses:

```
def _operator_fallbacks(monomorphic_operator, fallback_operator):
    def forward(a, b):
        if isinstance(b, (int, Fraction)):
            return monomorphic_operator(a, b)
        elif isinstance(b, float):
            return fallback_operator(float(a), b)
        elif isinstance(b, complex):
            return fallback_operator(complex(a), b)
        else:
            return NotImplemented
    forward.__name__ = '__' + fallback_operator.__name__ + '__'
    forward.__doc__ = monomorphic_operator.__doc__

    def reverse(b, a):
        if isinstance(a, Rational):
            # Includes ints.
            return monomorphic_operator(a, b)
        elif isinstance(a, numbers.Real):
            return fallback_operator(float(a), float(b))
        elif isinstance(a, numbers.Complex):
            return fallback_operator(complex(a), complex(b))
        else:
            return NotImplemented
    reverse.__name__ = '__r' + fallback_operator.__name__ + '__'
    reverse.__doc__ = monomorphic_operator.__doc__
```

```
    return forward, reverse

def _add(a, b):
    """a + b"""
    return Fraction(a.numerator * b.denominator +
                    b.numerator * a.denominator,
                    a.denominator * b.denominator)

__add__, __radd__ = _operator_fallbacks(_add, operator.add)

# ...
```

8.2. `math` — Mathematical functions

This module is always available. It provides access to the mathematical functions defined by the C standard.

These functions cannot be used with complex numbers; use the functions of the same name from the `cmath` module if you require support for complex numbers. The distinction between functions which support complex numbers and those which don't is made since most users do not want to learn quite as much mathematics as required to understand complex numbers. Receiving an exception instead of a complex result allows earlier detection of the unexpected complex number used as a parameter, so that the programmer can determine how and why it was generated in the first place.

The following functions are provided by this module. Except when explicitly noted otherwise, all return values are floats.

8.2.1. Number-theoretic and representation functions

`math.ceil(x)`

Return the ceiling of x , the smallest integer greater than or equal to x . If x is not a float, delegates to `x.__ceil__()`, which should return an **Integral** value.

`math.copysign(x, y)`

Return x with the sign of y . On a platform that supports signed zeros, `copysign(1.0, -0.0)` returns `-1.0`.

`math.fabs(x)`

Return the absolute value of x .

`math.factorial(x)`

Return x factorial. Raises **ValueError** if x is not integral or is negative.

`math.floor(x)`

Return the floor of x , the largest integer less than or equal to x . If x is not a float, delegates to `x.__floor__()`, which should return an **Integral** value.

`math.fmod(x, y)`

Return `fmod(x, y)`, as defined by the platform C library. Note that the Python expression `x % y` may not return the same result. The intent of the C standard is that `fmod(x, y)` be exactly (mathematically; to infinite precision) equal to `x - n*y` for some integer n such that the result has the same sign as x and magnitude less than `abs(y)`. Python's `x % y` returns a result with

the sign of y instead, and may not be exactly computable for float arguments. For example, `fmod(-1e-100, 1e100)` is `-1e-100`, but the result of Python's `-1e-100 % 1e100` is `1e100-1e-100`, which cannot be represented exactly as a float, and rounds to the surprising `1e100`. For this reason, function `fmod()` is generally preferred when working with floats, while Python's `x % y` is preferred when working with integers.

`math.frexp(x)`

Return the mantissa and exponent of x as the pair `(m, e)`. m is a float and e is an integer such that `x == m * 2**e` exactly. If x is zero, returns `(0.0, 0)`, otherwise `0.5 <= abs(m) < 1`. This is used to “pick apart” the internal representation of a float in a portable way.

`math.fsum(iterable)`

Return an accurate floating point sum of values in the iterable. Avoids loss of precision by tracking multiple intermediate partial sums:

```
>>> sum([.1, .1, .1, .1, .1, .1, .1, .1, .1, .1])
0.9999999999999999
>>> fsum([.1, .1, .1, .1, .1, .1, .1, .1, .1, .1])
1.0
```

The algorithm's accuracy depends on IEEE-754 arithmetic guarantees and the typical case where the rounding mode is half-even. On some non-Windows builds, the underlying C library uses extended precision addition and may occasionally double-round an intermediate sum causing it to be off in its least significant bit.

For further discussion and two alternative approaches, see the [ASPN cookbook recipes for accurate floating point summation](#).

`math.isfinite(x)`

Return `True` if `x` is neither an infinity nor a NaN, and `False` otherwise. (Note that `0.0` is considered finite.)

New in version 3.2.

`math.isinf(x)`

Return `True` if `x` is a positive or negative infinity, and `False` otherwise.

`math.isnan(x)`

Return `True` if `x` is a NaN (not a number), and `False` otherwise.

`math.ldexp(x, i)`

Return `x * (2**i)`. This is essentially the inverse of function `frexp()`.

`math.modf(x)`

Return the fractional and integer parts of `x`. Both results carry the sign of `x` and are floats.

`math.trunc(x)`

Return the `Real` value `x` truncated to an `Integral` (usually an integer). Delegates to `x.__trunc__()`.

Note that `frexp()` and `modf()` have a different call/return pattern than their C equivalents: they take a single argument and return a pair of values, rather than returning their second return value through an 'output parameter' (there is no such thing in Python).

For the `ceil()`, `floor()`, and `modf()` functions, note that *all* floating-point numbers of sufficiently large magnitude are exact integers. Python floats typically carry no more than 53 bits of precision (the same as the platform C double type), in which case any float `x` with

$\text{abs}(x) \geq 2^{52}$ necessarily has no fractional bits.

8.2.2. Power and logarithmic functions

`math.exp(x)`

Return `e**x`.

`math.expm1(x)`

Return `e**x - 1`. For small floats `x`, the subtraction in `exp(x) - 1` can result in a significant loss of precision; the `expm1()` function provides a way to compute this quantity to full precision:

```
>>> from math import exp, expm1
>>> exp(1e-5) - 1 # gives result accurate to 11 places
1.0000050000069649e-05
>>> expm1(1e-5) # result accurate to full precision
1.0000050000166668e-05
```

New in version 3.2.

`math.log(x[, base])`

With one argument, return the natural logarithm of `x` (to base `e`).

With two arguments, return the logarithm of `x` to the given `base`, calculated as `log(x)/log(base)`.

`math.log1p(x)`

Return the natural logarithm of `1+x` (base `e`). The result is calculated in a way which is accurate for `x` near zero.

`math.log10(x)`

Return the base-10 logarithm of `x`. This is usually more accurate than `log(x, 10)`.

`math.pow(x, y)`

Return `x` raised to the power `y`. Exceptional cases follow Annex

'F' of the C99 standard as far as possible. In particular, `pow(1.0, x)` and `pow(x, 0.0)` always return `1.0`, even when `x` is a zero or a NaN. If both `x` and `y` are finite, `x` is negative, and `y` is not an integer then `pow(x, y)` is undefined, and raises `ValueError`.

`math.sqrt(x)`

Return the square root of `x`.

8.2.3. Trigonometric functions

`math.acos(x)`

Return the arc cosine of x , in radians.

`math.asin(x)`

Return the arc sine of x , in radians.

`math.atan(x)`

Return the arc tangent of x , in radians.

`math.atan2(y, x)`

Return `atan(y / x)`, in radians. The result is between `-pi` and `pi`. The vector in the plane from the origin to point `(x, y)` makes this angle with the positive X axis. The point of `atan2()` is that the signs of both inputs are known to it, so it can compute the correct quadrant for the angle. For example, `atan(1)` and `atan2(1, 1)` are both `pi/4`, but `atan2(-1, -1)` is `-3*pi/4`.

`math.cos(x)`

Return the cosine of x radians.

`math.hypot(x, y)`

Return the Euclidean norm, `sqrt(x*x + y*y)`. This is the length of the vector from the origin to point `(x, y)`.

`math.sin(x)`

Return the sine of x radians.

`math.tan(x)`

Return the tangent of x radians.

8.2.4. Angular conversion

`math.degrees(x)`

Converts angle x from radians to degrees.

`math.radians(x)`

Converts angle x from degrees to radians.

8.2.5. Hyperbolic functions

`math.acosh(x)`

Return the inverse hyperbolic cosine of x .

`math.asinh(x)`

Return the inverse hyperbolic sine of x .

`math.atanh(x)`

Return the inverse hyperbolic tangent of x .

`math.cosh(x)`

Return the hyperbolic cosine of x .

`math.sinh(x)`

Return the hyperbolic sine of x .

`math.tanh(x)`

Return the hyperbolic tangent of x .

8.2.6. Special functions

`math.erf(x)`

Return the error function at x .

New in version 3.2.

`math.erfc(x)`

Return the complementary error function at x .

New in version 3.2.

`math.gamma(x)`

Return the Gamma function at x .

New in version 3.2.

`math.lgamma(x)`

Return the natural logarithm of the absolute value of the Gamma function at x .

New in version 3.2.

8.2.7. Constants

`math.pi`

The mathematical constant $\pi = 3.141592\dots$, to available precision.

`math.e`

The mathematical constant $e = 2.718281\dots$, to available precision.

CPython implementation detail: The `math` module consists mostly of thin wrappers around the platform C math library functions. Behavior in exceptional cases follows Annex F of the C99 standard where appropriate. The current implementation will raise `ValueError` for invalid operations like `sqrt(-1.0)` or `log(0.0)` (where C99 Annex F recommends signaling invalid operation or divide-by-zero), and `OverflowError` for results that overflow (for example, `exp(1000.0)`). A NaN will not be returned from any of the functions above unless one or more of the input arguments was a NaN; in that case, most functions will return a NaN, but (again following C99 Annex F) there are some exceptions to this rule, for example `pow(float('nan'), 0.0)` or `hypot(float('nan'), float('inf'))`.

Note that Python makes no effort to distinguish signaling NaNs from quiet NaNs, and behavior for signaling NaNs remains unspecified. Typical behavior is to treat all NaNs as though they were quiet.

Module `cmath`

Complex number versions of many of these functions.

 [Python v3.2 documentation](#) » [The Python Standard Library](#) [previous](#) | [next](#) | [modules](#) | [index](#)
» [8. Numeric and Mathematical Modules](#) »

8.3. `cmath` — Mathematical functions for complex numbers

This module is always available. It provides access to mathematical functions for complex numbers. The functions in this module accept integers, floating-point numbers or complex numbers as arguments. They will also accept any Python object that has either a `__complex__()` or a `__float__()` method: these methods are used to convert the object to a complex or floating-point number, respectively, and the function is then applied to the result of the conversion.

Note: On platforms with hardware and system-level support for signed zeros, functions involving branch cuts are continuous on *both* sides of the branch cut: the sign of the zero distinguishes one side of the branch cut from the other. On platforms that do not support signed zeros the continuity is as specified below.

8.3.1. Conversions to and from polar coordinates

A Python complex number `z` is stored internally using *rectangular* or *Cartesian* coordinates. It is completely determined by its *real part* `z.real` and its *imaginary part* `z.imag`. In other words:

```
z == z.real + z.imag*1j
```

Polar coordinates give an alternative way to represent a complex number. In polar coordinates, a complex number `z` is defined by the modulus r and the phase angle ϕ . The modulus r is the distance from `z` to the origin, while the phase ϕ is the counterclockwise angle, measured in radians, from the positive x-axis to the line segment that joins the origin to `z`.

The following functions can be used to convert from the native rectangular coordinates to polar coordinates and back.

`cmath.phase(x)`

Return the phase of `x` (also known as the *argument* of `x`), as a float. `phase(x)` is equivalent to `math.atan2(x.imag, x.real)`. The result lies in the range $[-\pi, \pi]$, and the branch cut for this operation lies along the negative real axis, continuous from above. On systems with support for signed zeros (which includes most systems in current use), this means that the sign of the result is the same as the sign of `x.imag`, even when `x.imag` is zero:

```
>>> phase(complex(-1.0, 0.0))
3.141592653589793
>>> phase(complex(-1.0, -0.0))
-3.141592653589793
```

Note: The modulus (absolute value) of a complex number x can be computed using the built-in `abs()` function. There is no separate `cmath` module function for this operation.

`cmath.polar(x)`

Return the representation of x in polar coordinates. Returns a pair `(r, phi)` where r is the modulus of x and phi is the phase of x . `polar(x)` is equivalent to `(abs(x), phase(x))`.

`cmath.rect(r, phi)`

Return the complex number x with polar coordinates r and phi . Equivalent to `r * (math.cos(phi) + math.sin(phi)*1j)`.

8.3.2. Power and logarithmic functions

`cmath.exp(x)`

Return the exponential value e^{**x} .

`cmath.log(x[, base])`

Returns the logarithm of x to the given *base*. If the *base* is not specified, returns the natural logarithm of x . There is one branch cut, from 0 along the negative real axis to $-\infty$, continuous from above.

`cmath.log10(x)`

Return the base-10 logarithm of x . This has the same branch cut as `log()`.

`cmath.sqrt(x)`

Return the square root of x . This has the same branch cut as `log()`.

8.3.3. Trigonometric functions

`cmath.acos(x)`

Return the arc cosine of x . There are two branch cuts: One extends right from 1 along the real axis to ∞ , continuous from below. The other extends left from -1 along the real axis to $-\infty$, continuous from above.

`cmath.asin(x)`

Return the arc sine of x . This has the same branch cuts as `acos()`.

`cmath.atan(x)`

Return the arc tangent of x . There are two branch cuts: One extends from $1j$ along the imaginary axis to ∞j , continuous from the right. The other extends from $-1j$ along the imaginary axis to $-\infty j$, continuous from the left.

`cmath.cos(x)`

Return the cosine of x .

`cmath.sin(x)`

Return the sine of x .

`cmath.tan(x)`

Return the tangent of x .

8.3.4. Hyperbolic functions

`cmath.acosh(x)`

Return the hyperbolic arc cosine of x . There is one branch cut, extending left from 1 along the real axis to $-\infty$, continuous from above.

`cmath.asinh(x)`

Return the hyperbolic arc sine of x . There are two branch cuts: One extends from $1j$ along the imaginary axis to ∞j , continuous from the right. The other extends from $-1j$ along the imaginary axis to $-\infty j$, continuous from the left.

`cmath.atanh(x)`

Return the hyperbolic arc tangent of x . There are two branch cuts: One extends from 1 along the real axis to ∞ , continuous from below. The other extends from -1 along the real axis to $-\infty$, continuous from above.

`cmath.cosh(x)`

Return the hyperbolic cosine of x .

`cmath.sinh(x)`

Return the hyperbolic sine of x .

`cmath.tanh(x)`

Return the hyperbolic tangent of x .

8.3.5. Classification functions

`cmath.isfinite(x)`

Return `True` if both the real and imaginary parts of `x` are finite, and `False` otherwise.

New in version 3.2.

`cmath.isinf(x)`

Return `True` if either the real or the imaginary part of `x` is an infinity, and `False` otherwise.

`cmath.isnan(x)`

Return `True` if either the real or the imaginary part of `x` is a NaN, and `False` otherwise.

8.3.6. Constants

`cmath.pi`

The mathematical constant π , as a float.

`cmath.e`

The mathematical constant e , as a float.

Note that the selection of functions is similar, but not identical, to that in module `math`. The reason for having two modules is that some users aren't interested in complex numbers, and perhaps don't even know what they are. They would rather have `math.sqrt(-1)` raise an exception than return a complex number. Also note that the functions defined in `cmath` always return a complex number, even if the answer can be expressed as a real number (in which case the complex number has an imaginary part of zero).

A note on branch cuts: They are curves along which the given function fails to be continuous. They are a necessary feature of many complex functions. It is assumed that if you need to compute with complex functions, you will understand about branch cuts. Consult almost any (not too elementary) book on complex variables for enlightenment. For information of the proper choice of branch cuts for numerical purposes, a good reference should be the following:

See also: Kahan, W: Branch cuts for complex elementary functions; or, Much ado about nothing's sign bit. In Iserles, A., and Powell, M. (eds.), The state of the art in numerical analysis. Clarendon Press (1987) pp165-211.

8.4. `decimal` — Decimal fixed point and floating point arithmetic

The `decimal` module provides support for decimal floating point arithmetic. It offers several advantages over the `float` datatype:

- Decimal “is based on a floating-point model which was designed with people in mind, and necessarily has a paramount guiding principle – computers must provide an arithmetic that works in the same way as the arithmetic that people learn at school.” – excerpt from the decimal arithmetic specification.
- Decimal numbers can be represented exactly. In contrast, numbers like `1.1` and `2.2` do not have an exact representations in binary floating point. End users typically would not expect `1.1 + 2.2` to display as `3.3000000000000003` as it does with binary floating point.
- The exactness carries over into arithmetic. In decimal floating point, `0.1 + 0.1 + 0.1 - 0.3` is exactly equal to zero. In binary floating point, the result is `5.5511151231257827e-017`. While near to zero, the differences prevent reliable equality testing and differences can accumulate. For this reason, decimal is preferred in accounting applications which have strict equality invariants.
- The decimal module incorporates a notion of significant places so that `1.30 + 1.20` is `2.50`. The trailing zero is kept to indicate significance. This is the customary presentation for monetary applications. For multiplication, the “schoolbook” approach uses all the figures in the multiplicands. For instance, `1.3 * 1.2` gives `1.56` while `1.30 * 1.20` gives `1.5600`.

- Unlike hardware based binary floating point, the decimal module has a user alterable precision (defaulting to 28 places) which can be as large as needed for a given problem:

```
>>> from decimal import *
>>> getcontext().prec = 6
>>> Decimal(1) / Decimal(7)
Decimal('0.142857')
>>> getcontext().prec = 28
>>> Decimal(1) / Decimal(7)
Decimal('0.1428571428571428571428571428571429')
```

- Both binary and decimal floating point are implemented in terms of published standards. While the built-in float type exposes only a modest portion of its capabilities, the decimal module exposes all required parts of the standard. When needed, the programmer has full control over rounding and signal handling. This includes an option to enforce exact arithmetic by using exceptions to block any inexact operations.
- The decimal module was designed to support “without prejudice, both exact unrounded decimal arithmetic (sometimes called fixed-point arithmetic) and rounded floating-point arithmetic.” – excerpt from the decimal arithmetic specification.

The module design is centered around three concepts: the decimal number, the context for arithmetic, and signals.

A decimal number is immutable. It has a sign, coefficient digits, and an exponent. To preserve significance, the coefficient digits do not truncate trailing zeros. Decimals also include special values such as **Infinity**, **-Infinity**, and **NaN**. The standard also differentiates **-0** from **+0**.

The context for arithmetic is an environment specifying precision, rounding rules, limits on exponents, flags indicating the results of operations, and trap enablers which determine whether signals are

treated as exceptions. Rounding options include `ROUND_CEILING`, `ROUND_DOWN`, `ROUND_FLOOR`, `ROUND_HALF_DOWN`, `ROUND_HALF_EVEN`, `ROUND_HALF_UP`, `ROUND_UP`, and `ROUND_05UP`.

Signals are groups of exceptional conditions arising during the course of computation. Depending on the needs of the application, signals may be ignored, considered as informational, or treated as exceptions. The signals in the decimal module are: `Clamped`, `InvalidOperation`, `DivisionByZero`, `Inexact`, `Rounded`, `Subnormal`, `Overflow`, and `Underflow`.

For each signal there is a flag and a trap enabler. When a signal is encountered, its flag is set to one, then, if the trap enabler is set to one, an exception is raised. Flags are sticky, so the user needs to reset them before monitoring a calculation.

8.4.1. Quick-start Tutorial

The usual start to using decimals is importing the module, viewing the current context with `getcontext()` and, if necessary, setting new values for precision, rounding, or enabled traps:

```
>>> from decimal import *
>>> getcontext()
Context(prec=28, rounding=ROUND_HALF_EVEN, Emin=-999999999, Emax=
      capitals=1, clamp=0, flags=[], traps=[Overflow, Divisio
      InvalidOperation])

>>> getcontext().prec = 7          # Set a new precision
```

Decimal instances can be constructed from integers, strings, floats, or tuples. Construction from an integer or a float performs an exact conversion of the value of that integer or float. Decimal numbers include special values such as `NaN` which stands for “Not a number”, positive and negative `Infinity`, and `-0`.

```
>>> getcontext().prec = 28
>>> Decimal(10)
Decimal('10')
>>> Decimal('3.14')
Decimal('3.14')
>>> Decimal(3.14)
Decimal('3.1400000000000000124344978758017532527446746826171875')
>>> Decimal((0, (3, 1, 4), -2))
Decimal('3.14')
>>> Decimal(str(2.0 ** 0.5))
Decimal('1.4142135623730951')
>>> Decimal(2) ** Decimal('0.5')
Decimal('1.414213562373095048801688724')
>>> Decimal('NaN')
Decimal('NaN')
>>> Decimal('-Infinity')
Decimal('-Infinity')
```

The significance of a new Decimal is determined solely by the number of digits input. Context precision and rounding only come into play during arithmetic operations.

```
>>> getcontext().prec = 6
>>> Decimal('3.0')
Decimal('3.0')
>>> Decimal('3.1415926535')
Decimal('3.1415926535')
>>> Decimal('3.1415926535') + Decimal('2.7182818285')
Decimal('5.85987')
>>> getcontext().rounding = ROUND_UP
>>> Decimal('3.1415926535') + Decimal('2.7182818285')
Decimal('5.85988')
```

Decimals interact well with much of the rest of Python. Here is a small decimal floating point flying circus:

```
>>> data = list(map(Decimal, '1.34 1.87 3.45 2.35 1.00 0.03 9.2
>>> max(data)
Decimal('9.25')
>>> min(data)
Decimal('0.03')
>>> sorted(data)
[Decimal('0.03'), Decimal('1.00'), Decimal('1.34'), Decimal('1.
  Decimal('2.35'), Decimal('3.45'), Decimal('9.25')]
>>> sum(data)
Decimal('19.29')
>>> a,b,c = data[:3]
>>> str(a)
'1.34'
>>> float(a)
1.34
>>> round(a, 1)
Decimal('1.3')
>>> int(a)
1
>>> a * 5
Decimal('6.70')
>>> a * b
Decimal('2.5058')
>>> c % a
Decimal('0.77')
```

```

>>> ExtendedContext
Context(prec=9, rounding=ROUND_HALF_EVEN, Emin=-999999999, Emax
      capitals=1, clamp=0, flags=[], traps=[])
>>> setcontext(ExtendedContext)
>>> Decimal(1) / Decimal(7)
Decimal('0.142857143')
>>> Decimal(42) / Decimal(0)
Decimal('Infinity')

>>> setcontext(BasicContext)
>>> Decimal(42) / Decimal(0)
Traceback (most recent call last):
  File "<pyshell#143>", line 1, in -toplevel-
    Decimal(42) / Decimal(0)
DivisionByZero: x / 0

```

Contexts also have signal flags for monitoring exceptional conditions encountered during computations. The flags remain set until explicitly cleared, so it is best to clear the flags before each set of monitored computations by using the `clear_flags()` method.

```

>>> setcontext(ExtendedContext)
>>> getcontext().clear_flags()
>>> Decimal(355) / Decimal(113)
Decimal('3.14159292')
>>> getcontext()
Context(prec=9, rounding=ROUND_HALF_EVEN, Emin=-999999999, Emax
      capitals=1, clamp=0, flags=[Inexact, Rounded], traps=[])

```

The *flags* entry shows that the rational approximation to π was rounded (digits beyond the context precision were thrown away) and that the result is inexact (some of the discarded digits were non-zero).

Individual traps are set using the dictionary in the `traps` field of a context:

```

>>> setcontext(ExtendedContext)
>>> Decimal(1) / Decimal(0)

```

```
Decimal('Infinity')
>>> getcontext().traps[DivisionByZero] = 1
>>> Decimal(1) / Decimal(0)
Traceback (most recent call last):
  File "<pyshell#112>", line 1, in -toplevel-
    Decimal(1) / Decimal(0)
DivisionByZero: x / 0
```

Most programs adjust the current context only once, at the beginning of the program. And, in many applications, data is converted to `Decimal` with a single cast inside a loop. With context set and decimals created, the bulk of the program manipulates the data no differently than with other Python numeric types.

8.4.2. Decimal objects

`class decimal.Decimal(value="0", context=None)`

Construct a new `Decimal` object based from `value`.

`value` can be an integer, string, tuple, `float`, or another `Decimal` object. If no `value` is given, returns `Decimal('0')`. If `value` is a string, it should conform to the decimal numeric string syntax after leading and trailing whitespace characters are removed:

```
sign          ::= '+' | '-'
digit         ::= '0' | '1' | '2' | '3' | '4' | '5' | '6'
indicator     ::= 'e' | 'E'
digits        ::= digit [digit]...
decimal-part  ::= digits '.' [digits] | ['.'] digits
exponent-part ::= indicator [sign] digits
infinity      ::= 'Infinity' | 'Inf'
nan           ::= 'NaN' [digits] | 'sNaN' [digits]
numeric-value ::= decimal-part [exponent-part] | infinity
numeric-string ::= [sign] numeric-value | [sign] nan
```

Other Unicode decimal digits are also permitted where `digit` appears above. These include decimal digits from various other alphabets (for example, Arabic-Indic and Devanāgarī digits) along with the fullwidth digits `'\uff10'` through `'\uff19'`.

If `value` is a `tuple`, it should have three components, a sign (`0` for positive or `1` for negative), a `tuple` of digits, and an integer exponent. For example, `Decimal((0, (1, 4, 1, 4), -3))` returns `Decimal('1.414')`.

If `value` is a `float`, the binary floating point value is losslessly converted to its exact decimal equivalent. This conversion can often require 53 or more digits of precision. For example,

Decimal instances and other numeric types are now fully supported.

In addition to the standard numeric properties, decimal floating point objects also have a number of specialized methods:

adjusted()

Return the adjusted exponent after shifting out the coefficient's rightmost digits until only the lead digit remains: `Decimal('321e+5').adjusted()` returns seven. Used for determining the position of the most significant digit with respect to the decimal point.

as_tuple()

Return a *named tuple* representation of the number: `DecimalTuple(sign, digits, exponent)`.

canonical()

Return the canonical encoding of the argument. Currently, the encoding of a **Decimal** instance is always canonical, so this operation returns its argument unchanged.

compare(*other*[, *context*])

Compare the values of two Decimal instances. `compare()` returns a Decimal instance, and if either operand is a NaN then the result is a NaN:

```
a or b is a NaN ==> Decimal('NaN')
a < b           ==> Decimal('-1')
a == b         ==> Decimal('0')
a > b         ==> Decimal('1')
```

compare_signal(*other*[, *context*])

This operation is identical to the `compare()` method, except that all NaNs signal. That is, if neither operand is a signaling

NaN then any quiet NaN operand is treated as though it were a signaling NaN.

compare_total(*other*)

Compare two operands using their abstract representation rather than their numerical value. Similar to the `compare()` method, but the result gives a total ordering on `Decimal` instances. Two `Decimal` instances with the same numeric value but different representations compare unequal in this ordering:

```
>>> Decimal('12.0').compare_total(Decimal('12'))
Decimal('-1')
```

Quiet and signaling NaNs are also included in the total ordering. The result of this function is `Decimal('0')` if both operands have the same representation, `Decimal('-1')` if the first operand is lower in the total order than the second, and `Decimal('1')` if the first operand is higher in the total order than the second operand. See the specification for details of the total order.

compare_total_mag(*other*)

Compare two operands using their abstract representation rather than their value as in `compare_total()`, but ignoring the sign of each operand. `x.compare_total_mag(y)` is equivalent to `x.copy_abs().compare_total(y.copy_abs())`.

conjugate()

Just returns self, this method is only to comply with the Decimal Specification.

copy_abs()

Return the absolute value of the argument. This operation is

unaffected by the context and is quiet: no flags are changed and no rounding is performed.

copy_negate()

Return the negation of the argument. This operation is unaffected by the context and is quiet: no flags are changed and no rounding is performed.

copy_sign(*other*)

Return a copy of the first operand with the sign set to be the same as the sign of the second operand. For example:

```
>>> Decimal('2.3').copy_sign(Decimal('-1.5'))
Decimal('-2.3')
```

This operation is unaffected by the context and is quiet: no flags are changed and no rounding is performed.

exp([*context*])

Return the value of the (natural) exponential function e^{**x} at the given number. The result is correctly rounded using the **ROUND_HALF_EVEN** rounding mode.

```
>>> Decimal(1).exp()
Decimal('2.718281828459045235360287471')
>>> Decimal(321).exp()
Decimal('2.561702493119680037517373933E+139')
```

from_float(*f*)

Classmethod that converts a float to a decimal number, exactly.

Note *Decimal.from_float(0.1)* is not the same as *Decimal('0.1')*. Since 0.1 is not exactly representable in binary floating point, the value is stored as the nearest representable value which is $0x1.999999999999ap-4$. That equivalent value

in decimal is
0.100000000000000000555111512312578270211815834045410.

Note: From Python 3.2 onwards, a `Decimal` instance can also be constructed directly from a `float`.

```
>>> Decimal.from_float(0.1)
Decimal('0.10000000000000000055511151231257827021181583404
>>> Decimal.from_float(float('nan'))
Decimal('NaN')
>>> Decimal.from_float(float('inf'))
Decimal('Infinity')
>>> Decimal.from_float(float('-inf'))
Decimal('-Infinity')
```

New in version 3.1.

fma(*other, third* [, *context*])

Fused multiply-add. Return `self*other+third` with no rounding of the intermediate product `self*other`.

```
>>> Decimal(2).fma(3, 5)
Decimal('11')
```

is_canonical()

Return `True` if the argument is canonical and `False` otherwise. Currently, a `Decimal` instance is always canonical, so this operation always returns `True`.

is_finite()

Return `True` if the argument is a finite number, and `False` if the argument is an infinity or a NaN.

is_infinite()

Return `True` if the argument is either positive or negative

infinity and **False** otherwise.

is_nan()

Return **True** if the argument is a (quiet or signaling) NaN and **False** otherwise.

is_normal()

Return **True** if the argument is a *normal* finite number. Return **False** if the argument is zero, subnormal, infinite or a NaN.

is_qnan()

Return **True** if the argument is a quiet NaN, and **False** otherwise.

is_signed()

Return **True** if the argument has a negative sign and **False** otherwise. Note that zeros and NaNs can both carry signs.

is_snan()

Return **True** if the argument is a signaling NaN and **False** otherwise.

is_subnormal()

Return **True** if the argument is subnormal, and **False** otherwise.

is_zero()

Return **True** if the argument is a (positive or negative) zero and **False** otherwise.

ln([context])

Return the natural (base e) logarithm of the operand. The result is correctly rounded using the **ROUND_HALF_EVEN**

rounding mode.

log10([*context*])

Return the base ten logarithm of the operand. The result is correctly rounded using the **ROUND_HALF_EVEN** rounding mode.

logb([*context*])

For a nonzero number, return the adjusted exponent of its operand as a **Decimal** instance. If the operand is a zero then `Decimal('-Infinity')` is returned and the **DivisionByZero** flag is raised. If the operand is an infinity then `Decimal('Infinity')` is returned.

logical_and(*other*[, *context*])

logical_and() is a logical operation which takes two *logical operands* (see *Logical operands*). The result is the digit-wise **and** of the two operands.

logical_invert([*context*])

logical_invert() is a logical operation. The result is the digit-wise inversion of the operand.

logical_or(*other*[, *context*])

logical_or() is a logical operation which takes two *logical operands* (see *Logical operands*). The result is the digit-wise **or** of the two operands.

logical_xor(*other*[, *context*])

logical_xor() is a logical operation which takes two *logical operands* (see *Logical operands*). The result is the digit-wise exclusive or of the two operands.

max(*other*[, *context*])

Like `max(self, other)` except that the context rounding rule is applied before returning and that `NaN` values are either signaled or ignored (depending on the context and whether they are signaling or quiet).

max_mag(*other*[, *context*])

Similar to the `max()` method, but the comparison is done using the absolute values of the operands.

min(*other*[, *context*])

Like `min(self, other)` except that the context rounding rule is applied before returning and that `NaN` values are either signaled or ignored (depending on the context and whether they are signaling or quiet).

min_mag(*other*[, *context*])

Similar to the `min()` method, but the comparison is done using the absolute values of the operands.

next_minus([*context*])

Return the largest number representable in the given context (or in the current thread's context if no context is given) that is smaller than the given operand.

next_plus([*context*])

Return the smallest number representable in the given context (or in the current thread's context if no context is given) that is larger than the given operand.

next_toward(*other*[, *context*])

If the two operands are unequal, return the number closest to

the first operand in the direction of the second operand. If both operands are numerically equal, return a copy of the first operand with the sign set to be the same as the sign of the second operand.

`normalize([context])`

Normalize the number by stripping the rightmost trailing zeros and converting any result equal to `Decimal('0')` to `Decimal('0e0')`. Used for producing canonical values for members of an equivalence class. For example, `Decimal('32.100')` and `Decimal('0.321000e+2')` both normalize to the equivalent value `Decimal('32.1')`.

`number_class([context])`

Return a string describing the *class* of the operand. The returned value is one of the following ten strings.

- `"-Infinity"`, indicating that the operand is negative infinity.
- `"-Normal"`, indicating that the operand is a negative normal number.
- `"-Subnormal"`, indicating that the operand is negative and subnormal.
- `"-Zero"`, indicating that the operand is a negative zero.
- `"+Zero"`, indicating that the operand is a positive zero.
- `"+Subnormal"`, indicating that the operand is positive and subnormal.
- `"+Normal"`, indicating that the operand is a positive normal number.
- `"+Infinity"`, indicating that the operand is positive infinity.
- `"NaN"`, indicating that the operand is a quiet NaN (Not a Number).

- "sNaN", indicating that the operand is a signaling NaN.

quantize(*exp*[, *rounding*[, *context*[, *watchexp*]]])

Return a value equal to the first operand after rounding and having the exponent of the second operand.

```
>>> Decimal('1.41421356').quantize(Decimal('1.000'))  
Decimal('1.414')
```

Unlike other operations, if the length of the coefficient after the quantize operation would be greater than precision, then an **InvalidOperation** is signaled. This guarantees that, unless there is an error condition, the quantized exponent is always equal to that of the right-hand operand.

Also unlike other operations, quantize never signals Underflow, even if the result is subnormal and inexact.

If the exponent of the second operand is larger than that of the first then rounding may be necessary. In this case, the rounding mode is determined by the `rounding` argument if given, else by the given `context` argument; if neither argument is given the rounding mode of the current thread's context is used.

If *watchexp* is set (default), then an error is returned whenever the resulting exponent is greater than **E_{max}** or less than **E_{tiny}**.

radix()

Return `Decimal(10)`, the radix (base) in which the **Decimal** class does all its arithmetic. Included for compatibility with the specification.

remainder_near(*other*[, *context*])

Compute the modulo as either a positive or negative value

depending on which is closest to zero. For instance, `Decimal(10).remainder_near(6)` returns `Decimal('-2')` which is closer to zero than `Decimal('4')`.

If both are equally close, the one chosen will have the same sign as *self*.

`rotate(other[, context])`

Return the result of rotating the digits of the first operand by an amount specified by the second operand. The second operand must be an integer in the range `-precision` through `precision`. The absolute value of the second operand gives the number of places to rotate. If the second operand is positive then rotation is to the left; otherwise rotation is to the right. The coefficient of the first operand is padded on the left with zeros to length `precision` if necessary. The sign and exponent of the first operand are unchanged.

`same_quantum(other[, context])`

Test whether *self* and *other* have the same exponent or whether both are `NaN`.

`scaleb(other[, context])`

Return the first operand with exponent adjusted by the second. Equivalently, return the first operand multiplied by `10**other`. The second operand must be an integer.

`shift(other[, context])`

Return the result of shifting the digits of the first operand by an amount specified by the second operand. The second operand must be an integer in the range `-precision` through `precision`. The absolute value of the second operand gives the number of places to shift. If the second operand is positive

then the shift is to the left; otherwise the shift is to the right. Digits shifted into the coefficient are zeros. The sign and exponent of the first operand are unchanged.

sqrt([*context*])

Return the square root of the argument to full precision.

to_eng_string([*context*])

Convert to an engineering-type string.

Engineering notation has an exponent which is a multiple of 3, so there are up to 3 digits left of the decimal place. For example, converts `Decimal('123E+1')` to `Decimal('1.23E+3')`

to_integral([*rounding*[, *context*]])

Identical to the `to_integral_value()` method. The `to_integral` name has been kept for compatibility with older versions.

to_integral_exact([*rounding*[, *context*]])

Round to the nearest integer, signaling `Inexact` or `Rounded` as appropriate if rounding occurs. The rounding mode is determined by the `rounding` parameter if given, else by the given `context`. If neither parameter is given then the rounding mode of the current context is used.

to_integral_value([*rounding*[, *context*]])

Round to the nearest integer without signaling `Inexact` or `Rounded`. If given, applies `rounding`; otherwise, uses the rounding method in either the supplied `context` or the current context.

8.4.2.1. Logical operands

The `logical_and()`, `logical_invert()`, `logical_or()`, and `logical_xor()` methods expect their arguments to be *logical operands*. A *logical operand* is a `Decimal` instance whose exponent and sign are both zero, and whose digits are all either `0` or `1`.

8.4.3. Context objects

Contexts are environments for arithmetic operations. They govern precision, set rules for rounding, determine which signals are treated as exceptions, and limit the range for exponents.

Each thread has its own current context which is accessed or changed using the `getcontext()` and `setcontext()` functions:

`decimal.getcontext()`

Return the current context for the active thread.

`decimal.setcontext(c)`

Set the current context for the active thread to *c*.

You can also use the `with` statement and the `localcontext()` function to temporarily change the active context.

`decimal.localcontext([c])`

Return a context manager that will set the current context for the active thread to a copy of *c* on entry to the with-statement and restore the previous context when exiting the with-statement. If no context is specified, a copy of the current context is used.

For example, the following code sets the current decimal precision to 42 places, performs a calculation, and then automatically restores the previous context:

```
from decimal import localcontext

with localcontext() as ctx:
    ctx.prec = 42 # Perform a high precision calculation
    s = calculate_something()
s = +s # Round the final result back to the default precision
```

New contexts can also be created using the `Context` constructor described below. In addition, the module provides three pre-made contexts:

`class decimal.` **BasicContext**

This is a standard context defined by the General Decimal Arithmetic Specification. Precision is set to nine. Rounding is set to `ROUND_HALF_UP`. All flags are cleared. All traps are enabled (treated as exceptions) except `Inexact`, `Rounded`, and `Subnormal`.

Because many of the traps are enabled, this context is useful for debugging.

`class decimal.` **ExtendedContext**

This is a standard context defined by the General Decimal Arithmetic Specification. Precision is set to nine. Rounding is set to `ROUND_HALF_EVEN`. All flags are cleared. No traps are enabled (so that exceptions are not raised during computations).

Because the traps are disabled, this context is useful for applications that prefer to have result value of `NaN` or `Infinity` instead of raising exceptions. This allows an application to complete a run in the presence of conditions that would otherwise halt the program.

`class decimal.` **DefaultContext**

This context is used by the `Context` constructor as a prototype for new contexts. Changing a field (such a precision) has the effect of changing the default for new contexts created by the `Context` constructor.

This context is most useful in multi-threaded environments. Changing one of the fields before threads are started has the effect of setting system-wide defaults. Changing the fields after threads have started is not recommended as it would require

thread synchronization to prevent race conditions.

In single threaded environments, it is preferable to not use this context at all. Instead, simply create contexts explicitly as described below.

The default values are precision=28, rounding=ROUND_HALF_EVEN, and enabled traps for Overflow, InvalidOperation, and DivisionByZero.

In addition to the three supplied contexts, new contexts can be created with the `Context` constructor.

```
class decimal.Context(prec=None, rounding=None, traps=None, flags=None, Emin=None, Emax=None, capitals=None, clamp=None)
```

Creates a new context. If a field is not specified or is `None`, the default values are copied from the `DefaultContext`. If the `flags` field is not specified or is `None`, all flags are cleared.

The `prec` field is a positive integer that sets the precision for arithmetic operations in the context.

The `rounding` option is one of:

- **ROUND_CEILING** (towards `Infinity`),
- **ROUND_DOWN** (towards zero),
- **ROUND_FLOOR** (towards `-Infinity`),
- **ROUND_HALF_DOWN** (to nearest with ties going towards zero),
- **ROUND_HALF_EVEN** (to nearest with ties going to nearest even integer),
- **ROUND_HALF_UP** (to nearest with ties going away from zero), or
- **ROUND_UP** (away from zero).
- **ROUND_05UP** (away from zero if last digit after rounding towards zero would have been 0 or 5; otherwise towards

zero)

The *traps* and *flags* fields list any signals to be set. Generally, new contexts should only set traps and leave the flags clear.

The *Emin* and *Emax* fields are integers specifying the outer limits allowable for exponents.

The *capitals* field is either `0` or `1` (the default). If set to `1`, exponents are printed with a capital ϵ ; otherwise, a lowercase e is used: `Decimal('6.02e+23')`.

The *clamp* field is either `0` (the default) or `1`. If set to `1`, the exponent e of a `Decimal` instance representable in this context is strictly limited to the range `Emin - prec + 1 <= e <= Emax - prec + 1`. If *clamp* is `0` then a weaker condition holds: the adjusted exponent of the `Decimal` instance is at most `Emax`. When *clamp* is `1`, a large normal number will, where possible, have its exponent reduced and a corresponding number of zeros added to its coefficient, in order to fit the exponent constraints; this preserves the value of the number but loses information about significant trailing zeros. For example:

```
>>> Context(prec=6, Emax=999, clamp=1).create_decimal('1.23e  
Decimal('1.23000E+999')
```

A *clamp* value of `1` allows compatibility with the fixed-width decimal interchange formats specified in IEEE 754.

The `Context` class defines several general purpose methods as well as a large number of methods for doing arithmetic directly in a given context. In addition, for each of the `Decimal` methods described above (with the exception of the `adjusted()` and `as_tuple()` methods) there is a corresponding `Context` method.

For example, for a `Context` instance `c` and `Decimal` instance `x`, `c.exp(x)` is equivalent to `x.exp(context=C)`. Each `Context` method accepts a Python integer (an instance of `int`) anywhere that a `Decimal` instance is accepted.

`clear_flags()`

Resets all of the flags to `0`.

`copy()`

Return a duplicate of the context.

`copy_decimal(num)`

Return a copy of the `Decimal` instance `num`.

`create_decimal(num)`

Creates a new `Decimal` instance from `num` but using `self` as context. Unlike the `Decimal` constructor, the context precision, rounding method, flags, and traps are applied to the conversion.

This is useful because constants are often given to a greater precision than is needed by the application. Another benefit is that rounding immediately eliminates unintended effects from digits beyond the current precision. In the following example, using unrounded inputs means that adding zero to a sum can change the result:

```
>>> getcontext().prec = 3
>>> Decimal('3.4445') + Decimal('1.0023')
Decimal('4.45')
>>> Decimal('3.4445') + Decimal(0) + Decimal('1.0023')
Decimal('4.44')
```

This method implements the to-number operation of the IBM specification. If the argument is a string, no leading or trailing whitespace is permitted.

`create_decimal_from_float(f)`

Creates a new `Decimal` instance from a float f but rounding using *self* as the context. Unlike the `Decimal.from_float()` class method, the context precision, rounding method, flags, and traps are applied to the conversion.

```
>>> context = Context(prec=5, rounding=ROUND_DOWN)
>>> context.create_decimal_from_float(math.pi)
Decimal('3.1415')
>>> context = Context(prec=5, traps=[Inexact])
>>> context.create_decimal_from_float(math.pi)
Traceback (most recent call last):
...
decimal.Inexact: None
```

New in version 3.1.

`Etiny()`

Returns a value equal to `Emin - prec + 1` which is the minimum exponent value for subnormal results. When underflow occurs, the exponent is set to `Etiny`.

`Etop()`

Returns a value equal to `Emax - prec + 1`.

The usual approach to working with decimals is to create `Decimal` instances and then apply arithmetic operations which take place within the current context for the active thread. An alternative approach is to use context methods for calculating within a specific context. The methods are similar to those for the `Decimal` class and are only briefly recounted here.

`abs(x)`

Returns the absolute value of x .

`add(x, y)`

Return the sum of x and y .

canonical(x)

Returns the same Decimal object x .

compare(x, y)

Compares x and y numerically.

compare_signal(x, y)

Compares the values of the two operands numerically.

compare_total(x, y)

Compares two operands using their abstract representation.

compare_total_mag(x, y)

Compares two operands using their abstract representation, ignoring sign.

copy_abs(x)

Returns a copy of x with the sign set to 0.

copy_negate(x)

Returns a copy of x with the sign inverted.

copy_sign(x, y)

Copies the sign from y to x .

divide(x, y)

Return x divided by y .

divide_int(x, y)

Return x divided by y , truncated to an integer.

divmod(x, y)

Divides two numbers and returns the integer part of the result.

exp(x)

Returns $e^{**} x$.

fma(x, y, z)

Returns x multiplied by y , plus z .

is_canonical(x)

Returns True if x is canonical; otherwise returns False.

is_finite(x)

Returns True if x is finite; otherwise returns False.

is_infinite(x)

Returns True if x is infinite; otherwise returns False.

is_nan(x)

Returns True if x is a qNaN or sNaN; otherwise returns False.

is_normal(x)

Returns True if x is a normal number; otherwise returns False.

is_qnan(x)

Returns True if x is a quiet NaN; otherwise returns False.

is_signed(x)

Returns True if x is negative; otherwise returns False.

is_snan(x)

Returns True if x is a signaling NaN; otherwise returns False.

is_subnormal(x)

Returns True if x is subnormal; otherwise returns False.

is_zero(x)

Returns True if x is a zero; otherwise returns False.

ln(x)

Returns the natural (base e) logarithm of x.

log10(x)

Returns the base 10 logarithm of x.

logb(x)

Returns the exponent of the magnitude of the operand's MSD.

logical_and(x, y)

Applies the logical operation *and* between each operand's digits.

logical_invert(x)

Invert all the digits in x.

logical_or(x, y)

Applies the logical operation *or* between each operand's digits.

logical_xor(x, y)

Applies the logical operation *xor* between each operand's digits.

max(x, y)

Compares two values numerically and returns the maximum.

max_mag(x, y)

Compares the values numerically with their sign ignored.

min(x, y)

Compares two values numerically and returns the minimum.

min_mag(x, y)

Compares the values numerically with their sign ignored.

minus(x)

Minus corresponds to the unary prefix minus operator in Python.

multiply(x, y)

Return the product of x and y .

next_minus(x)

Returns the largest representable number smaller than x .

next_plus(x)

Returns the smallest representable number larger than x .

next_toward(x, y)

Returns the number closest to x , in direction towards y .

normalize(x)

Reduces x to its simplest form.

number_class(x)

Returns an indication of the class of x .

plus(x)

Plus corresponds to the unary prefix plus operator in Python. This operation applies the context precision and rounding, so it is *not* an identity operation.

power(x, y[, modulo])

Return x to the power of y , reduced modulo `modulo` if given.

With two arguments, compute $x^{**}y$. If x is negative then y must be integral. The result will be inexact unless y is integral and the result is finite and can be expressed exactly in 'precision' digits. The result should always be correctly

rounded, using the rounding mode of the current thread's context.

With three arguments, compute `(x**y) % modulo`. For the three argument form, the following restrictions on the arguments hold:

- all three arguments must be integral
- `y` must be nonnegative
- at least one of `x` or `y` must be nonzero
- `modulo` must be nonzero and have at most 'precision' digits

The value resulting from `context.power(x, y, modulo)` is equal to the value that would be obtained by computing `(x**y) % modulo` with unbounded precision, but is computed more efficiently. The exponent of the result is zero, regardless of the exponents of `x`, `y` and `modulo`. The result is always exact.

quantize(x, y)

Returns a value equal to `x` (rounded), having the exponent of `y`.

radix()

Just returns 10, as this is Decimal, :)

remainder(x, y)

Returns the remainder from integer division.

The sign of the result, if non-zero, is the same as that of the original dividend.

remainder_near(x, y)

Returns $x - y * n$, where n is the integer nearest the exact value of x / y (if the result is 0 then its sign will be the sign of x).

rotate(x, y)

Returns a rotated copy of x , y times.

same_quantum(x, y)

Returns True if the two operands have the same exponent.

scaleb(x, y)

Returns the first operand after adding the second value its exp.

shift(x, y)

Returns a shifted copy of x , y times.

sqrt(x)

Square root of a non-negative number to context precision.

subtract(x, y)

Return the difference between x and y .

to_eng_string(x)

Converts a number to a string, using scientific notation.

to_integral_exact(x)

Rounds to an integer.

to_sci_string(x)

Converts a number to a string using scientific notation.

8.4.4. Signals

Signals represent conditions that arise during computation. Each corresponds to one context flag and one context trap enabler.

The context flag is set whenever the condition is encountered. After the computation, flags may be checked for informational purposes (for instance, to determine whether a computation was exact). After checking the flags, be sure to clear all flags before starting the next computation.

If the context's trap enabler is set for the signal, then the condition causes a Python exception to be raised. For example, if the `DivisionByZero` trap is set, then a `DivisionByZero` exception is raised upon encountering the condition.

`class decimal.Clamped`

Altered an exponent to fit representation constraints.

Typically, clamping occurs when an exponent falls outside the context's `Emin` and `Emax` limits. If possible, the exponent is reduced to fit by adding zeros to the coefficient.

`class decimal.DecimalException`

Base class for other signals and a subclass of `ArithmeticError`.

`class decimal.DivisionByZero`

Signals the division of a non-infinite number by zero.

Can occur with division, modulo division, or when raising a number to a negative power. If this signal is not trapped, returns `Infinity` or `-Infinity` with the sign determined by the inputs to the calculation.

class decimal. **Inexact**

Indicates that rounding occurred and the result is not exact.

Signals when non-zero digits were discarded during rounding. The rounded result is returned. The signal flag or trap is used to detect when results are inexact.

class decimal. **InvalidOperation**

An invalid operation was performed.

Indicates that an operation was requested that does not make sense. If not trapped, returns **NaN**. Possible causes include:

```
Infinity - Infinity
0 * Infinity
Infinity / Infinity
x % 0
Infinity % x
x._rescale( non-integer )
sqrt(-x) and x > 0
0 ** 0
x ** (non-integer)
x ** Infinity
```

class decimal. **Overflow**

Numerical overflow.

Indicates the exponent is larger than **E_{max}** after rounding has occurred. If not trapped, the result depends on the rounding mode, either pulling inward to the largest representable finite number or rounding outward to **Infinity**. In either case, **Inexact** and **Rounded** are also signaled.

class decimal. **Rounded**

Rounding occurred though possibly no information was lost.

Signaled whenever rounding discards digits; even if those digits

are zero (such as rounding 5.00 to 5.0). If not trapped, returns the result unchanged. This signal is used to detect loss of significant digits.

class decimal.**Subnormal**

Exponent was lower than `Emin` prior to rounding.

Occurs when an operation result is subnormal (the exponent is too small). If not trapped, returns the result unchanged.

class decimal.**Underflow**

Numerical underflow with result rounded to zero.

Occurs when a subnormal result is pushed to zero by rounding.

Inexact and **Subnormal** are also signaled.

The following table summarizes the hierarchy of signals:

```
exceptions.ArithmeticError(exceptions.Exception)
  DecimalException
    Clamped
    DivisionByZero(DecimalException, exceptions.ZeroDivisio
    Inexact
      Overflow(Inexact, Rounded)
      Underflow(Inexact, Rounded, Subnormal)
    InvalidOperation
    Rounded
    Subnormal
```

8.4.5. Floating Point Notes

8.4.5.1. Mitigating round-off error with increased precision

The use of decimal floating point eliminates decimal representation error (making it possible to represent `0.1` exactly); however, some operations can still incur round-off error when non-zero digits exceed the fixed precision.

The effects of round-off error can be amplified by the addition or subtraction of nearly offsetting quantities resulting in loss of significance. Knuth provides two instructive examples where rounded floating point arithmetic with insufficient precision causes the breakdown of the associative and distributive properties of addition:

```
# Examples from Seminumerical Algorithms, Section 4.2.2.
>>> from decimal import Decimal, getcontext
>>> getcontext().prec = 8

>>> u, v, w = Decimal(11111113), Decimal(-11111111), Decimal('7')
>>> (u + v) + w
Decimal('9.5111111')
>>> u + (v + w)
Decimal('10')

>>> u, v, w = Decimal(20000), Decimal(-6), Decimal('6.0000003')
>>> (u*v) + (u*w)
Decimal('0.01')
>>> u * (v+w)
Decimal('0.0060000')
```

The `decimal` module makes it possible to restore the identities by expanding the precision sufficiently to avoid loss of significance:

```
>>> getcontext().prec = 20
>>> u, v, w = Decimal(11111113), Decimal(-11111111), Decimal('7
>>> (u + v) + w
Decimal('9.51111111')
>>> u + (v + w)
Decimal('9.51111111')
>>>
>>> u, v, w = Decimal(20000), Decimal(-6), Decimal('6.0000003')
>>> (u*v) + (u*w)
Decimal('0.0060000')
>>> u * (v+w)
Decimal('0.0060000')
```

8.4.5.2. Special values

The number system for the `decimal` module provides special values including `NaN`, `sNaN`, `-Infinity`, `Infinity`, and two zeros, `+0` and `-0`.

Infinities can be constructed directly with: `Decimal('Infinity')`. Also, they can arise from dividing by zero when the `DivisionByZero` signal is not trapped. Likewise, when the `Overflow` signal is not trapped, infinity can result from rounding beyond the limits of the largest representable number.

The infinities are signed (affine) and can be used in arithmetic operations where they get treated as very large, indeterminate numbers. For instance, adding a constant to infinity gives another infinite result.

Some operations are indeterminate and return `NaN`, or if the `InvalidOperation` signal is trapped, raise an exception. For example, `0/0` returns `NaN` which means “not a number”. This variety of `NaN` is quiet and, once created, will flow through other computations always resulting in another `NaN`. This behavior can be useful for a series of computations that occasionally have missing inputs — it allows the calculation to proceed while flagging specific results as invalid.

A variant is `sNaN` which signals rather than remaining quiet after every operation. This is a useful return value when an invalid result needs to interrupt a calculation for special handling.

The behavior of Python's comparison operators can be a little surprising where a `NaN` is involved. A test for equality where one of the operands is a quiet or signaling `NaN` always returns `False` (even when doing `Decimal('NaN')==Decimal('NaN')`), while a test for inequality always returns `True`. An attempt to compare two Decimals using any of the `<`, `<=`, `>` or `>=` operators will raise the `InvalidOperation` signal if either operand is a `NaN`, and return `False` if this signal is not trapped. Note that the General Decimal Arithmetic specification does not specify the behavior of direct comparisons; these rules for comparisons involving a `NaN` were taken from the IEEE 854 standard (see Table 3 in section 5.7). To ensure strict standards-compliance, use the `compare()` and `compare-signal()` methods instead.

The signed zeros can result from calculations that underflow. They keep the sign that would have resulted if the calculation had been carried out to greater precision. Since their magnitude is zero, both positive and negative zeros are treated as equal and their sign is informational.

In addition to the two signed zeros which are distinct yet equal, there are various representations of zero with differing precisions yet equivalent in value. This takes a bit of getting used to. For an eye accustomed to normalized floating point representations, it is not immediately obvious that the following calculation returns a value equal to zero:

```
>>> 1 / Decimal('Infinity')
Decimal('0E-1000000026')
```

8.4.6. Working with threads

The `getcontext()` function accesses a different `context` object for each thread. Having separate thread contexts means that threads may make changes (such as `getcontext.prec=10`) without interfering with other threads.

Likewise, the `setcontext()` function automatically assigns its target to the current thread.

If `setcontext()` has not been called before `getcontext()`, then `getcontext()` will automatically create a new context for use in the current thread.

The new context is copied from a prototype context called `DefaultContext`. To control the defaults so that each thread will use the same values throughout the application, directly modify the `DefaultContext` object. This should be done *before* any threads are started so that there won't be a race condition between threads calling `getcontext()`. For example:

```
# Set applicationwide defaults for all threads about to be laun
DefaultContext.prec = 12
DefaultContext.rounding = ROUND_DOWN
DefaultContext.traps = ExtendedContext.traps.copy()
DefaultContext.traps[InvalidOperation] = 1
setcontext(DefaultContext)

# Afterwards, the threads can be started
t1.start()
t2.start()
t3.start()
. . .
```

8.4.7. Recipes

Here are a few recipes that serve as utility functions and that demonstrate ways to work with the `Decimal` class:

```
def moneyfmt(value, places=2, curr='', sep=',', dp='.',
             pos='', neg='-', trailneg=''):
    """Convert Decimal to a money formatted string.

    places:  required number of places after the decimal point
    curr:    optional currency symbol before the sign (may be blank)
    sep:     optional grouping separator (comma, period, space, etc)
    dp:      decimal point indicator (comma or period)
             only specify as blank when places is zero
    pos:     optional sign for positive numbers: '+', space or blank
    neg:     optional sign for negative numbers: '-', '(', space or blank
    trailneg: optional trailing minus indicator: ' ', '(', '-', ')>'

    >>> d = Decimal('-1234567.8901')
    >>> moneyfmt(d, curr='$')
    '-$1,234,567.89'
    >>> moneyfmt(d, places=0, sep='.', dp='', neg='', trailneg='')
    '1.234.568-'
    >>> moneyfmt(d, curr='$', neg='(', trailneg=')')
    '($1,234,567.89)'
    >>> moneyfmt(Decimal(123456789), sep=' ')
    '123 456 789.00'
    >>> moneyfmt(Decimal('-0.02'), neg='<', trailneg='>')
    '<0.02>'

    """
    q = Decimal(10) ** -places          # 2 places --> '0.01'
    sign, digits, exp = value.quantize(q).as_tuple()
    result = []
    digits = list(map(str, digits))
    build, next = result.append, digits.pop
    if sign:
        build(trailneg)
    for i in range(places):
        build(next() if digits else '0')
    if places:
        build(dp)
    if not digits:
        build('0')
```

```

        build('0')
    i = 0
    while digits:
        build(next())
        i += 1
        if i == 3 and digits:
            i = 0
            build(sep)
    build(curr)
    build(neg if sign else pos)
    return ''.join(reversed(result))

def pi():
    """Compute Pi to the current precision.

    >>> print(pi())
    3.141592653589793238462643383

    """
    getcontext().prec += 2 # extra digits for intermediate steps
    three = Decimal(3) # substitute "three=3.0" for regular floats
    lasts, t, s, n, na, d, da = 0, three, 3, 1, 0, 0, 24
    while s != lasts:
        lasts = s
        n, na = n+na, na+8
        d, da = d+da, da+32
        t = (t * n) / d
        s += t
    getcontext().prec -= 2
    return +s # unary plus applies the new precision

def exp(x):
    """Return e raised to the power of x. Result type matches x.

    >>> print(exp(Decimal(1)))
    2.718281828459045235360287471
    >>> print(exp(Decimal(2)))
    7.389056098930650227230427461
    >>> print(exp(2.0))
    7.38905609893
    >>> print(exp(2+0j))
    (7.38905609893+0j)

    """
    getcontext().prec += 2
    i, lasts, s, fact, num = 0, 0, 1, 1, 1
    while s != lasts:

```

```

        lasts = s
        i += 1
        fact *= i
        num *= x
        s += num / fact
    getcontext().prec -= 2
    return +s

```

```
def cos(x):
```

```
    """Return the cosine of x as measured in radians.
```

```

    The Taylor series approximation works best for a small value.
    For larger values, first compute x = x % (2 * pi).

```

```

>>> print(cos(Decimal('0.5')))
0.8775825618903727161162815826
>>> print(cos(0.5))
0.87758256189

(0.87758256189+0j)

```

```
    """
```

```

    getcontext().prec += 2
    i, lasts, s, fact, num, sign = 0, 0, 1, 1, 1, 1
    while s != lasts:
        lasts = s
        i += 2
        fact *= i * (i-1)
        num *= x * x
        sign *= -1
        s += num / fact * sign
    getcontext().prec -= 2
    return +s

```

```
def sin(x):
```

```
    """Return the sine of x as measured in radians.
```

```

    The Taylor series approximation works best for a small value.
    For larger values, first compute x = x % (2 * pi).

```

```

>>> print(sin(Decimal('0.5')))
0.4794255386042030002732879352
>>> print(sin(0.5))
0.479425538604
>>> print(sin(0.5+0j))
(0.479425538604+0j)

```

```
"""
getcontext().prec += 2
i, lasts, s, fact, num, sign = 1, 0, x, 1, x, 1
while s != lasts:
    lasts = s
    i += 2
    fact *= i * (i-1)
    num *= x * x
    sign *= -1
    s += num / fact * sign
getcontext().prec -= 2
return +s
```

8.4.8. Decimal FAQ

Q. It is cumbersome to type `decimal.Decimal('1234.5')`. Is there a way to minimize typing when using the interactive interpreter?

A. Some users abbreviate the constructor to just a single letter:

```
>>> D = decimal.Decimal
>>> D('1.23') + D('3.45')
Decimal('4.68')
```

Q. In a fixed-point application with two decimal places, some inputs have many places and need to be rounded. Others are not supposed to have excess digits and need to be validated. What methods should be used?

A. The `quantize()` method rounds to a fixed number of decimal places. If the `Inexact` trap is set, it is also useful for validation:

```
>>> TWOPLACES = Decimal(10) ** -2           # same as Decimal('0.01')
```

```
>>> # Round to two places
>>> Decimal('3.214').quantize(TWOPLACES)
Decimal('3.21')
```

```
>>> # Validate that a number does not exceed two places
>>> Decimal('3.21').quantize(TWOPLACES, context=Context(traps=[
Decimal('3.21')
```

```
>>> Decimal('3.214').quantize(TWOPLACES, context=Context(traps=
Traceback (most recent call last):
```

```
...
Inexact: None
```

Q. Once I have valid two place inputs, how do I maintain that

invariant throughout an application?

A. Some operations like addition, subtraction, and multiplication by an integer will automatically preserve fixed point. Others operations, like division and non-integer multiplication, will change the number of decimal places and need to be followed-up with a `quantize()` step:

```
>>> a = Decimal('102.72')           # Initial fixed-point value
>>> b = Decimal('3.17')
>>> a + b                             # Addition preserves fixed-
Decimal('105.89')
>>> a - b
Decimal('99.55')
>>> a * 42                             # So does integer multiplic
Decimal('4314.24')
>>> (a * b).quantize(TWOPLACES)       # Must quantize non-integer
Decimal('325.62')
>>> (b / a).quantize(TWOPLACES)       # And quantize division
Decimal('0.03')
```

In developing fixed-point applications, it is convenient to define functions to handle the `quantize()` step:

```
>>> def mul(x, y, fp=TWOPLACES):
...     return (x * y).quantize(fp)
>>> def div(x, y, fp=TWOPLACES):
...     return (x / y).quantize(fp)
```

```
>>> mul(a, b)                           # Automatically preserve fi
Decimal('325.62')
>>> div(b, a)
Decimal('0.03')
```

Q. There are many ways to express the same value. The numbers `200`, `200.000`, `2E2`, and `02E+4` all have the same value at various precisions. Is there a way to transform them to a single recognizable canonical value?

A. The `normalize()` method maps all equivalent values to a single representative:

```
>>> values = map(Decimal, '200 200.000 2E2 .02E+4'.split())
>>> [v.normalize() for v in values]
[Decimal('2E+2'), Decimal('2E+2'), Decimal('2E+2'), Decimal('2E
```

Q. Some decimal values always print with exponential notation. Is there a way to get a non-exponential representation?

A. For some values, exponential notation is the only way to express the number of significant places in the coefficient. For example, expressing `5.0E+3` as `5000` keeps the value constant but cannot show the original's two-place significance.

If an application does not care about tracking significance, it is easy to remove the exponent and trailing zeroes, losing significance, but keeping the value unchanged:

```
>>> def remove_exponent(d):
...     return d.quantize(Decimal(1)) if d == d.to_integral() e
```

```
>>> remove_exponent(Decimal('5E+3'))
Decimal('5000')
```

Q. Is there a way to convert a regular float to a `Decimal`?

A. Yes, any binary floating point number can be exactly expressed as a `Decimal` though an exact conversion may take more precision than intuition would suggest:

```
>>> Decimal(math.pi)
Decimal('3.141592653589793115997963468544185161590576171875')
```

Q. Within a complex calculation, how can I make sure that I haven't gotten a spurious result because of insufficient precision or rounding

anomalies.

A. The decimal module makes it easy to test results. A best practice is to re-run calculations using greater precision and with various rounding modes. Widely differing results indicate insufficient precision, rounding mode issues, ill-conditioned inputs, or a numerically unstable algorithm.

Q. I noticed that context precision is applied to the results of operations but not to the inputs. Is there anything to watch out for when mixing values of different precisions?

A. Yes. The principle is that all values are considered to be exact and so is the arithmetic on those values. Only the results are rounded. The advantage for inputs is that “what you type is what you get”. A disadvantage is that the results can look odd if you forget that the inputs haven’t been rounded:

```
>>> getcontext().prec = 3
>>> Decimal('3.104') + Decimal('2.104')
Decimal('5.21')
>>> Decimal('3.104') + Decimal('0.000') + Decimal('2.104')
Decimal('5.20')
```

The solution is either to increase precision or to force rounding of inputs using the unary plus operation:

```
>>> getcontext().prec = 3
>>> +Decimal('1.23456789')      # unary plus triggers rounding
Decimal('1.23')
```

Alternatively, inputs can be rounded upon creation using the `Context.create_decimal()` method:

```
>>> Context(prec=5, rounding=ROUND_DOWN).create_decimal('1.2345')
Decimal('1.2345')
```

8.5. fractions — Rational numbers

Source code: [Lib/fractions.py](#)

The `fractions` module provides support for rational number arithmetic.

A `Fraction` instance can be constructed from a pair of integers, from another rational number, or from a string.

```
class fractions.Fraction( numerator=0, denominator=1)
class fractions.Fraction( other_fraction)
class fractions.Fraction( float)
class fractions.Fraction( decimal)
class fractions.Fraction( string)
```

The first version requires that *numerator* and *denominator* are instances of `numbers.Rational` and returns a new `Fraction` instance with value `numerator/denominator`. If *denominator* is `0`, it raises a `ZeroDivisionError`. The second version requires that *other_fraction* is an instance of `numbers.Rational` and returns a `Fraction` instance with the same value. The next two versions accept either a `float` or a `decimal.Decimal` instance, and return a `Fraction` instance with exactly the same value. Note that due to the usual issues with binary floating-point (see *Floating Point Arithmetic: Issues and Limitations*), the argument to `Fraction(1.1)` is not exactly equal to `11/10`, and so `Fraction(1.1)` does *not* return `Fraction(11, 10)` as one might expect. (But see the documentation for the `limit_denominator()` method below.) The last version of the constructor expects a string or unicode instance. The usual form for this instance is:

```
[sign] numerator ['/' denominator]
```

where the optional `sign` may be either '+' or '-' and `numerator` and `denominator` (if present) are strings of decimal digits. In addition, any string that represents a finite value and is accepted by the `float` constructor is also accepted by the `Fraction` constructor. In either form the input string may also have leading and/or trailing whitespace. Here are some examples:

```
>>> from fractions import Fraction
>>> Fraction(16, -10)
Fraction(-8, 5)
>>> Fraction(123)
Fraction(123, 1)
>>> Fraction()
Fraction(0, 1)
>>> Fraction('3/7')
Fraction(3, 7)
[40794 refs]
>>> Fraction(' -3/7 ')
Fraction(-3, 7)
>>> Fraction('1.414213 \t\n')
Fraction(1414213, 1000000)
>>> Fraction('-.125')
Fraction(-1, 8)
>>> Fraction('7e-6')
Fraction(7, 1000000)
>>> Fraction(2.25)
Fraction(9, 4)
>>> Fraction(1.1)
Fraction(2476979795053773, 2251799813685248)
>>> from decimal import Decimal
>>> Fraction(Decimal('1.1'))
Fraction(11, 10)
```

The `Fraction` class inherits from the abstract base class `numbers.Rational`, and implements all of the methods and operations from that class. `Fraction` instances are hashable, and should be treated as immutable. In addition, `Fraction` has the following methods:

Changed in version 3.2: The `Fraction` constructor now accepts

`float` and `decimal.Decimal` instances.

`from_float(float)`

This class method constructs a `Fraction` representing the exact value of `flt`, which must be a `float`. Beware that `Fraction.from_float(0.3)` is not the same value as `Fraction(3, 10)`

Note: From Python 3.2 onwards, you can also construct a `Fraction` instance directly from a `float`.

`from_decimal(dec)`

This class method constructs a `Fraction` representing the exact value of `dec`, which must be a `decimal.Decimal` instance.

Note: From Python 3.2 onwards, you can also construct a `Fraction` instance directly from a `decimal.Decimal` instance.

`limit_denominator(max_denominator=1000000)`

Finds and returns the closest `Fraction` to `self` that has denominator at most `max_denominator`. This method is useful for finding rational approximations to a given floating-point number:

```
>>> from fractions import Fraction
>>> Fraction('3.1415926535897932').limit_denominator(1000)
Fraction(355, 113)
```

or for recovering a rational number that's represented as a float:

```
>>> from math import pi, cos
>>> Fraction(cos(pi/3))
```

```
Fraction(4503599627370497, 9007199254740992)
>>> Fraction(cos(pi/3)).limit_denominator()
Fraction(1, 2)
>>> Fraction(1.1).limit_denominator()
Fraction(11, 10)
```

`__floor__()`

Returns the greatest `int` `<= self`. This method can also be accessed through the `math.floor()` function:

```
>>> from math import floor
>>> floor(Fraction(355, 113))
3
```

`__ceil__()`

Returns the least `int` `>= self`. This method can also be accessed through the `math.ceil()` function.

`__round__()`

`__round__(ndigits)`

The first version returns the nearest `int` to `self`, rounding half to even. The second version rounds `self` to the nearest multiple of `Fraction(1, 10**ndigits)` (logically, if `ndigits` is negative), again rounding half toward even. This method can also be accessed through the `round()` function.

`fractions.gcd(a, b)`

Return the greatest common divisor of the integers `a` and `b`. If either `a` or `b` is nonzero, then the absolute value of `gcd(a, b)` is the largest integer that divides both `a` and `b`. `gcd(a, b)` has the same sign as `b` if `b` is nonzero; otherwise it takes the sign of `a`. `gcd(0, 0)` returns `0`.

8.6. `random` — Generate pseudo-random numbers

Source code: [Lib/random.py](#)

This module implements pseudo-random number generators for various distributions.

For integers, there is uniform selection from a range. For sequences, there is uniform selection of a random element, a function to generate a random permutation of a list in-place, and a function for random sampling without replacement.

On the real line, there are functions to compute uniform, normal (Gaussian), lognormal, negative exponential, gamma, and beta distributions. For generating distributions of angles, the von Mises distribution is available.

Almost all module functions depend on the basic function `random()`, which generates a random float uniformly in the semi-open range `[0.0, 1.0)`. Python uses the Mersenne Twister as the core generator. It produces 53-bit precision floats and has a period of $2^{19937}-1$. The underlying implementation in C is both fast and threadsafe. The Mersenne Twister is one of the most extensively tested random number generators in existence. However, being completely deterministic, it is not suitable for all purposes, and is completely unsuitable for cryptographic purposes.

The functions supplied by this module are actually bound methods of a hidden instance of the `random.Random` class. You can instantiate your own instances of `Random` to get generators that don't share state.

Class `Random` can also be subclassed if you want to use a different basic generator of your own devising: in that case, override the `random()`, `seed()`, `getstate()`, and `setstate()` methods. Optionally, a new generator can supply a `getrandbits()` method — this allows `randrange()` to produce selections over an arbitrarily large range.

The `random` module also provides the `SystemRandom` class which uses the system function `os.urandom()` to generate random numbers from sources provided by the operating system.

Bookkeeping functions:

`random.seed([x], version=2)`

Initialize the random number generator.

If `x` is omitted or `None`, the current system time is used. If randomness sources are provided by the operating system, they are used instead of the system time (see the `os.urandom()` function for details on availability).

If `x` is an `int`, it is used directly.

With version 2 (the default), a `str`, `bytes`, or `bytearray` object gets converted to an `int` and all of its bits are used. With version 1, the `hash()` of `x` is used instead.

Changed in version 3.2: Moved to the version 2 scheme which uses all of the bits in a string seed.

`random.getstate()`

Return an object capturing the current internal state of the generator. This object can be passed to `setstate()` to restore the state.

random. **setstate**(*state*)

state should have been obtained from a previous call to **getstate()**, and **setstate()** restores the internal state of the generator to what it was at the time **setstate()** was called.

random. **getrandbits**(*k*)

Returns a Python integer with *k* random bits. This method is supplied with the MersenneTwister generator and some other generators may also provide it as an optional part of the API. When available, **getrandbits()** enables **randrange()** to handle arbitrarily large ranges.

Functions for integers:

random. **randrange**([*start*], *stop*[, *step*])

Return a randomly selected element from `range(start, stop, step)`. This is equivalent to `choice(range(start, stop, step))`, but doesn't actually build a range object.

The positional argument pattern matches that of **range()**. Keyword arguments should not be used because the function may use them in unexpected ways.

Changed in version 3.2: **randrange()** is more sophisticated about producing equally distributed values. Formerly it used a style like `int(random()*n)` which could produce slightly uneven distributions.

random. **randint**(*a*, *b*)

Return a random integer *N* such that `a <= N <= b`. Alias for `randrange(a, b+1)`.

Functions for sequences:

`random.choice(seq)`

Return a random element from the non-empty sequence *seq*. If *seq* is empty, raises `IndexError`.

`random.shuffle(x[, random])`

Shuffle the sequence *x* in place. The optional argument *random* is a 0-argument function returning a random float in [0.0, 1.0); by default, this is the function `random()`.

Note that for even rather small `len(x)`, the total number of permutations of *x* is larger than the period of most random number generators; this implies that most permutations of a long sequence can never be generated.

`random.sample(population, k)`

Return a *k* length list of unique elements chosen from the population sequence or set. Used for random sampling without replacement.

Returns a new list containing elements from the population while leaving the original population unchanged. The resulting list is in selection order so that all sub-slices will also be valid random samples. This allows raffle winners (the sample) to be partitioned into grand prize and second place winners (the subslices).

Members of the population need not be *hashable* or unique. If the population contains repeats, then each occurrence is a possible selection in the sample.

To choose a sample from a range of integers, use an `range()` object as an argument. This is especially fast and space efficient for sampling from a large population: `sample(range(10000000), 60)`.

The following functions generate specific real-valued distributions. Function parameters are named after the corresponding variables in the distribution's equation, as used in common mathematical practice; most of these equations can be found in any statistics text.

random. **random()**

Return the next random floating point number in the range [0.0, 1.0).

random. **uniform(a, b)**

Return a random floating point number N such that $a \leq N \leq b$ for $a \leq b$ and $b \leq N \leq a$ for $b < a$.

The end-point value b may or may not be included in the range depending on floating-point rounding in the equation $a + (b-a) * \text{random}()$.

random. **triangular(low, high, mode)**

Return a random floating point number N such that $\text{low} \leq N \leq \text{high}$ and with the specified *mode* between those bounds. The *low* and *high* bounds default to zero and one. The *mode* argument defaults to the midpoint between the bounds, giving a symmetric distribution.

random. **betavariate(alpha, beta)**

Beta distribution. Conditions on the parameters are $\text{alpha} > 0$ and $\text{beta} > 0$. Returned values range between 0 and 1.

random. **expovariate(lambd)**

Exponential distribution. *lambd* is 1.0 divided by the desired mean. It should be nonzero. (The parameter would be called "lambda", but that is a reserved word in Python.) Returned values range from 0 to positive infinity if *lambd* is positive, and from negative infinity to 0 if *lambd* is negative.

random. **gammavariate**(*alpha*, *beta*)

Gamma distribution. (Not the gamma function!) Conditions on the parameters are `alpha > 0` and `beta > 0`.

random. **gauss**(*mu*, *sigma*)

Gaussian distribution. *mu* is the mean, and *sigma* is the standard deviation. This is slightly faster than the `normalvariate()` function defined below.

random. **lognormvariate**(*mu*, *sigma*)

Log normal distribution. If you take the natural logarithm of this distribution, you'll get a normal distribution with mean *mu* and standard deviation *sigma*. *mu* can have any value, and *sigma* must be greater than zero.

random. **normalvariate**(*mu*, *sigma*)

Normal distribution. *mu* is the mean, and *sigma* is the standard deviation.

random. **vonmisesvariate**(*mu*, *kappa*)

mu is the mean angle, expressed in radians between 0 and 2π , and *kappa* is the concentration parameter, which must be greater than or equal to zero. If *kappa* is equal to zero, this distribution reduces to a uniform random angle over the range 0 to 2π .

random. **paretovariate**(*alpha*)

Pareto distribution. *alpha* is the shape parameter.

random. **weibullvariate**(*alpha*, *beta*)

Weibull distribution. *alpha* is the scale parameter and *beta* is the shape parameter.

Alternative Generator:

`class random.SystemRandom([seed])`

Class that uses the `os.urandom()` function for generating random numbers from sources provided by the operating system. Not available on all systems. Does not rely on software state, and sequences are not reproducible. Accordingly, the `seed()` method has no effect and is ignored. The `getstate()` and `setstate()` methods raise `NotImplementedError` if called.

See also: M. Matsumoto and T. Nishimura, “Mersenne Twister: A 623-dimensionally equidistributed uniform pseudorandom number generator”, ACM Transactions on Modeling and Computer Simulation Vol. 8, No. 1, January pp.3-30 1998.

[Complementary-Multiply-with-Carry recipe](#) for a compatible alternative random number generator with a long period and comparatively simple update operations.

8.6.1. Notes on Reproducibility

Sometimes it is useful to be able to reproduce the sequences given by a pseudo random number generator. By re-using a seed value, the same sequence should be reproducible from run to run as long as multiple threads are not running.

Most of the random module's algorithms and seeding functions are subject to change across Python versions, but two aspects are guaranteed not to change:

- If a new seeding method is added, then a backward compatible seeder will be offered.
- The generator's `random()` method will continue to produce the same sequence when the compatible seeder is given the same seed.

8.6.2. Examples and Recipes

Basic usage:

```
>>> random.random()           # Random float x, 0.0
0.37444887175646646

>>> random.uniform(1, 10)     # Random float x, 1.0
1.1800146073117523

>>> random.randrange(10)      # Integer from 0 to 9
7

>>> random.randrange(0, 101, 2) # Even integer from 0
26

>>> random.choice('abcdefghij') # Single random elemen
'c'

>>> items = [1, 2, 3, 4, 5, 6, 7]
>>> random.shuffle(items)
>>> items
[7, 3, 2, 5, 6, 4, 1]

>>> random.sample([1, 2, 3, 4, 5], 3) # Three samples without
[4, 1, 5]
```

A common task is to make a `random.choice()` with weighted probabilities.

If the weights are small integer ratios, a simple technique is to build a sample population with repeats:

```
>>> weighted_choices = [('Red', 3), ('Blue', 2), ('Yellow', 1),
>>> population = [val for val, cnt in weighted_choices for i in
>>> random.choice(population)
'Green']
```

A more general approach is to arrange the weights in a cumulative

distribution with `itertools.accumulate()`, and then locate the random value with `bisect.bisect()`:

```
>>> choices, weights = zip(*weighted_choices)
>>> cumdist = list(itertools.accumulate(weights))
>>> x = random.random() * cumdist[-1]
>>> choices[bisect.bisect(cumdist, x)]
'Blue'
```

9. Functional Programming Modules

The modules described in this chapter provide functions and classes that support a functional programming style, and general operations on callables.

The following modules are documented in this chapter:

- 9.1. `itertools` — Functions creating iterators for efficient looping
 - 9.1.1. Itertool functions
 - 9.1.2. Itertools Recipes
- 9.2. `functools` — Higher order functions and operations on callable objects
 - 9.2.1. `partial` Objects
- 9.3. `operator` — Standard operators as functions
 - 9.3.1. Mapping Operators to Functions
- 9.4. Inplace Operators

9.1. `itertools` — Functions creating iterators for efficient looping

This module implements a number of *iterator* building blocks inspired by constructs from APL, Haskell, and SML. Each has been recast in a form suitable for Python.

The module standardizes a core set of fast, memory efficient tools that are useful by themselves or in combination. Together, they form an “iterator algebra” making it possible to construct specialized tools succinctly and efficiently in pure Python.

For instance, SML provides a tabulation tool: `tabulate(f)` which produces a sequence `f(0), f(1), ...`. The same effect can be achieved in Python by combining `map()` and `count()` to form `map(f, count())`.

These tools and their built-in counterparts also work well with the high-speed functions in the `operator` module. For example, the multiplication operator can be mapped across two vectors to form an efficient dot-product: `sum(map(operator.mul, vector1, vector2))`.

Infinite Iterators:

Iterator	Arguments	Results	Example
<code>count()</code>	start, [step]	start, start+step, start+2*step, ...	<code>count(10) --> 10</code> 11 12 13 14 ...
<code>cycle()</code>	p	p0, p1, ... plast, p0, p1, ...	<code>cycle('ABCD') --></code> A B C D A B C D ...
<code>repeat()</code>	elem [,n]	elem, elem, elem, ... endlessly or up to n times	<code>repeat(10, 3) --></code> 10 10 10

Iterators terminating on the shortest input sequence:

Iterator	Arguments	Results	Example
<code>accumulate()</code>	<code>p</code>	<code>p0, p0+p1, p0+p1+p2, ...</code>	<code>accumulate([1,2,3,4, --> 1 3 6 10 15</code>
<code>chain()</code>	<code>p, q, ...</code>	<code>p0, p1, ... plast, q0, q1, ...</code>	<code>chain('ABC', 'DEF') A B C D E F</code>
<code>compress()</code>	<code>data, selectors</code>	<code>(d[0] if s[0]), (d[1] if s[1]), ...</code>	<code>compress('ABCDEF', [1,0,1,0,1,1]) --> A E F</code>
<code>dropwhile()</code>	<code>pred, seq</code>	<code>seq[n], seq[n+1], starting when pred fails</code>	<code>dropwhile(lambda x: x<5, [1,4,6,4,1]) -- 4 1</code>
<code>filterfalse()</code>	<code>pred, seq</code>	<code>elements of seq where pred(elem) is False</code>	<code>filterfalse(lambda x: x%2, range(10)) --> 4 6 8</code>
<code>groupby()</code>	<code>iterable[, keyfunc]</code>	<code>sub-iterators grouped by value of keyfunc(v)</code>	
<code>islice()</code>	<code>seq, [start,] stop [, step]</code>	<code>elements from seq[start:stop:step]</code>	<code>islice('ABCDEFGH', 2, None) --> C D E F G</code>
<code>starmap()</code>	<code>func, seq</code>	<code>func(*seq[0]), func(*seq[1]), ...</code>	<code>starmap(pow, [(2,5), (3,2), (10,3)]) --> 9 1000</code>
<code>takewhile()</code>	<code>pred, seq</code>	<code>seq[0], seq[1], until pred fails</code>	<code>takewhile(lambda x: x<5, [1,4,6,4,1]) -- 4</code>
<code>tee()</code>	<code>it, n</code>	<code>it1, it2 , ... itn splits one iterator into n</code>	
<code>zip_longest()</code>	<code>p, q, ...</code>	<code>(p[0], q[0]), (p[1], q[1]), ...</code>	<code>zip_longest('ABCD', 'xy', fillvalue='-') > Ax By C- D-</code>

Combinatoric generators:

Iterator	Arguments	Results
	<code>p, q, ...</code>	<code>cartesian product,</code>

<code>product()</code>	<code>[repeat=1]</code>	equivalent to a nested for-loop
<code>permutations()</code>	<code>p, r]</code>	r-length tuples, all possible orderings, no repeated elements
<code>combinations()</code>	<code>p, r</code>	r-length tuples, in sorted order, no repeated elements
<code>combinations_with_replacement()</code>	<code>p, r</code>	r-length tuples, in sorted order, with repeated elements
<code>product('ABCD', repeat=2)</code>		AA AB AC AD BA BB BC BD CA CB CC CD DA DB DC DD
<code>permutations('ABCD', 2)</code>		AB AC AD BA BC BD CA CB CD DA DB DC
<code>combinations('ABCD', 2)</code>		AB AC AD BC BD CD
<code>combinations_with_replacement('ABCD', 2)</code>		AA AB AC AD BB BC BD CC CD DD

9.1.1. Itertool functions

The following module functions all construct and return iterators. Some provide streams of infinite length, so they should only be accessed by functions or loops that truncate the stream.

`itertools.accumulate(iterable)`

Make an iterator that returns accumulated sums. Elements may be any addable type including `Decimal` or `Fraction`. Equivalent to:

```
def accumulate(iterable):
    'Return running totals'
    # accumulate([1, 2, 3, 4, 5]) --> 1 3 6 10 15
    it = iter(iterable)
    total = next(it)
    yield total
    for element in it:
        total = total + element
        yield total
```

New in version 3.2.

`itertools.chain(*iterables)`

Make an iterator that returns elements from the first iterable until it is exhausted, then proceeds to the next iterable, until all of the iterables are exhausted. Used for treating consecutive sequences as a single sequence. Equivalent to:

```
def chain(*iterables):
    # chain('ABC', 'DEF') --> A B C D E F
    for it in iterables:
        for element in it:
            yield element
```

classmethod `chain.from_iterable(iterable)`

Alternate constructor for `chain()`. Gets chained inputs from a single iterable argument that is evaluated lazily. Equivalent to:

```

@classmethod
def from_iterable(iterables):
    # chain.from_iterable(['ABC', 'DEF']) --> A B C D E F
    for it in iterables:
        for element in it:
            yield element

```

itertools.**combinations**(*iterable*, *r*)

Return *r* length subsequences of elements from the input *iterable*.

Combinations are emitted in lexicographic sort order. So, if the input *iterable* is sorted, the combination tuples will be produced in sorted order.

Elements are treated as unique based on their position, not on their value. So if the input elements are unique, there will be no repeat values in each combination.

Equivalent to:

```

def combinations(iterable, r):
    # combinations('ABCD', 2) --> AB AC AD BC BD CD
    # combinations(range(4), 3) --> 012 013 023 123
    pool = tuple(iterable)
    n = len(pool)
    if r > n:
        return
    indices = list(range(r))
    yield tuple(pool[i] for i in indices)
    while True:
        for i in reversed(range(r)):
            if indices[i] != i + n - r:
                break
        else:
            return
        indices[i] += 1
        for j in range(i+1, r):
            indices[j] = indices[j-1] + 1
        yield tuple(pool[i] for i in indices)

```

The code for `combinations()` can be also expressed as a subsequence of `permutations()` after filtering entries where the elements are not in sorted order (according to their position in the input pool):

```
def combinations(iterable, r):
    pool = tuple(iterable)
    n = len(pool)
    for indices in permutations(range(n), r):
        if sorted(indices) == list(indices):
            yield tuple(pool[i] for i in indices)
```

The number of items returned is $n! / r! / (n-r)!$ when $0 \leq r \leq n$ or zero when $r > n$.

`itertools.combinations_with_replacement(iterable, r)`

Return r length subsequences of elements from the input *iterable* allowing individual elements to be repeated more than once.

Combinations are emitted in lexicographic sort order. So, if the input *iterable* is sorted, the combination tuples will be produced in sorted order.

Elements are treated as unique based on their position, not on their value. So if the input elements are unique, the generated combinations will also be unique.

Equivalent to:

```
def combinations_with_replacement(iterable, r):
    # combinations_with_replacement('ABC', 2) --> AA AB AC B
    pool = tuple(iterable)
    n = len(pool)
    if not n and r:
        return
    indices = [0] * r
    yield tuple(pool[i] for i in indices)
    while True:
        for i in reversed(range(r)):
```

```

        if indices[i] != n - 1:
            break
    else:
        return
    indices[i:] = [indices[i] + 1] * (r - i)
    yield tuple(pool[i] for i in indices)

```

The code for `combinations_with_replacement()` can be also expressed as a subsequence of `product()` after filtering entries where the elements are not in sorted order (according to their position in the input pool):

```

def combinations_with_replacement(iterable, r):
    pool = tuple(iterable)
    n = len(pool)
    for indices in product(range(n), repeat=r):
        if sorted(indices) == list(indices):
            yield tuple(pool[i] for i in indices)

```

The number of items returned is $(n+r-1)! / r! / (n-1)!$ when $n > 0$.

New in version 3.1.

`itertools.compress(data, selectors)`

Make an iterator that filters elements from *data* returning only those that have a corresponding element in *selectors* that evaluates to `True`. Stops when either the *data* or *selectors* iterables has been exhausted. Equivalent to:

```

def compress(data, selectors):
    # compress('ABCDEF', [1,0,1,0,1,1]) --> A C E F
    return (d for d, s in zip(data, selectors) if s)

```

New in version 3.1.

`itertools.count(start=0, step=1)`

Make an iterator that returns evenly spaced values starting with

n. Often used as an argument to `map()` to generate consecutive data points. Also, used with `zip()` to add sequence numbers. Equivalent to:

```
def count(start=0, step=1):
    # count(10) --> 10 11 12 13 14 ...
    # count(2.5, 0.5) -> 2.5 3.0 3.5 ...
    n = start
    while True:
        yield n
        n += step
```

When counting with floating point numbers, better accuracy can sometimes be achieved by substituting multiplicative code such as: `(start + step * i for i in count())`.

Changed in version 3.1: Added *step* argument and allowed non-integer arguments.

`itertools.cycle(iterable)`

Make an iterator returning elements from the iterable and saving a copy of each. When the iterable is exhausted, return elements from the saved copy. Repeats indefinitely. Equivalent to:

```
def cycle(iterable):
    # cycle('ABCD') --> A B C D A B C D A B C D ...
    saved = []
    for element in iterable:
        yield element
        saved.append(element)
    while saved:
        for element in saved:
            yield element
```

Note, this member of the toolkit may require significant auxiliary storage (depending on the length of the iterable).

`itertools.dropwhile(predicate, iterable)`

Make an iterator that drops elements from the iterable as long as

the predicate is true; afterwards, returns every element. Note, the iterator does not produce *any* output until the predicate first becomes false, so it may have a lengthy start-up time. Equivalent to:

```
def dropwhile(predicate, iterable):
    # dropwhile(lambda x: x<5, [1,4,6,4,1]) --> 6 4 1
    iterable = iter(iterable)
    for x in iterable:
        if not predicate(x):
            yield x
            break
    for x in iterable:
        yield x
```

`itertools.filterfalse(predicate, iterable)`

Make an iterator that filters elements from `iterable` returning only those for which the predicate is `False`. If `predicate` is `None`, return the items that are false. Equivalent to:

```
def filterfalse(predicate, iterable):
    # filterfalse(lambda x: x%2, range(10)) --> 0 2 4 6 8
    if predicate is None:
        predicate = bool
    for x in iterable:
        if not predicate(x):
            yield x
```

`itertools.groupby(iterable, key=None)`

Make an iterator that returns consecutive keys and groups from the `iterable`. The `key` is a function computing a key value for each element. If not specified or is `None`, `key` defaults to an identity function and returns the element unchanged. Generally, the `iterable` needs to already be sorted on the same key function.

The operation of `groupby()` is similar to the `uniq` filter in Unix. It generates a break or new group every time the value of the key function changes (which is why it is usually necessary to have

sorted the data using the same key function). That behavior differs from SQL's GROUP BY which aggregates common elements regardless of their input order.

The returned group is itself an iterator that shares the underlying iterable with `groupby()`. Because the source is shared, when the `groupby()` object is advanced, the previous group is no longer visible. So, if that data is needed later, it should be stored as a list:

```
groups = []
uniquekeys = []
data = sorted(data, key=keyfunc)
for k, g in groupby(data, keyfunc):
    groups.append(list(g))      # Store group iterator as a
    uniquekeys.append(k)
```

`groupby()` is equivalent to:

```
class groupby:
    # [k for k, g in groupby('AAAABBBCCDAABBB')] --> A B C D
    # [list(g) for k, g in groupby('AAAABBBCCD')] --> AAAA B
    def __init__(self, iterable, key=None):
        if key is None:
            key = lambda x: x
        self.keyfunc = key
        self.it = iter(iterable)
        self.tgtkey = self.currkey = self.currvalue = object()
    def __iter__(self):
        return self
    def __next__(self):
        while self.currkey == self.tgtkey:
            self.currvalue = next(self.it) # Exit on Stop
            self.currkey = self.keyfunc(self.currvalue)
        self.tgtkey = self.currkey
        return (self.currkey, self._grouper(self.tgtkey))
    def _grouper(self, tgtkey):
        while self.currkey == tgtkey:
            yield self.currvalue
            self.currvalue = next(self.it) # Exit on Stop
            self.currkey = self.keyfunc(self.currvalue)
```

`itertools.islice(iterable[, start], stop[, step])`

Make an iterator that returns selected elements from the iterable. If *start* is non-zero, then elements from the iterable are skipped until *start* is reached. Afterward, elements are returned consecutively unless *step* is set higher than one which results in items being skipped. If *stop* is `None`, then iteration continues until the iterator is exhausted, if at all; otherwise, it stops at the specified position. Unlike regular slicing, `islice()` does not support negative values for *start*, *stop*, or *step*. Can be used to extract related fields from data where the internal structure has been flattened (for example, a multi-line report may list a name field on every third line). Equivalent to:

```
def islice(iterable, *args):
    # islice('ABCDEFGH', 2) --> A B
    # islice('ABCDEFGH', 2, 4) --> C D
    # islice('ABCDEFGH', 2, None) --> C D E F G
    # islice('ABCDEFGH', 0, None, 2) --> A C E G
    s = slice(*args)
    it = iter(range(s.start or 0, s.stop or sys.maxsize, s.step))
    nexti = next(it)
    for i, element in enumerate(iterable):
        if i == nexti:
            yield element
            nexti = next(it)
```

If *start* is `None`, then iteration starts at zero. If *step* is `None`, then the step defaults to one.

`itertools.permutations(iterable, r=None)`

Return successive *r* length permutations of elements in the *iterable*.

If *r* is not specified or is `None`, then *r* defaults to the length of the *iterable* and all possible full-length permutations are generated.

Permutations are emitted in lexicographic sort order. So, if the input *iterable* is sorted, the permutation tuples will be produced in sorted order.

Elements are treated as unique based on their position, not on their value. So if the input elements are unique, there will be no repeat values in each permutation.

Equivalent to:

```
def permutations(iterable, r=None):
    # permutations('ABCD', 2) --> AB AC AD BA BC BD CA CB CD
    # permutations(range(3)) --> 012 021 102 120 201 210
    pool = tuple(iterable)
    n = len(pool)
    r = n if r is None else r
    if r > n:
        return
    indices = list(range(n))
    cycles = range(n, n-r, -1)
    yield tuple(pool[i] for i in indices[:r])
    while n:
        for i in reversed(range(r)):
            cycles[i] -= 1
            if cycles[i] == 0:
                indices[i:] = indices[i+1:] + indices[i:i+1]
                cycles[i] = n - i
            else:
                j = cycles[i]
                indices[i], indices[-j] = indices[-j], indices[i]
                yield tuple(pool[i] for i in indices[:r])
                break
        else:
            return
```

The code for `permutations()` can be also expressed as a subsequence of `product()`, filtered to exclude entries with repeated elements (those from the same position in the input pool):

```
def permutations(iterable, r=None):
```

```

pool = tuple(iterable)
n = len(pool)
r = n if r is None else r
for indices in product(range(n), repeat=r):
    if len(set(indices)) == r:
        yield tuple(pool[i] for i in indices)

```

The number of items returned is $n! / (n-r)!$ when $0 \leq r \leq n$ or zero when $r > n$.

`itertools.product(*iterables, repeat=1)`

Cartesian product of input iterables.

Equivalent to nested for-loops in a generator expression. For example, `product(A, B)` returns the same as `((x,y) for x in A for y in B)`.

The nested loops cycle like an odometer with the rightmost element advancing on every iteration. This pattern creates a lexicographic ordering so that if the input's iterables are sorted, the product tuples are emitted in sorted order.

To compute the product of an iterable with itself, specify the number of repetitions with the optional `repeat` keyword argument. For example, `product(A, repeat=4)` means the same as `product(A, A, A, A)`.

This function is equivalent to the following code, except that the actual implementation does not build up intermediate results in memory:

```

def product(*args, repeat=1):
    # product('ABCD', 'xy') --> Ax Ay Bx By Cx Cy Dx Dy
    # product(range(2), repeat=3) --> 000 001 010 011 100 10
    pools = [tuple(pool) for pool in args] * repeat
    result = [[]]
    for pool in pools:
        result = [x+[y] for x in result for y in pool]

```

```
for prod in result:
    yield tuple(prod)
```

`itertools.repeat(object[, times])`

Make an iterator that returns *object* over and over again. Runs indefinitely unless the *times* argument is specified. Used as argument to `map()` for invariant parameters to the called function. Also used with `zip()` to create an invariant part of a tuple record. Equivalent to:

```
def repeat(object, times=None):
    # repeat(10, 3) --> 10 10 10
    if times is None:
        while True:
            yield object
    else:
        for i in range(times):
            yield object
```

`itertools.starmap(function, iterable)`

Make an iterator that computes the function using arguments obtained from the iterable. Used instead of `map()` when argument parameters are already grouped in tuples from a single iterable (the data has been “pre-zipped”). The difference between `map()` and `starmap()` parallels the distinction between `function(a,b)` and `function(*c)`. Equivalent to:

```
def starmap(function, iterable):
    # starmap(pow, [(2,5), (3,2), (10,3)]) --> 32 9 1000
    for args in iterable:
        yield function(*args)
```

`itertools.takewhile(predicate, iterable)`

Make an iterator that returns elements from the iterable as long as the predicate is true. Equivalent to:

```

def takewhile(predicate, iterable):
    # takewhile(lambda x: x<5, [1,4,6,4,1]) --> 1 4
    for x in iterable:
        if predicate(x):
            yield x
        else:
            break

```

`itertools.tee(iterable, n=2)`

Return *n* independent iterators from a single iterable. Equivalent to:

```

def tee(iterable, n=2):
    it = iter(iterable)
    deques = [collections.deque() for i in range(n)]
    def gen(mydeque):
        while True:
            if not mydeque:           # when the local deque
                newval = next(it)     # fetch a new value
                for d in deques:      # load it to all the
                    d.append(newval)
            yield mydeque.popleft()
    return tuple(gen(d) for d in deques)

```

Once `tee()` has made a split, the original *iterable* should not be used anywhere else; otherwise, the *iterable* could get advanced without the tee objects being informed.

This iterator may require significant auxiliary storage (depending on how much temporary data needs to be stored). In general, if one iterator uses most or all of the data before another iterator starts, it is faster to use `list()` instead of `tee()`.

`itertools.zip_longest(*iterables, fillvalue=None)`

Make an iterator that aggregates elements from each of the iterables. If the iterables are of uneven length, missing values are filled-in with *fillvalue*. Iteration continues until the longest iterable is exhausted. Equivalent to:

```
def zip_longest(*args, fillvalue=None):
    # zip_longest('ABCD', 'xy', fillvalue='-') --> Ax By C-
    def sentinel(counter = ([fillvalue]*(len(args)-1)).pop):
        yield counter()          # yields the fillvalue, or r
    fillers = repeat(fillvalue)
    iters = [chain(it, sentinel(), fillers) for it in args]
    try:
        for tup in zip(*iters):
            yield tup
    except IndexError:
        pass
```

If one of the iterables is potentially infinite, then the `zip_longest()` function should be wrapped with something that limits the number of calls (for example `islice()` or `takewhile()`). If not specified, *fillvalue* defaults to `None`.

9.1.2. Itertools Recipes

This section shows recipes for creating an extended toolset using the existing itertools as building blocks.

The extended tools offer the same high performance as the underlying toolset. The superior memory performance is kept by processing elements one at a time rather than bringing the whole iterable into memory all at once. Code volume is kept small by linking the tools together in a functional style which helps eliminate temporary variables. High speed is retained by preferring “vectorized” building blocks over the use of for-loops and *generators* which incur interpreter overhead.

```
def take(n, iterable):
    "Return first n items of the iterable as a list"
    return list(islice(iterable, n))

def tabulate(function, start=0):
    "Return function(0), function(1), ..."
    return map(function, count(start))

def consume(iterator, n):
    "Advance the iterator n-steps ahead. If n is none, consume
    # Use functions that consume iterators at C speed.
    if n is None:
        # feed the entire iterator into a zero-length deque
        collections.deque(iterator, maxlen=0)
    else:
        # advance to the empty slice starting at position n
        next(islice(iterator, n, n), None)

def nth(iterable, n, default=None):
    "Returns the nth item or a default value"
    return next(islice(iterable, n, None), default)

def quantify(iterable, pred=bool):
    "Count how many times the predicate is true"
    return sum(map(pred, iterable))
```

```

def padnone(iterable):
    """Returns the sequence elements and then returns None inde

    Useful for emulating the behavior of the built-in map() fun
    """
    return chain(iterable, repeat(None))

def ncycles(iterable, n):
    "Returns the sequence elements n times"
    return chain.from_iterable(repeat(tuple(iterable), n))

def dotproduct(vec1, vec2):
    return sum(map(operator.mul, vec1, vec2))

def flatten(listOfLists):
    "Flatten one level of nesting"
    return chain.from_iterable(listOfLists)

def repeatfunc(func, times=None, *args):
    """Repeat calls to func with specified arguments.

    Example:  repeatfunc(random.random)
    """
    if times is None:
        return starmap(func, repeat(args))
    return starmap(func, repeat(args, times))

def pairwise(iterable):
    "s -> (s0,s1), (s1,s2), (s2, s3), ..."
    a, b = tee(iterable)
    next(b, None)
    return zip(a, b)

def grouper(n, iterable, fillvalue=None):
    "grouper(3, 'ABCDEFG', 'x') --> ABC DEF Gxx"
    args = [iter(iterable)] * n
    return zip_longest(*args, fillvalue=fillvalue)

def roundrobin(*iterables):
    "roundrobin('ABC', 'D', 'EF') --> A D E B F C"
    # Recipe credited to George Sakkis
    pending = len(iterables)
    nexts = cycle(iter(it).__next__ for it in iterables)
    while pending:
        try:
            for next in nexts:
                yield next()
        except StopIteration:
            pending -= 1
            nexts = cycle(nexts)

```

```

    except StopIteration:
        pending -= 1
        nexts = cycle(islice(nexts, pending))

def partition(pred, iterable):
    'Use a predicate to partition entries into false entries and
    # partition(is_odd, range(10)) --> 0 2 4 6 8 and 1 3 5 7
    t1, t2 = tee(iterable)
    return filterfalse(pred, t1), filter(pred, t2)

def powerset(iterable):
    "powerset([1,2,3]) --> () (1,) (2,) (3,) (1,2) (1,3) (2,3)
    s = list(iterable)
    return chain.from_iterable(combinations(s, r) for r in range(0, len(s)+1))

def unique_everseen(iterable, key=None):
    "List unique elements, preserving order. Remember all elements
    # unique_everseen('AAAABBBCCDAABBB') --> A B C D
    # unique_everseen('ABBCcAD', str.lower) --> A B C D
    seen = set()
    seen_add = seen.add
    if key is None:
        for element in filterfalse(seen.__contains__, iterable):
            seen_add(element)
            yield element
    else:
        for element in iterable:
            k = key(element)
            if k not in seen:
                seen_add(k)
                yield element

def unique_justseen(iterable, key=None):
    "List unique elements, preserving order. Remember only the
    # unique_justseen('AAAABBBCCDAABBB') --> A B C D A B
    # unique_justseen('ABBCcAD', str.lower) --> A B C A D
    return map(next, map(itemgetter(1), groupby(iterable, key)))

def iter_except(func, exception, first=None):
    """ Call a function repeatedly until an exception is raised

    Converts a call-until-exception interface to an iterator in
    Like __builtin__.iter(func, sentinel) but uses an exception
    of a sentinel to end the loop.

    Examples:
        iter_except(functools.partial(heapop, h), IndexError)

```

```

    iter_except(d.popitem, KeyError)
    iter_except(d.popleft, IndexError)
    iter_except(q.get_nowait, Queue.Empty)
    iter_except(s.pop, KeyError)

    """
    try:
        if first is not None:
            yield first()           # For database APIs needing
        while 1:
            yield func()
    except exception:
        pass

def random_product(*args, repeat=1):
    "Random selection from itertools.product(*args, **kwargs)"
    pools = [tuple(pool) for pool in args] * repeat
    return tuple(random.choice(pool) for pool in pools)

def random_permutation(iterable, r=None):
    "Random selection from itertools.permutations(iterable, r)"
    pool = tuple(iterable)
    r = len(pool) if r is None else r
    return tuple(random.sample(pool, r))

def random_combination(iterable, r):
    "Random selection from itertools.combinations(iterable, r)"
    pool = tuple(iterable)
    n = len(pool)
    indices = sorted(random.sample(range(n), r))
    return tuple(pool[i] for i in indices)

def random_combination_with_replacement(iterable, r):
    "Random selection from itertools.combinations_with_replacement"
    pool = tuple(iterable)
    n = len(pool)
    indices = sorted(random.randrange(n) for i in range(r))
    return tuple(pool[i] for i in indices)

```

Note, many of the above recipes can be optimized by replacing global lookups with local variables defined as default values. For example, the *dotproduct* recipe can be written as:

```

def dotproduct(vec1, vec2, sum=sum, map=map, mul=operator.mul):

```

```
return sum(map(mul, vec1, vec2))
```

 [Python v3.2 documentation](#) » [The Python Standard Library](#) [previous](#) | [next](#) | [modules](#) | [index](#)
» [9. Functional Programming Modules](#) »

9.2. `functools` — Higher order functions and operations on callable objects

Source code: [Lib/functools.py](#)

The `functools` module is for higher-order functions: functions that act on or return other functions. In general, any callable object can be treated as a function for the purposes of this module.

The `functools` module defines the following functions:

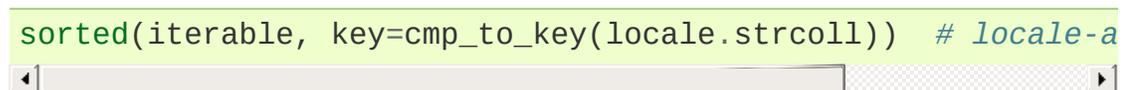

`functools.cmp_to_key(func)`

Transform an old-style comparison function to a key-function. Used with tools that accept key functions (such as `sorted()`, `min()`, `max()`, `heapq.nlargest()`, `heapq.nsmallest()`, `itertools.groupby()`). This function is primarily used as a transition tool for programs being converted from Py2.x which supported the use of comparison functions.

A compare function is any callable that accept two arguments, compares them, and returns a negative number for less-than, zero for equality, or a positive number for greater-than. A key function is a callable that accepts one argument and returns another value indicating the position in the desired collation sequence.

Example:

```
sorted(iterable, key=cmp_to_key(locale.strcoll)) # locale-a
```

New in version 3.2.

`@functools.lru_cache(maxsize=100)`

Decorator to wrap a function with a memoizing callable that saves up to the *maxsize* most recent calls. It can save time when an expensive or I/O bound function is periodically called with the same arguments.

Since a dictionary is used to cache results, the positional and keyword arguments to the function must be hashable.

If *maxsize* is set to None, the LRU feature is disabled and the cache can grow without bound.

To help measure the effectiveness of the cache and tune the *maxsize* parameter, the wrapped function is instrumented with a `cache_info()` function that returns a *named tuple* showing *hits*, *misses*, *maxsize* and *currsz*. In a multi-threaded environment, the hits and misses are approximate.

The decorator also provides a `cache_clear()` function for clearing or invalidating the cache.

The original underlying function is accessible through the `__wrapped__` attribute. This is useful for introspection, for bypassing the cache, or for rewrapping the function with a different cache.

An *LRU (least recently used) cache* works best when more recent calls are the best predictors of upcoming calls (for example, the most popular articles on a news server tend to change daily). The cache's size limit assures that the cache does not grow without bound on long-running processes such as web servers.

Example of an LRU cache for static web content:

```
@lru_cache(maxsize=20)
def get_pep(num):
    'Retrieve text of a Python Enhancement Proposal'
    resource = 'http://www.python.org/dev/peps/pep-%04d/' %
    try:
        with urllib.request.urlopen(resource) as s:
            return s.read()
    except urllib.error.HTTPError:
        return 'Not Found'

>>> for n in 8, 290, 308, 320, 8, 218, 320, 279, 289, 320, 9
...     pep = get_pep(n)
...     print(n, len(pep))

>>> print(get_pep.cache_info())
CacheInfo(hits=3, misses=8, maxsize=20, cursize=8)
```

Example of efficiently computing Fibonacci numbers using a cache to implement a dynamic programming technique:

```
@lru_cache(maxsize=None)
def fib(n):
    if n < 2:
        return n
    return fib(n-1) + fib(n-2)

>>> print([fib(n) for n in range(16)])
[0, 1, 1, 2, 3, 5, 8, 13, 21, 34, 55, 89, 144, 233, 377, 610]

>>> print(fib.cache_info())
CacheInfo(hits=28, misses=16, maxsize=None, cursize=16)
```

New in version 3.2.

@functools.total_ordering

Given a class defining one or more rich comparison ordering methods, this class decorator supplies the rest. This simplifies the effort involved in specifying all of the possible rich comparison operations:

The class must define one of `__lt__()`, `__le__()`, `__gt__()`, or `__ge__()`. In addition, the class should supply an `__eq__()` method.

For example:

```
@total_ordering
class Student:
    def __eq__(self, other):
        return ((self.lastname.lower(), self.firstname.lower()
                (other.lastname.lower(), other.firstname.lower()

    def __lt__(self, other):
        return ((self.lastname.lower(), self.firstname.lower()
                (other.lastname.lower(), other.firstname.lower()
```

New in version 3.2.

`functools.partial(func, *args, **keywords)`

Return a new `partial` object which when called will behave like `func` called with the positional arguments `args` and keyword arguments `keywords`. If more arguments are supplied to the call, they are appended to `args`. If additional keyword arguments are supplied, they extend and override `keywords`. Roughly equivalent to:

```
def partial(func, *args, **keywords):
    def newfunc(*fargs, **fkeywords):
        newkeywords = keywords.copy()
        newkeywords.update(fkeywords)
        return func(*(args + fargs), **newkeywords)
    newfunc.func = func
    newfunc.args = args
    newfunc.keywords = keywords
    return newfunc
```

The `partial()` is used for partial function application which “freezes” some portion of a function’s arguments and/or keywords resulting in a new object with a simplified signature. For

example, `partial()` can be used to create a callable that behaves like the `int()` function where the `base` argument defaults to two:

```
>>> from functools import partial
>>> basetwo = partial(int, base=2)
>>> basetwo.__doc__ = 'Convert base 2 string to an int.'
>>> basetwo('10010')
18
```

`functools.reduce(function, iterable[, initializer])`

Apply *function* of two arguments cumulatively to the items of *sequence*, from left to right, so as to reduce the sequence to a single value. For example, `reduce(lambda x, y: x+y, [1, 2, 3, 4, 5])` calculates `((((1+2)+3)+4)+5)`. The left argument, *x*, is the accumulated value and the right argument, *y*, is the update value from the *sequence*. If the optional *initializer* is present, it is placed before the items of the sequence in the calculation, and serves as a default when the sequence is empty. If *initializer* is not given and *sequence* contains only one item, the first item is returned.

`functools.update_wrapper(wrapper, wrapped, assigned=WRAPPER_ASSIGNMENTS, updated=WRAPPER_UPDATES)`

Update a *wrapper* function to look like the *wrapped* function. The optional arguments are tuples to specify which attributes of the original function are assigned directly to the matching attributes on the wrapper function and which attributes of the wrapper function are updated with the corresponding attributes from the original function. The default values for these arguments are the module level constants `WRAPPER_ASSIGNMENTS` (which assigns to the wrapper function's `__name__`, `__module__`, `__annotations__` and `__doc__`, the documentation string) and `WRAPPER_UPDATES` (which updates the wrapper function's `__dict__`, i.e. the instance dictionary).

To allow access to the original function for introspection and other purposes (e.g. bypassing a caching decorator such as `lru_cache()`), this function automatically adds a `__wrapped__` attribute to the wrapper that refers to the original function.

The main intended use for this function is in *decorator* functions which wrap the decorated function and return the wrapper. If the wrapper function is not updated, the metadata of the returned function will reflect the wrapper definition rather than the original function definition, which is typically less than helpful.

`update_wrapper()` may be used with callables other than functions. Any attributes named in *assigned* or *updated* that are missing from the object being wrapped are ignored (i.e. this function will not attempt to set them on the wrapper function). `AttributeError` is still raised if the wrapper function itself is missing any attributes named in *updated*.

New in version 3.2: Automatic addition of the `__wrapped__` attribute.

New in version 3.2: Copying of the `__annotations__` attribute by default.

Changed in version 3.2: Missing attributes no longer trigger an `AttributeError`.

```
@functools.wraps(wrapped,  
assigned=WRAPPER_ASSIGNMENTS,  
updated=WRAPPER_UPDATES)
```

This is a convenience function for invoking `partial(update_wrapper, wrapped=wrapped, assigned=assigned, updated=updated)` as a function decorator when defining a wrapper function. For example:

```
>>> from functools import wraps
>>> def my_decorator(f):
...     @wraps(f)
...     def wrapper(*args, **kwargs):
...         print('Calling decorated function')
...         return f(*args, **kwargs)
...     return wrapper
...
>>> @my_decorator
... def example():
...     """Docstring"""
...     print('Called example function')
...
>>> example()
Calling decorated function
Called example function
>>> example.__name__
'example'
>>> example.__doc__
'Docstring'
```

Without the use of this decorator factory, the name of the example function would have been `'wrapper'`, and the docstring of the original `example()` would have been lost.

9.2.1. `partial` Objects

`partial` objects are callable objects created by `partial()`. They have three read-only attributes:

`partial.func`

A callable object or function. Calls to the `partial` object will be forwarded to `func` with new arguments and keywords.

`partial.args`

The leftmost positional arguments that will be prepended to the positional arguments provided to a `partial` object call.

`partial.keywords`

The keyword arguments that will be supplied when the `partial` object is called.

`partial` objects are like `function` objects in that they are callable, weak referencable, and can have attributes. There are some important differences. For instance, the `__name__` and `__doc__` attributes are not created automatically. Also, `partial` objects defined in classes behave like static methods and do not transform into bound methods during instance attribute look-up.

9.3. operator — Standard operators as functions

The `operator` module exports a set of functions implemented in C corresponding to the intrinsic operators of Python. For example, `operator.add(x, y)` is equivalent to the expression `x+y`. The function names are those used for special class methods; variants without leading and trailing `_` are also provided for convenience.

The functions fall into categories that perform object comparisons, logical operations, mathematical operations and sequence operations.

The object comparison functions are useful for all objects, and are named after the rich comparison operators they support:

```
operator.lt(a, b)
operator.le(a, b)
operator.eq(a, b)
operator.ne(a, b)
operator.ge(a, b)
operator.gt(a, b)
operator.__lt__(a, b)
operator.__le__(a, b)
operator.__eq__(a, b)
operator.__ne__(a, b)
operator.__ge__(a, b)
operator.__gt__(a, b)
```

Perform “rich comparisons” between `a` and `b`. Specifically, `lt(a, b)` is equivalent to `a < b`, `le(a, b)` is equivalent to `a <= b`, `eq(a, b)` is equivalent to `a == b`, `ne(a, b)` is equivalent to `a != b`, `gt(a, b)` is equivalent to `a > b` and `ge(a, b)` is equivalent to `a >= b`.

Note that these functions can return any value, which may or may not be interpretable as a Boolean value. See [Comparisons](#) for more information about rich comparisons.

The logical operations are also generally applicable to all objects, and support truth tests, identity tests, and boolean operations:

operator.**not_**(*obj*)

operator.**__not__**(*obj*)

Return the outcome of **not** *obj*. (Note that there is no **__not__**() method for object instances; only the interpreter core defines this operation. The result is affected by the **__bool__**() and **__len__**() methods.)

operator.**truth**(*obj*)

Return **True** if *obj* is true, and **False** otherwise. This is equivalent to using the **bool** constructor.

operator.**is_**(*a*, *b*)

Return **a is b**. Tests object identity.

operator.**is_not**(*a*, *b*)

Return **a is not b**. Tests object identity.

The mathematical and bitwise operations are the most numerous:

operator.**abs**(*obj*)

operator.**__abs__**(*obj*)

Return the absolute value of *obj*.

operator.**add**(*a*, *b*)

operator.**__add__**(*a*, *b*)

Return **a + b**, for *a* and *b* numbers.

operator.**and**(*a*, *b*)

operator.**__and__**(*a*, *b*)

Return the bitwise and of *a* and *b*.

operator.**floordiv**(*a*, *b*)

operator.**__floordiv__**(*a*, *b*)

Return $a // b$.

operator.**index**(*a*)

operator.**__index__**(*a*)

Return *a* converted to an integer. Equivalent to `a.__index__()`.

operator.**inv**(*obj*)

operator.**invert**(*obj*)

operator.**__inv__**(*obj*)

operator.**__invert__**(*obj*)

Return the bitwise inverse of the number *obj*. This is equivalent to $\sim obj$.

operator.**lshift**(*a*, *b*)

operator.**__lshift__**(*a*, *b*)

Return *a* shifted left by *b*.

operator.**mod**(*a*, *b*)

operator.**__mod__**(*a*, *b*)

Return $a \% b$.

operator.**mul**(*a*, *b*)

operator.**__mul__**(*a*, *b*)

Return $a * b$, for *a* and *b* numbers.

operator.**neg**(*obj*)

operator.**__neg__**(*obj*)

Return *obj* negated (`-obj`).

operator . **or**(*a*, *b*)

operator . **__or__**(*a*, *b*)

Return the bitwise or of *a* and *b*.

operator . **pos**(*obj*)

operator . **__pos__**(*obj*)

Return *obj* positive (`+obj`).

operator . **pow**(*a*, *b*)

operator . **__pow__**(*a*, *b*)

Return `a ** b`, for *a* and *b* numbers.

operator . **rshift**(*a*, *b*)

operator . **__rshift__**(*a*, *b*)

Return *a* shifted right by *b*.

operator . **sub**(*a*, *b*)

operator . **__sub__**(*a*, *b*)

Return `a - b`.

operator . **truediv**(*a*, *b*)

operator . **__truediv__**(*a*, *b*)

Return `a / b` where `2/3` is `.66` rather than `0`. This is also known as “true” division.

operator . **xor**(*a*, *b*)

operator . **__xor__**(*a*, *b*)

Return the bitwise exclusive or of *a* and *b*.

Operations which work with sequences (some of them with mappings too) include:

operator.**concat**(*a*, *b*)

operator.**__concat__**(*a*, *b*)

Return *a* + *b* for *a* and *b* sequences.

operator.**contains**(*a*, *b*)

operator.**__contains__**(*a*, *b*)

Return the outcome of the test *b* in *a*. Note the reversed operands.

operator.**countOf**(*a*, *b*)

Return the number of occurrences of *b* in *a*.

operator.**delitem**(*a*, *b*)

operator.**__delitem__**(*a*, *b*)

Remove the value of *a* at index *b*.

operator.**getitem**(*a*, *b*)

operator.**__getitem__**(*a*, *b*)

Return the value of *a* at index *b*.

operator.**indexOf**(*a*, *b*)

Return the index of the first of occurrence of *b* in *a*.

operator.**setitem**(*a*, *b*, *c*)

operator.**__setitem__**(*a*, *b*, *c*)

Set the value of *a* at index *b* to *c*.

Example: Build a dictionary that maps the ordinals from 0 to 255 to their character equivalents.

```
>>> d = {}
>>> keys = range(256)
>>> vals = map(chr, keys)
>>> map(operator.setitem, [d]*len(keys), keys, vals)
```

The `operator` module also defines tools for generalized attribute and item lookups. These are useful for making fast field extractors as arguments for `map()`, `sorted()`, `itertools.groupby()`, or other functions that expect a function argument.

`operator.attrgetter(attr[, args...])`

Return a callable object that fetches `attr` from its operand. If more than one attribute is requested, returns a tuple of attributes. After, `f = attrgetter('name')`, the call `f(b)` returns `b.name`. After, `f = attrgetter('name', 'date')`, the call `f(b)` returns `(b.name, b.date)`. Equivalent to:

```
def attrgetter(*items):
    if any(not isinstance(item, str) for item in items):
        raise TypeError('attribute name must be a string')
    if len(items) == 1:
        attr = items[0]
        def g(obj):
            return resolve_attr(obj, attr)
    else:
        def g(obj):
            return tuple(resolve_attr(obj, attr) for attr in items)
    return g

def resolve_attr(obj, attr):
    for name in attr.split("."):
        obj = getattr(obj, name)
    return obj
```

The attribute names can also contain dots; after `f = attrgetter('date.month')`, the call `f(b)` returns `b.date.month`.

`operator.itemgetter(item[, args...])`

Return a callable object that fetches `item` from its operand using the operand's `__getitem__()` method. If multiple items are specified, returns a tuple of lookup values. Equivalent to:

```

def itemgetter(*items):
    if len(items) == 1:
        item = items[0]
        def g(obj):
            return obj[item]
    else:
        def g(obj):
            return tuple(obj[item] for item in items)
    return g

```

The items can be any type accepted by the operand's `__getitem__()` method. Dictionaries accept any hashable value. Lists, tuples, and strings accept an index or a slice:

```

>>> itemgetter(1)('ABCDEFGH')
'B'
>>> itemgetter(1,3,5)('ABCDEFGH')
('B', 'D', 'F')
>>> itemgetter(slice(2, None))('ABCDEFGH')
'CDEFGH'

```

Example of using `itemgetter()` to retrieve specific fields from a tuple record:

```

>>> inventory = [('apple', 3), ('banana', 2), ('pear', 5), ('orange', 1)]
>>> getcount = itemgetter(1)
>>> list(map(getcount, inventory))
[3, 2, 5, 1]
>>> sorted(inventory, key=getcount)
[('orange', 1), ('banana', 2), ('apple', 3), ('pear', 5)]

```

`operator.methodcaller(name[, args...])`

Return a callable object that calls the method `name` on its operand. If additional arguments and/or keyword arguments are given, they will be given to the method as well. After `f = methodcaller('name')`, the call `f(b)` returns `b.name()`. After `f = methodcaller('name', 'foo', bar=1)`, the call `f(b)` returns `b.name('foo', bar=1)`. Equivalent to:

```
def methodcaller(name, *args, **kwargs):  
    def caller(obj):  
        return getattr(obj, name)(*args, **kwargs)  
    return caller
```

9.3.1. Mapping Operators to Functions

This table shows how abstract operations correspond to operator symbols in the Python syntax and the functions in the `operator` module.

Operation	Syntax	Function
Addition	<code>a + b</code>	<code>add(a, b)</code>
Concatenation	<code>seq1 + seq2</code>	<code>concat(seq1, seq2)</code>
Containment Test	<code>obj in seq</code>	<code>contains(seq, obj)</code>
Division	<code>a / b</code>	<code>div(a, b)</code>
Division	<code>a // b</code>	<code>floordiv(a, b)</code>
Bitwise And	<code>a & b</code>	<code>and_(a, b)</code>
Bitwise Exclusive Or	<code>a ^ b</code>	<code>xor(a, b)</code>
Bitwise Inversion	<code>~ a</code>	<code>invert(a)</code>
Bitwise Or	<code>a b</code>	<code>or_(a, b)</code>
Exponentiation	<code>a ** b</code>	<code>pow(a, b)</code>
Identity	<code>a is b</code>	<code>is_(a, b)</code>
Identity	<code>a is not b</code>	<code>is_not(a, b)</code>
Indexed Assignment	<code>obj[k] = v</code>	<code>setitem(obj, k, v)</code>
Indexed Deletion	<code>del obj[k]</code>	<code>delitem(obj, k)</code>
Indexing	<code>obj[k]</code>	<code>getitem(obj, k)</code>
Left Shift	<code>a << b</code>	<code>lshift(a, b)</code>
Modulo	<code>a % b</code>	<code>mod(a, b)</code>
Multiplication	<code>a * b</code>	<code>mul(a, b)</code>
Negation (Arithmetic)	<code>- a</code>	<code>neg(a)</code>

Negation (Logical)	<code>not a</code>	<code>not_(a)</code>
Positive	<code>+ a</code>	<code>pos(a)</code>
Right Shift	<code>a >> b</code>	<code>rshift(a, b)</code>
Sequence Repetition	<code>seq * i</code>	<code>repeat(seq, i)</code>
Slice Assignment	<code>seq[i:j] = values</code>	<code>setitem(seq, slice(i, j), values)</code>
Slice Deletion	<code>del seq[i:j]</code>	<code>delitem(seq, slice(i, j))</code>
Slicing	<code>seq[i:j]</code>	<code>getitem(seq, slice(i, j))</code>
String Formatting	<code>s % obj</code>	<code>mod(s, obj)</code>
Subtraction	<code>a - b</code>	<code>sub(a, b)</code>
Truth Test	<code>obj</code>	<code>truth(obj)</code>
Ordering	<code>a < b</code>	<code>lt(a, b)</code>
Ordering	<code>a <= b</code>	<code>le(a, b)</code>
Equality	<code>a == b</code>	<code>eq(a, b)</code>
Difference	<code>a != b</code>	<code>ne(a, b)</code>
Ordering	<code>a >= b</code>	<code>ge(a, b)</code>
Ordering	<code>a > b</code>	<code>gt(a, b)</code>

9.4. Inplace Operators

Many operations have an “in-place” version. Listed below are functions providing a more primitive access to in-place operators than the usual syntax does; for example, the *statement* `x += y` is equivalent to `x = operator.iadd(x, y)`. Another way to put it is to say that `z = operator.iadd(x, y)` is equivalent to the compound statement `z = x; z += y`.

In those examples, note that when an in-place method is called, the computation and assignment are performed in two separate steps. The in-place functions listed below only do the first step, calling the in-place method. The second step, assignment, is not handled.

For immutable targets such as strings, numbers, and tuples, the updated value is computed, but not assigned back to the input variable:

```
>>> a = 'hello'
>>> iadd(a, ' world')
'hello world'
>>> a
'hello'
```

For mutable targets such as lists and dictionaries, the inplace method will perform the update, so no subsequent assignment is necessary:

```
>>> s = ['h', 'e', 'l', 'l', 'o']
>>> iadd(s, [' ', 'w', 'o', 'r', 'l', 'd'])
['h', 'e', 'l', 'l', 'o', ' ', 'w', 'o', 'r', 'l', 'd']
>>> s
['h', 'e', 'l', 'l', 'o', ' ', 'w', 'o', 'r', 'l', 'd']
```

`operator.iadd(a, b)`

`operator.__iadd__(a, b)`

`a = iadd(a, b)` is equivalent to `a += b`.

operator. **iand**(*a*, *b*)

operator. **__iand__**(*a*, *b*)

`a = iand(a, b)` is equivalent to `a &= b`.

operator. **iconcat**(*a*, *b*)

operator. **__iconcat__**(*a*, *b*)

`a = iconcat(a, b)` is equivalent to `a += b` for *a* and *b* sequences.

operator. **ifloordiv**(*a*, *b*)

operator. **__ifloordiv__**(*a*, *b*)

`a = ifloordiv(a, b)` is equivalent to `a //= b`.

operator. **ilshift**(*a*, *b*)

operator. **__ilshift__**(*a*, *b*)

`a = ilshift(a, b)` is equivalent to `a <<= b`.

operator. **imod**(*a*, *b*)

operator. **__imod__**(*a*, *b*)

`a = imod(a, b)` is equivalent to `a %= b`.

operator. **imul**(*a*, *b*)

operator. **__imul__**(*a*, *b*)

`a = imul(a, b)` is equivalent to `a *= b`.

operator. **ior**(*a*, *b*)

operator. **__ior__**(*a*, *b*)

`a = ior(a, b)` is equivalent to `a |= b`.

operator. **ipow**(*a*, *b*)

operator. **__ipow__**(*a*, *b*)

`a = ipow(a, b)` is equivalent to `a **= b`.

`operator.irshift(a, b)`

`operator.__irshift__(a, b)`

`a = irshift(a, b)` is equivalent to `a >>= b`.

`operator.isub(a, b)`

`operator.__isub__(a, b)`

`a = isub(a, b)` is equivalent to `a -= b`.

`operator.itruediv(a, b)`

`operator.__itruediv__(a, b)`

`a = itrueidiv(a, b)` is equivalent to `a /= b`.

`operator.ixor(a, b)`

`operator.__ixor__(a, b)`

`a = ixor(a, b)` is equivalent to `a ^= b`.

10. File and Directory Access

The modules described in this chapter deal with disk files and directories. For example, there are modules for reading the properties of files, manipulating paths in a portable way, and creating temporary files. The full list of modules in this chapter is:

- 10.1. `os.path` — Common pathname manipulations
- 10.2. `fileinput` — Iterate over lines from multiple input streams
- 10.3. `stat` — Interpreting `stat()` results
- 10.4. `filecmp` — File and Directory Comparisons
 - 10.4.1. The `dircmp` class
- 10.5. `tempfile` — Generate temporary files and directories
 - 10.5.1. Examples
- 10.6. `glob` — Unix style pathname pattern expansion
- 10.7. `fnmatch` — Unix filename pattern matching
- 10.8. `linecache` — Random access to text lines
- 10.9. `shutil` — High-level file operations
 - 10.9.1. Directory and files operations
 - 10.9.1.1. copytree example
 - 10.9.2. Archiving operations
 - 10.9.2.1. Archiving example
- 10.10. `macpath` — Mac OS 9 path manipulation functions

See also:

Module `os`

Operating system interfaces, including functions to work with files at a lower level than Python *file objects*.

Module `io`

Python's built-in I/O library, including both abstract classes and some concrete classes such as file I/O.

Built-in function `open()`

The standard way to open files for reading and writing with Python.

 [Python v3.2 documentation](#) » [The Python Standard Library](#) [previous](#) | [next](#) | [modules](#) | [index](#)

»

10.1. `os.path` — Common pathname manipulations

This module implements some useful functions on pathnames. To read or write files see `open()`, and for accessing the filesystem see the `os` module. The path parameters can be passed as either strings, or bytes. Applications are encouraged to represent file names as (Unicode) character strings. Unfortunately, some file names may not be representable as strings on Unix, so applications that need to support arbitrary file names on Unix should use bytes objects to represent path names. Vice versa, using bytes objects cannot represent all file names on Windows (in the standard `mbscs` encoding), hence Windows applications should use string objects to access all files.

Note: All of these functions accept either only bytes or only string objects as their parameters. The result is an object of the same type, if a path or file name is returned.

Note: Since different operating systems have different path name conventions, there are several versions of this module in the standard library. The `os.path` module is always the path module suitable for the operating system Python is running on, and therefore usable for local paths. However, you can also import and use the individual modules if you want to manipulate a path that is *always* in one of the different formats. They all have the same interface:

- `posixpath` for UNIX-style paths
- `ntpath` for Windows paths
- `macpath` for old-style MacOS paths
- `os2emxpath` for OS/2 EMX paths

`os.path.abspath(path)`

Return a normalized absolutized version of the pathname *path*. On most platforms, this is equivalent to `normpath(join(os.getcwd(), path))`.

`os.path.basename(path)`

Return the base name of pathname *path*. This is the second half of the pair returned by `split(path)`. Note that the result of this function is different from the Unix **basename** program; where **basename** for `'/foo/bar/'` returns `'bar'`, the `basename()` function returns an empty string (`''`).

`os.path.commonprefix(list)`

Return the longest path prefix (taken character-by-character) that is a prefix of all paths in *list*. If *list* is empty, return the empty string (`''`). Note that this may return invalid paths because it works a character at a time.

`os.path.dirname(path)`

Return the directory name of pathname *path*. This is the first half of the pair returned by `split(path)`.

`os.path.exists(path)`

Return `True` if *path* refers to an existing path. Returns `False` for broken symbolic links. On some platforms, this function may return `False` if permission is not granted to execute `os.stat()` on the requested file, even if the *path* physically exists.

`os.path.lexists(path)`

Return `True` if *path* refers to an existing path. Returns `True` for broken symbolic links. Equivalent to `exists()` on platforms lacking `os.lstat()`.

`os.path.expanduser(path)`

On Unix and Windows, return the argument with an initial component of `~` or `~user` replaced by that *user*'s home directory.

On Unix, an initial `~` is replaced by the environment variable `HOME` if it is set; otherwise the current user's home directory is looked up in the password directory through the built-in module `pwd`. An initial `~user` is looked up directly in the password directory.

On Windows, `HOME` and `USERPROFILE` will be used if set, otherwise a combination of `HOMEPATH` and `HOMEDRIVE` will be used. An initial `~user` is handled by stripping the last directory component from the created user path derived above.

If the expansion fails or if the path does not begin with a tilde, the path is returned unchanged.

`os.path.expandvars(path)`

Return the argument with environment variables expanded. Substrings of the form `$name` or `${name}` are replaced by the value of environment variable *name*. Malformed variable names and references to non-existing variables are left unchanged.

On Windows, `%name%` expansions are supported in addition to `$name` and `${name}`.

`os.path.getatime(path)`

Return the time of last access of *path*. The return value is a number giving the number of seconds since the epoch (see the `time` module). Raise `os.error` if the file does not exist or is inaccessible.

If `os.stat_float_times()` returns `True`, the result is a floating point number.

`os.path.getmtime(path)`

Return the time of last modification of *path*. The return value is a number giving the number of seconds since the epoch (see the `time` module). Raise `os.error` if the file does not exist or is inaccessible.

If `os.stat_float_times()` returns `True`, the result is a floating point number.

`os.path.getctime(path)`

Return the system's ctime which, on some systems (like Unix) is the time of the last change, and, on others (like Windows), is the creation time for *path*. The return value is a number giving the number of seconds since the epoch (see the `time` module). Raise `os.error` if the file does not exist or is inaccessible.

`os.path.getsize(path)`

Return the size, in bytes, of *path*. Raise `os.error` if the file does not exist or is inaccessible.

`os.path.isabs(path)`

Return `True` if *path* is an absolute pathname. On Unix, that means it begins with a slash, on Windows that it begins with a (back)slash after chopping off a potential drive letter.

`os.path.isfile(path)`

Return `True` if *path* is an existing regular file. This follows symbolic links, so both `islink()` and `isfile()` can be true for the same path.

`os.path.isdir(path)`

Return `True` if *path* is an existing directory. This follows symbolic links, so both `islink()` and `isdir()` can be true for the same

`path`.

`os.path.islink(path)`

Return `True` if `path` refers to a directory entry that is a symbolic link. Always `False` if symbolic links are not supported.

`os.path.ismount(path)`

Return `True` if pathname `path` is a *mount point*: a point in a file system where a different file system has been mounted. The function checks whether `path`'s parent, `path/..`, is on a different device than `path`, or whether `path/..` and `path` point to the same i-node on the same device — this should detect mount points for all Unix and POSIX variants.

`os.path.join(path1[, path2[, ...]])`

Join one or more path components intelligently. If any component is an absolute path, all previous components (on Windows, including the previous drive letter, if there was one) are thrown away, and joining continues. The return value is the concatenation of `path1`, and optionally `path2`, etc., with exactly one directory separator (`os.sep`) inserted between components, unless `path2` is empty. Note that on Windows, since there is a current directory for each drive, `os.path.join("c:", "foo")` represents a path relative to the current directory on drive `c:` (`c:foo`), not `c:\foo`.

`os.path.normcase(path)`

Normalize the case of a pathname. On Unix and Mac OS X, this returns the path unchanged; on case-insensitive filesystems, it converts the path to lowercase. On Windows, it also converts forward slashes to backward slashes. Raise a `TypeError` if the type of `path` is not `str` or `bytes`.

`os.path.normpath(path)`

Normalize a pathname. This collapses redundant separators and up-level references so that `A//B`, `A/B/`, `A/./B` and `A/foo/../B` all become `A/B`.

It does not normalize the case (use `normcase()` for that). On Windows, it converts forward slashes to backward slashes. It should be understood that this may change the meaning of the path if it contains symbolic links!

`os.path.realpath(path)`

Return the canonical path of the specified filename, eliminating any symbolic links encountered in the path (if they are supported by the operating system).

`os.path.relpath(path, start=None)`

Return a relative filepath to `path` either from the current directory or from an optional `start` point.

`start` defaults to `os.curdir`.

Availability: Unix, Windows.

`os.path.samefile(path1, path2)`

Return `True` if both pathname arguments refer to the same file or directory. On Unix, this is determined by the device number and inode number and raises an exception if a `os.stat()` call on either pathname fails.

On Windows, two files are the same if they resolve to the same final path name using the Windows API call `GetFinalPathNameByHandle`. This function raises an exception if handles cannot be obtained to either file.

Availability: Unix, Windows.

Changed in version 3.2: Added Windows support.

`os.path.sameopenfile(fp1, fp2)`

Return `True` if the file descriptors *fp1* and *fp2* refer to the same file.

Availability: Unix, Windows.

Changed in version 3.2: Added Windows support.

`os.path.samestat(stat1, stat2)`

Return `True` if the stat tuples *stat1* and *stat2* refer to the same file. These structures may have been returned by `fstat()`, `lstat()`, or `stat()`. This function implements the underlying comparison used by `samefile()` and `sameopenfile()`.

Availability: Unix.

`os.path.split(path)`

Split the pathname *path* into a pair, (`head`, `tail`) where *tail* is the last pathname component and *head* is everything leading up to that. The *tail* part will never contain a slash; if *path* ends in a slash, *tail* will be empty. If there is no slash in *path*, *head* will be empty. If *path* is empty, both *head* and *tail* are empty. Trailing slashes are stripped from *head* unless it is the root (one or more slashes only). In all cases, `join(head, tail)` returns a path to the same location as *path* (but the strings may differ).

`os.path.splitdrive(path)`

Split the pathname *path* into a pair (`drive`, `tail`) where *drive* is either a mount point or the empty string. On systems which do not use drive specifications, *drive* will always be the empty string. In all cases, `drive + tail` will be the same as *path*.

On Windows, splits a pathname into drive/UNC sharepoint and relative path.

If the path contains a drive letter, drive will contain everything up to and including the colon. e.g. `splitdrive("c:/dir")` returns `("c:", "/dir")`

If the path contains a UNC path, drive will contain the host name and share, up to but not including the fourth separator. e.g. `splitdrive("//host/computer/dir")` returns `("//host/computer", "/dir")`

`os.path.splittext(path)`

Split the pathname *path* into a pair `(root, ext)` such that `root + ext == path`, and *ext* is empty or begins with a period and contains at most one period. Leading periods on the basename are ignored; `splittext('.cshrc')` returns `('.cshrc', '')`.

`os.path.splitunc(path)`

Deprecated since version 3.1: Use `splitdrive` instead.

Split the pathname *path* into a pair `(unc, rest)` so that *unc* is the UNC mount point (such as `r'\\host\mount'`), if present, and *rest* the rest of the path (such as `r'\path\file.ext'`). For paths containing drive letters, *unc* will always be the empty string.

Availability: Windows.

`os.path.supports_unicode_filenames`

True if arbitrary Unicode strings can be used as file names (within limitations imposed by the file system).

10.2. `fileinput` — Iterate over lines from multiple input streams

Source code: [Lib/fileinput.py](#)

This module implements a helper class and functions to quickly write a loop over standard input or a list of files. If you just want to read or write one file see `open()`.

The typical use is:

```
import fileinput
for line in fileinput.input():
    process(line)
```

This iterates over the lines of all files listed in `sys.argv[1:]`, defaulting to `sys.stdin` if the list is empty. If a filename is '-', it is also replaced by `sys.stdin`. To specify an alternative list of filenames, pass it as the first argument to `input()`. A single file name is also allowed.

All files are opened in text mode by default, but you can override this by specifying the *mode* parameter in the call to `input()` or `FileInput`. If an I/O error occurs during opening or reading a file, `IOError` is raised.

If `sys.stdin` is used more than once, the second and further use will return no lines, except perhaps for interactive use, or if it has been explicitly reset (e.g. using `sys.stdin.seek(0)`).

Empty files are opened and immediately closed; the only time their presence in the list of filenames is noticeable at all is when the last

file opened is empty.

Lines are returned with any newlines intact, which means that the last line in a file may not have one.

You can control how files are opened by providing an opening hook via the *openhook* parameter to `fileinput.input()` or `FileInput()`. The hook must be a function that takes two arguments, *filename* and *mode*, and returns an accordingly opened file-like object. Two useful hooks are already provided by this module.

The following function is the primary interface of this module:

```
fileinput.input(files=None, inplace=False, backup="", bufsize=0,  
mode='r', openhook=None)
```

Create an instance of the `FileInput` class. The instance will be used as global state for the functions of this module, and is also returned to use during iteration. The parameters to this function will be passed along to the constructor of the `FileInput` class.

The `FileInput` instance can be used as a context manager in the `with` statement. In this example, *input* is closed after the `with` statement is exited, even if an exception occurs:

```
with fileinput.input(files=('spam.txt', 'eggs.txt')) as f:  
    for line in f:  
        process(line)
```

Changed in version 3.2: Can be used as a context manager.

The following functions use the global state created by `fileinput.input()`; if there is no active state, `RuntimeError` is raised.

```
fileinput.filename()
```

Return the name of the file currently being read. Before the first line has been read, returns `None`.

`fileinput.fileeno()`

Return the integer “file descriptor” for the current file. When no file is opened (before the first line and between files), returns `-1`.

`fileinput.lineno()`

Return the cumulative line number of the line that has just been read. Before the first line has been read, returns `0`. After the last line of the last file has been read, returns the line number of that line.

`fileinput.filelineno()`

Return the line number in the current file. Before the first line has been read, returns `0`. After the last line of the last file has been read, returns the line number of that line within the file.

`fileinput.isfirstline()`

Returns true if the line just read is the first line of its file, otherwise returns false.

`fileinput.isstdin()`

Returns true if the last line was read from `sys.stdin`, otherwise returns false.

`fileinput.nextfile()`

Close the current file so that the next iteration will read the first line from the next file (if any); lines not read from the file will not count towards the cumulative line count. The filename is not changed until after the first line of the next file has been read. Before the first line has been read, this function has no effect; it cannot be used to skip the first file. After the last line of the last file has been read, this function has no effect.

`fileinput.close()`

Close the sequence.

The class which implements the sequence behavior provided by the module is available for subclassing as well:

```
class fileinput.FileInput(files=None, inplace=False, backup="",  
bufsize=0, mode='r', openhook=None)
```

Class **FileInput** is the implementation; its methods **filename()**, **fileno()**, **lineno()**, **filelineno()**, **isfirstline()**, **isstdin()**, **nextfile()** and **close()** correspond to the functions of the same name in the module. In addition it has a **readline()** method which returns the next input line, and a **__getitem__()** method which implements the sequence behavior. The sequence must be accessed in strictly sequential order; random access and **readline()** cannot be mixed.

With *mode* you can specify which file mode will be passed to **open()**. It must be one of **'r'**, **'rU'**, **'U'** and **'rb'**.

The *openhook*, when given, must be a function that takes two arguments, *filename* and *mode*, and returns an accordingly opened file-like object. You cannot use *inplace* and *openhook* together.

A **FileInput** instance can be used as a context manager in the **with** statement. In this example, *input* is closed after the **with** statement is exited, even if an exception occurs:

```
with FileInput(files=('spam.txt', 'eggs.txt')) as input:  
    process(input)
```

Changed in version 3.2: Can be used as a context manager.

Optional in-place filtering: if the keyword argument **inplace=True** is passed to **fileinput.input()** or to the **FileInput** constructor, the file is moved to a backup file and standard output is directed to the input file (if a file of the same name as the backup file already exists, it will

be replaced silently). This makes it possible to write a filter that rewrites its input file in place. If the *backup* parameter is given (typically as `backup='.<some extension>'`), it specifies the extension for the backup file, and the backup file remains around; by default, the extension is `'.bak'` and it is deleted when the output file is closed. In-place filtering is disabled when standard input is read.

Note: The current implementation does not work for MS-DOS 8+3 filesystems.

The two following opening hooks are provided by this module:

`fileinput.hook_compressed(filename, mode)`

Transparently opens files compressed with gzip and bzip2 (recognized by the extensions `'.gz'` and `'.bz2'`) using the `gzip` and `bz2` modules. If the filename extension is not `'.gz'` or `'.bz2'`, the file is opened normally (ie, using `open()` without any decompression).

Usage example: `fi` =
`fileinput.FileInput(openhook=fileinput.hook_compressed)`

`fileinput.hook_encoded(encoding)`

Returns a hook which opens each file with `codecs.open()`, using the given *encoding* to read the file.

Usage example: `fi` =
`fileinput.FileInput(openhook=fileinput.hook_encoded("iso-8859-1"))`

10.3. `stat` — Interpreting `stat()` results

Source code: [Lib/stat.py](#)

The `stat` module defines constants and functions for interpreting the results of `os.stat()`, `os.fstat()` and `os.lstat()` (if they exist). For complete details about the `stat()`, `fstat()` and `lstat()` calls, consult the documentation for your system.

The `stat` module defines the following functions to test for specific file types:

`stat.S_ISDIR(mode)`

Return non-zero if the mode is from a directory.

`stat.S_ISCHR(mode)`

Return non-zero if the mode is from a character special device file.

`stat.S_ISBLK(mode)`

Return non-zero if the mode is from a block special device file.

`stat.S_ISREG(mode)`

Return non-zero if the mode is from a regular file.

`stat.S_ISFIFO(mode)`

Return non-zero if the mode is from a FIFO (named pipe).

`stat.S_ISLNK(mode)`

Return non-zero if the mode is from a symbolic link.

`stat.S_ISSOCK(mode)`

Return non-zero if the mode is from a socket.

Two additional functions are defined for more general manipulation of the file's mode:

`stat.S_IMODE(mode)`

Return the portion of the file's mode that can be set by `os.chmod()`—that is, the file's permission bits, plus the sticky bit, set-group-id, and set-user-id bits (on systems that support them).

`stat.S_IFMT(mode)`

Return the portion of the file's mode that describes the file type (used by the `s_is*()` functions above).

Normally, you would use the `os.path.is*()` functions for testing the type of a file; the functions here are useful when you are doing multiple tests of the same file and wish to avoid the overhead of the `stat()` system call for each test. These are also useful when checking for information about a file that isn't handled by `os.path`, like the tests for block and character devices.

All the variables below are simply symbolic indexes into the 10-tuple returned by `os.stat()`, `os.fstat()` or `os.lstat()`.

`stat.ST_MODE`

Inode protection mode.

`stat.ST_INO`

Inode number.

`stat.ST_DEV`

Device inode resides on.

`stat.ST_NLINK`

Number of links to the inode.

`stat.ST_UID`

User id of the owner.

`stat.ST_GID`

Group id of the owner.

`stat.ST_SIZE`

Size in bytes of a plain file; amount of data waiting on some special files.

`stat.ST_ATIME`

Time of last access.

`stat.ST_MTIME`

Time of last modification.

`stat.ST_CTIME`

The “ctime” as reported by the operating system. On some systems (like Unix) is the time of the last metadata change, and, on others (like Windows), is the creation time (see platform documentation for details).

The interpretation of “file size” changes according to the file type. For plain files this is the size of the file in bytes. For FIFOs and sockets under most flavors of Unix (including Linux in particular), the “size” is the number of bytes waiting to be read at the time of the call to `os.stat()`, `os.fstat()`, or `os.lstat()`; this can sometimes be useful, especially for polling one of these special files after a non-blocking open. The meaning of the size field for other character and block devices varies more, depending on the implementation of the underlying system call.

The variables below define the flags used in the `ST_MODE` field.

Use of the functions above is more portable than use of the first set of flags:

stat . **S_IFMT**

Bit mask for the file type bit fields.

stat . **S_IFSOCK**

Socket.

stat . **S_IFLNK**

Symbolic link.

stat . **S_IFREG**

Regular file.

stat . **S_IFBLK**

Block device.

stat . **S_IFDIR**

Directory.

stat . **S_IFCHR**

Character device.

stat . **S_IFIFO**

FIFO.

The following flags can also be used in the *mode* argument of `os.chmod()`:

stat . **S_ISUID**

Set UID bit.

stat . **S_ISGID**

Set-group-ID bit. This bit has several special uses. For a directory it indicates that BSD semantics is to be used for that directory: files created there inherit their group ID from the directory, not

from the effective group ID of the creating process, and directories created there will also get the **S_ISGID** bit set. For a file that does not have the group execution bit (**S_IXGRP**) set, the set-group-ID bit indicates mandatory file/record locking (see also **S_ENFMT**).

stat. **S_ISVTX**

Sticky bit. When this bit is set on a directory it means that a file in that directory can be renamed or deleted only by the owner of the file, by the owner of the directory, or by a privileged process.

stat. **S_IRWXU**

Mask for file owner permissions.

stat. **S_IRUSR**

Owner has read permission.

stat. **S_IWUSR**

Owner has write permission.

stat. **S_IXUSR**

Owner has execute permission.

stat. **S_IRWXG**

Mask for group permissions.

stat. **S_IRGRP**

Group has read permission.

stat. **S_IWGRP**

Group has write permission.

stat. **S_IXGRP**

Group has execute permission.

stat. **S_IRWXO**

Mask for permissions for others (not in group).

stat.**S_IROTH**

Others have read permission.

stat.**S_IWOTH**

Others have write permission.

stat.**S_IXOTH**

Others have execute permission.

stat.**S_ENFMT**

System V file locking enforcement. This flag is shared with **S_ISGID**: file/record locking is enforced on files that do not have the group execution bit (**S_IXGRP**) set.

stat.**S_IREAD**

Unix V7 synonym for **S_IRUSR**.

stat.**S_IWRITE**

Unix V7 synonym for **S_IWUSR**.

stat.**S_IEXEC**

Unix V7 synonym for **S_IXUSR**.

Example:

```
import os, sys
from stat import *

def walktree(top, callback):
    '''recursively descend the directory tree rooted at top,
       calling the callback function for each regular file'''

    for f in os.listdir(top):
        pathname = os.path.join(top, f)
        mode = os.stat(pathname)[ST_MODE]
        if S_ISDIR(mode):
            # It's a directory, recurse into it
            walktree(pathname, callback)
        elif S_ISREG(mode):
            # It's a file, call the callback function
```

```
        callback(pathname)
    else:
        # Unknown file type, print a message
        print('Skipping %s' % pathname)

def visitfile(file):
    print('visiting', file)

if __name__ == '__main__':
    walktree(sys.argv[1], visitfile)
```

» [10. File and Directory Access](#) »

10.4. `filecmp` — File and Directory Comparisons

Source code: [Lib/filecmp.py](#)

The `filecmp` module defines functions to compare files and directories, with various optional time/correctness trade-offs. For comparing files, see also the `difflib` module.

The `filecmp` module defines the following functions:

`filecmp.cmp(f1, f2, shallow=True)`

Compare the files named *f1* and *f2*, returning `True` if they seem equal, `False` otherwise.

Unless *shallow* is given and is false, files with identical `os.stat()` signatures are taken to be equal.

Files that were compared using this function will not be compared again unless their `os.stat()` signature changes.

Note that no external programs are called from this function, giving it portability and efficiency.

`filecmp.cmpfiles(dir1, dir2, common, shallow=True)`

Compare the files in the two directories *dir1* and *dir2* whose names are given by *common*.

Returns three lists of file names: *match*, *mismatch*, *errors*. *match* contains the list of files that match, *mismatch* contains the names of those that don't, and *errors* lists the names of files which could not be compared. Files are listed in *errors* if they don't exist in

one of the directories, the user lacks permission to read them or if the comparison could not be done for some other reason.

The *shallow* parameter has the same meaning and default value as for `filecmp.cmp()`.

For example, `cmpfiles('a', 'b', ['c', 'd/e'])` will compare `a/c` with `b/c` and `a/d/e` with `b/d/e`. `'c'` and `'d/e'` will each be in one of the three returned lists.

Example:

```
>>> import filecmp
>>> filecmp.cmp('undoc.rst', 'undoc.rst')
True
>>> filecmp.cmp('undoc.rst', 'index.rst')
False
```

10.4.1. The `dircmp` class

`dircmp` instances are built using this constructor:

```
class filecmp. dircmp(a, b, ignore=None, hide=None)
```

Construct a new directory comparison object, to compare the directories *a* and *b*. *ignore* is a list of names to ignore, and defaults to `['RCS', 'CVS', 'tags']`. *hide* is a list of names to hide, and defaults to `[os.curdir, os.pardir]`.

The `dircmp` class provides the following methods:

report()

Print (to `sys.stdout`) a comparison between *a* and *b*.

report_partial_closure()

Print a comparison between *a* and *b* and common immediate subdirectories.

report_full_closure()

Print a comparison between *a* and *b* and common subdirectories (recursively).

The `dircmp` offers a number of interesting attributes that may be used to get various bits of information about the directory trees being compared.

Note that via `__getattr__()` hooks, all attributes are computed lazily, so there is no speed penalty if only those attributes which are lightweight to compute are used.

left_list

Files and subdirectories in *a*, filtered by *hide* and *ignore*.

right_list

Files and subdirectories in *b*, filtered by *hide* and *ignore*.

common

Files and subdirectories in both *a* and *b*.

left_only

Files and subdirectories only in *a*.

right_only

Files and subdirectories only in *b*.

common_dirs

Subdirectories in both *a* and *b*.

common_files

Files in both *a* and *b*

common_funny

Names in both *a* and *b*, such that the type differs between the directories, or names for which `os.stat()` reports an error.

same_files

Files which are identical in both *a* and *b*.

diff_files

Files which are in both *a* and *b*, whose contents differ.

funny_files

Files which are in both *a* and *b*, but could not be compared.

subdirs

A dictionary mapping names in `common_dirs` to `dircmp` objects.

10.5. `tempfile` — Generate temporary files and directories

Source code: [Lib/tempfile.py](#)

This module generates temporary files and directories. It works on all supported platforms. It provides three new functions, `NamedTemporaryFile()`, `mkstemp()`, and `mkdtemp()`, which should eliminate all remaining need to use the insecure `mktemp()` function. Temporary file names created by this module no longer contain the process ID; instead a string of six random characters is used.

Also, all the user-callable functions now take additional arguments which allow direct control over the location and name of temporary files. It is no longer necessary to use the global `tempdir` and `template` variables. To maintain backward compatibility, the argument order is somewhat odd; it is recommended to use keyword arguments for clarity.

The module defines the following user-callable items:

`tempfile. TemporaryFile(mode='w+b', buffering=None, encoding=None, newline=None, suffix="", prefix='tmp', dir=None)`

Return a *file-like object* that can be used as a temporary storage area. The file is created using `mkstemp()`. It will be destroyed as soon as it is closed (including an implicit close when the object is garbage collected). Under Unix, the directory entry for the file is removed immediately after the file is created. Other platforms do not support this; your code should not rely on a temporary file created using this function having or not having a visible name in the file system.

The *mode* parameter defaults to `'w+b'` so that the file created can be read and written without being closed. Binary mode is used so that it behaves consistently on all platforms without regard for the data that is stored. *buffering*, *encoding* and *newline* are interpreted as for `open()`.

The *dir*, *prefix* and *suffix* parameters are passed to `mkstemp()`.

The returned object is a true file object on POSIX platforms. On other platforms, it is a file-like object whose `file` attribute is the underlying true file object. This file-like object can be used in a `with` statement, just like a normal file.

```
tempfile.NamedTemporaryFile(mode='w+b', buffering=None,
encoding=None, newline=None, suffix="", prefix='tmp', dir=None,
delete=True)
```

This function operates exactly as `TemporaryFile()` does, except that the file is guaranteed to have a visible name in the file system (on Unix, the directory entry is not unlinked). That name can be retrieved from the `name` member of the file object. Whether the name can be used to open the file a second time, while the named temporary file is still open, varies across platforms (it can be so used on Unix; it cannot on Windows NT or later). If *delete* is true (the default), the file is deleted as soon as it is closed. The returned object is always a file-like object whose `file` attribute is the underlying true file object. This file-like object can be used in a `with` statement, just like a normal file.

```
tempfile.SpooledTemporaryFile(max_size=0, mode='w+b',
buffering=None, encoding=None, newline=None, suffix="",
prefix='tmp', dir=None)
```

This function operates exactly as `TemporaryFile()` does, except that data is spooled in memory until the file size exceeds *max_size*, or until the file's `fileno()` method is called, at which

point the contents are written to disk and operation proceeds as with `TemporaryFile()`.

The resulting file has one additional method, `rollover()`, which causes the file to roll over to an on-disk file regardless of its size.

The returned object is a file-like object whose `_file` attribute is either a `StringIO` object or a true file object, depending on whether `rollover()` has been called. This file-like object can be used in a `with` statement, just like a normal file.

`tempfile.TemporaryDirectory(suffix="", prefix='tmp', dir=None)`

This function creates a temporary directory using `mkdtemp()` (the supplied arguments are passed directly to the underlying function). The resulting object can be used as a context manager (see *With Statement Context Managers*). On completion of the context (or destruction of the temporary directory object), the newly created temporary directory and all its contents are removed from the filesystem.

The directory name can be retrieved from the `name` member of the returned object.

The directory can be explicitly cleaned up by calling the `cleanup()` method.

New in version 3.2.

`tempfile.mkstemp(suffix="", prefix='tmp', dir=None, text=False)`

Creates a temporary file in the most secure manner possible. There are no race conditions in the file's creation, assuming that the platform properly implements the `os.O_EXCL` flag for `os.open()`. The file is readable and writable only by the creating user ID. If the platform uses permission bits to indicate whether a

file is executable, the file is executable by no one. The file descriptor is not inherited by child processes.

Unlike `TemporaryFile()`, the user of `mkstemp()` is responsible for deleting the temporary file when done with it.

If *suffix* is specified, the file name will end with that suffix, otherwise there will be no suffix. `mkstemp()` does not put a dot between the file name and the suffix; if you need one, put it at the beginning of *suffix*.

If *prefix* is specified, the file name will begin with that prefix; otherwise, a default prefix is used.

If *dir* is specified, the file will be created in that directory; otherwise, a default directory is used. The default directory is chosen from a platform-dependent list, but the user of the application can control the directory location by setting the `TMPDIR`, `TEMP` or `TMP` environment variables. There is thus no guarantee that the generated filename will have any nice properties, such as not requiring quoting when passed to external commands via `os.popen()`.

If *text* is specified, it indicates whether to open the file in binary mode (the default) or text mode. On some platforms, this makes no difference.

`mkstemp()` returns a tuple containing an OS-level handle to an open file (as would be returned by `os.open()`) and the absolute pathname of that file, in that order.

```
tempfile.mkdtemp(suffix="", prefix='tmp', dir=None)
```

Creates a temporary directory in the most secure manner possible. There are no race conditions in the directory's creation. The directory is readable, writable, and searchable only by the

creating user ID.

The user of `mkdtemp()` is responsible for deleting the temporary directory and its contents when done with it.

The *prefix*, *suffix*, and *dir* arguments are the same as for `mkstemp()`.

`mkdtemp()` returns the absolute pathname of the new directory.

`tempfile.mktemp(suffix="", prefix='tmp', dir=None)`

Deprecated since version 2.3: Use `mkstemp()` instead.

Return an absolute pathname of a file that did not exist at the time the call is made. The *prefix*, *suffix*, and *dir* arguments are the same as for `mkstemp()`.

Warning: Use of this function may introduce a security hole in your program. By the time you get around to doing anything with the file name it returns, someone else may have beaten you to the punch. `mktemp()` usage can be replaced easily with `NamedTemporaryFile()`, passing it the `delete=False` parameter:

```
>>> f = NamedTemporaryFile(delete=False)
>>> f
<open file '<fdopen>', mode 'w+b' at 0x384698>
>>> f.name
'/var/folders/5q/5qTPn6xq2RaWqk+1Ytw3-U+++TI/-Tmp-/tmpG7V1'
>>> f.write("Hello World!\n")
>>> f.close()
>>> os.unlink(f.name)
>>> os.path.exists(f.name)
False
```

The module uses two global variables that tell it how to construct a

temporary name. They are initialized at the first call to any of the functions above. The caller may change them, but this is discouraged; use the appropriate function arguments, instead.

`tempfile.tempdir`

When set to a value other than `None`, this variable defines the default value for the *dir* argument to all the functions defined in this module.

If `tempdir` is unset or `None` at any call to any of the above functions, Python searches a standard list of directories and sets *tempdir* to the first one which the calling user can create files in. The list is:

1. The directory named by the `TMPDIR` environment variable.
2. The directory named by the `TEMP` environment variable.
3. The directory named by the `TMP` environment variable.
4. A platform-specific location:
 - On Windows, the directories `C:\TEMP`, `C:\TMP`, `\TEMP`, and `\TMP`, in that order.
 - On all other platforms, the directories `/tmp`, `/var/tmp`, and `/usr/tmp`, in that order.
5. As a last resort, the current working directory.

`tempfile.gettempdir()`

Return the directory currently selected to create temporary files in. If `tempdir` is not `None`, this simply returns its contents; otherwise, the search described above is performed, and the result returned.

`tempfile.gettemprefix()`

Return the filename prefix used to create temporary files. This does not contain the directory component.

10.5.1. Examples

Here are some examples of typical usage of the `tempfile` module:

```
>>> import tempfile

# create a temporary file and write some data to it
>>> fp = tempfile.TemporaryFile()
>>> fp.write('Hello world!')
# read data from file
>>> fp.seek(0)
>>> fp.read()
'Hello world!'
# close the file, it will be removed
>>> fp.close()

# create a temporary file using a context manager
>>> with tempfile.TemporaryFile() as fp:
...     fp.write('Hello world!')
...     fp.seek(0)
...     fp.read()
'Hello world!'
>>>
# file is now closed and removed

# create a temporary directory using the context manager
>>> with tempfile.TemporaryDirectory() as tmpdirname:
...     print 'created temporary directory', tmpdirname
>>>
# directory and contents have been removed
```

10.6. glob — Unix style pathname pattern expansion

Source code: [Lib/glob.py](#)

The `glob` module finds all the pathnames matching a specified pattern according to the rules used by the Unix shell. No tilde expansion is done, but `*`, `?`, and character ranges expressed with `[]` will be correctly matched. This is done by using the `os.listdir()` and `fnmatch.fnmatch()` functions in concert, and not by actually invoking a subshell. (For tilde and shell variable expansion, use `os.path.expanduser()` and `os.path.expandvars()`.)

`glob.glob(pathname)`

Return a possibly-empty list of path names that match *pathname*, which must be a string containing a path specification. *pathname* can be either absolute (like `/usr/src/Python-1.5/Makefile`) or relative (like `../../Tools/*/*.gif`), and can contain shell-style wildcards. Broken symlinks are included in the results (as in the shell).

`glob.iglob(pathname)`

Return an *iterator* which yields the same values as `glob()` without actually storing them all simultaneously.

For example, consider a directory containing only the following files: `1.gif`, `2.txt`, and `card.gif`. `glob()` will produce the following results. Notice how any leading components of the path are preserved.

```
>>> import glob
>>> glob.glob('./[0-9].*')
['./1.gif', './2.txt']
```

```
>>> glob.glob('*.gif')
['1.gif', 'card.gif']
>>> glob.glob('?.gif')
['1.gif']
```

Module `fnmatch`

Shell-style filename (not path) expansion

 [Python v3.2 documentation](#) » [The Python Standard Library](#) [previous](#) | [next](#) | [modules](#) | [index](#)

» [10. File and Directory Access](#) »

10.7. fnmatch — Unix filename pattern matching

Source code: [Lib/fnmatch.py](#)

This module provides support for Unix shell-style wildcards, which are *not* the same as regular expressions (which are documented in the `re` module). The special characters used in shell-style wildcards are:

Pattern	Meaning
*	matches everything
?	matches any single character
[seq]	matches any character in <i>seq</i>
[!seq]	matches any character not in <i>seq</i>

Note that the filename separator ('/' on Unix) is *not* special to this module. See module `glob` for pathname expansion (`glob` uses `fnmatch()` to match pathname segments). Similarly, filenames starting with a period are not special for this module, and are matched by the `*` and `?` patterns.

`fnmatch.fnmatch(filename, pattern)`

Test whether the *filename* string matches the *pattern* string, returning `True` or `False`. If the operating system is case-insensitive, then both parameters will be normalized to all lower- or upper-case before the comparison is performed. `fnmatchcase()` can be used to perform a case-sensitive comparison, regardless of whether that's standard for the operating system.

This example will print all file names in the current directory with the extension `.txt`:

```
import fnmatch
import os

for file in os.listdir('.'):
    if fnmatch.fnmatch(file, '*.txt'):
        print(file)
```

`fnmatch.fnmatchcase(filename, pattern)`

Test whether *filename* matches *pattern*, returning `True` or `False`; the comparison is case-sensitive.

`fnmatch.filter(names, pattern)`

Return the subset of the list of *names* that match *pattern*. It is the same as `[n for n in names if fnmatch(n, pattern)]`, but implemented more efficiently.

`fnmatch.translate(pattern)`

Return the shell-style *pattern* converted to a regular expression.

Be aware there is no way to quote meta-characters.

Example:

```
>>> import fnmatch, re
>>>
>>> regex = fnmatch.translate('*.txt')
>>> regex
'.*\.\.txt$'
>>> reobj = re.compile(regex)
>>> reobj.match('foobar.txt')
<_sre.SRE_Match object at 0x...>
```

Module `glob`

Unix shell-style path expansion.

 [Python v3.2 documentation](#) » [The Python Standard Library](#) [previous](#) | [next](#) | [modules](#) | [index](#)
» [10. File and Directory Access](#) »

10.8. `linecache` — Random access to text lines

Source code: [Lib/linecache.py](#)

The `linecache` module allows one to get any line from any file, while attempting to optimize internally, using a cache, the common case where many lines are read from a single file. This is used by the `traceback` module to retrieve source lines for inclusion in the formatted traceback.

The `linecache` module defines the following functions:

`linecache.getline(filename, lineno, module_globals=None)`

Get line *lineno* from file named *filename*. This function will never raise an exception — it will return `''` on errors (the terminating newline character will be included for lines that are found).

If a file named *filename* is not found, the function will look for it in the module search path, `sys.path`, after first checking for a **PEP 302** `__loader__` in *module_globals*, in case the module was imported from a zipfile or other non-filesystem import source.

`linecache.clearcache()`

Clear the cache. Use this function if you no longer need lines from files previously read using `getline()`.

`linecache.checkcache(filename=None)`

Check the cache for validity. Use this function if files in the cache may have changed on disk, and you require the updated version. If *filename* is omitted, it will check all the entries in the cache.

Example:

```
>>> import linecache
>>> linecache.getline('/etc/passwd', 4)
'sys:x:3:3:sys:/dev:/bin/sh\n'
```

 [Python v3.2 documentation](#) » [The Python Standard Library](#) [previous](#) | [next](#) | [modules](#) | [index](#)
» [10. File and Directory Access](#) »

10.9. `shutil` — High-level file operations

Source code: [Lib/shutil.py](#)

The `shutil` module offers a number of high-level operations on files and collections of files. In particular, functions are provided which support file copying and removal. For operations on individual files, see also the `os` module.

Warning: Even the higher-level file copying functions (`copy()`, `copy2()`) cannot copy all file metadata.

On POSIX platforms, this means that file owner and group are lost as well as ACLs. On Mac OS, the resource fork and other metadata are not used. This means that resources will be lost and file type and creator codes will not be correct. On Windows, file owners, ACLs and alternate data streams are not copied.

10.9.1. Directory and files operations

`shutil.copyfileobj(fsrc, fdst[, length])`

Copy the contents of the file-like object *fsrc* to the file-like object *fdst*. The integer *length*, if given, is the buffer size. In particular, a negative *length* value means to copy the data without looping over the source data in chunks; by default the data is read in chunks to avoid uncontrolled memory consumption. Note that if the current file position of the *fsrc* object is not 0, only the contents from the current file position to the end of the file will be copied.

`shutil.copyfile(src, dst)`

Copy the contents (no metadata) of the file named *src* to a file named *dst*. *dst* must be the complete target file name; look at [copy\(\)](#) for a copy that accepts a target directory path. If *src* and *dst* are the same files, **Error** is raised. The destination location must be writable; otherwise, an **IOError** exception will be raised. If *dst* already exists, it will be replaced. Special files such as character or block devices and pipes cannot be copied with this function. *src* and *dst* are path names given as strings.

`shutil.copymode(src, dst)`

Copy the permission bits from *src* to *dst*. The file contents, owner, and group are unaffected. *src* and *dst* are path names given as strings.

`shutil.copystat(src, dst)`

Copy the permission bits, last access time, last modification time, and flags from *src* to *dst*. The file contents, owner, and group are unaffected. *src* and *dst* are path names given as strings.

`shutil.copy(src, dst)`

Copy the file *src* to the file or directory *dst*. If *dst* is a directory, a file with the same basename as *src* is created (or overwritten) in the directory specified. Permission bits are copied. *src* and *dst* are path names given as strings.

`shutil.copy2(src, dst)`

Similar to `copy()`, but metadata is copied as well – in fact, this is just `copy()` followed by `copystat()`. This is similar to the Unix command `cp -p`.

`shutil.ignore_patterns(*patterns)`

This factory function creates a function that can be used as a callable for `copytree()`'s *ignore* argument, ignoring files and directories that match one of the glob-style *patterns* provided. See the example below.

`shutil.copytree(src, dst, symlinks=False, ignore=None, copy_function=copy2, ignore_dangling_symlinks=False)`

Recursively copy an entire directory tree rooted at *src*. The destination directory, named by *dst*, must not already exist; it will be created as well as missing parent directories. Permissions and times of directories are copied with `copystat()`, individual files are copied using `copy2()`.

If *symlinks* is true, symbolic links in the source tree are represented as symbolic links in the new tree; if false or omitted, the contents of the linked files are copied to the new tree.

When *symlinks* is false, if the file pointed by the symlink doesn't exist, an exception will be added in the list of errors raised in a `Error` exception at the end of the copy process. You can set the optional *ignore_dangling_symlinks* flag to true if you want to silence this exception. Notice that this option has no effect on platforms that don't support `os.symlink()`.

If *ignore* is given, it must be a callable that will receive as its arguments the directory being visited by `copytree()`, and a list of its contents, as returned by `os.listdir()`. Since `copytree()` is called recursively, the *ignore* callable will be called once for each directory that is copied. The callable must return a sequence of directory and file names relative to the current directory (i.e. a subset of the items in its second argument); these names will then be ignored in the copy process. `ignore_patterns()` can be used to create such a callable that ignores names based on glob-style patterns.

If exception(s) occur, an **Error** is raised with a list of reasons.

If *copy_function* is given, it must be a callable that will be used to copy each file. It will be called with the source path and the destination path as arguments. By default, `copy2()` is used, but any function that supports the same signature (like `copy()`) can be used.

Changed in version 3.2: Added the *copy_function* argument to be able to provide a custom copy function.

Changed in version 3.2: Added the *ignore_dangling_symlinks* argument to silent dangling symlinks errors when *symlinks* is false.

`shutil.rmtree(path, ignore_errors=False, onerror=None)`

Delete an entire directory tree; *path* must point to a directory (but not a symbolic link to a directory). If *ignore_errors* is true, errors resulting from failed removals will be ignored; if false or omitted, such errors are handled by calling a handler specified by *onerror* or, if that is omitted, they raise an exception.

If *onerror* is provided, it must be a callable that accepts three parameters: *function*, *path*, and *excinfo*. The first parameter,

function, is the function which raised the exception; it will be `os.path.islink()`, `os.listdir()`, `os.remove()` or `os.rmdir()`. The second parameter, *path*, will be the path name passed to *function*. The third parameter, *excinfo*, will be the exception information return by `sys.exc_info()`. Exceptions raised by *onerror* will not be caught.

`shutil.move(src, dst)`

Recursively move a file or directory to another location.

If the destination is on the current filesystem, then simply use `rename`. Otherwise, copy `src` (with `copy2()`) to the `dst` and then remove `src`.

exception `shutil.Error`

This exception collects exceptions that raised during a multi-file operation. For `copytree()`, the exception argument is a list of 3-tuples (*srcname*, *dstname*, *exception*).

10.9.1.1. copytree example

This example is the implementation of the `copytree()` function, described above, with the docstring omitted. It demonstrates many of the other functions provided by this module.

```
def copytree(src, dst, symlinks=False):
    names = os.listdir(src)
    os.makedirs(dst)
    errors = []
    for name in names:
        srcname = os.path.join(src, name)
        dstname = os.path.join(dst, name)
        try:
            if symlinks and os.path.islink(srcname):
                linkto = os.readlink(srcname)
                os.symlink(linkto, dstname)
            elif os.path.isdir(srcname):
```

```

        copytree(srcname, dstname, symlinks)
    else:
        copy2(srcname, dstname)
        # XXX What about devices, sockets etc.?
    except (IOError, os.error) as why:
        errors.append((srcname, dstname, str(why)))
    # catch the Error from the recursive copytree so that w
    # continue with other files
    except Error as err:
        errors.extend(err.args[0])
try:
    copystat(src, dst)
except WindowsError:
    # can't copy file access times on Windows
    pass
except OSError as why:
    errors.extend((src, dst, str(why)))
if errors:
    raise Error(errors)

```

Another example that uses the `ignore_patterns()` helper:

```

from shutil import copytree, ignore_patterns

copytree(source, destination, ignore=ignore_patterns('*.*pyc', '

```

This will copy everything except `.pyc` files and files or directories whose name starts with `tmp`.

Another example that uses the `ignore` argument to add a logging call:

```

from shutil import copytree
import logging

def _logpath(path, names):
    logging.info('Working in %s' % path)
    return [] # nothing will be ignored

copytree(source, destination, ignore=_logpath)

```

10.9.2. Archiving operations

```
shutil.make_archive(base_name, format[, root_dir[, base_dir[,  
verbose[, dry_run[, owner[, group[, logger]]]]]])
```

Create an archive file (such as zip or tar) and return its name.

base_name is the name of the file to create, including the path, minus any format-specific extension. *format* is the archive format: one of “zip”, “tar”, “bztar” (if the `bz2` module is available) or “gztar”.

root_dir is a directory that will be the root directory of the archive; for example, we typically `chdir` into *root_dir* before creating the archive.

base_dir is the directory where we start archiving from; i.e. *base_dir* will be the common prefix of all files and directories in the archive.

root_dir and *base_dir* both default to the current directory.

owner and *group* are used when creating a tar archive. By default, uses the current owner and group.

logger is an instance of `logging.Logger`.

New in version 3.2.

```
shutil.get_archive_formats()
```

Returns a list of supported formats for archiving. Each element of the returned sequence is a tuple (name, description)

By default `shutil` provides these formats:

- *gztar*: gzip'ed tar-file
- *bztar*: bzip2'ed tar-file (if the `bz2` module is available.)
- *tar*: uncompressed tar file
- *zip*: ZIP file

You can register new formats or provide your own archiver for any existing formats, by using `register_archive_format()`.

New in version 3.2.

```
shutil.register_archive_format(name, function[, extra_args[,  
description]])
```

Registers an archiver for the format *name*. *function* is a callable that will be used to invoke the archiver.

If given, *extra_args* is a sequence of (name, value) pairs that will be used as extra keywords arguments when the archiver callable is used.

description is used by `get_archive_formats()` which returns the list of archivers. Defaults to an empty list.

New in version 3.2.

```
shutil.unregister_archive_format(name)
```

Remove the archive format *name* from the list of supported formats.

New in version 3.2.

```
shutil.unpack_archive(filename[, extract_dir[, format]])
```

Unpack an archive. *filename* is the full path of the archive.

extract_dir is the name of the target directory where the archive is unpacked. If not provided, the current working directory is used.

format is the archive format: one of “zip”, “tar”, or “gztar”. Or any other format registered with `register_unpack_format()`. If not provided, `unpack_archive()` will use the archive file name extension and see if an unpacker was registered for that extension. In case none is found, a `ValueError` is raised.

New in version 3.2.

`shutil.register_unpack_format(name, extensions, function[, extra_args[, description]])`

Registers an unpack format. *name* is the name of the format and *extensions* is a list of extensions corresponding to the format, like `.zip` for Zip files.

function is the callable that will be used to unpack archives. The callable will receive the path of the archive, followed by the directory the archive must be extracted to.

When provided, *extra_args* is a sequence of `(name, value)` tuples that will be passed as keywords arguments to the callable.

description can be provided to describe the format, and will be returned by the `get_unpack_formats()` function.

New in version 3.2.

`shutil.unregister_unpack_format(name)`

Unregister an unpack format. *name* is the name of the format.

New in version 3.2.

`shutil.get_unpack_formats()`

Return a list of all registered formats for unpacking. Each element of the returned sequence is a tuple `(name, extensions,`

description).

By default `shutil` provides these formats:

- `gztar`: gzip'ed tar-file
- `bztar`: bzip2'ed tar-file (if the `bz2` module is available.)
- `tar`: uncompressed tar file
- `zip`: ZIP file

You can register new formats or provide your own unpacker for any existing formats, by using `register_unpack_format()`.

New in version 3.2.

10.9.2.1. Archiving example

In this example, we create a gzip'ed tar-file archive containing all files found in the `.ssh` directory of the user:

```
>>> from shutil import make_archive
>>> import os
>>> archive_name = os.path.expanduser(os.path.join('~', 'myarch
>>> root_dir = os.path.expanduser(os.path.join('~', '.ssh'))
>>> make_archive(archive_name, 'gztar', root_dir)
'/Users/tarek/myarchive.tar.gz'
```

The resulting archive contains:

```
$ tar -tzvf /Users/tarek/myarchive.tar.gz
drwx----- tarek/staff      0 2010-02-01 16:23:40 ./
-rw-r--r--  tarek/staff    609 2008-06-09 13:26:54 ./authorized
-rwxr-xr-x  tarek/staff     65 2008-06-09 13:26:54 ./config
-rwx----- tarek/staff    668 2008-06-09 13:26:54 ./id_dsa
-rwxr-xr-x  tarek/staff    609 2008-06-09 13:26:54 ./id_dsa.pub
-rw-----  tarek/staff   1675 2008-06-09 13:26:54 ./id_rsa
-rw-r--r--  tarek/staff    397 2008-06-09 13:26:54 ./id_rsa.pub
-rw-r--r--  tarek/staff  37192 2010-02-06 18:23:10 ./known_host
```

10.10. `macpath` — Mac OS 9 path manipulation functions

This module is the Mac OS 9 (and earlier) implementation of the `os.path` module. It can be used to manipulate old-style Macintosh pathnames on Mac OS X (or any other platform).

The following functions are available in this module: `normcase()`, `normpath()`, `isabs()`, `join()`, `split()`, `isdir()`, `isfile()`, `walk()`, `exists()`. For other functions available in `os.path` dummy counterparts are available.

11. Data Persistence

The modules described in this chapter support storing Python data in a persistent form on disk. The `pickle` and `marshal` modules can turn many Python data types into a stream of bytes and then recreate the objects from the bytes. The various DBM-related modules support a family of hash-based file formats that store a mapping of strings to other strings.

The list of modules described in this chapter is:

- **11.1. `pickle`** — Python object serialization
 - 11.1.1. Relationship to other Python modules
 - 11.1.2. Data stream format
 - 11.1.3. Module Interface
 - 11.1.4. What can be pickled and unpickled?
 - 11.1.5. Pickling Class Instances
 - 11.1.5.1. Persistence of External Objects
 - 11.1.5.2. Handling Stateful Objects
 - 11.1.6. Restricting Globals
 - 11.1.7. Examples
- **11.2. `copyreg`** — Register `pickle` support functions
- **11.3. `shelve`** — Python object persistence
 - 11.3.1. Restrictions
 - 11.3.2. Example
- **11.4. `marshal`** — Internal Python object serialization
- **11.5. `dbm`** — Interfaces to Unix “databases”
 - 11.5.1. `dbm.gnu` — GNU’s reinterpretation of `dbm`
 - 11.5.2. `dbm.ndbm` — Interface based on `ndbm`
 - 11.5.3. `dbm.dumb` — Portable DBM implementation
- **11.6. `sqlite3`** — DB-API 2.0 interface for SQLite databases
 - 11.6.1. Module functions and constants
 - 11.6.2. Connection Objects

- 11.6.3. Cursor Objects
- 11.6.4. Row Objects
- 11.6.5. SQLite and Python types
 - 11.6.5.1. Introduction
 - 11.6.5.2. Using adapters to store additional Python types in SQLite databases
 - 11.6.5.2.1. Letting your object adapt itself
 - 11.6.5.2.2. Registering an adapter callable
 - 11.6.5.3. Converting SQLite values to custom Python types
 - 11.6.5.4. Default adapters and converters
- 11.6.6. Controlling Transactions
- 11.6.7. Using `sqlite3` efficiently
 - 11.6.7.1. Using shortcut methods
 - 11.6.7.2. Accessing columns by name instead of by index
 - 11.6.7.3. Using the connection as a context manager
- 11.6.8. Common issues
 - 11.6.8.1. Multithreading

11.1. `pickle` — Python object serialization

The `pickle` module implements a fundamental, but powerful algorithm for serializing and de-serializing a Python object structure. “Pickling” is the process whereby a Python object hierarchy is converted into a byte stream, and “unpickling” is the inverse operation, whereby a byte stream is converted back into an object hierarchy. Pickling (and unpickling) is alternatively known as “serialization”, “marshalling,” [1] or “flattening”, however, to avoid confusion, the terms used here are “pickling” and “unpickling”..

Warning: The `pickle` module is not intended to be secure against erroneous or maliciously constructed data. Never unpickle data received from an untrusted or unauthenticated source.

11.1.1. Relationship to other Python modules

The `pickle` module has an transparent optimizer (`_pickle`) written in C. It is used whenever available. Otherwise the pure Python implementation is used.

Python has a more primitive serialization module called `marshal`, but in general `pickle` should always be the preferred way to serialize Python objects. `marshal` exists primarily to support Python's `.pyc` files.

The `pickle` module differs from `marshal` in several significant ways:

- The `pickle` module keeps track of the objects it has already serialized, so that later references to the same object won't be serialized again. `marshal` doesn't do this.

This has implications both for recursive objects and object sharing. Recursive objects are objects that contain references to themselves. These are not handled by `marshal`, and in fact, attempting to `marshal` recursive objects will crash your Python interpreter. Object sharing happens when there are multiple references to the same object in different places in the object hierarchy being serialized. `pickle` stores such objects only once, and ensures that all other references point to the master copy. Shared objects remain shared, which can be very important for mutable objects.

- `marshal` cannot be used to serialize user-defined classes and their instances. `pickle` can save and restore class instances transparently, however the class definition must be importable

and live in the same module as when the object was stored.

- The `marshal` serialization format is not guaranteed to be portable across Python versions. Because its primary job in life is to support `.pyc` files, the Python implementers reserve the right to change the serialization format in non-backwards compatible ways should the need arise. The `pickle` serialization format is guaranteed to be backwards compatible across Python releases.

Note that serialization is a more primitive notion than persistence; although `pickle` reads and writes file objects, it does not handle the issue of naming persistent objects, nor the (even more complicated) issue of concurrent access to persistent objects. The `pickle` module can transform a complex object into a byte stream and it can transform the byte stream into an object with the same internal structure. Perhaps the most obvious thing to do with these byte streams is to write them onto a file, but it is also conceivable to send them across a network or store them in a database. The module `shelve` provides a simple interface to pickle and unpickle objects on DBM-style database files.

11.1.2. Data stream format

The data format used by `pickle` is Python-specific. This has the advantage that there are no restrictions imposed by external standards such as XDR (which can't represent pointer sharing); however it means that non-Python programs may not be able to reconstruct pickled Python objects.

By default, the `pickle` data format uses a compact binary representation. The module `pickletools` contains tools for analyzing data streams generated by `pickle`.

There are currently 4 different protocols which can be used for pickling.

- Protocol version 0 is the original human-readable protocol and is backwards compatible with earlier versions of Python.
- Protocol version 1 is the old binary format which is also compatible with earlier versions of Python.
- Protocol version 2 was introduced in Python 2.3. It provides much more efficient pickling of *new-style classes*.
- Protocol version 3 was added in Python 3.0. It has explicit support for bytes and cannot be unpickled by Python 2.x pickle modules. This is the current recommended protocol, use it whenever it is possible.

Refer to [PEP 307](#) for information about improvements brought by protocol 2. See `pickletools`'s source code for extensive comments about opcodes used by pickle protocols.

11.1.3. Module Interface

To serialize an object hierarchy, you first create a pickler, then you call the pickler's `dump()` method. To de-serialize a data stream, you first create an unpickler, then you call the unpickler's `load()` method. The `pickle` module provides the following constant:

`pickle.HIGHEST_PROTOCOL`

The highest protocol version available. This value can be passed as a *protocol* value.

`pickle.DEFAULT_PROTOCOL`

The default protocol used for pickling. May be less than `HIGHEST_PROTOCOL`. Currently the default protocol is 3; a backward-incompatible protocol designed for Python 3.0.

The `pickle` module provides the following functions to make the pickling process more convenient:

`pickle.dump(obj, file, protocol=None, *, fix_imports=True)`

Write a pickled representation of *obj* to the open *file object file*. This is equivalent to `Pickler(file, protocol).dump(obj)`.

The optional *protocol* argument tells the pickler to use the given protocol; supported protocols are 0, 1, 2, 3. The default protocol is 3; a backward-incompatible protocol designed for Python 3.0.

Specifying a negative protocol version selects the highest protocol version supported. The higher the protocol used, the more recent the version of Python needed to read the pickle produced.

The *file* argument must have a `write()` method that accepts a single bytes argument. It can thus be an on-disk file opened for

binary writing, a `io.BytesIO` instance, or any other custom object that meets this interface.

If `fix_imports` is `True` and `protocol` is less than 3, pickle will try to map the new Python 3.x names to the old module names used in Python 2.x, so that the pickle data stream is readable with Python 2.x.

`pickle.dumps(obj, protocol=None, *, fix_imports=True)`

Return the pickled representation of the object as a `bytes` object, instead of writing it to a file.

The optional `protocol` argument tells the pickler to use the given protocol; supported protocols are 0, 1, 2, 3. The default protocol is 3; a backward-incompatible protocol designed for Python 3.0.

Specifying a negative protocol version selects the highest protocol version supported. The higher the protocol used, the more recent the version of Python needed to read the pickle produced.

If `fix_imports` is `True` and `protocol` is less than 3, pickle will try to map the new Python 3.x names to the old module names used in Python 2.x, so that the pickle data stream is readable with Python 2.x.

`pickle.load(file, *, fix_imports=True, encoding="ASCII", errors="strict")`

Read a pickled object representation from the open `file object file` and return the reconstituted object hierarchy specified therein. This is equivalent to `Unpickler(file).load()`.

The protocol version of the pickle is detected automatically, so no protocol argument is needed. Bytes past the pickled object's representation are ignored.

The argument *file* must have two methods, a `read()` method that takes an integer argument, and a `readline()` method that requires no arguments. Both methods should return bytes. Thus *file* can be an on-disk file opened for binary reading, a `io.BytesIO` object, or any other custom object that meets this interface.

Optional keyword arguments are *fix_imports*, *encoding* and *errors*, which are used to control compatibility support for pickle stream generated by Python 2.x. If *fix_imports* is `True`, pickle will try to map the old Python 2.x names to the new names used in Python 3.x. The *encoding* and *errors* tell pickle how to decode 8-bit string instances pickled by Python 2.x; these default to 'ASCII' and 'strict', respectively.

```
pickle.loads(bytes_object, *, fix_imports=True, encoding="ASCII", errors="strict")
```

Read a pickled object hierarchy from a `bytes` object and return the reconstituted object hierarchy specified therein

The protocol version of the pickle is detected automatically, so no protocol argument is needed. Bytes past the pickled object's representation are ignored.

Optional keyword arguments are *fix_imports*, *encoding* and *errors*, which are used to control compatibility support for pickle stream generated by Python 2.x. If *fix_imports* is `True`, pickle will try to map the old Python 2.x names to the new names used in Python 3.x. The *encoding* and *errors* tell pickle how to decode 8-bit string instances pickled by Python 2.x; these default to 'ASCII' and 'strict', respectively.

The `pickle` module defines three exceptions:

exception `pickle.PickleError`

Common base class for the other pickling exceptions. It inherits

Exception.

exception pickle.**PicklingError**

Error raised when an unpicklable object is encountered by **Pickler**. It inherits **PickleError**.

Refer to *What can be pickled and unpickled?* to learn what kinds of objects can be pickled.

exception pickle.**UnpicklingError**

Error raised when there a problem unpickling an object, such as a data corruption or a security violation. It inherits **PickleError**.

Note that other exceptions may also be raised during unpickling, including (but not necessarily limited to) **AttributeError**, **EOFError**, **ImportError**, and **IndexError**.

The **pickle** module exports two classes, **Pickler** and **Unpickler**:

```
class pickle.Pickler(file, protocol=None, *, fix_imports=True)
```

This takes a binary file for writing a pickle data stream.

The optional *protocol* argument tells the pickler to use the given protocol; supported protocols are 0, 1, 2, 3. The default protocol is 3; a backward-incompatible protocol designed for Python 3.0.

Specifying a negative protocol version selects the highest protocol version supported. The higher the protocol used, the more recent the version of Python needed to read the pickle produced.

The *file* argument must have a `write()` method that accepts a single bytes argument. It can thus be an on-disk file opened for binary writing, a **io.BytesIO** instance, or any other custom object that meets this interface.

If *fix_imports* is True and *protocol* is less than 3, pickle will try to map the new Python 3.x names to the old module names used in Python 2.x, so that the pickle data stream is readable with Python 2.x.

dump(obj)

Write a pickled representation of *obj* to the open file object given in the constructor.

persistent_id(obj)

Do nothing by default. This exists so a subclass can override it.

If `persistent_id()` returns `None`, *obj* is pickled as usual. Any other value causes `Pickler` to emit the returned value as a persistent ID for *obj*. The meaning of this persistent ID should be defined by `Unpickler.persistent_load()`. Note that the value returned by `persistent_id()` cannot itself have a persistent ID.

See [Persistence of External Objects](#) for details and examples of uses.

fast

Deprecated. Enable fast mode if set to a true value. The fast mode disables the usage of memo, therefore speeding the pickling process by not generating superfluous PUT opcodes. It should not be used with self-referential objects, doing otherwise will cause `Pickler` to recurse infinitely.

Use `pickletools.optimize()` if you need more compact pickles.

```
class pickle.Unpickler(file, *, fix_imports=True, encoding="ASCII", errors="strict")
```

This takes a binary file for reading a pickle data stream.

The protocol version of the pickle is detected automatically, so no protocol argument is needed.

The argument *file* must have two methods, a `read()` method that takes an integer argument, and a `readline()` method that requires no arguments. Both methods should return bytes. Thus *file* can be an on-disk file object opened for binary reading, a `io.BytesIO` object, or any other custom object that meets this interface.

Optional keyword arguments are *fix_imports*, *encoding* and *errors*, which are used to control compatibility support for pickle stream generated by Python 2.x. If *fix_imports* is True, pickle will try to map the old Python 2.x names to the new names used in Python 3.x. The *encoding* and *errors* tell pickle how to decode 8-bit string instances pickled by Python 2.x; these default to 'ASCII' and 'strict', respectively.

load()

Read a pickled object representation from the open file object given in the constructor, and return the reconstituted object hierarchy specified therein. Bytes past the pickled object's representation are ignored.

persistent_load(*pid*)

Raise an `UnpicklingError` by default.

If defined, `persistent_load()` should return the object specified by the persistent ID *pid*. If an invalid persistent ID is encountered, an `UnpicklingError` should be raised.

See [Persistence of External Objects](#) for details and examples of uses.

find_class(*module*, *name*)

Import *module* if necessary and return the object called *name* from it, where the *module* and *name* arguments are `str` objects. Note, unlike its name suggests, `find_class()` is also used for finding functions.

Subclasses may override this to gain control over what type of objects and how they can be loaded, potentially reducing security risks. Refer to [Restricting Globals](#) for details.

11.1.4. What can be pickled and unpickled?

The following types can be pickled:

- **None**, **True**, and **False**
- integers, floating point numbers, complex numbers
- strings, bytes, bytearray
- tuples, lists, sets, and dictionaries containing only picklable objects
- functions defined at the top level of a module
- built-in functions defined at the top level of a module
- classes that are defined at the top level of a module
- instances of such classes whose `__dict__` or `__setstate__()` is picklable (see section *Pickling Class Instances* for details)

Attempts to pickle unpicklable objects will raise the `PicklingError` exception; when this happens, an unspecified number of bytes may have already been written to the underlying file. Trying to pickle a highly recursive data structure may exceed the maximum recursion depth, a `RuntimeError` will be raised in this case. You can carefully raise this limit with `sys.setrecursionlimit()`.

Note that functions (built-in and user-defined) are pickled by “fully qualified” name reference, not by value. This means that only the function name is pickled, along with the name of module the function is defined in. Neither the function’s code, nor any of its function attributes are pickled. Thus the defining module must be importable in the unpickling environment, and the module must contain the named object, otherwise an exception will be raised. [2]

Similarly, classes are pickled by named reference, so the same restrictions in the unpickling environment apply. Note that none of the class’s code or data is pickled, so in the following example the

class attribute `attr` is not restored in the unpickling environment:

```
class Foo:
    attr = 'A class attribute'

picklestring = pickle.dumps(Foo)
```

These restrictions are why picklable functions and classes must be defined in the top level of a module.

Similarly, when class instances are pickled, their class's code and data are not pickled along with them. Only the instance data are pickled. This is done on purpose, so you can fix bugs in a class or add methods to the class and still load objects that were created with an earlier version of the class. If you plan to have long-lived objects that will see many versions of a class, it may be worthwhile to put a version number in the objects so that suitable conversions can be made by the class's `__setstate__()` method.

11.1.5. Pickling Class Instances

In this section, we describe the general mechanisms available to you to define, customize, and control how class instances are pickled and unpickled.

In most cases, no additional code is needed to make instances picklable. By default, pickle will retrieve the class and the attributes of an instance via introspection. When a class instance is unpickled, its `__init__()` method is usually *not* invoked. The default behaviour first creates an uninitialized instance and then restores the saved attributes. The following code shows an implementation of this behaviour:

```
def save(obj):
    return (obj.__class__, obj.__dict__)

def load(cls, attributes):
    obj = cls.__new__(cls)
    obj.__dict__.update(attributes)
    return obj
```

Classes can alter the default behaviour by providing one or several special methods:

object. `__getnewargs__()`

In protocol 2 and newer, classes that implements the `__getnewargs__()` method can dictate the values passed to the `__new__()` method upon unpickling. This is often needed for classes whose `__new__()` method requires arguments.

object. `__getstate__()`

Classes can further influence how their instances are pickled; if the class defines the method `__getstate__()`, it is called and the returned object is pickled as the contents for the instance, instead

of the contents of the instance's dictionary. If the `__getstate__()` method is absent, the instance's `__dict__` is pickled as usual.

`object.__setstate__(state)`

Upon unpickling, if the class defines `__setstate__()`, it is called with the unpickled state. In that case, there is no requirement for the state object to be a dictionary. Otherwise, the pickled state must be a dictionary and its items are assigned to the new instance's dictionary.

Note: If `__getstate__()` returns a false value, the `__setstate__()` method will not be called upon unpickling.

Refer to the section *Handling Stateful Objects* for more information about how to use the methods `__getstate__()` and `__setstate__()`.

Note: At unpickling time, some methods like `__getattr__()`, `__getattribute__()`, or `__setattr__()` may be called upon the instance. In case those methods rely on some internal invariant being true, the type should implement `__getnewargs__()` to establish such an invariant; otherwise, neither `__new__()` nor `__init__()` will be called.

As we shall see, pickle does not use directly the methods described above. In fact, these methods are part of the copy protocol which implements the `__reduce__()` special method. The copy protocol provides a unified interface for retrieving the data necessary for pickling and copying objects. [3]

Although powerful, implementing `__reduce__()` directly in your classes is error prone. For this reason, class designers should use the high-level interface (i.e., `__getnewargs__()`, `__getstate__()` and

`__setstate__()`) whenever possible. We will show, however, cases where using `__reduce__()` is the only option or leads to more efficient pickling or both.

`object.__reduce__()`

The interface is currently defined as follows. The `__reduce__()` method takes no argument and shall return either a string or preferably a tuple (the returned object is often referred to as the “reduce value”).

If a string is returned, the string should be interpreted as the name of a global variable. It should be the object’s local name relative to its module; the pickle module searches the module namespace to determine the object’s module. This behaviour is typically useful for singletons.

When a tuple is returned, it must be between two and five items long. Optional items can either be omitted, or `None` can be provided as their value. The semantics of each item are in order:

- A callable object that will be called to create the initial version of the object.
- A tuple of arguments for the callable object. An empty tuple must be given if the callable does not accept any argument.
- Optionally, the object’s state, which will be passed to the object’s `__setstate__()` method as previously described. If the object has no such method then, the value must be a dictionary and it will be added to the object’s `__dict__` attribute.
- Optionally, an iterator (and not a sequence) yielding successive items. These items will be appended to the object either using `obj.append(item)` or, in batch, using `obj.extend(list_of_items)`. This is primarily used for list subclasses, but may be used by other classes as long as

they have `append()` and `extend()` methods with the appropriate signature. (Whether `append()` or `extend()` is used depends on which pickle protocol version is used as well as the number of items to append, so both must be supported.)

- Optionally, an iterator (not a sequence) yielding successive key-value pairs. These items will be stored to the object using `obj[key] = value`. This is primarily used for dictionary subclasses, but may be used by other classes as long as they implement `__setitem__()`.

`object.__reduce_ex__(protocol)`

Alternatively, a `__reduce_ex__()` method may be defined. The only difference is this method should take a single integer argument, the protocol version. When defined, pickle will prefer it over the `__reduce__()` method. In addition, `__reduce__()` automatically becomes a synonym for the extended version. The main use for this method is to provide backwards-compatible reduce values for older Python releases.

11.1.5.1. Persistence of External Objects

For the benefit of object persistence, the `pickle` module supports the notion of a reference to an object outside the pickled data stream. Such objects are referenced by a persistent ID, which should be either a string of alphanumeric characters (for protocol 0) [4] or just an arbitrary object (for any newer protocol).

The resolution of such persistent IDs is not defined by the `pickle` module; it will delegate this resolution to the user defined methods on the pickler and unpickler, `persistent_id()` and `persistent_load()` respectively.

To pickle objects that have an external persistent id, the pickler must

have a custom `persistent_id()` method that takes an object as an argument and returns either `None` or the persistent id for that object. When `None` is returned, the pickler simply pickles the object as normal. When a persistent ID string is returned, the pickler will pickle that object, along with a marker so that the unpickler will recognize it as a persistent ID.

To unpickle external objects, the unpickler must have a custom `persistent_load()` method that takes a persistent ID object and returns the referenced object.

Here is a comprehensive example presenting how persistent ID can be used to pickle external objects by reference.

```
# Simple example presenting how persistent ID can be used to pi  
# external objects by reference.  
  
import pickle  
import sqlite3  
from collections import namedtuple  
  
# Simple class representing a record in our database.  
MemoRecord = namedtuple("MemoRecord", "key, task")  
  
class DBPickler(pickle.Pickler):  
  
    def persistent_id(self, obj):  
        # Instead of pickling MemoRecord as a regular class ins  
        # persistent ID.  
        if isinstance(obj, MemoRecord):  
            # Here, our persistent ID is simply a tuple, containi  
            # key, which refers to a specific record in the dat  
            return ("MemoRecord", obj.key)  
        else:  
            # If obj does not have a persistent ID, return None  
            # needs to be pickled as usual.  
            return None  
  
class DBUnpickler(pickle.Unpickler):  
  
    def __init__(self, file, connection):
```

```

    super().__init__(file)
    self.connection = connection

def persistent_load(self, pid):
    # This method is invoked whenever a persistent ID is en
    # Here, pid is the tuple returned by DBPickler.
    cursor = self.connection.cursor()
    type_tag, key_id = pid
    if type_tag == "MemoRecord":
        # Fetch the referenced record from the database and
        cursor.execute("SELECT * FROM memos WHERE key=?", (
            key, task = cursor.fetchone()
        ))
        return MemoRecord(key, task)
    else:
        # Always raises an error if you cannot return the c
        # Otherwise, the unpickler will think None is the o
        # by the persistent ID.
        raise pickle.UnpicklingError("unsupported persisten

def main():
    import io, pprint

    # Initialize and populate our database.
    conn = sqlite3.connect(":memory:")
    cursor = conn.cursor()
    cursor.execute("CREATE TABLE memos(key INTEGER PRIMARY KEY,
        tasks = (
            'give food to fish',
            'prepare group meeting',
            'fight with a zebra',
        )
    )
    for task in tasks:
        cursor.execute("INSERT INTO memos VALUES(NULL, ?)", (ta

    # Fetch the records to be pickled.
    cursor.execute("SELECT * FROM memos")
    memos = [MemoRecord(key, task) for key, task in cursor]
    # Save the records using our custom DBPickler.
    file = io.BytesIO()
    DBPickler(file).dump(memos)

    print("Pickled records:")
    pprint.pprint(memos)

    # Update a record, just for good measure.
    cursor.execute("UPDATE memos SET task='learn italian' WHERE

```

```

# Load the records from the pickle data stream.
file.seek(0)
memos = DBUnpickler(file, conn).load()

print("Unpickled records:")
pprint.pprint(memos)

if __name__ == '__main__':
    main()

```

11.1.5.2. Handling Stateful Objects

Here's an example that shows how to modify pickling behavior for a class. The `TextReader` class opens a text file, and returns the line number and line contents each time its `readline()` method is called. If a `TextReader` instance is pickled, all attributes *except* the file object member are saved. When the instance is unpickled, the file is reopened, and reading resumes from the last location. The `__setstate__()` and `__getstate__()` methods are used to implement this behavior.

```

class TextReader:
    """Print and number lines in a text file."""

    def __init__(self, filename):
        self.filename = filename
        self.file = open(filename)
        self.lineno = 0

    def readline(self):
        self.lineno += 1
        line = self.file.readline()
        if not line:
            return None
        if line.endswith('\n'):
            line = line[:-1]
        return "%i: %s" % (self.lineno, line)

    def __getstate__(self):

```

```
# Copy the object's state from self.__dict__ which contains  
# all our instance attributes. Always use the dict.copy  
# method to avoid modifying the original state.  
state = self.__dict__.copy()  
# Remove the unpicklable entries.  
del state['file']  
return state  
  
def __setstate__(self, state):  
# Restore instance attributes (i.e., filename and lineno)  
self.__dict__.update(state)  
# Restore the previously opened file's state. To do so,  
# reopen it and read from it until the line count is re-  
file = open(self.filename)  
for _ in range(self.lineno):  
    file.readline()  
# Finally, save the file.  
self.file = file
```

A sample usage might be something like this:

```
>>> reader = TextReader("hello.txt")  
>>> reader.readline()  
'1: Hello world!'  
>>> reader.readline()  
'2: I am line number two.'  
>>> new_reader = pickle.loads(pickle.dumps(reader))  
>>> new_reader.readline()  
'3: Goodbye!'
```

11.1.6. Restricting Globals

By default, unpickling will import any class or function that it finds in the pickle data. For many applications, this behaviour is unacceptable as it permits the unpickler to import and invoke arbitrary code. Just consider what this hand-crafted pickle data stream does when loaded:

```
>>> import pickle
>>> pickle.loads(b"cos\nsystem\n(S'echo hello world'\ntR.")
hello world
0
```

In this example, the unpickler imports the `os.system()` function and then apply the string argument “echo hello world”. Although this example is inoffensive, it is not difficult to imagine one that could damage your system.

For this reason, you may want to control what gets unpickled by customizing `Unpickler.find_class()`. Unlike its name suggests, `find_class()` is called whenever a global (i.e., a class or a function) is requested. Thus it is possible to either forbid completely globals or restrict them to a safe subset.

Here is an example of an unpickler allowing only few safe classes from the `builtins` module to be loaded:

```
import builtins
import io
import pickle

safe_builtins = {
    'range',
    'complex',
    'set',
    'frozenset',
    'slice',
```

```

}

class RestrictedUnpickler(pickle.Unpickler):

    def find_class(self, module, name):
        # Only allow safe classes from builtins.
        if module == "builtins" and name in safe_builtins:
            return getattr(builtins, name)
        # Forbid everything else.
        raise pickle.UnpicklingError("global '%s.%s' is forbidden"
                                      (module, name))

    def restricted_loads(s):
        """Helper function analogous to pickle.loads()."""
        return RestrictedUnpickler(io.BytesIO(s)).load()

```

A sample usage of our unpickler working has intended:

```

>>> restricted_loads(pickle.dumps([1, 2, range(15)]))
[1, 2, range(0, 15)]
>>> restricted_loads(b"cos\nsystem\n(S'echo hello world'\ntR.")
Traceback (most recent call last):
...
pickle.UnpicklingError: global 'os.system' is forbidden
>>> restricted_loads(b'cbuiltins\neval\n'
...                   b'(S\'getattr(__import__("os"), "system")\'
...                   b'("echo hello world")\'\ntR.}')
Traceback (most recent call last):
...
pickle.UnpicklingError: global 'builtins.eval' is forbidden

```

As our examples shows, you have to be careful with what you allow to be unpickled. Therefore if security is a concern, you may want to consider alternatives such as the marshalling API in `xmlrpc.client` or third-party solutions.

11.1.7. Examples

For the simplest code, use the `dump()` and `load()` functions.

```
import pickle

# An arbitrary collection of objects supported by pickle.
data = {
    'a': [1, 2.0, 3, 4+6j],
    'b': ("character string", b"byte string"),
    'c': set([None, True, False])
}

with open('data.pickle', 'wb') as f:
    # Pickle the 'data' dictionary using the highest protocol available
    pickle.dump(data, f, pickle.HIGHEST_PROTOCOL)
```

The following example reads the resulting pickled data.

```
import pickle

with open('data.pickle', 'rb') as f:
    # The protocol version used is detected automatically, so we
    # have to specify it.
    data = pickle.load(f)
```

Module `copyreg`

Pickle interface constructor registration for extension types.

Module `pickletools`

Tools for working with and analyzing pickled data.

Module `shelve`

Indexed databases of objects; uses `pickle`.

Module `copy`

Shallow and deep object copying.

Module `marshal`

High-performance serialization of built-in types.

Footnotes

[1] Don't confuse this with the `marshal` module

[2] The exception raised will likely be an `ImportError` or an `AttributeError` but it could be something else.

[3] The `copy` module uses this protocol for shallow and deep copying operations.

[4] The limitation on alphanumeric characters is due to the fact the persistent IDs, in protocol 0, are delimited by the newline character. Therefore if any kind of newline characters occurs in persistent IDs, the resulting pickle will become unreadable.

11.2. copyreg — Register pickle support functions

The `copyreg` module provides support for the `pickle` module. The `copy` module is likely to use this in the future as well. It provides configuration information about object constructors which are not classes. Such constructors may be factory functions or class instances.

`copyreg.constructor(object)`

Declares *object* to be a valid constructor. If *object* is not callable (and hence not valid as a constructor), raises `TypeError`.

`copyreg.pickle(type, function, constructor=None)`

Declares that *function* should be used as a “reduction” function for objects of type *type*. *function* should return either a string or a tuple containing two or three elements.

The optional *constructor* parameter, if provided, is a callable object which can be used to reconstruct the object when called with the tuple of arguments returned by *function* at pickling time. `TypeError` will be raised if *object* is a class or *constructor* is not callable.

See the `pickle` module for more details on the interface expected of *function* and *constructor*.

11.3. `shelve` — Python object persistence

Source code: [Lib/shelve.py](#)

A “shelf” is a persistent, dictionary-like object. The difference with “dbm” databases is that the values (not the keys!) in a shelf can be essentially arbitrary Python objects — anything that the `pickle` module can handle. This includes most class instances, recursive data types, and objects containing lots of shared sub-objects. The keys are ordinary strings.

`shelve.open(filename, flag='c', protocol=None, writeback=False)`

Open a persistent dictionary. The filename specified is the base filename for the underlying database. As a side-effect, an extension may be added to the filename and more than one file may be created. By default, the underlying database file is opened for reading and writing. The optional *flag* parameter has the same interpretation as the *flag* parameter of `dbm.open()`.

By default, version 3 pickles are used to serialize values. The version of the pickle protocol can be specified with the *protocol* parameter.

Because of Python semantics, a shelf cannot know when a mutable persistent-dictionary entry is modified. By default modified objects are written *only* when assigned to the shelf (see [Example](#)). If the optional *writeback* parameter is set to `True`, all entries accessed are also cached in memory, and written back on `sync()` and `close()`; this can make it handier to mutate mutable entries in the persistent dictionary, but, if many entries are accessed, it can consume vast amounts of memory for the

cache, and it can make the close operation very slow since all accessed entries are written back (there is no way to determine which accessed entries are mutable, nor which ones were actually mutated).

Note: Do not rely on the shelf being closed automatically; always call `close()` explicitly when you don't need it any more, or use a `with` statement with `contextlib.closing()`.

Warning: Because the `shelve` module is backed by `pickle`, it is insecure to load a shelf from an untrusted source. Like with `pickle`, loading a shelf can execute arbitrary code.

Shelf objects support all methods supported by dictionaries. This eases the transition from dictionary based scripts to those requiring persistent storage.

Two additional methods are supported:

`Shelf.sync()`

Write back all entries in the cache if the shelf was opened with `writeback` set to `True`. Also empty the cache and synchronize the persistent dictionary on disk, if feasible. This is called automatically when the shelf is closed with `close()`.

`Shelf.close()`

Synchronize and close the persistent `dict` object. Operations on a closed shelf will fail with a `ValueError`.

See also: [Persistent dictionary recipe](#) with widely supported storage formats and having the speed of native dictionaries.

11.3.1. Restrictions

- The choice of which database package will be used (such as `dbm.ndbm` or `dbm.gnu`) depends on which interface is available. Therefore it is not safe to open the database directly using `dbm`. The database is also (unfortunately) subject to the limitations of `dbm`, if it is used — this means that (the pickled representation of) the objects stored in the database should be fairly small, and in rare cases key collisions may cause the database to refuse updates.
- The `shelve` module does not support *concurrent* read/write access to shelved objects. (Multiple simultaneous read accesses are safe.) When a program has a shelf open for writing, no other program should have it open for reading or writing. Unix file locking can be used to solve this, but this differs across Unix versions and requires knowledge about the database implementation used.

```
class shelve.Shelf(dict, protocol=None, writeback=False,  
keyencoding='utf-8')
```

A subclass of `collections.MutableMapping` which stores pickled values in the *dict* object.

By default, version 0 pickles are used to serialize values. The version of the pickle protocol can be specified with the *protocol* parameter. See the `pickle` documentation for a discussion of the pickle protocols.

If the *writeback* parameter is `True`, the object will hold a cache of all entries accessed and write them back to the *dict* at `sync` and `close` times. This allows natural operations on mutable entries, but can consume much more memory and make `sync` and `close` take a long time.

The *keyencoding* parameter is the encoding used to encode keys before they are used with the underlying dict.

New in version 3.2: The *keyencoding* parameter; previously, keys were always encoded in UTF-8.

```
class shelve.BsdDbShelf(dict, protocol=None, writeback=False,
keyencoding='utf-8')
```

A subclass of `Shelf` which exposes `first()`, `next()`, `previous()`, `last()` and `set_location()` which are available in the third-party `bsddb` module from `pybsddb` but not in other database modules. The *dict* object passed to the constructor must support those methods. This is generally accomplished by calling one of `bsddb.hashopen()`, `bsddb.btopen()` or `bsddb.rnopen()`. The optional *protocol*, *writeback*, and *keyencoding* parameters have the same interpretation as for the `Shelf` class.

```
class shelve.DbfilenameShelf(filename, flag='c', protocol=None,
writeback=False)
```

A subclass of `Shelf` which accepts a *filename* instead of a dict-like object. The underlying file will be opened using `dbm.open()`. By default, the file will be created and opened for both read and write. The optional *flag* parameter has the same interpretation as for the `open()` function. The optional *protocol* and *writeback* parameters have the same interpretation as for the `Shelf` class.

11.3.2. Example

To summarize the interface (`key` is a string, `data` is an arbitrary object):

```
import shelve

d = shelve.open(filename) # open -- file may get suffix added b
                          # library

d[key] = data             # store data at key (overwrites old data if
                          # using an existing key)
data = d[key]             # retrieve a COPY of data at key (raise KeyErro
                          # such key)
del d[key]                # delete data stored at key (raises KeyError
                          # if no such key)
flag = key in d           # true if the key exists
klist = list(d.keys())    # a list of all existing keys (slow!)

# as d was opened WITHOUT writeback=True, beware:
d['xx'] = [0, 1, 2]       # this works as expected, but...
d['xx'].append(3)         # *this doesn't!* -- d['xx'] is STILL [0

# having opened d without writeback=True, you need to code care
temp = d['xx']            # extracts the copy
temp.append(5)           # mutates the copy
d['xx'] = temp           # stores the copy right back, to persist it

# or, d=shelve.open(filename,writeback=True) would let you just
# d['xx'].append(5) and have it work as expected, BUT it would
# consume more memory and make the d.close() operation slower.

d.close()                # close it
```

Module `dbm`

Generic interface to `dbm`-style databases.

Module `pickle`

Object serialization used by `shelve`.

 [Python v3.2 documentation](#) » [The Python Standard Library](#) [previous](#) | [next](#) | [modules](#) | [index](#)
» [11. Data Persistence](#) »

11.4. marshal — Internal Python object serialization

This module contains functions that can read and write Python values in a binary format. The format is specific to Python, but independent of machine architecture issues (e.g., you can write a Python value to a file on a PC, transport the file to a Sun, and read it back there). Details of the format are undocumented on purpose; it may change between Python versions (although it rarely does). [1]

This is not a general “persistence” module. For general persistence and transfer of Python objects through RPC calls, see the modules `pickle` and `shelve`. The `marshal` module exists mainly to support reading and writing the “pseudo-compiled” code for Python modules of `.pyc` files. Therefore, the Python maintainers reserve the right to modify the marshal format in backward incompatible ways should the need arise. If you’re serializing and de-serializing Python objects, use the `pickle` module instead – the performance is comparable, version independence is guaranteed, and pickle supports a substantially wider range of objects than marshal.

Warning: The `marshal` module is not intended to be secure against erroneous or maliciously constructed data. Never unmarshal data received from an untrusted or unauthenticated source.

Not all Python object types are supported; in general, only objects whose value is independent from a particular invocation of Python can be written and read by this module. The following types are supported: booleans, integers, floating point numbers, complex numbers, strings, bytes, bytearray, tuples, lists, sets, frozensets, dictionaries, and code objects, where it should be understood that

tuples, lists, sets, frozensets and dictionaries are only supported as long as the values contained therein are themselves supported; and recursive lists, sets and dictionaries should not be written (they will cause infinite loops). The singletons `None`, `Ellipsis` and `StopIteration` can also be marshalled and unmarshalled.

There are functions that read/write files as well as functions operating on strings.

The module defines these functions:

`marshal.dump(value, file[, version])`

Write the value on the open file. The value must be a supported type. The file must be an open file object such as `sys.stdout` or returned by `open()` or `os.popen()`. It must be opened in binary mode (`'wb'` or `'w+b'`).

If the value has (or contains an object that has) an unsupported type, a `ValueError` exception is raised — but garbage data will also be written to the file. The object will not be properly read back by `load()`.

The *version* argument indicates the data format that `dump` should use (see below).

`marshal.load(file)`

Read one value from the open file and return it. If no valid value is read (e.g. because the data has a different Python version's incompatible marshal format), raise `EOFError`, `ValueError` or `TypeError`. The file must be an open file object opened in binary mode (`'rb'` or `'r+b'`).

Note: If an object containing an unsupported type was marshalled with `dump()`, `load()` will substitute `None` for the

unmarshallable type.

`marshal.dumps(value[, version])`

Return the string that would be written to a file by `dump(value, file)`. The value must be a supported type. Raise a `ValueError` exception if value has (or contains an object that has) an unsupported type.

The *version* argument indicates the data format that `dumps` should use (see below).

`marshal.loads(string)`

Convert the string to a value. If no valid value is found, raise `EOFError`, `ValueError` or `TypeError`. Extra characters in the string are ignored.

In addition, the following constants are defined:

`marshal.version`

Indicates the format that the module uses. Version 0 is the historical format, version 1 shares interned strings and version 2 uses a binary format for floating point numbers. The current version is 2.

Footnotes

[1]

The name of this module stems from a bit of terminology used by the designers of Modula-3 (amongst others), who use the term “marshalling” for shipping of data around in a self-contained form. Strictly speaking, “to marshal” means to convert some data from internal to external form (in an RPC buffer for instance) and “unmarshalling” for the reverse process.

11.5. dbm — Interfaces to Unix “databases”

`dbm` is a generic interface to variants of the DBM database — `dbm.gnu` or `dbm.ndbm`. If none of these modules is installed, the slow-but-simple implementation in module `dbm.dumb` will be used. There is a [third party interface](#) to the Oracle Berkeley DB.

exception `dbm.error`

A tuple containing the exceptions that can be raised by each of the supported modules, with a unique exception also named `dbm.error` as the first item — the latter is used when `dbm.error` is raised.

`dbm.whichdb(filename)`

This function attempts to guess which of the several simple database modules available — `dbm.gnu`, `dbm.ndbm` or `dbm.dumb` — should be used to open a given file.

Returns one of the following values: `None` if the file can't be opened because it's unreadable or doesn't exist; the empty string ('') if the file's format can't be guessed; or a string containing the required module name, such as `'dbm.ndbm'` or `'dbm.gnu'`.

`dbm.open(filename, flag='r', mode=0o666)`

Open the database file `filename` and return a corresponding object.

If the database file already exists, the `whichdb()` function is used to determine its type and the appropriate module is used; if it does not exist, the first module listed above that can be imported is used.

The optional *flag* argument can be:

Value	Meaning
'r'	Open existing database for reading only (default)
'w'	Open existing database for reading and writing
'c'	Open database for reading and writing, creating it if it doesn't exist
'n'	Always create a new, empty database, open for reading and writing

The optional *mode* argument is the Unix mode of the file, used only when the database has to be created. It defaults to octal `0o666` (and will be modified by the prevailing `umask`).

The object returned by `open()` supports the same basic functionality as dictionaries; keys and their corresponding values can be stored, retrieved, and deleted, and the `in` operator and the `keys()` method are available, as well as `get()` and `setdefault()`.

Changed in version 3.2: `get()` and `setdefault()` are now available in all database modules.

Key and values are always stored as bytes. This means that when strings are used they are implicitly converted to the default encoding before being stored.

The following example records some hostnames and a corresponding title, and then prints out the contents of the database:

```
import dbm

# Open database, creating it if necessary.
db = dbm.open('cache', 'c')

# Record some values
db[b'hello'] = b'there'
db['www.python.org'] = 'Python Website'
db['www.cnn.com'] = 'Cable News Network'
```

```
# Note that the keys are considered bytes now.
assert db[b'www.python.org'] == b'Python Website'
# Notice how the value is now in bytes.
assert db['www.cnn.com'] == b'Cable News Network'

# Often-used methods of the dict interface work too.
print(db.get('python.org', b'not present'))

# Storing a non-string key or value will raise an exception (most
likely a TypeError).
db['www.yahoo.com'] = 4

# Close when done.
db.close()
```

See also:

Module `shelve`

Persistence module which stores non-string data.

The individual submodules are described in the following sections.

11.5.1. `dbm.gnu` — GNU's reinterpretation of `dbm`

Platforms: Unix

This module is quite similar to the `dbm` module, but uses the GNU library `gdbm` instead to provide some additional functionality. Please note that the file formats created by `dbm.gnu` and `dbm.ndbm` are incompatible.

The `dbm.gnu` module provides an interface to the GNU DBM library. `dbm.gnu.gdbm` objects behave like mappings (dictionaries), except that keys and values are always converted to bytes before storing. Printing a `gdbm` object doesn't print the keys and values, and the `items()` and `values()` methods are not supported.

exception `dbm.gnu.error`

Raised on `dbm.gnu`-specific errors, such as I/O errors. `KeyError` is raised for general mapping errors like specifying an incorrect key.

`dbm.gnu.open(filename[, flag[, mode]])`

Open a `gdbm` database and return a `gdbm` object. The `filename` argument is the name of the database file.

The optional `flag` argument can be:

Value	Meaning
'r'	Open existing database for reading only (default)
'w'	Open existing database for reading and writing
'c'	Open database for reading and writing, creating it if it doesn't exist
	Always create a new, empty database, open for

'n'	reading and writing
-----	---------------------

The following additional characters may be appended to the flag to control how the database is opened:

Value	Meaning
'f'	Open the database in fast mode. Writes to the database will not be synchronized.
's'	Synchronized mode. This will cause changes to the database to be immediately written to the file.
'u'	Do not lock database.

Not all flags are valid for all versions of `gdbm`. The module constant `open_flags` is a string of supported flag characters. The exception `error` is raised if an invalid flag is specified.

The optional *mode* argument is the Unix mode of the file, used only when the database has to be created. It defaults to octal `00666`.

In addition to the dictionary-like methods, `gdbm` objects have the following methods:

`gdbm.firstkey()`

It's possible to loop over every key in the database using this method and the `nextkey()` method. The traversal is ordered by `gdbm`'s internal hash values, and won't be sorted by the key values. This method returns the starting key.

`gdbm.nextkey(key)`

Returns the key that follows *key* in the traversal. The following code prints every key in the database `db`, without having to create a list in memory that contains them all:

```
k = db.firstkey()
```

```
while k != None:  
    print(k)  
    k = db.nextkey(k)
```

`gdbm.reorganize()`

If you have carried out a lot of deletions and would like to shrink the space used by the `gdbm` file, this routine will reorganize the database. `gdbm` objects will not shorten the length of a database file except by using this reorganization; otherwise, deleted file space will be kept and reused as new (key, value) pairs are added.

`gdbm.sync()`

When the database has been opened in fast mode, this method forces any unwritten data to be written to the disk.

11.5.2. `dbm.ndbm` — Interface based on `ndbm`

Platforms: Unix

The `dbm.ndbm` module provides an interface to the Unix “(n)dbm” library. Dbm objects behave like mappings (dictionaries), except that keys and values are always stored as bytes. Printing a `dbm` object doesn’t print the keys and values, and the `items()` and `values()` methods are not supported.

This module can be used with the “classic” `ndbm` interface or the GNU GDBM compatibility interface. On Unix, the **configure** script will attempt to locate the appropriate header file to simplify building this module.

exception `dbm.ndbm.error`

Raised on `dbm.ndbm`-specific errors, such as I/O errors. `KeyError` is raised for general mapping errors like specifying an incorrect key.

`dbm.ndbm.library`

Name of the `ndbm` implementation library used.

`dbm.ndbm.open(filename[, flag[, mode]])`

Open a dbm database and return a `dbm` object. The *filename* argument is the name of the database file (without the `.dir` or `.pag` extensions).

The optional *flag* argument must be one of these values:

Value	Meaning
'r'	Open existing database for reading only (default)
'w'	Open existing database for reading and writing

'c'	Open database for reading and writing, creating it if it doesn't exist
'n'	Always create a new, empty database, open for reading and writing

The optional *mode* argument is the Unix mode of the file, used only when the database has to be created. It defaults to octal `00666` (and will be modified by the prevailing `umask`).

11.5.3. `dbm.dumb` — Portable DBM implementation

Note: The `dbm.dumb` module is intended as a last resort fallback for the `dbm` module when a more robust module is not available. The `dbm.dumb` module is not written for speed and is not nearly as heavily used as the other database modules.

The `dbm.dumb` module provides a persistent dictionary-like interface which is written entirely in Python. Unlike other modules such as `dbm.gnu` no external library is required. As with other persistent mappings, the keys and values are always stored as bytes.

The module defines the following:

exception `dbm.dumb.error`

Raised on `dbm.dumb`-specific errors, such as I/O errors. `KeyError` is raised for general mapping errors like specifying an incorrect key.

`dbm.dumb.open(filename[, flag[, mode]])`

Open a `dumbdbm` database and return a `dumbdbm` object. The *filename* argument is the basename of the database file (without any specific extensions). When a `dumbdbm` database is created, files with `.dat` and `.dir` extensions are created.

The optional *flag* argument is currently ignored; the database is always opened for update, and will be created if it does not exist.

The optional *mode* argument is the Unix mode of the file, used only when the database has to be created. It defaults to octal `0o666` (and will be modified by the prevailing `umask`).

In addition to the methods provided by the `collections.MutableMapping` class, `dumbdbm` objects provide the following method:

`dumbdbm.sync()`

Synchronize the on-disk directory and data files. This method is called by the `shelve.sync()` method.

11.6. `sqlite3` — DB-API 2.0 interface for SQLite databases

SQLite is a C library that provides a lightweight disk-based database that doesn't require a separate server process and allows accessing the database using a nonstandard variant of the SQL query language. Some applications can use SQLite for internal data storage. It's also possible to prototype an application using SQLite and then port the code to a larger database such as PostgreSQL or Oracle.

`sqlite3` was written by Gerhard Häring and provides a SQL interface compliant with the DB-API 2.0 specification described by [PEP 249](#).

To use the module, you must first create a `Connection` object that represents the database. Here the data will be stored in the `/tmp/example` file:

```
conn = sqlite3.connect('/tmp/example')
```

You can also supply the special name `:memory:` to create a database in RAM.

Once you have a `Connection`, you can create a `Cursor` object and call its `execute()` method to perform SQL commands:

```
c = conn.cursor()

# Create table
c.execute('''create table stocks
(date text, trans text, symbol text,
qty real, price real)''')

# Insert a row of data
c.execute("""insert into stocks
```

```

        values ('2006-01-05', 'BUY', 'RHAT', 100, 35.14)"""")
# Save (commit) the changes
conn.commit()

# We can also close the cursor if we are done with it
c.close()

```

Usually your SQL operations will need to use values from Python variables. You shouldn't assemble your query using Python's string operations because doing so is insecure; it makes your program vulnerable to an SQL injection attack.

Instead, use the DB-API's parameter substitution. Put `?` as a placeholder wherever you want to use a value, and then provide a tuple of values as the second argument to the cursor's `execute()` method. (Other database modules may use a different placeholder, such as `%s` or `:1`.) For example:

```

# Never do this -- insecure!
symbol = 'IBM'
c.execute("... where symbol = '%s'" % symbol)

# Do this instead
t = (symbol,)
c.execute('select * from stocks where symbol=?', t)

# Larger example
for t in [('2006-03-28', 'BUY', 'IBM', 1000, 45.00),
         ('2006-04-05', 'BUY', 'MSOFT', 1000, 72.00),
         ('2006-04-06', 'SELL', 'IBM', 500, 53.00),
        ]:
    c.execute('insert into stocks values (?, ?, ?, ?, ?)', t)

```

To retrieve data after executing a SELECT statement, you can either treat the cursor as an *iterator*, call the cursor's `fetchone()` method to retrieve a single matching row, or call `fetchall()` to get a list of the matching rows.

This example uses the iterator form:

```
>>> c = conn.cursor()
>>> c.execute('select * from stocks order by price')
>>> for row in c:
...     print(row)
...
('2006-01-05', 'BUY', 'RHAT', 100, 35.14)
('2006-03-28', 'BUY', 'IBM', 1000, 45.0)
('2006-04-06', 'SELL', 'IBM', 500, 53.0)
('2006-04-05', 'BUY', 'MSOFT', 1000, 72.0)
>>>
```

11.6.1. Module functions and constants

`sqlite3.PARSE_DECLTYPES`

This constant is meant to be used with the *detect_types* parameter of the `connect()` function.

Setting it makes the `sqlite3` module parse the declared type for each column it returns. It will parse out the first word of the declared type, i. e. for “integer primary key”, it will parse out “integer”, or for “number(10)” it will parse out “number”. Then for that column, it will look into the converters dictionary and use the converter function registered for that type there.

`sqlite3.PARSE_COLNAMES`

This constant is meant to be used with the *detect_types* parameter of the `connect()` function.

Setting this makes the SQLite interface parse the column name for each column it returns. It will look for a string formed [mytype] in there, and then decide that ‘mytype’ is the type of the column. It will try to find an entry of ‘mytype’ in the converters dictionary and then use the converter function found there to return the value. The column name found in `cursor.description` is only the first word of the column name, i. e. if you use something like `'as "x [datetime]"'` in your SQL, then we will parse out everything until the first blank for the column name: the column name would simply be “x”.

`sqlite3.connect(database[, timeout, detect_types, isolation_level, check_same_thread, factory, cached_statements])`

Opens a connection to the SQLite database file *database*. You can use `":memory:"` to open a database connection to a database

that resides in RAM instead of on disk.

When a database is accessed by multiple connections, and one of the processes modifies the database, the SQLite database is locked until that transaction is committed. The *timeout* parameter specifies how long the connection should wait for the lock to go away until raising an exception. The default for the timeout parameter is 5.0 (five seconds).

For the *isolation_level* parameter, please see the `Connection.isolation_level` property of `Connection` objects.

SQLite natively supports only the types TEXT, INTEGER, FLOAT, BLOB and NULL. If you want to use other types you must add support for them yourself. The *detect_types* parameter and the using custom **converters** registered with the module-level `register_converter()` function allow you to easily do that.

detect_types defaults to 0 (i. e. off, no type detection), you can set it to any combination of `PARSE_DECLTYPES` and `PARSE_COLNAMES` to turn type detection on.

By default, the `sqlite3` module uses its `Connection` class for the connect call. You can, however, subclass the `Connection` class and make `connect()` use your class instead by providing your class for the *factory* parameter.

Consult the section *SQLite and Python types* of this manual for details.

The `sqlite3` module internally uses a statement cache to avoid SQL parsing overhead. If you want to explicitly set the number of statements that are cached for the connection, you can set the *cached_statements* parameter. The currently implemented default is to cache 100 statements.

`sqlite3.register_converter(typename, callable)`

Registers a callable to convert a bytestring from the database into a custom Python type. The callable will be invoked for all database values that are of the type *typename*. Confer the parameter *detect_types* of the `connect()` function for how the type detection works. Note that the case of *typename* and the name of the type in your query must match!

`sqlite3.register_adapter(type, callable)`

Registers a callable to convert the custom Python type *type* into one of SQLite's supported types. The callable *callable* accepts as single parameter the Python value, and must return a value of the following types: int, float, str or bytes.

`sqlite3.complete_statement(sql)`

Returns **True** if the string *sql* contains one or more complete SQL statements terminated by semicolons. It does not verify that the SQL is syntactically correct, only that there are no unclosed string literals and the statement is terminated by a semicolon.

This can be used to build a shell for SQLite, as in the following example:

```
# A minimal SQLite shell for experiments

import sqlite3

con = sqlite3.connect(":memory:")
con.isolation_level = None
cur = con.cursor()

buffer = ""

print("Enter your SQL commands to execute in sqlite3.")
print("Enter a blank line to exit.")

while True:
    line = input()
```

```
if line == "":
    break
buffer += line
if sqlite3.complete_statement(buffer):
    try:
        buffer = buffer.strip()
        cur.execute(buffer)

        if buffer.lstrip().upper().startswith("SELECT"):
            print(cur.fetchall())
    except sqlite3.Error as e:
        print("An error occurred:", e.args[0])
    buffer = ""

con.close()
```

sqlite3.**enable_callback_tracebacks**(*flag*)

By default you will not get any tracebacks in user-defined functions, aggregates, converters, authorizer callbacks etc. If you want to debug them, you can call this function with *flag* as `True`. Afterwards, you will get tracebacks from callbacks on `sys.stderr`. Use `False` to disable the feature again.

11.6.2. Connection Objects

`class sqlite3.Connection`

A SQLite database connection has the following attributes and methods:

`Connection.isolation_level`

Get or set the current isolation level. `None` for autocommit mode or one of “DEFERRED”, “IMMEDIATE” or “EXCLUSIVE”. See section *Controlling Transactions* for a more detailed explanation.

`Connection.in_transaction`

`True` if a transaction is active (there are uncommitted changes), `False` otherwise. Read-only attribute.

New in version 3.2.

`Connection.cursor([cursorClass])`

The `cursor` method accepts a single optional parameter `cursorClass`. If supplied, this must be a custom cursor class that extends `sqlite3.Cursor`.

`Connection.commit()`

This method commits the current transaction. If you don't call this method, anything you did since the last call to `commit()` is not visible from other database connections. If you wonder why you don't see the data you've written to the database, please check you didn't forget to call this method.

`Connection.rollback()`

This method rolls back any changes to the database since the last call to `commit()`.

`Connection.close()`

This closes the database connection. Note that this does not automatically call `commit()`. If you just close your database connection without calling `commit()` first, your changes will be lost!

`Connection.execute(sql[, parameters])`

This is a nonstandard shortcut that creates an intermediate cursor object by calling the cursor method, then calls the cursor's `execute` method with the parameters given.

`Connection.executemany(sql[, parameters])`

This is a nonstandard shortcut that creates an intermediate cursor object by calling the cursor method, then calls the cursor's `executemany` method with the parameters given.

`Connection.executescript(sql_script)`

This is a nonstandard shortcut that creates an intermediate cursor object by calling the cursor method, then calls the cursor's `executescript` method with the parameters given.

`Connection.create_function(name, num_params, func)`

Creates a user-defined function that you can later use from within SQL statements under the function name *name*. *num_params* is the number of parameters the function accepts, and *func* is a Python callable that is called as the SQL function.

The function can return any of the types supported by SQLite: bytes, str, int, float and None.

Example:

```
import sqlite3
import hashlib
```

```

def md5sum(t):
    return hashlib.md5(t).hexdigest()

con = sqlite3.connect(":memory:")
con.create_function("md5", 1, md5sum)
cur = con.cursor()
cur.execute("select md5(?)", ("foo",))
print(cur.fetchone()[0])

```

Connection.**create_aggregate**(*name*, *num_params*, *aggregate_class*)

Creates a user-defined aggregate function.

The aggregate class must implement a `step` method, which accepts the number of parameters *num_params*, and a `finalize` method which will return the final result of the aggregate.

The `finalize` method can return any of the types supported by SQLite: bytes, str, int, float and None.

Example:

```

import sqlite3

class MySum:
    def __init__(self):
        self.count = 0

    def step(self, value):
        self.count += value

    def finalize(self):
        return self.count

con = sqlite3.connect(":memory:")
con.create_aggregate("mysum", 1, MySum)
cur = con.cursor()
cur.execute("create table test(i)")
cur.execute("insert into test(i) values (1)")
cur.execute("insert into test(i) values (2)")
cur.execute("select mysum(i) from test")
print(cur.fetchone()[0])

```

Connection.**create_collation**(*name*, *callable*)

Creates a collation with the specified *name* and *callable*. The callable will be passed two string arguments. It should return -1 if the first is ordered lower than the second, 0 if they are ordered equal and 1 if the first is ordered higher than the second. Note that this controls sorting (ORDER BY in SQL) so your comparisons don't affect other SQL operations.

Note that the callable will get its parameters as Python bytestrings, which will normally be encoded in UTF-8.

The following example shows a custom collation that sorts “the wrong way”:

```
import sqlite3

def collate_reverse(string1, string2):
    if string1 == string2:
        return 0
    elif string1 < string2:
        return 1
    else:
        return -1

con = sqlite3.connect(":memory:")
con.create_collation("reverse", collate_reverse)

cur = con.cursor()
cur.execute("create table test(x)")
cur.executemany("insert into test(x) values (?)", [("a",), (
cur.execute("select x from test order by x collate reverse")
for row in cur:
    print(row)
con.close()
```

To remove a collation, call `create_collation` with `None` as callable:

```
con.create_collation("reverse", None)
```

Connection.**interrupt()**

You can call this method from a different thread to abort any queries that might be executing on the connection. The query will then abort and the caller will get an exception.

Connection.**set_authorizer**(*authorizer_callback*)

This routine registers a callback. The callback is invoked for each attempt to access a column of a table in the database. The callback should return **SQLITE_OK** if access is allowed, **SQLITE_DENY** if the entire SQL statement should be aborted with an error and **SQLITE_IGNORE** if the column should be treated as a NULL value. These constants are available in the **sqlite3** module.

The first argument to the callback signifies what kind of operation is to be authorized. The second and third argument will be arguments or **None** depending on the first argument. The 4th argument is the name of the database (“main”, “temp”, etc.) if applicable. The 5th argument is the name of the inner-most trigger or view that is responsible for the access attempt or **None** if this access attempt is directly from input SQL code.

Please consult the SQLite documentation about the possible values for the first argument and the meaning of the second and third argument depending on the first one. All necessary constants are available in the **sqlite3** module.

Connection.**set_progress_handler**(*handler, n*)

This routine registers a callback. The callback is invoked for every *n* instructions of the SQLite virtual machine. This is useful if you want to get called from SQLite during long-running operations, for example to update a GUI.

If you want to clear any previously installed progress handler, call

the method with `None` for *handler*.

`Connection.enable_load_extension(enabled)`

This routine allows/disallows the SQLite engine to load SQLite extensions from shared libraries. SQLite extensions can define new functions, aggregates or whole new virtual table implementations. One well-known extension is the fulltext-search extension distributed with SQLite.

New in version 3.2.

```
import sqlite3

con = sqlite3.connect(":memory:")

# enable extension loading
con.enable_load_extension(True)

# Load the fulltext search extension
con.execute("select load_extension('./fts3.so')")

# alternatively you can load the extension using an API call
# con.load_extension("./fts3.so")

# disable extension loading again
con.enable_load_extension(False)

# example from SQLite wiki
con.execute("create virtual table recipe using fts3(name, in
con.executescript("""
    insert into recipe (name, ingredients) values ('broccoli
    insert into recipe (name, ingredients) values ('pumpkin
    insert into recipe (name, ingredients) values ('broccoli
    insert into recipe (name, ingredients) values ('pumpkin
    """)
for row in con.execute("select rowid, name, ingredients from
print(row)
```

Loadable extensions are disabled by default. See [1].

`Connection.load_extension(path)`

This routine loads a SQLite extension from a shared library. You have to enable extension loading with `enable_load_extension()` before you can use this routine.

New in version 3.2.

Loadable extensions are disabled by default. See [1].

Connection.**row_factory**

You can change this attribute to a callable that accepts the cursor and the original row as a tuple and will return the real result row. This way, you can implement more advanced ways of returning results, such as returning an object that can also access columns by name.

Example:

```
import sqlite3

def dict_factory(cursor, row):
    d = {}
    for idx, col in enumerate(cursor.description):
        d[col[0]] = row[idx]
    return d

con = sqlite3.connect(":memory:")
con.row_factory = dict_factory
cur = con.cursor()
cur.execute("select 1 as a")
print(cur.fetchone()["a"])
```

If returning a tuple doesn't suffice and you want name-based access to columns, you should consider setting `row_factory` to the highly-optimized `sqlite3.Row` type. `Row` provides both index-based and case-insensitive name-based access to columns with almost no memory overhead. It will probably be better than your own custom dictionary-based approach or even a `db_row` based solution.

Connection.`text_factory`

Using this attribute you can control what objects are returned for the `TEXT` data type. By default, this attribute is set to `str` and the `sqlite3` module will return Unicode objects for `TEXT`. If you want to return bytestrings instead, you can set it to `bytes`.

For efficiency reasons, there's also a way to return `str` objects only for non-ASCII data, and `bytes` otherwise. To activate it, set this attribute to `sqlite3.OptimizedUnicode`.

You can also set it to any other callable that accepts a single bytestring parameter and returns the resulting object.

See the following example code for illustration:

```
import sqlite3

con = sqlite3.connect(":memory:")
cur = con.cursor()

# Create the table
con.execute("create table person(lastname, firstname)")

AUSTRIA = "\xd6sterreich"

# by default, rows are returned as Unicode
cur.execute("select ?", (AUSTRIA,))
row = cur.fetchone()
assert row[0] == AUSTRIA

# but we can make sqlite3 always return bytestrings ...
con.text_factory = str
cur.execute("select ?", (AUSTRIA,))
row = cur.fetchone()
assert type(row[0]) == str
# the bytestrings will be encoded in UTF-8, unless you store
# database ...
assert row[0] == AUSTRIA.encode("utf-8")

# we can also implement a custom text_factory ...
# here we implement one that will ignore Unicode characters
```

```

# decoded from UTF-8
con.text_factory = lambda x: str(x, "utf-8", "ignore")
cur.execute("select ?", ("this is latin1 and would normally
                        "\xe4\xf6\xfc".encode("latin1"),))

row = cur.fetchone()
assert type(row[0]) == str

# sqlite3 offers a built-in optimized text_factory that will
# objects, if the data is in ASCII only, and otherwise return
con.text_factory = sqlite3.OptimizedUnicode
cur.execute("select ?", (AUSTRIA,))
row = cur.fetchone()
assert type(row[0]) == str

cur.execute("select ?", ("Germany",))
row = cur.fetchone()
assert type(row[0]) == str

```

Connection.**total_changes**

Returns the total number of database rows that have been modified, inserted, or deleted since the database connection was opened.

Connection.**iterdump**

Returns an iterator to dump the database in an SQL text format. Useful when saving an in-memory database for later restoration. This function provides the same capabilities as the `.dump` command in the **sqlite3** shell.

Example:

```

# Convert file existing_db.db to SQL dump file dump.sql
import sqlite3, os

con = sqlite3.connect('existing_db.db')
with open('dump.sql', 'w') as f:
    for line in con.iterdump():
        f.write('%s\n' % line)

```

11.6.3. Cursor Objects

`class sqlite3.Cursor`

A `Cursor` instance has the following attributes and methods.

`cursor.execute(sql[, parameters])`

Executes an SQL statement. The SQL statement may be parametrized (i. e. placeholders instead of SQL literals). The `sqlite3` module supports two kinds of placeholders: question marks (qmark style) and named placeholders (named style).

This example shows how to use parameters with qmark style:

```
import sqlite3

con = sqlite3.connect("mydb")

cur = con.cursor()

who = "Yeltsin"
age = 72

cur.execute("select name_last, age from people where name_la
print(cur.fetchone())
```

This example shows how to use the named style:

```
import sqlite3

con = sqlite3.connect("mydb")

cur = con.cursor()

who = "Yeltsin"
age = 72

cur.execute("select name_last, age from people where name_la
            {"who": who, "age": age})
```

```
print(cur.fetchone())
```

`execute()` will only execute a single SQL statement. If you try to execute more than one statement with it, it will raise a Warning. Use `executescript()` if you want to execute multiple SQL statements with one call.

Cursor.`executemany(sql, seq_of_parameters)`

Executes an SQL command against all parameter sequences or mappings found in the sequence `sql`. The `sqlite3` module also allows using an *iterator* yielding parameters instead of a sequence.

```
import sqlite3

class IterChars:
    def __init__(self):
        self.count = ord('a')

    def __iter__(self):
        return self

    def __next__(self):
        if self.count > ord('z'):
            raise StopIteration
        self.count += 1
        return (chr(self.count - 1),) # this is a 1-tuple

con = sqlite3.connect(":memory:")
cur = con.cursor()
cur.execute("create table characters(c)")

theIter = IterChars()
cur.executemany("insert into characters(c) values (?)", theIter)

cur.execute("select c from characters")
print(cur.fetchall())
```

Here's a shorter example using a *generator*:

```

import sqlite3

def char_generator():
    import string
    for c in string.letters[:26]:
        yield (c,)

con = sqlite3.connect(":memory:")
cur = con.cursor()
cur.execute("create table characters(c)")

cur.executemany("insert into characters(c) values (?)", char

cur.execute("select c from characters")
print(cur.fetchall())

```

Cursor.**executescript**(*sql_script*)

This is a nonstandard convenience method for executing multiple SQL statements at once. It issues a `COMMIT` statement first, then executes the SQL script it gets as a parameter.

sql_script can be an instance of `str` or `bytes`.

Example:

```

import sqlite3

con = sqlite3.connect(":memory:")
cur = con.cursor()
cur.executescript("""
    create table person(
        firstname,
        lastname,
        age
    );

    create table book(
        title,
        author,
        published
    );

```

```
insert into book(title, author, published)
values (
    'Dirk Gently's Holistic Detective Agency',
    'Douglas Adams',
    1987
);
"""
```

Cursor.**fetchone()**

Fetches the next row of a query result set, returning a single sequence, or **None** when no more data is available.

Cursor.**fetchmany()** ([*size=cursor.arraysize*])

Fetches the next set of rows of a query result, returning a list. An empty list is returned when no more rows are available.

The number of rows to fetch per call is specified by the *size* parameter. If it is not given, the cursor's *arraysize* determines the number of rows to be fetched. The method should try to fetch as many rows as indicated by the *size* parameter. If this is not possible due to the specified number of rows not being available, fewer rows may be returned.

Note there are performance considerations involved with the *size* parameter. For optimal performance, it is usually best to use the *arraysize* attribute. If the *size* parameter is used, then it is best for it to retain the same value from one **fetchmany()** call to the next.

Cursor.**fetchall()**

Fetches all (remaining) rows of a query result, returning a list. Note that the cursor's *arraysize* attribute can affect the performance of this operation. An empty list is returned when no rows are available.

Cursor.**rowcount**

Although the **Cursor** class of the **sqlite3** module implements this

attribute, the database engine's own support for the determination of "rows affected"/"rows selected" is quirky.

For `DELETE` statements, SQLite reports `rowcount` as 0 if you make a `DELETE FROM table` without any condition.

For `executemany()` statements, the number of modifications are summed up into `rowcount`.

As required by the Python DB API Spec, the `rowcount` attribute "is -1 in case no `executeXX()` has been performed on the cursor or the rowcount of the last operation is not determinable by the interface".

This includes `SELECT` statements because we cannot determine the number of rows a query produced until all rows were fetched.

Cursor.`lastrowid`

This read-only attribute provides the rowid of the last modified row. It is only set if you issued a `INSERT` statement using the `execute()` method. For operations other than `INSERT` or when `executemany()` is called, `lastrowid` is set to `None`.

Cursor.`description`

This read-only attribute provides the column names of the last query. To remain compatible with the Python DB API, it returns a 7-tuple for each column where the last six items of each tuple are `None`.

It is set for `SELECT` statements without any matching rows as well.

11.6.4. Row Objects

`class sqlite3.Row`

A `Row` instance serves as a highly optimized `row_factory` for `Connection` objects. It tries to mimic a tuple in most of its features.

It supports mapping access by column name and index, iteration, representation, equality testing and `len()`.

If two `Row` objects have exactly the same columns and their members are equal, they compare equal.

`keys()`

This method returns a tuple of column names. Immediately after a query, it is the first member of each tuple in `Cursor.description`.

Let's assume we initialize a table as in the example given above:

```
conn = sqlite3.connect(":memory:")
c = conn.cursor()
c.execute('''create table stocks
(date text, trans text, symbol text,
qty real, price real)''')
c.execute("""insert into stocks
            values ('2006-01-05', 'BUY', 'RHAT', 100, 35.14)""")
conn.commit()
c.close()
```

Now we plug `Row` in:

```
>>> conn.row_factory = sqlite3.Row
>>> c = conn.cursor()
>>> c.execute('select * from stocks')
<sqlite3.Cursor object at 0x7f4e7dd8fa80>
>>> r = c.fetchone()
>>> type(r)
```

```
<class 'sqlite3.Row'>
>>> tuple(r)
('2006-01-05', 'BUY', 'RHAT', 100.0, 35.14)
>>> len(r)
5
>>> r[2]
'RHAT'
>>> r.keys()
['date', 'trans', 'symbol', 'qty', 'price']
>>> r['qty']
100.0
>>> for member in r:
...     print(member)
...
2006-01-05
BUY
RHAT
100.0
35.14
```

11.6.5. SQLite and Python types

11.6.5.1. Introduction

SQLite natively supports the following types: `NULL`, `INTEGER`, `REAL`, `TEXT`, `BLOB`.

The following Python types can thus be sent to SQLite without any problem:

Python type	SQLite type
<code>None</code>	<code>NULL</code>
<code>int</code>	<code>INTEGER</code>
<code>float</code>	<code>REAL</code>
<code>str</code>	<code>TEXT</code>
<code>bytes</code>	<code>BLOB</code>

This is how SQLite types are converted to Python types by default:

SQLite type	Python type
<code>NULL</code>	<code>None</code>
<code>INTEGER</code>	<code>int</code>
<code>REAL</code>	<code>float</code>
<code>TEXT</code>	depends on <code>text_factory</code> , <code>str</code> by default
<code>BLOB</code>	<code>bytes</code>

The type system of the `sqlite3` module is extensible in two ways: you can store additional Python types in a SQLite database via object adaptation, and you can let the `sqlite3` module convert SQLite types to different Python types via converters.

11.6.5.2. Using adapters to store additional Python types in SQLite databases

As described before, SQLite supports only a limited set of types natively. To use other Python types with SQLite, you must **adapt** them to one of the `sqlite3` module's supported types for SQLite: one of `NoneType`, `int`, `float`, `str`, `bytes`.

The `sqlite3` module uses Python object adaptation, as described in **PEP 246** for this. The protocol to use is `PrepareProtocol`.

There are two ways to enable the `sqlite3` module to adapt a custom Python type to one of the supported ones.

11.6.5.2.1. Letting your object adapt itself

This is a good approach if you write the class yourself. Let's suppose you have a class like this:

```
class Point:
    def __init__(self, x, y):
        self.x, self.y = x, y
```

Now you want to store the point in a single SQLite column. First you'll have to choose one of the supported types first to be used for representing the point. Let's just use `str` and separate the coordinates using a semicolon. Then you need to give your class a method `__conform__(self, protocol)` which must return the converted value. The parameter `protocol` will be `PrepareProtocol`.

```
import sqlite3

class Point:
    def __init__(self, x, y):
        self.x, self.y = x, y

    def __conform__(self, protocol):
        if protocol is sqlite3.PrepareProtocol:
            return "%f;%f" % (self.x, self.y)

con = sqlite3.connect(":memory:")
```

```
cur = con.cursor()

p = Point(4.0, -3.2)
cur.execute("select ?", (p,))
print(cur.fetchone()[0])
```

11.6.5.2.2. Registering an adapter callable
